CHAPTER 22

Metals in Bone

Aluminum, Boron, Cadmium, Chromium, Lead, Silicon, and Strontium

Felix Bronner

Department of BioStructure and Function, The University of Connecticut Health Center, Farmington, Connecticut 06030

Introduction

The mineral phase of bone is made up principally of calcium and phosphate. In the course of mineral deposition, a variety of metals are taken up that may be present in the bloodstream as the blood plasma courses over the skeletal tissue. Uptake by the bone mineral is a function of the affinity of a given metal for the bone mineral and extracellular matrix and of the metal's concentration in the plasma. It is also a function of the degree of mineralization of the skeleton. Bone lead content, for example, is higher in persons who have a low calcium intake and presumably have lower bone calcium than in individuals with a high calcium intake (Hernandez-Avila *et al.,* 1996). If, in addition, the metal interacts with bone cells, their metabolism may be affected, which in turn may alter osteoblast and osteoclast function. Fluoride and bisphosphonates are examples of compounds that become part of the bone mineral, but also have an inhibitory effect on osteoclasts.

Once a metal becomes incorporated in the bone mineral, its return to the circulation will depend on when the bone mineral that contains the metal will be resorbed. Metals deposited or exchanged with other metals on the surface of the bone mineral tend to be exchanged rapidly. As additional bone mineral is deposited, the opportunity for isoionic or heteroionic exchange diminishes and osteoclastic resorption becomes the dominant process responsible for the metal's reentry into the circulation. There it is subject to the stochastic processes of loss from the circulation via excretion (urine and stool), redeposition in bone, or soft tissue uptake. The latter usually accounts for only a minute fraction of the loss out of the circulation, but, from a toxicological viewpoint, may constitute the most significant event for the organism. Because the turnover of bone mineral varies in trabecular and cortical bone and in various regions of the skeleton, uptake of a given metal in the skeleton will be in those regions with the highest turnover rate, but retention will be highest in those with the lowest turnover rate. For this reason, one can think of bone not only as a reservoir for a variety of elements, including metals, but as an organ that provides storage for the unexcreted fraction of a body burden. Attempts at predicting the degree of reentry into the circulation of a metal such as lead are at the base of measuring the levels of a metal on bone surfaces (Farias, 1998).

It is also evident that conditions that affect the rate of bone turnover will alter the concentration of a given mineral in the circulation. For example, fetal bone formation and calcification are at a maximum during the third trimester of pregnancy, when deposition of maternal bone mineral in the fetal skeleton becomes important (Franklin *et al.,* 1997), and more so when the newborn is in the low birth weight category (Gonzalez-Cossio *et al.,* 1997). Similarly, end-stage renal failure patients with secondary hyperparathyroidism mobilized more lead from their skeletons, with a dramatic decrease following parathyroidectomy (Kessler *et al.,* 1999).

Aluminum

Interest in the interaction between aluminum (Al) and bone was stimulated as a result of the observation that patients with renal dystrophy accumulated aluminum in their skeleton in quantities that tended to exceed those accumulated by patients with comparable rates of bone turnover, as in hyperparathyroidism (Goodman and Duarte, 1991). Moreover, all accumulation was enhanced markedly as a result of long-term dialysis, leading to bone disease characterized by impaired mineralization and diminished bone cell activity (Goodman and Duarte, 1991). Bone disease of this type has also been described in individuals with chronic renal disease who are not on dialysis (O'Brien *et al.,* 1990) and in persons receiving total parenteral nutrition (Klein *et al.,* 1982), as well as in aluminum welders (Elinder *et al.,* 1991).

Whereas in the majority of healthy subjects, Al plasma concentrations are ~2 μg/liter, many have higher plasma concentrations (Sharp *et al.,* 1993), inasmuch as ingestion of Al-containing substances leads to increased plasma concentrations. Higher plasma levels reflect higher intakes, although differences due to gender (Sharp *et al.,* 1993) or metabolism (absorption, excretion, and bone turnover) have not been explored systematically. What seems reasonably certain is that Al accumulation in bone increases as the plasma concentration increases, whether due to increased intake, as in dialysis with liquids that contain Al, or under conditions of decreased capacity for excretion, as in renal osteodystrophy. Bone accumulation of Al can also increase when turnover is diminished, as in diabetes mellitus (Pei *et al.,* 1993). As aluminum accumulates in the skeleton, it inhibits mineralization and acts on bone cells.

Goodman and Duarte (1991) have reviewed the evidence concerning the effect of aluminum on calcification and the mineralization front, but feel they cannot separate clearly physicochemical from biological effects. Aluminum appears to enter skeletal tissue along with calcium, competing with it, inhibiting hydroxyapatite formation *in vitro* (Blumenthal and Posner, 1984). Data on the *in vivo* effect of Al on bone mineralization are less plentiful, but nevertheless point to the overall toxicity of Al, although Al concentrations that interfere with calcification *in vivo* are likely to be higher. Bouglé *et al.* (1998), for example, reported that both bone mineral density and bone mineral content of the lumbar spine decreased significantly as serum Al levels increased in low birth infants. This was not true for full-term infants. One explanation is that bone development is incomplete in the low birth infants and that Al does indeed interfere with the initiation and progression of bone mineralization. Similarly in adults, Kausz and colleagues (1999) concluded that a patient's plasma Al level does not predict well the presence of aluminum bone disease, a well-described complication encountered in persons undergoing dialysis. As stated earlier, initial bone uptake is proportional to the Al concentration of the plasma, but once taken up by bone, it is the fate of this bone that will determine how much of the initial deposit will remain in that bone site. Therefore, the plasma Al concentration at any time reflects ingested Al, as well as the amount of Al that is released by bone. Moreover, the effect of Al on bone cells is not instantaneous. Inasmuch as the amount of Al found in bone at any instant is a complicated function of plasma levels over time and of bone turnover as a function of time, Al bone and plasma levels at a given moment are not likely to be closely related. The risk of acute Al toxicity can be assessed by plasma analysis. High bone levels, to be sure, indicate high prior exposure, but single plasma or bone analyses are unlikely to provide information on Al toxicity. This statement is illustrated by the report of Suzuki *et al.* (1995), who found Al accumulation in the bones of their patients on chronic hemodialysis, even though the water and dialysis fluid contained less than 10 μg Al/liter over the preceding decade. Goodman and Duarte (1991) have pointed out that an effect of aluminum on bone may require concentrations of 30–40 mg Al/kg dry bone, a concentration equivalent to 1 to 2% of the calcium content (Widdowson and Dickerson, 1964), whereas the Al concentration in bone of normal subjects is only 5–7 mg/kg dry bone (Hodsman *et al.,* 1982).

In addition to inhibiting the formation of calcium hydroxyapatite, detectable only at high or with prolonged rates of Al entry into the skeleton, Al also interferes with the formation of calcified and uncalcified nodules in primary cultures of neonatal mouse calvarial cells (Sprague *et al.,* 1993). Those nodules are specific for isolated calvarial cells, which are osteoblastic in nature. Bellows and colleagues (1995) have shown that Al inhibits *in vitro* mineralization of osteoid nodules, both in its initiation and in its progression phases. More recently, these investigators, working with long-term rat calvaria cell cultures, showed that Al initially accelerated the rate of osteoprogenitor cell differentiation. Al also initially accelerated the formation of osteoid nodules, while at the same time inhibiting mineralization. Ultimately, however, Al exerted toxic effects, with nodules and matrix disintegrating by days 17 to 19 of the cultures (Bellows *et al.,* 1999). Kidder *et al.* (1993) have reported that Al suppressed the proliferation of marrow fibroblast-like stromal cells, as well as of calvarial osteoblasts (cf. Sprague *et al.,* 1993). Interestingly enough, in more mature, confluent cultures, the addition of Al stimulated DNA synthesis and collagen production independently of the presence of 1,25-dihydroxycholecalciferol, the active vitamin D metabolite (Kidder *et al.,* 1993). The fact that fluoride appears to inhibit Al accumulation in rat bone (Ittel *et al.,* 1993) may be taken as supporting a cellular effect of Al, although a physicochemical effect cannot be excluded.

Goodman and Duarte (1991) stated that the amount of surface stainable aluminum is the best available indicator of aluminum toxicity and estimated that when surface levels of Al exceed 30%, bone formation and/or mineralization is affected adversely. Al toxicity that results from Al accumulation is by now a well-known complication of patients in chronic renal failure. Chelators are the treatment of choice

for ridding the body of metals. In the case of Al toxicity, desferrioxamine treatment and elimination of all exogenous Al sources are indicated with careful attention to avoid or at least minimize side affects, including infections (D'Haese *et al.,* 1996).

Specific mechanisms by which Al acts on bone and other cells have not been elucidated. Jeffrey *et al.* (1997) discussed possible effects on cell signaling, mechanisms by which Al inhibits hemoglobin synthesis, and effects of Al on PTH secretion. These reviewers also list a series of recommendations for further study of the multiple actions of Al in the mammalian organism.

Boron

It is uncertain whether boron (B) an essential element for many plant species, is essential for mammals. However, as reported by Nielsen and Hunt (cited by King *et al.,* 1991), a low B diet appears to exacerbate the effects of vitamin D deficiency in chicks, with B supplementation reducing the effects of vitamin D deficiency. It was therefore suggested that B may play a role in bone metabolism. Moreover, Nielsen *et al.* (1987) had reported that increasing the dietary intake of B from 0.25 to 3.25 mg/day in postmenopausal women increased plasma estradiol and testosterone concentrations and decreased urinary calcium output. For this reason, B may play a role in postmenopausal osteoporosis. This possibility was investigated by Beattie and Peace (1993), who studied six postmenopausal women volunteers on a metabolic ward on two levels of B intake, 0.33 and 3.33 mg/day, each subject on each of the two B intakes for 3 weeks. There was no effect on minerals, steroids, or urinary pyridinium cross-link excretion, a measure of collagen turnover. All subjects in this study, as they shifted from an acclimation period diet that they consumed for 2 days to the low B diet, supplemented with additional B 3 weeks later, experienced an increase in Ca absorption and urinary Ca excretion. This increase in absorption and excretion was, however, unaffected by the later increase in B intake and cannot, therefore, be attributed to B.

Hegsted and colleagues (1991) studied the effect of B addition on vitamin D deficiency in rats. They placed weanling rats, 21 days of age, on a vitamin D-deficient diet and 12 weeks later, when both the B-supplemented and B-deficient rats were hypocalcemic, the supplemented groups had higher net calcium absorption and were in somewhat more positive balance. However, there were no effects on soft tissue calcium levels and none on a variety of bone parameters (bone mineral density and length of femur, bone and ash weight, bone Ca, Mg, and P). Hypocalcemia, which on a low calcium diet can be brought about in 2–3 weeks, takes much longer to develop and is less severe when calcium intake has been high (Bronner and Freund, 1975). It is also uncertain whether these animals developed genuine vitamin D deficiency, as their intestinal calbindin D_{9k} content, the molecular measure of vitamin D deficiency (Bronner and Freund, 1975), was not determined.

In a careful study of the effect of B on chick nutrition, Hunt and colleagues (1994) found that B addition modified the effects of vitamin D deficiency and proposed that the plasma B level is regulated homeostatically. The effects on vitamin D_3 deficiency were minor, and the inference concerning B homeostasis was not based on rigorous experimentation because urinary B output was not measured. Conceivably, a zero intake of B may aggravate metabolic defects due to vitamin D deficiency, but B is so widely distributed in nature that a genuine B deficiency can probably be achieved only under strict laboratory conditions.

Utilizing young adult male rats, Chapin *et al.* (1997) studied the effect of increasing B intake, in the form of boric acid, from 0 to 9000 ppm boric acid for 9 weeks. They found that bone B increased in all treated animals and that even though within 1 week of the cessation of feeding B in the diet, serum and urine B values had dropped to normal, bone retained its B level for as long as 32 weeks after cessation of the B diet. The only change in bone these investigators found was a 5–10% increase in vertebral resistance to crush force. The authors point out that these increases occurred at exposure levels that were "substantially below those that were previously reported to be toxic." Future studies are needed to evaluate possible benefits of B intake on bone metabolism and strength.

Cadmium

Cadmium (Cd) intoxication, whether acute or chronic, is principally the result of heavy metal mining, i.e., for lead, zinc, or copper, with Cd often not the object of the mining process, but constituting a contaminant. Cd mining, as in certain areas of Belgium, and Cd smelting also constitute major sources of Cd and lead to Cd toxicity in exposed workers. The most dramatic and attention-drawing incident of Cd poisoning occurred in Japan during the latter part of World War II, although the nature of the disease, which became known as the itai-itai disease, and its relationship to Cd poisoning were not fully understood until the 1960s (Nogawa, 1981). "Itai" is Japanese for the exclamation "ouch," associated with tenderness and pain to the touch. The main symptoms of this disease were osteomalacia in postmenopausal women, traced to a high Cd content of rice grown in certain areas whose irrigation water came from a river that had become severely contaminated with Cd because of upstream mining (Nogawa, 1981; Tsuchiya, 1981).

The three organ systems that are principally affected by Cd poisoning are the respiratory system, implicated particularly in acute poisoning due to Cd contamination of dust, the kidney, and the skeleton. Principal renal symptoms are proteinuria, glycosuria, and microglobulinuria. Osteomalacia and osteoporosis are the skeletal symptoms that have been identified in patients with itai-itai disease and in others that have

had a chronic low-dose exposure for a long time (Tsuchiya, 1981). Uriu and colleagues (2000) have shown that "chronic Cd exposure exacerbated the uncoupling between bone formation and resorption in ovariectomized rats. . . . " Their findings thus add weight to the reported bone effects of chronic cadmium exposure, including decreased mechanical strength. In a similar earlier study, Hiratsuka *et al.* (1997) also showed that chronic Cd intoxication caused osteomalacic lesions in ovariectomized rats. In individuals with skeletal symptoms, calcium deficiency aggravated the disease, and high doses of vitamin D, leading to increased calcium absorption, have been reported to overcome or minimize the symptoms (Nogawa, 1981).

The effect of Cd is very much a function of the dose taken in. Cd appears to have an effect on epithelial cells in the intestine and to react with bone cells. It causes diminished calcium absorption and increased calcium loss from bone (Wilson and Bhattacharyya, 1997). It appears to bind to cells as well as to proteins, causing cell desquamation in the intestine and changes in cell-to-cell binding in the kidney. The latter lead to direct or indirect interference with the hydroxylation of 25-hydroxyvitamin D_3 (Kjellstrom, 1992) so that biosynthesis of the intestinal and renal calbindins is diminished (Kimura, 1981; Sagawara, 1974). This in turn leads to a diminution of the active, transcellular transport of calcium in the duodenum (Bronner *et al.,* 1986) and to diminished active reabsorption of calcium in the distal convoluted tubule (Bronner, 1989, 1991). Moreover, Cd binds to calbindin D, displacing Ca^{2+} (Fullmer and Wasserman, 1977), so that active Ca transport is interfered with. A direct linear relationship exists between Cd intake and Ca excretion in the urine (Nogawa, 1981), doubtless due to Cd-induced damage of the tight junctions of the renal tubule. As a result, less calcium is reabsorbed in the renal distal tubule and calciuria results. Thus, Cd input induces Ca loss.

The effect of Cd on bone is a dual one, direct interaction with bone cells, diminishing their ability to mineralize (Miyahara *et al.,* 1988), inhibiting procollagen C-proteinases (Hojima *et al.,* 1994), thereby preventing collagen self-assembly in the extracellular matrix and effectively decreasing collagen production (Miyahara *et al.,* 1988).

Blumenthal and colleagues (1995) reported that Cd has an inhibitory effect on hydroxyapatite formation *in vitro* and suggested that "the interference of Cd with mineralization can be partially explained by its inhibitory effect on hydroxyapatite nucleation and growth. . . . " This would be in addition to any direct effect of Cd on bone cell function. Thus, Long (1997) has reported that $200-500\ \mu M$ Cd causes changes in cell morphology and causes a decrease in osteoblast and osteoclast number and in alkaline phosphatase activity, all of which are likely to contribute to diminished collagen production and impaired mineralization. A second indirect effect of Cd is to accelerate bone turnover, particularly bone resorption (Chang *et al.,* 1981), a result of the induced calcium deficiency. It is uncertain whether the increase is due to the stimulation of parathyroid hormone release resulting from the tendency toward hypocalcemia.

Shank and Vetta (1981) have calculated that if Cd were administered five times, with intervals of 48 hr between each administration, then 48 hr after the last dose the liver content would account for about two-thirds of the dose and the kidney for 7 to 8%. It is not surprising, therefore, that bone effects are not manifested until later in chronic exposure and that these result from direct effects of Cd on bone cells and hydroxyapatite formation, as well as from the consequences of changes in calcium metabolism. It is because these changes are similar to those of calcium and vitamin D deficiency that bone effects resulting from Cd accumulation are aggravated by conditions that intensify or aggravate calcium needs.

It is not surprising, therefore, that Cd may be a risk factor for osteoporosis (Jarup *et al.,* 1998).

Chromium

The element chromium (Cr) belongs to the first series of the transition elements and occurs in several oxidation states, with the trivalent the most stable (Mertz, 1969). It is thought to be an essential micronutrient, appears essential for optimal glucose utilization, and its deficiency "can be a cause of or an aggravating factor in the glucose intolerance of infants" that suffer from protein calorie insufficiency or have noninsulin-dependent diabetes (Hambidge, 1974). Its role in skeletal metabolism is largely unexplored, with interest stimulated by the increasing use, especially in elderly adults, of metal-containing prostheses, where Cr constitutes part of the alloy. For example, Berry *et al.* (1993) have reported that extensive osteolysis occurred around an aseptic, well-fixed, stable, uncemented total knee prosthesis and concluded that debris resulting from wear, in the form of polyethylene, metal, or both, may be responsible for the breakdown of bone.

Kinetic analyses of the distribution Cr in the body have shown (Onkelinx, 1977) in rats that about 40% of the ^{51}Cr that is lost out of the central compartments flows to a "sink," consisting of various soft tissues and bone. Total bone content is some 2.5 times higher than that of all other tissues after 262 hr, i.e., when uptake approaches a plateau. DoCauto *et al.* (1995) did a kinetic study in humans and found that the compartment with slowest turnover, presumably similar to the "sink" in the rat study (Onkelinx, 1977), reached a near-plateau of about 35% of the injected dose Cr(III) between days 7 and 58 after dose administration; thereafter this compartment began to empty out so that by day 248 it contained only 17% of the dose. In the rat study (Onkelinx, 1977), the bone gained Cr with time, whereas the other tissues either lost or held onto their Cr. Thomann *et al.* (1994) have identified a "major storage compartment" in rats that received Cr in their drinking water for 6 weeks and were studied 140 days later, a period during which they no longer received Cr. The half-life of Cr in that storage compartment, made up of bone, skin, hair, and muscle, was in excess of 100 days. Their study thus confirms the

essential findings reported by Onkelinx (1977). Thomann *et al.* (1994) suggested, as can be inferred from the Onkelinx (1977) study as well, that the storage compartment may function to maintain " . . . elevated body burdens and tissue concentrations of Cr. . . . " If the findings in rats apply to humans, bone could constitute a Cr reservoir.

Cr deficiency or Cr excess may lead to bone changes. Deficiency is difficult to produce in the laboratory and unlikely to be encountered in humans, even though low intakes in the elderly have been associated with glucose intolerance (Hambidge, 1977). The association of high local metal concentrations, including Cr with failed joint prostheses, has been reported (James *et al.* 1993), but the specifics of the effects of Cr excess on bone cells and tissues have not.

Lead

Lead (Pb) contamination of the environment, largely due to the widespread use of Pb compounds in paints and in gasoline, has become a major public health problem. The use of Pb-containing gasoline has been severely restricted in the United States and paints, both exterior and interior, are now formulated without Pb in many countries. Nevertheless, Pb contamination continues to remain an important problem throughout the world. As is true for many trace elements, the body Pb burden is located largely in the skeleton, which serves as the major site of Pb deposit (Aufderheide and Wittmers, 1992). Even when there is little or no further Pb ingestion or inhalation, Pb is liberated from bone as bone turns over (Durbin, 1992). Consequently, the skeleton is not only the major site of Pb deposit, but can become the major source of endogenous Pb (Berglund *et al.,* 2000). As a result, as pointed out by Rust *et al.* (1999), even if intervention such as removal of Pb paint could reduce a child's Pb exposure by 50%, the actual decline in blood Pb may be only 25% because of bone turnover and the consequent release of Pb from bone into the circulation. It is Pb that is released into the circulation and enters soft tissues that constitutes the major health hazard.

It may be obvious that greater bone turnover leads to greater Pb release. A telling illustration is the report by Hac and Krechniak (1996), who showed that after cessation of Pb exposure, the accumulated Pb content of rat hair declined very rapidly to the preexposure level, whereas in that same period only one-third of the accumulated bone Pb was lost, hair obviously turning over much faster than bone.

The importance of bone as a reservoir for Pb and the effects of bone turnover have been illustrated in several reports. For example, Gulson *et al.* (1998) have shown that in the postpregnancy period of women who breast fed their infants the change in blood Pb concentration was significantly greater than during the second and third trimesters. A portion of the calcium in breast milk is of skeletal origin (Bronner, 1960), and bone turnover must therefore be greater than in women who do not breast feed.

Another interesting example of the importance of bone turnover are the observations that Pb is a risk factor for hypertension (Houston and Johnson, 1999; Hu *et al.,* 1996). A possible explanation may be that higher calcium intakes favor lower blood pressure (McCarron *et al.,* 1989) and that Pb in bone, in replacing calcium, lowers, if only slightly, the blood calcium level. This in turn may affect blood pressure by lowering angiotension release or by an indirect effect on the vasculature. This inference derives support from deCastro and Medley (1997), who, on the basis of blood pressure and blood Pb measurements in high school students, suggested a possible association exists between chronic bone Pb accumulation and later adolescent hypertension.

When Pb is ingested, it largely follows the routes of calcium. It binds to calbindin in the duodenum, therefore vitamin D enhances Pb absorption (Fullmer, 1992). In situations of calcium deficiency, when intestinal calbindin levels are high, Pb absorption is enhanced (Fullmer, 1992). On high calcium intakes, most of the calcium and therefore, presumably, most of the Pb are absorbed by the paracellular route, largely in the ileum (Marcus and Lengemann, 1962; Pansu *et al.,* 1993; Duflos *et al.,* 1995). Pb that has entered the body fluids leaves these via the urine, via the intestine, and by entry into bone. Figure 1 is a model of the rates of Pb entry to and return from the two major bone compartments, cortical and trabecular, and of the loss rate via urine. The model, derived from findings in chronically exposed Pb workers, does not take into account losses of endogenous Pb in the stool; O'Flaherty (1993) stated that the ratio for urinary Pb clearance to that of endogenous Pb in the feces varies from 1:1 to 3:1. O'Flaherty also stated (1993) that Pb behaves like calcium in movements into, within, and out of bone. If one assumes that Pb in general behaves like calcium, one can calculate from Fig. 2 that when Pb leaves the body pool, it has a 70% chance of entering bone, whereas the corresponding figure from Fig. 1 would be 55%, neglecting endogenous fecal output. Also, according to Fig. 1, nearly two-thirds of the Pb flow would be to cortical bone and a little over one-third to trabecular bone. However, trabecular bone turns over faster than cortical bone so that in Pb that enters the circulation from bone, a larger proportion than one-third would be of trabecular origin.

Rabinowitz *et al.* (1976) did a kinetic analysis of Pb, given as a stable isotope tracer, in five healthy male volunteers

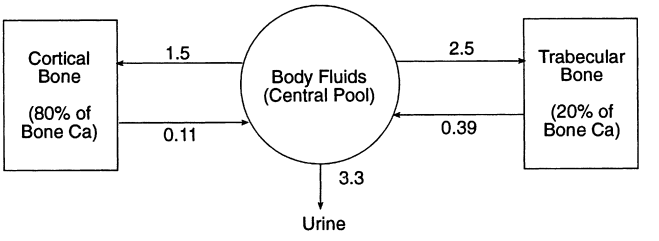

Figure 1 Model of how the adult body handles lead. Arrows refer to turnover rates per year. Based on data of chronically exposed lead workers (Christofferson *et al.,* 1987).

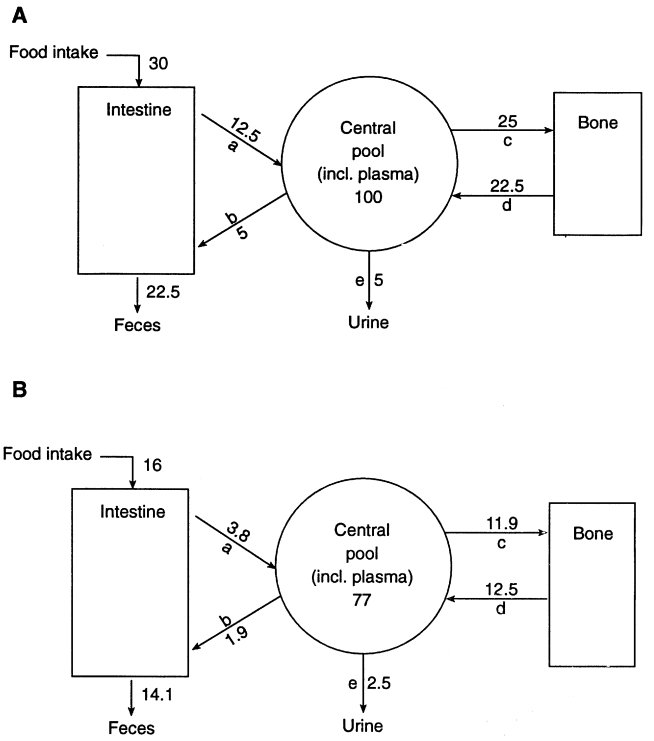

Figure 2 Models of calcium metabolism in a 14-year-old girl (A) and a 62-year-old postmenopausal woman (B). Arrows refer to flows, mmol $Ca \cdot day^{-1}$; units for the central pools are mmol Ca (from Bronner, 1994).

and found that 54–78% of the Pb leaving the blood per day was excreted in the urine and that the body pool of Pb consisted of three compartments, with the third and largest assigned to bone. Pb in the first compartment had a mean life of 36 ± 5 days, of 30 to 55 days in compartment 2, and a much longer life (10^4 days) in compartment 3. Pb absorption was calculated to vary from 6.5 to 13.7%, averaging ~10%.

O'Flaherty (1991) has listed the various routes by which Pb, like calcium, enters bone, i.e., exchange with calcium in the bone mineral, and accretion, i.e., the net transfer into a single microscopic volume of bone, by an increase in either volume (apposition) or mineralization (increase in density). The end result is that some 90% of the body burden of Pb accumulates in bone (Aufderheide and Wittmers, 1992). Because the surface uptake or binding of calcium and therefore presumably of Pb to the bone mineral is the dominant process of entry into bone (Bronner and Stein, 1992), the bone surface tends to have the highest Pb content. Ultimately, some of the surface Pb is lost by removal or by being "buried" by newly deposited bone mineral. For this reason, the microdistribution of Pb in bone is of importance and that is why the bone surface content of Pb has been considered more important for evaluating the body Pb burden than total bone content. How this can and should be evaluated is controversial (Jones *et al.,* 1992).

Some studies have reported on the effect of Pb addition on cultured bone cells. Schanne *et al.* (1989) found that Pb concentrations in the culture medium of 5 and 25 μM increased the intracellular calcium ion concentration in ROS 17/2.8 cells and speculated that Pb toxicity may be mediated by disturbances of intracellular $[Ca^{2+}]$. However, it seems unlikely that raising the $[Ca^{2+}]$ from 0.13 to 0.25 μM would significantly impair the cell's ability to function. In a later paper these authors (Schanne *et al.,* 1992) reported that the addition of Pb to a culture of ROS 17/2.8 cells, which are classified as osteoblastic osteosarcoma cells, interfered with a $1,25(OH)_2D_3$- induced increase in intracellular Ca^{2+}. Moreover, $1,25(OH)_2D_3$ raised $[Ca^{2+}]$ to 0.24 μM, i.e., the value that in the earlier paper was considered potentially harmful. Somewhat similar observations have been reported by Long and Rosen (1994). Klein and Wiren (1993), studying the same cell line, found that Pb concentrations between 2 and 200 μM had no effect on cell number, DNA, or protein synthesis. However, Pb addition caused a decrease in mRNA concentrations of alkaline phosphatase, type 1 procollagen, and osteocalcin.

Hicks *et al.* (1996) have reported that sublethal doses of Pb caused suppression of alkaline phosphatase in isolated chick chondrocytes, as well as of type II and type X collagen expression, and a decrease in thymidine incorporation. The authors suggested that Pb may inhibit endochondral bone formation. Gonzalez-Risla and colleagues (1997) found that Pb exposure inhibited development of the cartilage growth plate of rats and suggested that this may be one cause of the adverse effects of Pb exposure on skeletal development. Another cause may involve disruption of mineralization during growth (Hamilton and O'Flaherty, 1995).

Dowd *et al.* (1994) have reported that submicromolar concentrations of free Pb compete with Ca^{2+} binding to osteocalcin and, because Pb^{2+} inhibits osteocalcin binding to hydroxyapatite, may lead to significant osteocalcin inactivation and ultimately might affect bone mineral dynamics. A related observation was made by Sauk *et al.* (1992), who found that Pb addition inhibited the release of osteonectin/SPARC by ROS 17/2.8 cells and lowered the cellular content of osteonectin/SPARC mRNA. How these *in vitro* effects relate to the *in vivo* effects of Pb poisoning is not yet known.

Miyahara *et al.* (1994) reported that Pb may induce the formation of osteoclast-like cells by increasing the intracellular concentrations of Ca^{2+} and cAMP. Conceivably, therefore, Pb alters Ca channels in a way that allows increased inflow of extracellular Ca^{2+}. Those Pb-sensitive channels, which also permit increased Pb inflow (Schanne *et al.,* 1989), appear therefore to be located in both osteoclasts and osteoblasts. What role these events play in altering bone metabolism is uncertain.

The overall effect of Pb poisoning on bone is unclear. Aufderheide and Wittmers (1992) state that toxic Pb levels may distort the normal macrodistribution of Pb in bone, but this is not established. Koo *et al.* (1991) failed to find significant changes in vitamin D metabolism, bone mineral content, and Ca and P_i plasma concentrations in children of adequate nutritional status who had been chronically exposed to low to moderate Pb levels.

However, Needleman and colleagues (1996) concluded from their study of the relationship between body Pb burden and social adjustment in public school children that high bone Pb levels were associated with attention deficit, aggression, and delinquency and that these effects followed a developmental course. Indeed, it is the overall effect of raised blood levels of Pb on development and behavior of children that led to the advocacy of Pb removal from the environment and the policy of minimizing Pb contamination.

Thus, regardless of the direct effect of Pb on bone, the skeleton clearly constitutes the major Pb store in the body. Consequently, skeletal Pb content will reflect and determine overall exposure and risk.

Silicon

Silicon (Si) atomic number 14, atomic weight 28.03, belongs to the periodic group IVb and is classified as part of the carbon family, which includes germanium, tin, and Pb (Moeller, 1952). Carlisle (1986) has listed the Si concentration in various soft tissues of rats and monkeys as varying typically between 1 and 2 μg/g wet weight; in humans the Si concentration appears to be about one order of magnitude higher. Connective tissues tend to have a high Si content, mainly because Si is an integral component of glycosaminoglycans and their protein complexes, which contribute to the tissue structures (Carlisle, 1986)

In 1972, Schwarz and Milne reported that the addition of 50 mg Si/100g diet increased the growth rate of rats by some 30%, and Carlisle, in the same year, found a comparable increase in the daily weight gain of chicks. Carlisle (1986) has reported that the addition of Si hastened mineralization in weanling rats and that Si deficiency in chicks (Carlisle, 1972) led to abnormally shaped bones. Over the past 20-odd years, there have been many reports that have or have not verified the initial findings (see Carlisle, 1986, for a review of reports until the mid-1980s). Thus, Seaborn and Nielsen (1994) have reported that when Si, as sodium metasilicate, was fed to weanling rats at the rate of 25 μg/g fresh diet, the decreased Ca and Mg content of the femur found in the control animals was reversed. In these experiments, it proved possible to substitute germanium for Si, but germanium did not replace Si in other effects that result from Si deficiency. However, Eliot and Edwards (1991) concluded on the basis of 16-day experiments with broiler chicks that "dietary silicon supplementation has no effect on growth and skeletal development. . . . " Eisinger and Clairet (1993) analyzed bone mineral density in 53 women with osteoporosis and found that in 8 subjects Si supplementation induced a statistically significant increase in femoral bone mineral density.

Rico and colleagues (2000) studied the effect of 30-day Si supplementation in ovariectomized rats and showed that supplementation overcame the losses of bone mass in the fifth lumbar vertebra and in the femur found in the ovariectomized controls. The authors concluded that Si "may have a potential therapeutic application in the treatment of involutive osteoporosis."

One reason for interest in possible Si effects on bone is that granules of special glasses have been used for the repair of bone defects in the dental field (Gatti and Zaffi, 1991a). These vitreous materials contain Si, as do materials used to complete suturectomy for the treatment of craniosynostosis (Antikainen, 1993). In the case of the granules, analyses of the embedded jaws showed (Gatti and Zaffi, 1991b) that Si had diffused into the surrounding tissue. There also was no osteoinduction, but it is not clear whether this was caused by Si or the procedure. As such procedures or prostheses become more prevalent, it may be desirable to study potential effects of Si on bone tissue and cells. The effect of Si on bone structure and bone strength needs further study.

Strontium

Strontium (Sr) like calcium, is a periodic group IIa element and, while not very abundant, constituting only 0.03% of the igneous rocks of the earth, is usually classified as a "familiar element" because of the existence of readily available natural sources (Moeller, 1952). It is not an essential element and interest in Sr metabolism stems from the fact that ^{90}Sr "is an abundant and potentially hazardous by-product of nuclear fission" (Underwood, 1977). Although tests of nuclear explosions have largely ceased, the fact that Sr behaves metabolically like calcium to a large extent has helped maintain interest in this element (Blumsohn *et al.,* 1994; Kollenkirchen, 1995).

In a detailed formal study (Bronner *et al.,* 1963) it was found that although Sr and Ca followed the same metabolic pathway qualitatively, there were significant quantitative differences in how the body handled these two elements. The major difference was in the urine, with the fraction of Sr excreted in the urine three times that of Ca on average. In the stool, the fecal loss of endogenous Sr was greater than that of Ca, but only moderately so (10%). In terms of the fraction of injected isotope that was calculated to reach bone, there was no difference on the average, but the ratio "varied from patient to patient and was not consistent in a given patient." Blumsohn *et al.* (1994) have reexplored the relationship between Sr and Ca absorption in patients with osteoporosis and with chronic renal failure. Sr absorption was approximately half that of Ca absorption, but the time course of the two was similar when evaluated by deconvolution. Stable Sr is less expensive than stable Ca, but differences in absorption between the two elements are sufficiently great that measuring calcium absorption with a calcium isotope seems more meaningful. Treatment with $1,25(OH)_2D_3$ stimulated Sr absorption more than Ca absorption. A possible explanation is that Sr binds more tightly than Ca^{2+} to the newly induced calbindin (Fullmer and Wasserman, 1977)

Fed in large amounts, Sr has long been known to cause rickets in experimental animals (Lehnerdt, 1910, quoted by Neufeld and Boskey, 1994). In Turkish children growing up in regions where the soil Sr content was >350 ppm, the incidence of rickets was nearly twice that in children from regions where the Sr content was lower (Ozgur *et al.,* 1996). Strontium interferes with intestinal calcium absorption and synthesis of $1,25(OH)_2D_3$ (Omdahl and DeLuca, 1972) and interferes with mineralization (Sobel and Hanok, 1952), apparently via direct action on bone cells (Neufeld and Boskey, 1994), although the nature of this action is as yet unclear. One way in which bone formation may be interfered with by Sr is to delay the natural progression of osteoid to bone, i.e., at the stage of conversion of cartilage to bone. This interference is consistent with the greater accumulation of complexed acidic phospholipids in Sr-fed rats or in mesenchymal cell micromass cultures (Neufeld and Boskey, 1994). Davis *et al.* (2000) reported that Sr becomes associated with the collagen matrix produced in cell culture. It would be interesting to know to what extent the inhibitory effect of Sr can be attributed to displacing Ca^{2+} in other calcium-mediated processes.

There have been reports that nontoxic amounts of Sr may be beneficial in osteoporosis (Storey, 1961 and McCaslin and James, 1981, quoted by Morohashi *et al.* 1994, Brandi, 1993) and in rats, where 0.19% $SrCl_2$ in the diet stimulated bone formation (as evaluated histomorphometrically) and raised the trabecular calcified bone volume by 10% (Marie *et al.,* 1985). More recently, Marie *et al.* (1993) have reported that an organic distrontium salt, S12911, inhibited the increase in bone resorption in ovariectomized rats, without reducing bone formation. It is unclear, however, how much of this effect is due to Sr. In mice, 0.27% $SrCl_2$ in the diet increased the osteoid surface, but had no effect on trabecular calcified bone volume (Marie and Hott, 1985). Grynpas *et al.* (1996) fed 0.2% Sr to 28-day old rats consuming a 0.5% Ca and 0.5% P diet and found that the number of bone-forming sites and the vertebral bone volume had increased by 17% compared with controls. No detectable adverse effects on mineralization, mineral profile, or mineral chemistry were observed in the Sr-fed animals. Similarly, Morohashi *et al.* (1994) found no harmful effects when rats were fed 0.05 or 0.10% Sr in a semisynthetic vitamin D-deficient diet, whereas 0.5% Sr depressed bone calcium content and the bone calcium deposition rate. In these studies, the limiting Sr concentration was 175 μM; beyond that level, calcium metabolism was depressed. However, at the lower Sr intakes, there also was no beneficial effect of Sr intake. It would thus seem that as Sr replaces Ca, the metabolism of calcium is depressed, with high Sr intakes leading to rickets and poor bone formation and mineralization.

An interesting use of Sr has been in the radiotherapy of painful bone metastases with ^{89}Sr (Robinson *et al.,* 1995, Pons *et al.,* 1997; Papatheophanis, 1997). Such treatment has been reported more widely for pain relief in patients with prostatic cancer, but has also found application in patients with breast cancer (Pons *et al.,* 1997). Immediately following the injection of $^{89}SrCl_2$, patients experienced a flare reaction of pain. Thereafter pain relief lasted on the average 6 months, with treatment effectively repeatable for another 6 months (Pons *et al.,* 1997). As yet there is no indication that ^{89}Sr is tumoricidal.

Concluding Remarks

All of the metals discussed in detail in this chapter appear to have an effect on the skeleton, but in nearly all there is no clear distinction between cellular effects and effects due to accumulation in the bone mineral and/or the extracellular matrix. Significant accumulation of a given metal in a mineral can be expected to alter the characteristics of the mineral, but it is important to know these changes in detail. Furthermore, by studying the detailed mechanisms of metal accumulation—heteroionic exchange and/or deposition—one might learn more about mineralization. Similarly, by studying the qualitative and quantitative effects on bone cells in culture, mechanisms of cellular action might be laid bare. From a practical viewpoint, moreover, the role of metals used in prostheses needs and is now getting intensive exploration. Dental implants and knee and hip prostheses have raised questions concerning the possible toxicity of the materials used in these procedures. Thus, Wang *et al.* (1996) investigated the cause of osteolysis, a major cause of aseptic loosening in total joint arthroplasty. They studied the effect of titanium, cobalt, and chromium, metals used commonly in joint prostheses, and found a metal-induced increase in the release of bone cytokines. The authors then raised the question whether this can contribute to osteolysis, an event that in turn can severely compromise the outcome of total joint arthroplasty. However, Pohl and colleagues (2000) found no impairment of periodontal healing following the insertion of titanium posts. Piatelli *et al.* (1998) had come to a similar conclusion regarding titanium implants. Aluminum oxide is used with ceramics, and studies on the effect of this metal on biocompatability of the implants have generally found no major problems (Chang *et al.,* 1996; Piatelli *et al.,* 1996, 1998; Shinzato *et al.,* 1999; Okada *et al.,* 2000), but truly long-term results are still outstanding. It seems clear that the study of metals in bone continues to provide wide opportunities for research to all with an interest in either a given metal or the biology of bone.

CHAPTER 23

Biology of the Extracellular Ca^{2+}-Sensing Receptor

Edward M. Brown

Endocrine-Hypertension Division, Brigham and Women's Hospital and Harvard Medical School, Boston, Massachusetts 02115

Introduction

Complex, free-living terrestrial organisms, such as humans, maintain their level of extracellular ionized calcium (Ca_o^{2+}) within a narrow range of about 1.1–1.3 m*M* (Bringhurst *et al.,* 1998; Brown, 1991). This near constancy of Ca_o^{2+} ensures that Ca^{2+} ions are available for their extracellular roles, including serving as a cofactor for clotting factors, adhesion molecules, and other proteins and controlling neuronal excitability (Brown, 1991). Moreover, calcium and phosphate salts form the mineral phase of bone, which affords a rigid framework that protects vital bodily structures and permits locomotion and other movements. The skeleton also provides a nearly inexhaustible reservoir of these ions when their availability in the diet is insufficient for the body's needs (Bringhurst *et al.,* 1998).

In contrast to Ca_o^{2+}, the cytosolic-free calcium concentration (Ca_i^{2+}) has a basal level—about 100 n*M*—that is nearly 10,000-fold lower (Pozzan *et al.,* 1994). Ca_i^{2+}, however, can increase 10-fold or more when cells are stimulated by extracellular signals acting on their respective cell surface receptors as a result of influx of Ca^{2+} and/or its release from intracellular stores (Pozzan *et al.,* 1994). Ca_i^{2+} plays central roles in regulating cellular processes as varied as muscular contraction, cellular motility, differentiation and proliferation, hormonal secretion, and apoptosis (Pietrobon *et al.,* 1990). Because all intracellular Ca^{2+} ultimately originates from that present in the extracellular fluids (ECF), maintaining near constancy of Ca_o^{2+} also ensures that this ion is available for its myriad intracellular roles.

The level of Ca_o^{2+} is maintained by a homeostatic mechanism in mammals that comprises the parathyroid glands, calcitonin (CT)-secreting C cells, kidney, bone, and intestine (Bringhurst *et al.,* 1998; Brown, 1991). A key element of this system are cells that are capable of sensing small deviations in Ca_o^{2+} from its usual level and responding in ways that normalize it (Brown, 1991). Calcium ions have long been known to traverse the plasma membrane through various types of ion channels and other transport mechanisms (Pietrobon *et al.,* 1990); however, the actual mechanism by which Ca_o^{2+} was "sensed" remained an enigma for many years. This chapter provides an update on our present understanding of the process of Ca_o^{2+} sensing, which has increased greatly over the past decade, especially as it relates to the mechanism that maintains Ca_o^{2+} homeostasis.

It is becoming increasingly clear, however, that Ca_o^{2+} serves as a versatile extracellular first messenger—in many instances acting via the Ca^{2+}-sensing receptor (CaR)—that controls numerous physiological processes beyond those governing Ca_o^{2+} homeostasis (for review, see Brown *et al.,* (1999). While it is beyond the scope of this chapter to review the "nonhomeostatic" roles of the CaR in detail, an emerging body of evidence supports the concept that the receptor participates in important interactions between the system regulating Ca_o^{2+} metabolism and other homeostatic systems (i.e., that controlling water metabolism). These interactions may be crucial for the successful adaptation of complex life forms to the terrestrial environment. This chapter will likewise address these recently emerging homeostatic relationships.

Cloning of the CaR

Just a decade ago, the concept that there was a specific Ca_o^{2+}-sensing "receptor" was only supported by indirect evidence derived from studies of a very limited number of

Ca_o^{2+}-sensing cells, particularly parathyroid cells (Brown, 1991; Juhlin *et al.,* 1987; Nemeth and Scarpa, 1987; Shoback *et al.,* 1988). It was necessary, therefore, in devising a strategy for cloning the putative receptor to employ an approach that detected its Ca_o^{2+}-sensing activity using a bioassay—namely, expression cloning in *Xenopus laevis* oocytes. Racke *et al.* (1993) and Shoback and co-workers (Chen *et al.,* 1994) both demonstrated that *X. laevis* oocytes became responsive to Ca_o^{2+}-sensing receptor agonists after they were injected with messenger RNA (mRNA) extracted from bovine parathyroid glands but not with water as a negative control. Brown *et al.* (1993) were then able to implement this strategy to screen a bovine parathyroid cDNA library, permitting the isolation of a full-length, functional clone of the Ca_o^{2+}-sensing receptor. The use of conventional, hybridization-based approaches subsequently permitted the cloning of cDNAs coding for CaRs from human parathyroid (Garrett *et al.,* 1995b) and kidney (Aida *et al.,* 1995b), rat kidney (Riccardi *et al.,* 1995), brain (namely striatum) (Ruat *et al.,* 1995), and C cell (Garrett *et al.,* 1995c); rabbit kidney (Butters *et al.,* 1997); and chicken parathyroid (Diaz *et al.,* 1997) (reviewed in Brown *et al.,* 1999). All exhibit very similar predicted structures and represent tissue and species homologues of the same ancestral gene.

Predicted Structure of the CaR and Its Relationships to Other G Protein-Coupled Receptors

Topology of the CaR protein predicted from its nucleotide sequence is illustrated in Fig. 1. It has three principal structural domains, which include (a) a large, 600 amino acid extracellular amino-terminal domain (ECD), (b) a "serpentine" seven membrane-spanning motif that is characteristic of the superfamily of G protein-coupled receptors (GPCRs), and (c) a sizable carboxyl-terminal (C-) tail of about 200 amino acids. Several different subfamilies of GPCRs have been

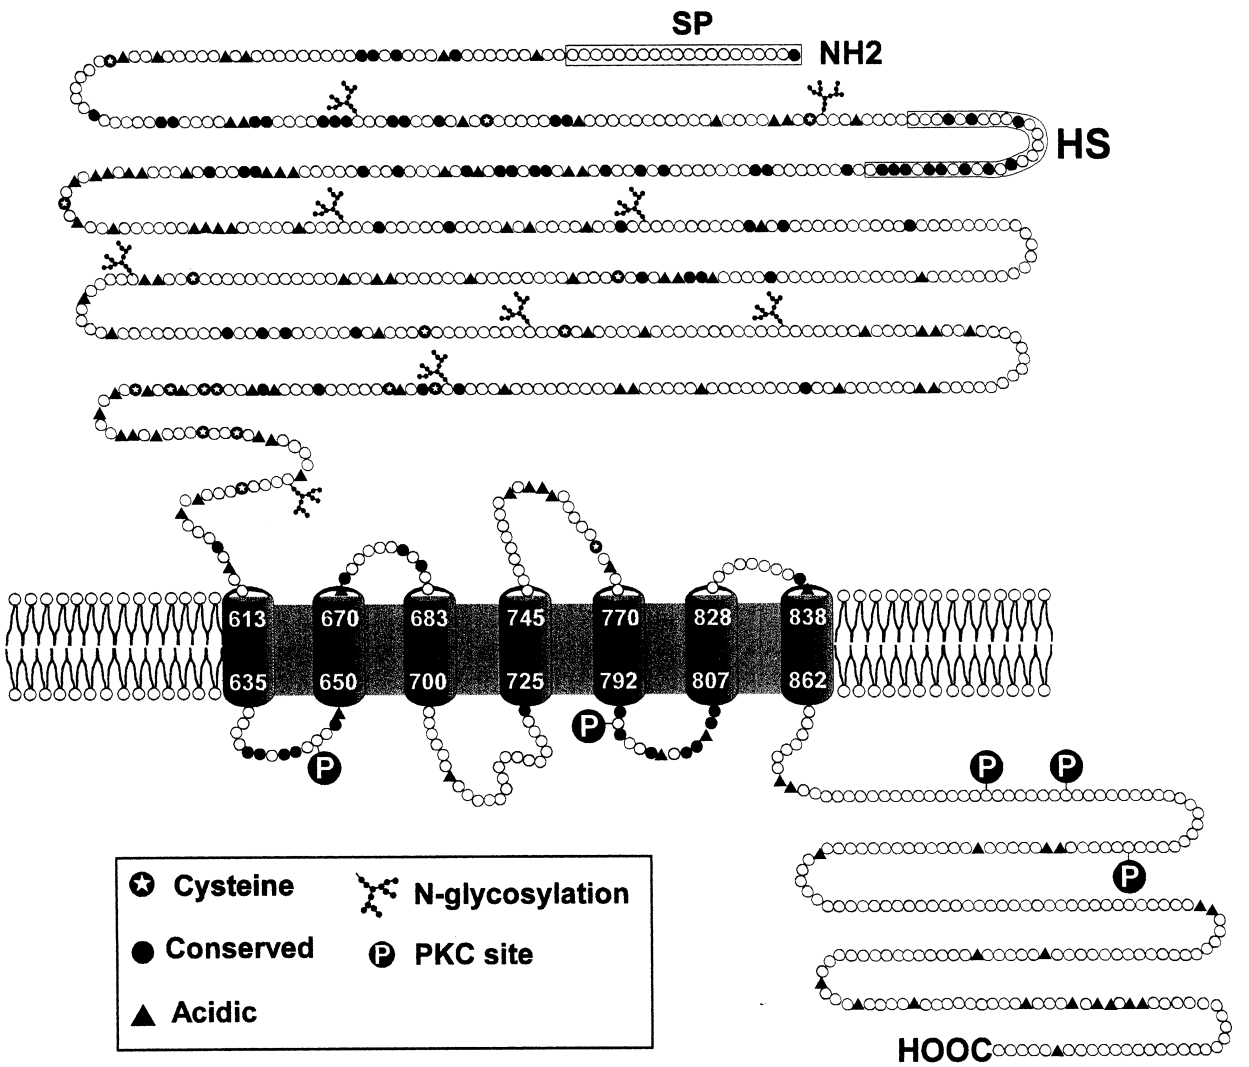

Figure 1 Predicted structure of the CaR (see text for additional details). SP, signal peptide; HS, hydrophobic segment. Reproduced with permission from Brown *et al.* (1993).

identified that share striking topological similarities with the CaR, particularly in their respective, large ECDs. They also share a modest (20–30%) overall degree of amino acid identity with the CaR. These structurally related GPCRs are designated family C receptors (Kolakowski, 1994). They comprise three separate groups: metabotropic glutamate receptors (mGluRs) (group I), the CaR and a family of putative pheromone receptors (group II), and the $GABA_B$ receptors (group III). mGluRs are activated by glutamate, the major excitatory neurotransmitter in the central nervous system (CNS) (Nakanishi, 1994). The $GABA_B$ receptors are GPCRs that recognize γ-aminobutyric acid (GABA), the principal inhibitory neurotransmitter of the CNS (Kaupmann *et al.,* 1997; Ng *et al.,* 1999). The putative pheromone receptors within group II reside solely in neurons of the rat vomeronasal organ (VNO) expressing the guanine nucleotide regulatory (G) protein, $G\alpha_o$ (Matsunami and Buck, 1997). The VNO is a sensory organ that controls instinctual behavior, particularly in rodents, via input from environmental pheromones (Matsunami and Buck, 1997). Additional GPCRs that are closely related to the CaR and pheromone receptors have been characterized in mammals (Hoon *et al.,* 1999) and fish (Cao *et al.,* 1998). These are, respectively, taste and putative odorant receptors. The latter may be evolutionary precursors of the pheromone receptors identified in rats. Both exhibit the topology characteristic of the family C GPCRs.

Therefore, all of the family C GPCRs share the property of having small molecules as ligands that provide environmental cues (i.e., pheromones) or serve as extracellular messengers within the CNS (e.g., glutamate or GABA) or in bodily fluids more generally (namely Ca_o^{2+}). As detailed later ligands of the CaR and the other family C GPCRs are thought to bind to their respective ECDs. In contrast, most other GPCRs binding small ligands, such as epinephrine or dopamine, have binding sites within their TMDs and/or extracellular loops (ECLs). The ligand-binding capacity of the family C ECDs probably has its origin in a family of extracellular binding proteins in bacteria (O'Hara *et al.,* 1993), the so-called periplasmic binding proteins (PBPs). These serve as receptors for a wide variety of small ligands present in the environment, including ions (including Mg_o^{2+}, but apparently not Ca_o^{2+}), amino acids, and other nutrients (Tam and Saier, 1993). PBPs promote bacterial chemotaxis toward these environmental nutrients and other substances and facilitate their cellular uptake by activating specific transport systems in the cell membrane (Tam and Saier, 1993).

The family C GPCRs, therefore, can be thought of as representing fusion proteins, which comprise an extracellular ligand-binding motif (the ECD) linked to a signal-transducing motif (the seven transmembrane domains) that couples the sensing of extracellular signals to intracellular signaling systems (i.e., G proteins and their associated second messenger pathways). It is of interest that some of the biological functions regulated by the CaR are the same as those controlled by the PBPs, namely chemotaxis [e.g., of monocytes toward elevated levels of Ca_o^{2+} (Sugimoto *et al.,* 1993)] and cellular transport [i.e., of Ca_o^{2+} by CaR-regulated, Ca^{2+}-permeable channels (Chang *et al.,* 1995)]. Moreover, as detailed later, the CaR binds not only Ca_o^{2+} but also additional ligands, including amino acids (Conigrave *et al.,* 2000), which further supports its evolutionary and functional relationships to the other family C GPCRs and, ultimately, to PBPs.

Biochemical Properties of the CaR

Studies using chimeric receptors comprising the ECD of the CaR coupled to the TMDs and C tail of the mGluRs (and vice versa) have demonstrated that Ca_o^{2+} binds to the ECD of the CaR (Hammerland *et al.,* 1999). Studies have indicated that specific residues within the ECD (e.g., Ser147 and Ser170) may be involved, directly or indirectly, in the binding of Ca_o^{2+}. These residues are equivalent to those that are thought to participate in binding glutamate to the mGluRs and GABA to the $GABA_B$ receptor (Brauner-Osborne *et al.,* 1999). Given the apparent "positive cooperativity" of the CaR and the resultant steep slope of the curve describing its activation by various polycationic agonists (e.g., Ca_o^{2+} and Mg_o^{2+}) (Brown, 1991), however, it is likely that the CaR binds several calcium ions. Further work is needed, therefore, in defining more precisely the identity of this putative Ca_o^{2+}-binding site(s). Interestingly, the CaR resides on the cell surface primarily in the form of a dimer (Bai *et al.,* 1998a; Ward *et al.,* 1998). CaR monomers within the dimeric receptor are linked by disulfide bonds within their ECDs that involve the cysteines at amino acid positions 129 and 131 (Ray *et al.,* 1999). Moreover, functional interactions can occur between the monomeric subunits of the dimeric CaR because two individually inactive CaRs that harbor inactivating mutations in different functional domains (e.g., the ECD and C tail) can reconstitute substantial biological activity when they heterodimerize after cotransfection in human embryonic kidney (HEK293) cells (Bai *et al.,* 1999). Therefore, even though the individual CaRs lack biological activity, they "complement" one another's defects through a mechanism that must involve intermolecular interactions to form a partially active heterodimer.

As noted previously, the CaR exhibits apparent positive cooperativity, which is essential to ensure that it responds over the narrow range of Ca_o^{2+} regulating, for instance, PTH secretion. This cooperativity could result, at least in part, from the presence of Ca_o^{2+}-binding sites on both of the individual ECDs of the dimeric CaR and/or at the site(s) where the two ECDs in the dimer interact with one another. Eventually, solution of the three-dimensional structure of the receptor's ECD by X-ray crystallography will no doubt illuminate how the CaR binds Ca_o^{2+} and its other agonists and modulators.

The ECD of the CaR on the cell surface is N-glycosylated extensively with complex carbohydrates (Bai *et al.,*

1996). Eight of the predicted N-glycosylation sites in the ECD of the human CaR are glycosylated (Ray *et al.,* 1998). Disrupting four or five of these sites decreases the cell surface expression of the receptor by 50–90%. Therefore, glycosylation of at least three sites is required for robust cell surface expression, although glycosylation *per* se does not appear to be critical for the capacity of the CaR to bind Ca_o^{2+} and activate its intracellular signaling pathways (Ray *et al.,* 1998).

Within its intracellular loops and C tail, the human CaR harbors five predicted protein kinase C (PKC) and two predicted protein kinase A (PKA) phosphorylation sites (Bai *et al.,* 1998b; *Garrett et al.,* 1995b). The functional significance of the PKA sites is not known. Activation of PKC diminishes CaR-mediated stimulation of phospholipase C (PLC), and studies utilizing site-directed mutagenesis have demonstrated that phosphorylation of a single, key PKC site in the C tail of the CaR at thr888 can account for most of the inhibitory effect of PKC on the function of the receptor (Bai *et al.,* 1998b). Therefore, PKC-induced phosphorylation of the C tail may afford a means of conferring negative feedback regulation on the coupling of the receptor to PLC. That is, PLC-elicited activation of protein kinase C — through the ensuing phosphorylation of the CaR at thr888 — limits further activation of this pathway.

Intracellular Signaling by the CaR

Activation of the CaR by its agonists stimulates the activities of phospholipases C, A_2 (PLA_2), and D (PLD) in bovine parathyroid cells and in HEK293 cells stably transfected with the human CaR (Kifor *et al.,* 1997). In most cells, CaR-evoked activation of PLC involves the participation of the pertussis toxin-insensitive G protein(s), $G_{q/11}$ (Hawkins *et al.,* 1989), although in some it can take place through a pertussis toxin-sensitive pathway, most likely via one or more isoforms of the G_i subfamily of G proteins (Emanuel *et al.,* 1996). In bovine parathyroid cells and CaR-transfected HEK293 cells, CaR-mediated stimulation of PLA_2 and PLD occurs through PKC-dependent mechanisms, presumably via receptor-dependent activation of PLC (Kifor *et al.,* 1997).

The high Ca_o^{2+}-induced, transient increase in Ca_i^{2+} in bovine parathyroid cells and CaR-transfected HEK293 cells likely results from activation of PLC (Kifor *et al.,* 1997) and resultant IP_3-mediated release of intracellular Ca^{2+} stores (Bai *et al.,* 1996). High Ca_o^{2+} also elicits sustained elevations in Ca_i^{2+} in both CaR-transfected HEK293 cells (Bai *et al.,* 1996) and bovine parathyroid cells (Brown, 1991), acting through an incompletely defined influx pathway(s) for Ca^{2+}. Via the patch-clamp technique, we have shown that the CaR activates a Ca_o^{2+}-permeable, nonselective cation channel (NCC) in CaR-transfected HEK cells (Ye *et al.,* 1996). An NCC with similar properties is present in bovine parathyroid cells and is likewise activated by high Ca_o^{2+} — an effect presumably mediated by the CaR (Chang *et al.,* 1995). This latter NCC may participate in the high Ca_o^{2+}-induced, sustained elevation in Ca_i^{2+} in parathyroid cells (Brown *et al.,* 1990).

High Ca_o^{2+} reduces agonist-stimulated cAMP accumulation in bovine parathyroid cells markedly (Chen *et al.,* 1989), an action that is thought to involve inhibition of adenylate cylcase by one or more isoforms of G_i, as it is pertussis toxin sensitive (Chen *et al.,* 1989). Other cells, however, can exhibit high Ca_o^{2+}-elicited diminution of cAMP accumulation that involves indirect pathways, including inhibition of a Ca_i^{2+}-inhibited isoform of adenylate cyclase due to the associated rise in Ca_i^{2+} (de Jesus Ferreira *et al.,* 1998). The CaR also activates mitogen-activated protein kinase (MAPK) in several types of cells, including rat-1 fibroblasts (McNeil *et al.,* 1998b), ovarian surface cells (McNeil *et al.,* 1998a), and CaR-transfected but not nontransfected HEK293 cells (Kifor *et al.,* 2001). As is the case with other GPCRs, the CaR stimulates the activity of MAPK through both PKC- and tyrosine kinase-dependent pathways. The latter involves, in part, c-Src-like cytoplasmic tyrosine kinases. The PKC-dependent activation of MAPK is presumably downstream of G_q-mediated activation of PLC, whereas that involving tyrosine kinases may utilize the G_i-dependent pathway involving $\beta\gamma$ subunits released as a consequence of the activation of this G protein (Kifor *et al.,* 2001; McNeil *et al.,* 1998b).

The CaR Gene and Its Regulation

Relatively little is presently known regarding the structure of the CaR gene, especially its upstream regulatory regions and the factors controlling its expression. The human CaR gene is on the long arm of chromosome 3, as demonstrated by linkage analysis (Chou *et al.,* 1992), and in band 3q13.3–21, as documented by fluorescent *in situ* hybridization (Janicic *et al.,* 1995). Rat and mouse CaR genes reside on chromosomes 11 and 16, respectively (Janicic *et al.,* 1995). The CaR gene has seven exons: the first includes the upstream untranslated region, the next five encode various regions of the ECD, and the last encodes the rest of the CaR from its first TMD to the C terminus (Pearce *et al.,* 1995). Characterization of the upstream regulatory regions of the gene will be of great interest because expression of the CaR can change in a various physiologically relevant circumstances — some of which are delineated next.

Several factors increase CaR expression. Both high Ca_o^{2+} and $1,25(OH)_2D_3$ upregulate expression of the gene in certain cell types. High Ca_o^{2+} increases expression of the CaR in ACTH-secreting, pituitary-derived AtT-20 cells (Emanuel *et al.,* 1996), whereas administration of $1,25(OH)_2D_3$ elevates expression of the CaR *in vivo* in kidney and parathyroid of the rat in some (Brown *et al.,* 1996) but not all studies (Rogers *et al.,* 1995). Interleukin-1β increases the level of CaR mRNA modestly in bovine parathyroid gland fragments, which may contribute to the associated reduction in PTH secretion that was observed

in this study (Nielsen *et al.,* 1997). In rat kidney, substantial upregulation of the CaR takes place during the peri- and immediate postnatal period; the resultant higher level of expression of the receptor then persists throughout adulthood (Chattopadhyay *et al.,* 1996). There is likewise a developmental increase in expression of the CaR in rat brain. In contrast to that occurring in the kidney, however, the rise in the expression of the CaR in the brain occurs about a week postnatally (Chattopadhyay *et al.,* 1997). Moreover, the increase in CaR expression in the brain is only transient—it decreases severalfold approximately 2 weeks later and reaches a lower level that remains stable thereafter (Chattopadhyay *et al.,* 1997). The biological importance of these developmental changes in the expression of the receptor is currently unknown.

In contrast, several instances have been defined in which CaR expression decreases. Calf parathyroid cells exhibit a rapid, marked (80–85%) reduction in expression of the receptor after they are placed in culture (Brown *et al.,* 1995; *Mithal et al.,* 1995), which is likely to be a major factor that contributes to the associated reduction in high Ca_o^{2+}-evoked inhibition of PTH secretion. The expression of the CaR in the kidney decreases in a model of chronic renal insufficiency in the rat induced by subtotal nephrectomy (Mathias *et al.,* 1998). This latter reduction in CaR expression might contribute to the hypocalciuria that occurs in human renal insufficiency, as reduced renal CaR expression and/or activity increases tubular reabsorption of Ca^{2+} in humans with inactivating mutations of the receptor (Brown, 1999). Because $1,25(OH)_2D_3$ upregulates renal CaR expression (Brown *et al.,* 1996), the reduction in CaR expression in the setting of impaired renal function could be the result, in part, of the concomitant decrease in circulating levels of $1,25(OH)_2D_3$ (Bringhurst *et al.,* 1998). The mechanisms that underlie these alterations in expression of the CaR gene, however, including the relative importance of changes in gene transcription vs posttranscriptional mechanisms, require further investigation.

Roles of the CaR in Tissues Maintaining Ca_o^{2+} Homeostasis

Parathyroid

The parathyroid glands of several species express high levels of CaR mRNA and protein, including those of humans (Kifor *et al.,* 1996), rats (Autry *et al.,* 1997), mice (Ho *et al.,* 1995), rabbits (Butters *et al.,* 1997), and chickens (Diaz *et al.,* 1997). Indeed, the level of CaR expression in the parathyroid chief cells is one of the highest, if not the highest, in the cells and tissues examined to date. Abundant evidence, reviewed later, supports the importance of the CaR as the key mediator of the inhibitory action of elevated Ca_o^{2+} on PTH secretion. Despite several decades of study, however, the principal intracellular signaling mechanism(s) through which it exerts this action remains unclear (for review, see Diaz *et al.,* 1998). Evidence supporting the role of the CaR in Ca_o^{2+}-regulated PTH release is as follows: As noted earlier, the reduced CaR expression in bovine parathyroid cells maintained in culture is associated with a progressive loss of high Ca_o^{2+}-induced inhibition of PTH secretion (Brown *et al.,* 1995; Mithal *et al.,* 1995). In addition, individuals with familial hypocalciuric hypercalcemia (FHH), who are heterozygous for inactivating mutations of the CaR gene (Brown, 1999), or mice that are heterozygous for targeted disruption of the CaR gene (Ho *et al.,* 1995) exhibit modest right shifts in their set points for Ca_o^{2+}-regulated PTH secretion (the level of high Ca_o^{2+} half-maximally inhibiting PTH release), indicative of "Ca_o^{2+} resistance." Moreover, humans and mice homozygous for loss of the normal CaR (Brown, 1999; Ho *et al.,* 1995) show much greater impairment of high Ca_o^{2+}-elicited suppression of PTH release, showing that that the "Ca_o^{2+} resistance" of the parathyroid is related inversely to the number of normally functioning CaR alleles. Therefore, the biochemical findings in mice in which the CaR has been "knocked-out," as well as in humans with naturally occurring inactivating mutations of the CaR, prove the central role of the CaR in Ca_o^{2+}-regulated PTH release.

Another aspect of parathyroid function that is likely to be CaR regulated is PTH gene expression. Garrett *et al.* (1995a) showed in preliminary studies that the "calcimimetic" CaR activator NPS R-568, which activates the receptor allosterically through a mechanism involving an increase in the apparent affinity of the CaR for Ca_o^{2+} (Nemeth *et al.,* 1998b), decreases the level of PTH mRNA in bovine parathyroid cells. Finally, the CaR, directly or indirectly, tonically inhibits the proliferation of parathyroid cells, as persons homozygous for inactivating mutations of the CaR (Brown, 1999) or mice homozygous for "knockout" of the CaR gene (Ho *et al.,* 1995) exhibit marked parathyroid cellular hyperplasia. Treatment of rats with experimentally induced renal impairment with the calcimimetic NPS R-568 prevented the parathyroid hyperplasia that would otherwise have been anticipated to occur in this setting (Wada *et al.,* 1998), providing further evidence that activation of the CaR suppresses parathyroid cellular proliferation.

C Cells

Unlike the effect of Ca_o^{2+} on PTH release, elevating Ca_o^{2+} stimulates CT secretion—a response that conforms to the classical, positive relationship between Ca^{2+} and activation of exocytosis in most other hormone-secreting cells (Bringhurst *et al.,* 1998; Brown, 1991). This observation was one of several pieces of indirect evidence that the mechanism underlying Ca_o^{2+} sensing in C cells might differ in a fundamental way from that in parathyroid cells. More recent data, however, have demonstrated that rat, human, and rabbit C cells express the CaR (Butters *et al.,* 1997; Freichel *et al.,* 1996; Garrett *et al.,* 1995c). Moreover,

cloning of the CaR from a rat C cell tumor cell line showed it to be identical to that expressed in rat kidney (Garrett *et al.,* 1995c). Available evidence indicates that the CaR mediates the stimulatory effect of high Ca_o^{2+} on CT secretion; however, studies definitively proving the involvement of the CaR in high Ca_o^{2+}-evoked CT secretion, e.g., by "knocking out" the CaR in C cells *in vitro* using a dominant-negative construct or in mice *in vivo* utilizing targeted inactivation of the CaR gene, have not yet been reported. Tamir and co-workers have suggested that the following sequence of steps mediates CaR-stimulated CT secretion (McGehee *et al.,* 1997). High Ca_o^{2+} first stimulates phosphatidylcholine-specific PLC, which generates diacylglycerol, thereby activating an NCC through a PKC-dependent mechanism. The activated NCC then enhances cellular uptake of Na^+ and Ca^{2+}, producing cellular depolarization and consequent stimulation of voltage-dependent, principally L-type Ca^{2+} channels that elevate Ca_i^{2+} and activate exocytosis of 5-hydroxytryptamine- and CT-containing secretory granules.

Kidney

In the kidney of the adult rat, the CaR is expressed along almost the entire nephron, with the highest levels of protein expression at the basolateral aspect of the epithelial cells of the cortical thick ascending limb (CTAL) (Riccardi *et al.,* 1998). The latter plays a key role in the hormone (e.g., PTH)-regulated reabsorption of divalent minerals (De Rouffignac and Quamme, 1994; Friedman and Gesek, 1995). The CaR is also present on the basolateral membranes of the cells of the distal convoluted tubule (DCT), where Ca^{2+} reabsorption—similar to that in the CTAL— is stimulated by PTH. Further sites of renal CaR expression include the base of the microvilli of the proximal tubular brush border (Riccardi *et al.,* 1998), the basolateral surface of the tubular cells of the medullary thick ascending limb (MTAL) (Riccardi *et al.,* 1998), and the luminal side of the epithelial cells of the inner medullary collecting duct (IMCD) (Sands *et al.,* 1997). None of these latter nephron segments play major roles in renal Ca_o^{2+} handling, but the CaR expressed in them could conceivably modulate the handling of other solutes and/or water. As will be discussed in more detail later, the CaR in the CTAL, in addition to modulating reabsorption of Ca^{2+} and Mg^{2+}, also participates in controlling the renal handling of Na^+, K^+, and Cl^- (Hebert *et al.,* 1997). Finally, the CaR expressed in the IMCD likely mediates the well-recognized inhibitory action of high Ca_o^{2+} on vasopressin-evoked water reabsorption (Sands *et al.,* 1997, 1998), which is one cause of the defective urinary-concentrating ability in some patients with hypercalcemia (Brown, 1999; Brown *et al.,* 1999).

The localization of the CaR on the basolateral membrane in the CTAL indicates that it might represent the mediator of the previously demonstrated inhibitory effect of high peritubular but not luminal levels of Ca_o^{2+} on Ca^{2+} and Mg^{2+} reabsorption in perfused tubular segments from this portion of the nephron (De Rouffignac and Quamme, 1994). Figure 2 shows a schematic illustration of how the CaR may inhibit PTH-enhanced divalent cation reabsorption in the CTAL. As indicated in detail in Fig. 2, the CaR acts in a "lasix-like" fashion to diminish overall activity of the Na^+-K^+-$2Cl^-$ cotransporter, which generates the lumen-positive, transepithelial potential gradient that normally drives passive paracellular reabsorption of about 50% of NaCl and most of the Ca^{2+} and Mg^{2+} in this part of the nephron (Hebert *et al.,* 1997). It is of interest that individuals with FHH manifest a markedly reduced ability to upregulate urinary excretion of Ca^{2+} despite their hypercalcemia—even when they have been rendered aparathyroid by total parathyroidectomy (Attie *et al.,* 1983). Thus, the PTH-independent, excessive reabsorption of Ca^{2+} in FHH likely results, in part, from a decreased complement of normally functioning CaRs in the CTAL. This defect renders the tubule "resistant" to Ca_o^{2+} and reduces the normal, high Ca_o^{2+}-evoked hypercalciuria that occurs in this nephron segment (Brown, 1999). Thus, in normal persons, hypercalcemia-evoked hypercalciuria likely has two distinct CaR-mediated components: (1) suppression of PTH secretion and (2) direct inhibition of tubular reabsorption of Ca^{2+} in the CTAL. It is not presently known whether the CaR also modulates PTH-enhanced Ca^{2+} reabsorption in the DCT. The Ca^{2+}-permeable channels, ECaC1 (Hoenderop *et al.,* 1999) and CaT2 (Peng *et al.,* 2000) (which were cloned from rabbit and rat kidney, respectively, and are orthologs of the same gene), may participate in the apical entry of Ca^{2+} in this part of the nephron. They represent potential targets for the mutually antagonistic regulation of Ca^{2+} reabsorption in the DCT and connecting segment by PTH and the CaR.

Intestine

The intestine is a key participant in maintaining Ca_o^{2+} homeostasis by virtue of its capacity for the regulated absorption of dietary Ca_o^{2+} through the action of $1,25(OH)_2D_3$, the most active naturally occurring metabolite of vitamin D (Bringhurst *et al.,* 1998; Brown, 1991). The duodenum is the principal site for l,25-dihydroxyvitamin D_3 [$l,25(OH)_2D_3$]-stimulated intestinal Ca^{2+} absorption through a transcellular pathway of active transport. The latter is thought to involve initial Ca^{2+} entry through the newly cloned, Ca^{2+}-permeable channel known as CaT1 (Peng *et al.,* 1999) or ECaC2 (Hoenderop *et al.,* 1999) (both are products of the same gene and are closely related to but distinct from CaT2 and ECaC1). Calcium ions subsequently diffuse across the cell—a process facilitated by the vitamin D-dependent Ca^{2+}-binding protein, calbindin—and are eventually extruded at the basolateral cell surface by the Ca^{2+}-ATPase and, perhaps, the Na^+-Ca^{2+} exchanger. Jejunum and ileum absorb less Ca^{2+} than the duodenum (particularly when expressed as absorption per unit surface area). They also secrete Ca^{2+}, which may chelate fatty acids and bile acids, thereby producing insoluble "calcium soaps" and mitigating possible damaging effects of free fatty

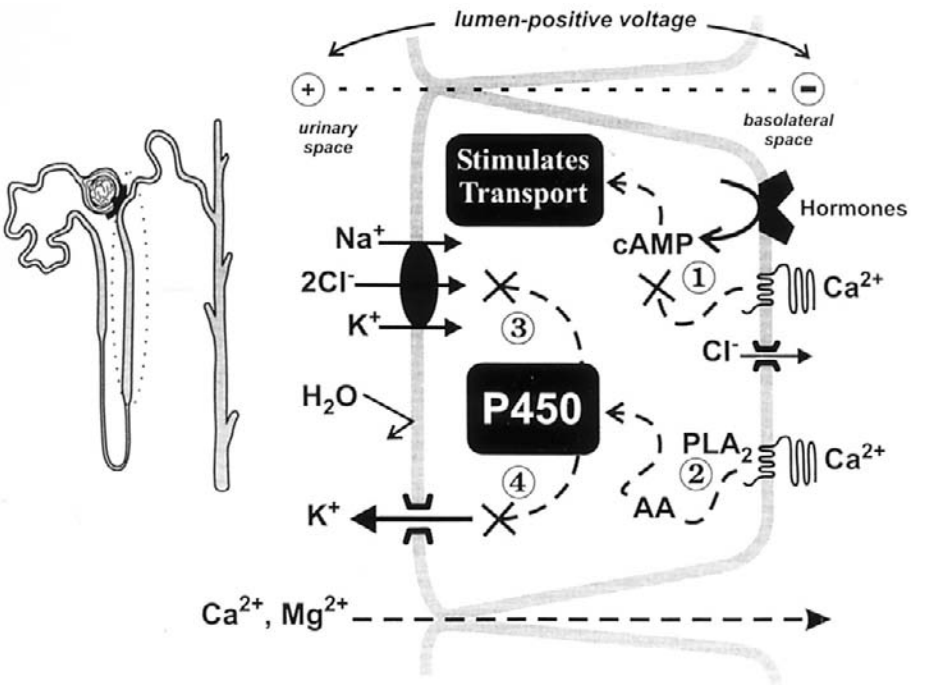

Figure 2 Possible mechanisms by which the CaR modulates intracellular second messenger pathways and ionic transport in the CTAL. Hormones that elevate cAMP (i.e., PTH) stimulate paracellular Ca^{2+} and Mg^{2+} reabsorption by increasing the activities of the Na^+-K^+-$2Cl^-$ cotransporter and an apical K^+ channel and, therefore, increasing the magnitude of V_t. The CaR, which like the PTH receptor is on the basolateral membrane, inhibits PTH-stimulated adenylate cyclase and activates PLA_2 (2). This latter action increases free arachidonic acid, which is metabolized by the P450 pathway to an inhibitor of the apical K^+ channel (4) and, perhaps, the cotransporter (3). Actions of the CaR on both adenylate cyclase and PLA_2 will reduce V_t and, therefore, diminish paracellular divalent cation transport. Reproduced with permission from Brown and Hebert (1997a).

acids and bile salts on colonic epithelial cells. The major function of the colon in fluid and electrolyte metabolism is the absorption of water and Na^+. Nevertheless, it absorbs substantial amounts of Ca^{2+} in humans by both vitamin D-dependent and -independent routes, especially in its proximal segments (Favus, 1992), where it expresses levels of CaT1 similar to those in the duodenum (Peng *et al.,* 1999).

The CaR is expressed in all segments of the intestine in the rat. The highest levels of expression of the receptor are on the basal surface of the small intestinal absorptive cells, the epithelial cells of the crypts of both the small intestine and colon, and in the enteric nervous system (Chattopadhyay *et al.,* 1998). Does the CaR have any role in systemic Ca_o^{2+} homeostasis in these locations? The CaR expressed in the enteric nervous system, which regulates the secretomotor functions of the gastrointestinal tract, could potentially mediate known effects of high and low Ca_o^{2+} to reduce and increase GI motility, respectively, in hyper- and hypocalcemic individuals (Bringhurst *et al.,* 1998). Such an effect on gastrointestinal motility, however, even if it were CaR mediated, would not have any obvious relevance to systemic Ca_o^{2+} homeostasis, other than perhaps indirectly, by modulating the time available for absorption of Ca^{2+} and other nutrients. Currently available evidence, however, does suggest a possible role for the CaR in directly modulating intestinal Ca^{2+} absorption. Hypercalcemia is known to inhibit dietary Ca^{2+} absorption (Krishnamra *et al.,* 1994). Moreover, direct measurements of Ca_o^{2+} within the interstitial fluid underneath small intestinal absorptive epithelial cells has shown that Ca_o^{2+} increases by nearly two-fold if luminal levels of Ca_o^{2+} are elevated to 5–10 m*M*—similar to those achieved after the intake of Ca^{2+}-containing foods (Mupanomunda *et al.,* 1999). This level of Ca_o^{2+} would be more than sufficient to stimulate the CaR expressed on the basolateral surface of small intestinal absorptive cells. Thus it is conceivable that there is a homeostatically relevant, negative feedback regulation of intestinal Ca^{2+} absorption occurring via the local increases in Ca_o^{2+} that take place during the absorptive process. It is not presently known if the CaR modulates small interstitial or colonic Ca^{2+} secretion, although hypercalcemia has been shown to stimulate intestinal Ca^{2+} secretion in some studies (Krishnamra *et al.,* 1994).

Bone and Cartilage

The levels of Ca_o^{2+} achieved within the bony microenvironment probably vary substantially during the regulated

turnover of the skeleton via osteoclastic resorption of bone followed by its restoration by bone-forming osteoblasts—a process that totally replaces the human skeleton approximately every 10 years (Bringhurst *et al.,* 1998). In fact, Ca_o^{2+} directly beneath resorbing osteoclasts can be as high as 8–40 m*M* (Silver *et al.,* 1988). Moreover, Ca_o^{2+} has a variety of actions on bone cell functions *in vitro* that could serve physiologically useful purposes, although it has not yet known if these same actions occur *in viv*o. For example, high Ca_o^{2+} stimulates parameters of osteoblastic functions that could enhance their recruitment to sites of future bone formation, including chemotaxis and proliferation, and promote their differentiation to osteoblasts with a more mature phenotype (Quarles, 1997; Yamaguchi *et al.,* 1999). Furthermore, elevated levels of Ca_o^{2+} suppress both the formation (Kanatani *et al.,* 1999) and the activity (Zaidi *et al.,* 1999) of osteoclasts *in vitro.* Therefore, Ca_o^{2+} has effects on cells of both osteoblastic and osteoclastic lineages and/or their precursors that are homeostatically appropriate. Raising Ca_o^{2+} would, for example, produce net movement of Ca^{2+} into bone by stimulating bone formation and inhibiting its resorption. In addition, locally elevated levels of Ca_o^{2+} produced by osteoclasts at sites of active bone resorption could potentially contribute to "coupling" bone resorption to the ensuing replacement of the missing bone by osteoblasts, by promoting proliferation and recruitment of preosteoblasts within the vicinity to these sites and enhancing their differentiation (Quarles, 1997; Yamaguchi *et al.,* 1999). As detailed later, the molecular identity of the Ca_o^{2+}-sensing mechanism(s) in bone cells remain(s) controversial, although the CaR has been found by several groups of investigators to be present in at least some cells of both osteoblast and osteoclast lineages and could, therefore, potentially participate in this process.

Substantial indirect evidence amassed prior to and around the time that the CaR was cloned suggested that the Ca_o^{2+}-sensing mechanism in osteoblasts and osteoclasts differed in certain pharmacological and other properties from those exhibited the CaR (Quarles, 1997; Zaidi *et al.,* 1999). Moreover, some investigators have been unable to detect expression of the CaR in osteoblast-like (Pi *et al.,* 1999) and osteoclast-like cells (Seuwen *et al.,* 1999). More recent studies, however, have provided strong support for the presence of the CaR in a variety of cells originating from the bone and bone marrow, although its physiological and functional implications in these cells remain uncertain. These CaR-expressing cells include hematopoietic precursors of some (i.e., erythroid and platelet progenitors) but not all lineages (e.g., myeloid precursors) (House *et al.,* 1997), some osteoblast-like and osteoclast-like cell lines, and cells of both lineages when studied *in situ* in sections of bone (Yamaguchi *et al.,* 1999). ST-2 stromal cells (Yamaguchi *et al.,* 1998a), a stromal cell line derived from the same mesenchymal stem cells giving rise to osteoblasts, express CaR mRNA and protein, as do osteoblast-like cell lines (e.g., the Saos-2, MC-3T3-E1, UMR-106, and MG-63 cell lines) (Chang *et al.,* 1999b; Yamaguchi *et al.,* 1998b,c). Furthermore, Chang *et al.* (1999b) have shown that both CaR mRNA and protein are expressed in most osteoblasts in sections of murine, rat, and bovine bone. Regarding cells of the osteoclast lineage, more than 80% of human peripheral blood monocytes, which arise from the same hematopoietic lineage giving rise to osteoclast precursors, express abundant levels of CaR mRNA and protein (Yamaguchi *et al.,* 1998d). Preosteoclast-like cells generated *in vitro* also show expression of the CaR (Kanatani *et al.,* 1999), and osteoclasts isolated from rabbit bone likewise express the receptor (Kameda *et al.,* 1998). In murine, rat, and bovine bone sections, in contrast, only a minority of the multinucleated osteoclasts expressed CaR mRNA and protein (Chang *et al.,* 1999b). Additional studies are required to clarify whether primarily osteoclast precursors, rather than mature osteoclasts, express the CaR. Furthermore, more work is necessary in which the activity of the CaR in bone cells and their precursors is "knocked out," utilizing genetic and/or pharmacological methodologies to determine if the CaR actually mediates some or even all of the known actions of Ca_o^{2+} on these cells. One study failed to detect expression of the CaR in transformed osteoblast-like cells derived from either wild-type mice or those with knock-out of the CaR (Pi *et al.,* 2000). However, these cells still showed some responses to Ca_o^{2+} and Al^{3+} (e.g., mitogenesis), suggesting the presence of another Ca_o^{2+} sensor, as this group has suggested in earlier studies (Quarles *et al.,* 1997).

While chondrocytes—the cells that form cartilage—do not participate directly in systemic Ca_o^{2+} homeostasis, they play a key role in skeletal development and growth by providing a cartilaginous model of the future skeleton that is gradually replaced by actual bone. Furthermore, the growth plate represents a site where chondrocytes play a crucial role in the longitudinal growth that persists until the skeleton is fully mature at the end of puberty. The availability of Ca^{2+} is important for ensuring proper growth and differentiation of chondrocytes and resultant skeletal growth *in vivo* (Jacenko and Tuan, 1995; Reginato *et al.,* 1993). Moreover, changing the level of Ca_o^{2+} *in vivo* modulates the differentiation and/or other properties of cells of the cartilage lineage (Bonen and Schmid, 1991; Wong and Tuan, 1995). Chondrocytes arise from the same mesenchymal stem cell lineage that gives rise to osteoblasts, smooth muscle cells, adipocytes, and fibroblasts (Boyan *et al.,* 1999; Dennis *et al.,* 1999). It is interesting, therefore, that the rat cartilage cell line RCJ3.1C5.18 showed readily detectable levels of CaR mRNA and protein (Chang *et al.,* 1999a). In addition, some cartilage cells in sections of intact bone express CaR mRNA and protein, including the hypertrophic chondrocytes in the growth plate, which are key participants in the growth of long bones (Chang *et al.,* 1999b). Thus the CaR is a candidate for mediating, at least in part, the previously described direct actions of Ca_o^{2+} on chondrocytes and cartilage growth.

In fact, elevating Ca_o^{2+} exerts several direct effects on RCJ3.1C5.18 cells dose dependently, reducing the levels of the mRNAs that encode a major proteoglycan in

cartilage, aggrecan, the α_1 chains of type II and X collagens, and alkaline phosphatase (Chang *et al.,* 1999a). In addition, treatment of this cell line with a CaR antisense oligonucleotide for 48–72 hrs reduced the level of CaR protein expression significantly, in association with enhanced expression of aggrecan mRNA (Chang *et al.,* 1999a), suggesting a mediatory role of the CaR in regulating this gene. These results demonstrate, therefore, that (1) Ca_o^{2+} modulates the expression of several important genes in this chondrocytic cell line, (2) this cartilage-like cell line expresses CaR mRNA and protein, and (3) the receptor mediates at least some of these actions of Ca_o^{2+} in this chondrocytic model. Thus the CaR could potentially not only modulate bone turnover and/or the coupling of bone resorption to its later replacement by osteoblasts through its actions on bone cells and/or their precursors, but might also participate in the control of skeletal growth through its effects on chondrocytes.

The CaR and Integration of Calcium and Water Metabolism

In addition to its roles in tissues involved directly in Ca_o^{2+} homeostasis, increasing evidence indicates that the CaR is located in other cells and tissues where it contributes to integrating the functions of distinct homeostatic systems, as discussed in this section. An illustrative example is the capacity of the CaR to integrate certain aspects of mineral and water metabolism. Some hypercalcemic patients exhibit reduced urinary-concentrating capacity and, occasionally, frank nephrogenic diabetes insipidus (Gill and Bartter, 1961; Suki *et al.,* 1969). The presence of CaR in several segments of the nephron that participate in regulating urinary concentration (Riccardi *et al.,* 1998; Sands *et al.,* 1997) has suggested a novel mechanism(s) for the long-recognized but poorly understood inhibitory actions of high Ca_o^{2+} on renal-concentrating capacity. Studies have shown that high Ca_o^{2+}, probably by activating CaRs residing on the apical membrane of cells of the IMCD, reversibly inhibits vasopressin-elicited water flow by about 35–40% in perfused rat IMCD tubules (Sands *et al.,* 1997). Indeed, the CaR is present in the same apical endosomes that contain the vasopressin-regulated water channel aquaporin-2 (Sands *et al.,* 1997). This observation indicates that the receptor potentially reduces vasopressin-enhanced water flow in the IMCD by either promoting the endocytosis or blocking the exocytosis of these endosomes (Sands *et al.,* 1997). Furthermore, induction of chronic hypercalcemia in rats through treatment with vitamin D reduces the level of expression of the aquaporin-2 protein but not its mRNA (Sands *et al.,* 1998), which would further decrease vasopressin-activated water flow in the terminal-collecting duct. In addition to the mechanisms just described, high Ca_o^{2+}-elicited, CaR-mediated reduction in the reabsorption of NaCl in the MTAL (Wang *et al.,* 1996, 1997), by decreasing the medullary countercurrent gradient, would diminish even further the maximal urinary-concentrating power of hypercalcemic patients (Fig. 3).

What is the evidence that these effects of high Ca_o^{2+} on the renal concentrating mechanism are mediated by the CaR? Of interest in this regard, persons with inactivating mutations of the CaR are capable of concentrating their urine normally despite their hypercalcemia (Marx *et al.,* 1981), presumably because they are "resistant" to the usual suppressive effects of high Ca_o^{2+} on the urinary-concentrating mechanism. Conversely, individuals with activating CaR mutations can develop symptoms of diminished urinary-concentrating capacity (e.g., polyuria and polydipsia), even at normal levels of Ca_o^{2+}, when treated with vitamin D and calcium supplementation, probably because their renal CaRs are overly sensitive to Ca_o^{2+} (Pearce *et al.,* 1996). These experiments in nature, therefore, support the postulated, CaR-mediated link between Ca_o^{2+} and water homeostasis.

Is the defective renal handling of water in hypercalcemic patients of any physiological relevance? We have suggested previously that it provides a mechanism that integrates the renal handling of divalent cations, especially Ca^{2+}, and water, thereby allowing appropriate "trade-offs" in how the kidney coordinates calcium and water metabolism under specific physiological conditions (Hebert *et al.,* 1997) (Fig. 3). For example, in a situation where a systemic load of Ca^{2+} must be disposed of, the resultant CaR-mediated inhibition of PTH secretion and direct inhibition of tubular reabsorption of Ca^{2+} promote calciuria. The consequent elevation in luminal Ca_o^{2+} in the IMCD, particularly in a dehydrated individual, could predispose to the formation of Ca^{2+}-containing renal stones, were not for the concomitant, CaR-mediated inhibition of maximal urinary concentration. Furthermore, there are abundant CaRs in the subfornical organ (SFO) (Rogers *et al.,* 1997)—an important hypothalamic thirst center (Simpson and Routenberg, 1975)—that may ensure a physiologically appropriate increase in drinking. This increased intake of free water could prevent dehydration that might otherwise be a consequence of renal loss of free water due to the concomitant, CaR-induced inhibition of the urinary-concentrating mechanism (Fig. 3).

Finally, available data support the existence of a "calcium appetite" in rats (Tordoff, 1994) that may furnish a mechanism for modulating the intake of calcium-containing foods in a physiologically relevant manner during hypo- and hypercalcemia. Some reduction in the intake of Ca_o^{2+}-containing foods might also occur as a result of the activation of CaRs in the area postrema of the brain—a "nausea center" (Rogers *et al.,* 1997)—due to the resultant anorexia/nausea. We have hypothesized, therefore, that the CaR mediates multiple layers of integration and coordination of the homeostatic systems governing water and calcium metabolism. In doing so, it may contribute to the ability of terrestrial organisms to adjust to the only intermittent availability of environmental calcium and water (Hebert *et al.,* 1997).

CaR-mediated modulation of vasopressin-induced water flow in the IMCD represents an example of "local" Ca_o^{2+}

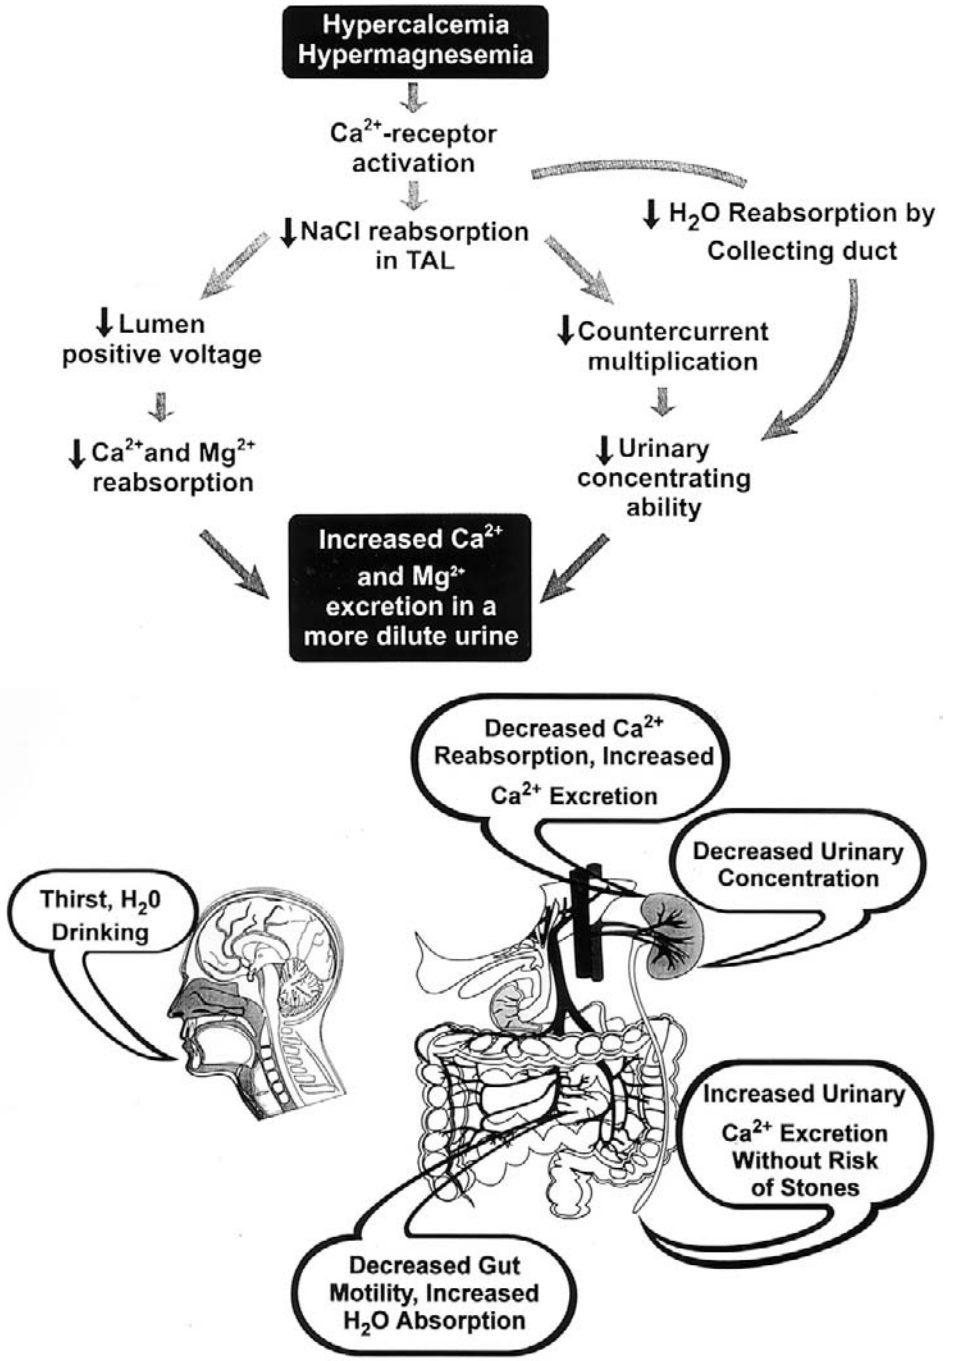

Figure 3 Mechanisms that may interrelate systemic Ca_o^{2+} and water homeostasis (see text for further details). (Top) Mechanisms through which the CaR reduces maximal urinary-concentrating ability. Reproduced with permission from Brown and Hebert (1997b). (Bottom) Additional extrarenal mechanisms integrating Ca_o^{2+} and water homeostasis, such as Ca_o^{2+}-evoked activation of the CaR in the SFO, which would enhance water intake and mitigate loss of free water that would otherwise result from a diminished maximal urinary-concentrating capacity. Reproduced with permission from Brown *et al.* (1996).

homeostasis. That is, Ca_o^{2+} within a specific microenvironment, which is outside of the blood and the various compartments of the ECF in direct contact with the circulation, is only allowed to rise to a certain level (Brown *et al.,* 1999). Interestingly, changes in the level of Ca_o^{2+} resulting from the mechanism governing systemic Ca_o^{2+} homeostasis are traditionally thought to occur through fine adjustments of the movements of Ca^{2+} into or out of the ECF (i.e., by intestine, bone, or kidney) (Brown, 1991). In contrast, CaR-mediated regulation of Ca_o^{2+} in the IMCD primarily results

from alterations in the movement of water. Perhaps even this formulation is oversimplified. On the one hand, vasopressin is known to increase distal tubular reabsorption of calcium (Hoenderop *et al.,* 2000), which would also reduce the level of Ca_o^{2+} in the collecting duct. On the other, the increased thirst in hypercalcemic patients, in addition to providing more free water so as to mitigate any associated rise in Ca_o^{2+} in the IMCD, would also dilute Ca_o^{2+} in the ECF. Further studies will no doubt illuminate additional subtleties related to how the body integrates divalent mineral and water metabolism.

Other CaR Agonists and Modulators: The CaR as an Integrator of Physiological Signals and as a "Nutrient Sensor"

A variety of divalent cations (Sr_o^{2+}), trivalent cations (e.g., Gd_o^{2+}), and even organic polycations [i.e., spermine (Quinn *et al.,* 1997)] are effective CaR agonists. It is likely that they all interact with one or more binding sites within the ECD of the receptor (Brown *et al.,* 1999). Only a few of these polycationic agonists, however, are thought to be present within biological fluids at levels that would activate the CaR (Quinn *et al.,* 1997). In addition to Ca_o^{2+}, Mg_o^{2+} and spermine are two such putative, physiological CaR agonists. It is probable that in specific microenvironments [e.g., within the gastrointestinal (GI) tract and central nervous system] the concentrations of spermine are high enough to activate the CaR even at levels of Ca_o^{2+} that are insufficient to do so by themselves (Brown *et al.,* 1999; Quinn *et al.,* 1997). In fact, all of the polycationic CaR agonists potentiate one anothers' stimulatory effects on the receptor. In other words, only small increments in the level of any given agonist (i.e., spermine) may be sufficient to activate the CaR when a threshold level of another agonist is present in the local microenvironment (e.g., Ca_o^{2+}) (Brown *et al.,* 1999).

Is the CaR also a Mg_o^{2+} -sensing receptor? Some evidence supporting the role of the CaR in sensing and, therefore, "setting" Mg_o^{2+} comes from the experiments in nature that firmly established the role of the CaR as a central element in Ca_o^{2+} homeostasis. Namely, persons with hypercalcemia due to heterozygous-inactivating mutations of the CaR (e.g., FHH) exhibit serum Mg^{2+} levels that are in the upper part of the normal range or mildly elevated. Moreover, some patients with neonatal severe hyperparathyroidism due to homozygous-inactivating CaR mutations can have more pronounced hypermagnesemia (Aida *et al.,* 1995a). Conversely, persons harboring activating mutations of the CaR can manifest mild reductions in Mg_o^{2+} (Brown, 1999). Mg_o^{2+} is about 2-fold less potent than Ca_o^{2+} on a molar basis in activating the CaR (Brown *et al.,* 1993; Butters *et al.,* 1997). One might justifiably ask, therefore, how Mg_o^{2+} could regulate its own homeostasis by modulating PTH secretion — an important component of CaR-mediated control of Ca_o^{2+} — when circulating levels of Mg_o^{2+} are, if anything, lower than those of Ca_o^{2+} (Bringhurst *et al.,* 1998)? It is possible that even small changes in Mg_o^{2+} can modulate the activity of the CaR in parathyroid cells because the receptor has been sensitized by ambient levels of Ca_o^{2+} that are close to its "set point" (i.e., on the steepest portion of the curve relating PTH to Ca_o^{2+}). A more likely scenario, however, is that Mg_o^{2+} acts on the CaR in the CTAL to regulate its own level in the ECF, as follows: the fraction of Mg^{2+} reabsorbed in the proximal tubule is less than for other solutes (e.g., Ca^{2+}, Na^+, Cl^-, and water). As a result, there is a 1.6- to 1.8-fold rise in the level of Mg_o^{2+} in the tubular fluid of the CTAL (De Rouffignac and Quamme, 1994), which should, therefore, reach a sufficiently high level to activate the CaR in this nephron segment and, therefore, reduce the reabsorption of Mg_o^{2+}. Recall that not only Ca_o^{2+} but also Mg_o^{2+} inhibits the reabsorption of both divalent cations in perfused CTAL (De Rouffignac and Quamme, 1994).

Another factor modulating the actions of Ca_o^{2+} and other polycations on the CaR is ionic strength per se (e.g., alterations in the concentration of NaCl) (Quinn *et al.,* 1998). Elevating ionic strength decreases and reducing ionic strength enhances the sensitivity of the CaR to activation by Ca_o^{2+} and Mg_o^{2+}. The impact of changing ionic strength on the responsiveness of the CaR to divalent cations may be especially relevant in particular microenvironments, such as the GI or urinary tracts, where ionic strength can vary greatly, easily encompassing the range over which this parameter modulates the function of the receptor (Quinn *et al.,* 1998).

In addition to the polycationic CaR agonists just noted, novel "calcimimetic," allosteric activators of the receptor have been developed. These are small hydrophobic molecules, which are derivatives of phenylalkylamines and activate the CaR by increasing its apparent affinity for Ca_o^{2+}. They do so by interacting with the transmembrane domains of the receptor (Nemeth *et al.,* 1998b), in contrast to Ca_o^{2+}, which binds to the ECD (Hammerland *et al.,* 1999). Calcimimetics are called "modulators" rather than "agonists" because they only activate the CaR in the presence of Ca_o^{2+}. In contrast, the polycationic agonists of the CaR (e.g., Gd_o^{2+}) activate it even in the nominal absence of Ca_o^{2+} (Nemeth *et al.,* 1998b). Calcimimetics are currently in phase II/III clinical trials for the treatment of primary and uremic hyperparathyroidism, and results to date strongly suggest that these agents will provide the first effective medical therapy for controlling the hypersecretion of PTH in these two conditions. CaR antagonists, so-called "calcilytics," are also entering clinical trials. The principal therapeutic application envisioned for these agents at the moment is in the treatment of osteoporosis (Nemeth *et al.,* 1998a). Because intermittent exogenous administration of PTH can produce sizable increases in bone mineral density, once daily administration of a short-acting calcilytic would presumably accomplish the same goal by producing a "pulse" of endogenous PTH secretion (Gowen *et al.,* 2000; Nemeth *et al.,* 1998a).

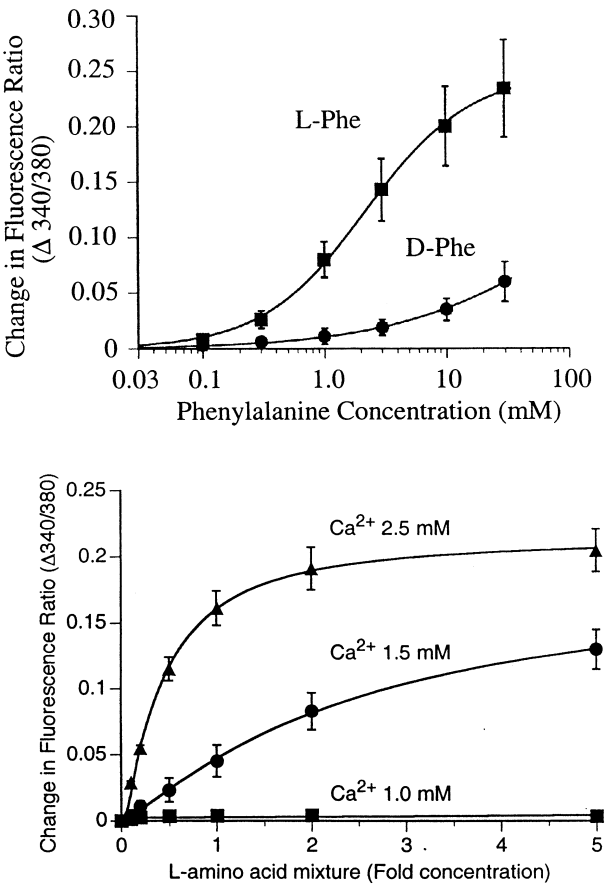

Figure 4 Amino acid sensing by the CaR. (Top) Activation of the CaR by phenylalanine (L-phenylalanine > D-phenylalanine) at 2.5 m*M* Ca_o^{2+} in HEK293 cells transfected stably with the CaR as reflected by amino acid-induced increases in the cytosolic Ca^{2+} concentration in cells loaded with the Ca^{2+}-sensitive intracellular dye fura-2. Increases in the fluorescence ratio (340/380 nm) indicate CaR-mediated increases in Ca_i^{2+}. (Bottom) Marked impact on the level of Ca_o^{2+} on the capacity of the CaR to sense the mixture of L amino acids that emulates that present in the blood under fasting conditions (see text for details). Reproduced with permission from Conigrave *et al.* (2000).

We have identified another class of endogenous CaR modulators, namely certain amino acids (Conigrave *et al.,* 2000) (Fig. 4). Activation of the CaR by specific amino acids, particularly the aromatic amino acids, phenylalanine, tyrosine, histidine, and tryptophan, only occurs when Ca_o^{2+} is 1 m*M* or higher. Although individual amino acids are of relatively low potency (e.g., they act at concentrations of 0.1–1 m*M* or higher), a mixture of amino acids with a composition similar to that present in human serum under fasting conditions substantially enhances the sensitivity of the CaR to Ca_o^{2+}. That is, optimal concentrations of the mixture reduce the EC_{50} for Ca_o^{2+} (the level of Ca_o^{2+} half-maximally activating the receptor) by nearly 2 m*M* (e.g., by 40–50%) in HEK293 cells stably transfected with the CaR (Conigrave *et al.,* 2000).

While the implications of these direct actions of amino acids on the CaR are not yet clear, they could potentially explain several long-standing but poorly understood observations appearing to link protein and Ca_o^{2+} metabolism. Additionally, they suggest future lines of research directed at elucidating the possible role of the receptor in "nutrient sensing" more generally, rather than just as a sensor of divalent cations. For example, ingestion of a high protein diet can nearly double the rate of urinary calcium excretion relative to that observed on a low protein intake (Insogna and Broadus, 1987). This effect of dietary protein has traditionally been ascribed to the buffering of acidic products of protein metabolism by bone as well as a direct calciuric action of the acid load (Lemann *et al.,* 1966). However, direct activation of CaRs in the CTAL as a result of increases in serum levels of amino acids might contribute as well. Moreover, reducing dietary protein intake has been shown to have marked effects on circulating calciotropic hormones, nearly doubling serum PTH and $1,25(OH)_2D_3$ levels in normal women (Kerstetter *et al.,* 1997). Could these latter changes result from the concomitant decrease in the circulating levels of amino acids, despite little, if any, change in Ca_o^{2+}? Is it possible that the reduced intake of dietary protein commonly recommended for patients with chronic renal insufficiency (Bringhurst *et al.,* 1998) actually exacerbates their secondary hyperparathyroidism?

These observations suggest that the CaR is not solely a Ca_o^{2+} (and probably a Mg_o^{2+}) receptor but may also serve as a more general "nutrient" and environmental sensor, which detects changes in Ca_o^{2+} and Mg_o^{2+}, not in isolation, but in the context of the ambient levels of certain amino acids. Further testing of this hypothesis may enhance our understanding of the mechanisms by which complex organisms coordinate homeostatic systems that have traditionally been thought of as functioning largely independently, such as those controlling protein and mineral metabolism. This homeostatic integration may be particularly important within specific parts of the life cycle, such as during somatic growth. Skeletal growth in childhood requires the precisely coordinated deposition of both bone matrix and mineral. Moreover, mineral ions and amino acids must also be assimilated during the growth of soft tissues—all of which contain varying mixtures of mineral ions and protein. For instance, smooth muscle cells contain half as much calcium as bone when expressed on the basis of wet weight (Brown and MacLeod, 2001).

Coordinating mineral ion and protein metabolism might be particularly relevant in the GI tract. Indeed, the presence of an "amino acid receptor" regulating the secretion of gastrin, gastric acid, and cholecystokinin has been postulated (Conigrave *et al.,* 2000). Furthermore, the pharmacological profile of the actions of different amino acids on these parameters is strikingly similar to that for the effects of the same amino acids on the CaR (Mangel *et al.,* 1995; McArthur *et al.,* 1983; Taylor *et al.,* 1982; Conigrave *et al.,* 2000). CaRs in the GI tract system could serve as a particularly suitable target for sensing the availability of dietary protein and mineral ions, which are generally ingested together (i.e., in milk). Further studies are needed, therefore, to investigate whether the CaR represents, in

fact, this putative amino acid receptor. Such investigations may reveal whether the sensing of amino acids by the CaR, taken in the context of ambient levels of Ca_o^{2+} and Mg_o^{2+} within the GI tract and elsewhere, provides the molecular basis for a physiologically important link between the systems governing protein and mineral metabolism.

Are There Additional Ca_0^{2+} Sensors?

As noted earlier and described in detail in other reviews (Quarles, 1997; Zaidi *et al.,* 1999), Ca_o^{2+} sensors in addition to the CaR may exist on osteoblasts and osteoclasts. Moreover, studies have revealed that some of the mGluRs can sense Ca_o^{2+} in addition to recognizing glutamate as their principal physiological agonist, although the physiological importance of this Ca_o^{2+} sensing is not clear at present. Kubo *et al.* (1998) showed that mGluRs 1, 3, and 5 sense levels of Ca_o^{2+} between 0.1 and 10 m*M,* whereas mGluR2 is substantially less responsive to Ca_o^{2+}. All three of the mGluRs that are capable of sensing Ca_o^{2+} have identical serines and threonines, respectively, at amino acid positions that are equivalent to amino acid residues 165 and 188 in mGluR1a (Brauner-Osborne *et al.,* 1999). These two residues have been shown to play key roles in the binding of glutamate to the respective ECDs of the MGluRs (O'Hara *et al.,* 1993). In contrast, while mGluRs 1a, 3, and 5 have serines at positions equivalent to amino acid residue 166 in mGluR1a, mGluR2 has an aspartate rather than a serine at this position (Kubo *et al.,* 1998). Changing this serine to an aspartate in mGluRs 1a, 3, and 5 substantially reduces their capacities to respond to Ca_o^{2+}, whereas substituting the aspartate in mGluR2 with a serine enhances its apparent affinity for Ca_o^{2+} to a level comparable to those of mGluRs 1, 3, and 5 (Kubo *et al.,* 1998). Thus the serines in mGluRs 3 and 5 at amino acid positions homologous to residue 166 in mGluR1a appear to play important roles in the capacities of these three receptors to sense Ca_o^{2+}.

Interestingly, another study has shown that changes in Ca_o^{2+} also modulate the function of the activated $GABA_B$ receptors, whereas Ca_o^{2+} has no effect on these receptors in the absence of added GABA (Wise *et al.,* 1999). Ca_o^{2+} potentiates the stimulatory effect of GABA on the binding of GTP to the receptor and increases the coupling of the $GABA_B$ receptor to stimulation of a K^+ channel and inhibition of forskolin-stimulated adenylate cyclase activity. The effects of Ca_o^{2+} on the $GABA_B$ receptor, unlike those on the CaR, were not reproduced by other polyvalent cations. Thus, similar to the CaR, which senses Ca_o^{2+} but is modulated by various amino acids (although not by glutamate) (Conigrave *et al.,* 2000), mGluRs and $GABA_B$ receptors sense their primary physiological ligands, glutamate and GABA, respectively, as well as Ca_o^{2+}. These observations further emphasize the structural, functional, and evolutionary relationships among the three types of receptors.

Finally, Ca_o^{2+} could also, of course, modulate the functions of proteins other than GPCRs. For instance, the recently cloned Ca_o^{2+} channels CaT1, CaT2, ECaC1, and ECaC2 can be viewed as operating on a macroscopic level as facilitated transporters. That is, they exhibit Michaelis–Menten-like kinetics, their activities (measured as $^{45}Ca^{2+}$ uptake in *X. laevis* oocytes) increase with the level of Ca_o^{2+} until Ca^{2+} uptake saturates above about 1 m*M* Ca_o^{2+}. They could potentially function, therefore, as Ca_o^{2+} sensors. That is, they would tend to "set" the level of Ca_o^{2+} within the local ECF by increasing Ca^{2+} uptake when Ca_o^{2+} is high and reducing it when it is low.

Summary

The discovery of the CaR has provided a molecular mechanism that mediates many of the known actions of Ca_o^{2+} on the cells and tissues that participate directly in systemic Ca_o^{2+} homeostasis, such as parathyroid and certain renal cells. There is still much to be learned, however, about the various functions of the receptor in these tissues, particularly in intestinal and bone cells, as well as in the numerous other CaR-expressing cells that are not directly involved in systemic Ca_o^{2+} homeostasis. In these latter, "nonhomeostatic" cells, the CaR probably serves a variety of roles that enable it to serve as a versatile first messenger, capable of regulating numerous cellular functions. Moreover, the ability of the CaR to integrate and coordinate several different ionic and nutritional signals may permit it to act as a central homeostatic element not only for mineral ion homeostasis, but also for processes relevant to Mg_o^{2+}, water, and protein metabolism.

CHAPTER 24

Receptors for Parathyroid Hormone (PTH) and PTH-Related Peptide

Thomas J. Gardella, Harald Jüppner, F. Richard Bringhurst, and John T. Potts, Jr.

Departments of Medicine and Pediatrics, Endocrine Unit, Harvard Medical School, Massachusetts General Hospital, Boston, Massachusetts 02114

Introduction

The biological actions of parathyroid hormone (PTH) and parathyroid hormone-related protein (PTHrP) have attracted ever wider interest in recent years because of the rapid advances in the study of the developmental biology of bone in which PTHrP and its receptor play a major role, as well as demonstration of the therapeutic potential of PTH in fracture prevention in osteoporosis.

One principal receptor, the type-1 PTH/PTHrP receptor (PTH1R), is the chief mediator of both the homeostatic actions of PTH and the paracrine actions of PTHrP on endochondral bone development. This receptor interacts equivalently with the amino-terminal domains of PTH and PTHrP. As discussed later, however, additional receptors clearly interact differentially with PTH versus PTHrP and/or with regions of the two ligands other than their amino-terminal domains. The tools of molecular biology have been central in the efforts to clone and express the PTH1R and the closely related PTH-2 receptor, as well as to characterize both ligand-binding requirements and signaling properties of these receptors. Work with the receptors for PTH and PTHrP has proven pivotal in studies aimed at understanding the physiological role of PTH in calcium and phosphate homeostasis in greater depth and the critical paracrine role played by PTHrP in the complex network of different signaling factors that directs endochondral bone development.

At the same time that the reductionist approaches based on analyses of cloned receptors expressed in cell lines have helped clarify initial steps in PTH action and provided a detailed analysis of ligand/receptor/signaling events *in vitro,* the tools of molecular biology have also made possible a new level of integrative physiological analyses of bone biology *in vivo* through the use of mice modified genetically through selective gene knockout and/or transgenic overexpression of the PTH1 receptor and/or its ligands. Much of this latter work, as well as the overall biological actions and physiological role of PTH, is outlined in subsequent chapters on PTH. This chapter focuses on the receptors per se, particularly those that are cloned and well characterized, such as the PTH1R and PTH2R, and those that are still uncloned but of potential biological significance in overall PTH or PTHrP action, especially the receptor for the carboxyl-terminal portion of PTH for which much recent biochemical data have accumulated.

Receptors for PTH, PTHrP, and TIP39: The PTH1R and PTH2R

Cloning, Gene Structure, Evolution, and Expression

Because of the pleiotropic actions of PTH, which involve both direct and indirect effects, as well as multiple signal

transduction mechanisms, it was initially thought that several different receptors mediated the biological responses of this peptide hormone. Furthermore, the realization that some of these actions were PTHrP rather than PTH dependent seemed to increase the probability that more than one receptor would be involved. It was somewhat surprising therefore that initial cloning approaches led to the isolation of cDNAs encoding only a single G protein-coupled receptor, the PTH/PTHrP receptor or PTH-1 receptor (PTH1R). The recombinant PTH1R interacts equivalently with PTH and PTHrP and activates at least two distinct second messenger pathways: adenylate cyclase/protein kinase A (AC/PKA) and phospholipase C/protein kinase C (PLC/PKC) (Abou-Samra *et al.,* 1992; Jüppner *et al.,* 1991; Schipani *et al.,* 1993). These findings with the recombinant receptor confirmed earlier studies using different clonal cell lines or renal membrane preparations that had shown that PTH and PTHrP bind to and activate the same G protein-coupled receptor with similar efficiency and efficacy (Jüppner *et al.,* 1988; Nissenson *et al.,* 1988; Orloff *et al.,* 1989; Shigeno *et al.,* 1988). Based on these and subsequent findings, such as the similar phenotypes observed in mice that are null for either PTHrP or the PTH-1 receptor (Karaplis *et al.,* 1994; Lanske *et al.,* 1996; Vortkamp *et al.,* 1996), it now seems very likely that most of the endocrine actions of PTH and paracrine/autocrine actions of PTHrP on bone development are mediated through the PTH-1 receptor. Studies have identified two other G protein-coupled receptors that are closely related to the PTH1R. One of these, the PTH-2 receptor (PTH2R), responds selectively to TIP39, a recently discovered hypothalamic peptide (Usdin, 1999; Usdin *et al.,* 1995), and the other, the PTH-3 receptor (PTH3R), was identified in zebrafish and responds to human PTHrP more efficiently than to human PTH (Rubin and Jüppner, 1999), although it responds to rat PTH more efficiently than either hPTH(1-34) or hPTHrP(1-34) (Hoare *et al.,* 2000b). A review of the published sequence of the human genome indicates that there is no gene sequence detected that might be expected to yield the PTH-3 receptor (Venter *et al.,* 2001).

The PTH-1 receptor belongs to a distinct family of G protein-coupled receptors (GPCR), called class II (or family B) receptors (see the G protein-coupled receptor data base at www.gpcr.org/7tm/). The first cDNAs encoding mammalian PTH-1 receptors were isolated through expression cloning techniques from cell lines that had been widely used in classical PTH/PTH receptor studies: the opossum kidney cell line OK and the rat osteosarcoma cell line ROS 17/2.8 (Abou-Samra *et al.,* 1992; Jüppner *et al.,* 1991). Subsequently, cDNAs encoding human (Eggenberger *et al.,* 1997; Schipani *et al.,* 1993; Schneider *et al.,* 1993), mouse (Karperien *et al.,* 1994), rat (Pausova *et al.,* 1994), chicken (Vortkamp *et al.,* 1996), porcine (Smith *et al.,* 1996), dog (Smock *et al.,* 1999), frog (Bergwitz *et al.,* 1998), and fish (Rubin and Jüppner, 1999) PTH-1 receptors were isolated through hybridization techniques from various tissue and cell sources, i.e., kidney, brain, whole embryos, osteoblast-like cells, and embryonic stem cells. Northern blot and *in situ* studies (Tian *et al.,* 1993; Urena *et al.,* 1993; van de Stolpe *et al.,* 1993), as well as data provided through available public (expressed sequence tag) (EST) databases, confirmed that the PTH-1 receptor is expressed in a wide variety of fetal and adult tissues. With the exception of the tetraploid African clawed frog *Xenopus laevis,* which expresses two non-allelic isoforms of the PTH-1 receptor (Bergwitz *et al.,* 1998), all investigated species have only one copy of the PTH-1 receptor per haploid genome.

The possible existence of other receptors for PTH or PTHrP with unique, organ-specific pharmacological characteristics had been suggested by the distinct ligand binding (Chorev *et al.,* 1990a,b; McKee *et al.,* 1988) and second messenger signaling profiles observed in different clonal cell lines (Cole *et al.,* 1987; Yamaguchi *et al.,* 1987a,b). However, the molecular cloning of identical full-length PTH-1 receptor cDNAs from human kidney, brain, and bone-derived cells (Eggenberger *et al.,* 1997; Schipani *et al.,* 1993; Schneider *et al.,* 1993) suggested that the previously observed pharmacological differences arose from species-specific variations in the receptor primary sequence rather than the tissue-specific expression of distinct receptors.

The gene encoding the human PTH-1 receptor is located on chromosome 3 (locus 3p22-p21.1). The intron/exon structure of the gene has been analyzed in detail (Bettoun *et al.,* 1997; Manen *et al.,* 1998; Schipani *et al.,* 1995) and was shown to have an organization similar to that of genes encoding the rat and mouse homologues (Kong *et al.,* 1994; McCuaig *et al.,* 1994) (Fig. 1). In each of these mammals, the PTH1R gene spans at least 20 kbp of DNA and consists of 14 coding exons and at least three noncoding exons. The size of the coding exons in the human PTH-1 receptor gene ranges from 42 bp (exon M7) to more than 400 bp (exon T); the size of the introns varies from 81 bp (between exons M6 and M6/7) to more than 10 kbp (between exons S and E1).

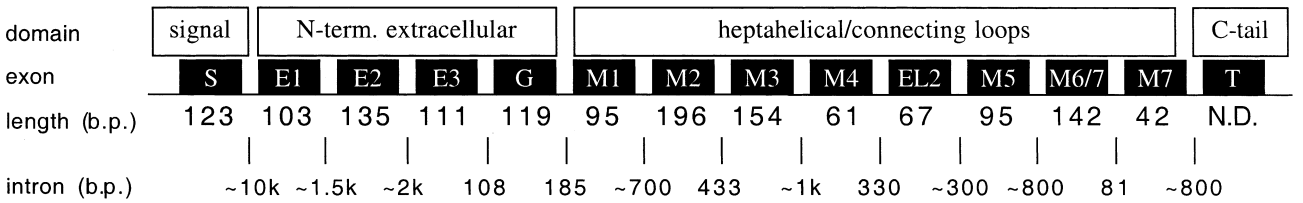

Figure 1 Intron/exon structure of the human PTH-1 receptor gene. The 14 coding exons of the human PTH1R gene are indicated as black boxes, and the corresponding receptor domains are indicated above in open boxes. The lengths in nucleotide basepairs (k = 1/1000) of the exons and the intervening introns are also indicated.

Two promoters for the PTH-1 receptor have been described in rodents (Joun *et al.,* 1997; Kong *et al.,* 1994; McCuaig *et al.,* 1994, 1995). The P1 promoter (also referred as U3) is active mainly in the adult kidney, whereas the P2 promoter (also referred to as U1) is active in several fetal and adult tissues, including cartilage and bone. In humans, a third promoter, P3 (also referred to as S), also appears to be active in some tissues, including kidney and bone (Bettoun *et al.,* 1998; Giannoukos *et al.,* 1999; Manen *et al.,* 1998). Several frequent polymorphisms were identified within the human PTH-1 receptor gene; these include an intronic *Bsm*I polymorphism located between the 5′ noncoding exon U1 and the coding exon S (Hustmyer *et al.,* 1993) and a silent *Bsr*DI polymorphism in exon M7 (nucleotide 1417 of human PTH-1 receptor cDNA) (Schipani *et al.,* 1994).

At the protein level, all mammalian PTH-1 receptors have a relatively long amino-terminal extracellular domain (~170 amino acids in the human PTH1R after removal of the signal sequence by signal peptidase cleavage). This domain is encoded by five exons: S (encoding the signal sequence), E1, E2, E3, and G [encoding the four N-linked glycosylation sites (Zhou *et al.,* 2000)]. Genes encoding other class II G protein-coupled receptors for which the genomic structure has been explored have a similar organization, except that the equivalent of exon E2 is lacking (Jüppner, 1994; Jüppner and Schipani, 1996). The protein segment encoded by exon E2 is also missing in the PTH-2 receptors, as well as in the PTH-1 receptors from *X. laevis* and zebrafish (Bergwitz *et al.,* 1998; Rubin *et al.,* 1999). Earlier *in vitro* mutational studies showed that the E2 segment of the PTH1R can be modified or deleted without a measurable impact on receptor surface expression or function (Jüppner *et al.,* 1994; Lee *et al.,* 1994). Taken together, these findings led to the conclusion that the addition of this nonessential exon in the mammalian PTH-1 receptors was a relatively recent evolutionary modification to the PTH-1 receptor gene (Rubin and Jüppner, 1999); the biological role of this receptor region, if any, is unknown.

Class II Receptors

The molecular cloning of the PTH-1 receptor (Abou-Samra *et al.,* 1992; Jüppner *et al.,* 1991), along with the receptors for secretin (Ishihara *et al.,* 1991) and calcitonin (Lin *et al.,* 1991) that same year, made it clear that these peptide hormone receptors formed a distinct GPCR family. Except for the structural similarity provided by the seven membrane-spanning helices, members of the class II (family B) peptide hormone GPCR family share virtually no amino acid sequence homology with most other GPCRs, such as the β-adrenergic receptor, a class I GPCR. All members of the secretin/calcitonin/PTH receptor family, including an insect and several other invertebrate peptide hormone receptors (Reagan, 1994, 1996; Sulston *et al.,* 1992), share about 45 strictly conserved amino acid residues. Furthermore, all receptors of this family have a relatively long amino-terminal, extracellular domain, and most use at least two different signal transduction pathways, adenylate cyclase and phospholipase C (Jüppner, 1994; Jüppner and Schipani, 1996). Each of these related receptors contains up to four sites for potential asparagine-linked glycosylation, eight conserved extracellular cysteine residues that appear to be important for ligand/receptor interaction and/or proper receptor processing or folding (Gaudin *et al.,* 1995; Knudsen *et al.,* 1997; Lee *et al.,* 1994; Qi *et al.,* 1997), and several other "signature" residues. It is predicted that within the membrane-embedded region there is an overall topological similarity between these class II heptahelical receptors and G protein-coupled receptors of other families, such as the β-adrenergic receptor (Sheikh *et al.,* 1999), or those represented by the metabotropic glutamate receptor and the calcium-sensing receptor (class III receptors; reviewed in Chapter 23), although the receptors from each class share no primary sequence homology.

A distinctive subgroup of class II receptors has been identified. These receptors have, in addition to the usual hallmarks of the peptide hormone-binding class II receptors, extremely large (>600 amino acid) extensions of the amino-terminal extracellular domain, in which are found arrays of protein sequence motifs that are typically seen in single membrane-spanning proteins involved in cell adhesion (e.g., cadherin, laminin, thrombospondin, lectin, and mucin) (Abe *et al.,* 1999; Baud *et al.,* 1995; Hamann *et al.,* 1995; Usui *et al.,* 1999). The biological roles of these distinctive heptahelical proteins, the identity of their cognate ligands, and their evolutionary relationship to the other class II receptors remain to be established.

Mechanisms of Ligand Recognition and Activation by PTH Receptors

Current data indicate that the PTH receptor interacts with multiple regions of PTH peptide ligands; these contacts establish binding affinity and/or promote receptor activation. Much information on these interactions has been gained from studies that used intact native PTH receptors expressed in various cell systems and synthetic PTH and PTHrP analogs. PTH(1-34) and PTHrP(1-34) bind to and activate the PTH-1 receptor with affinities and potencies in the low nanomolar range. The first 13 amino acids of PTH and PTHrP have been highly conserved in evolution with eight identities; the (15-34) regions share only moderate homology with three amino acid identities. The N-terminal portions of the two peptides play key roles in receptor activation, whereas the (15-34) portions are required for high-affinity receptor binding (Abou-Samra *et al.,* 1989; Caulfield *et al.,* 1990; Nussbaum *et al.,* 1980).

Ligand Determinants of PTH Receptor Activation

cAMP Signaling Response

Amino-terminally truncated PTH or PTHrP analogs, such as PTH(3-34), PTH(7-34), and PTHrP(7-34), bind to the PTH-1 receptor with high affinity and elicit little or no

increase in cAMP accumulation. Such fragments yield the most potent PTH-1 receptor competitive antagonists (Nutt *et al.,* 1990). Bulky amino acid modifications within the amino-terminal portion of (1-34)-length peptides (e.g., at positions 2, 3, and 6) also confer antagonistic properties to the peptides (Behar *et al.,* 1999; Carter *et al.,* 1999a; Cohen *et al.,* 1991; Gardella *et al.,* 1991). Peptides consisting only of the amino-terminal residues of PTH exhibit severely diminished receptor-binding affinity and hence cAMP-signaling potency. The shortest amino-terminal peptide of the native sequence that retains full PTH-1 receptor-binding affinity and cAMP-signaling potency is PTH(1-31) (Whitfield and Morley, 1995). PTH(1-14) has been shown to be the shortest native amino-terminal PTH peptide for which at least some cAMP agonist activity can be detected, albeit the EC_{50} of the cAMP response induced by PTH(1-14) in LLC-PK1 porcine kidney cells transfected stably with high levels of the human PTH1R (~100 μM) is markedly higher than that observed for PTH(1-34) (~3 n*M*) (Luck *et al.,* 1999). A series of structure–activity relationship studies on the PTH(1-14) scaffold peptide was undertaken as part of an effort to better understand how residues in the amino-terminal portion of PTH mediate receptor activation (Carter and Gardella, 2001; Luck *et al.,* 1999; Shimizu *et al.,* 2001; Shimizu *et al.,* 2000b). An alanine scan analysis of PTH(1-14) demonstrated the functional importance of residues (1-9) and suggested that this sequence represents a minimum-length receptor-activation domain (Luck *et al.,* 1999). Further substitution analyses revealed that the PTH(1-14) sequence could accommodate amino acid changes at a number of positions (Carter and Gardella, 2001; Shimizu *et al.,* 2000b, 2001) many of which improved signaling potency and binding affinity. The most active analog was [$Ala^{3,12}$, Gln^{10}, homoArg^{11}, Trp^{14}]PTH(1-14), which is ~2000-fold more potent as a cAMP agonist in stably transfected LLC-PK1 cells than was native PTH(1-14) and is only ~60-fold weaker than PTH(1-34) (Shimizu *et al.,* 2001). The relevant substitutions also conferred activity to the otherwise inactive PTH(1-11) fragment; these modified PTH(1-11) analogs are currently the shortest free peptide sequences that can activate the PTH-1 receptor (Shimizu *et al.,* 2000b, 2001).

NON-cAMP SIGNALING RESPONSES

While it is well established that the amino-terminal residues of PTH mediate AC/PKA signaling, there is still some uncertainty regarding the ligand determinants of PLC/PKC/calcium signaling. Several studies have indicated that residues in the C-terminal portion of PTH(1-34) mediate PKC activation; perhaps most notably, the tetrapeptide PTH(29-32) was shown to be sufficient for activating PKC in ROS 17/2 rat osteosarcoma cells (Jouishomme *et al.,* 1994), as well as in Chinese hamster ovary cells transfected with the rat PTH-1 receptor (Azarani *et al.,* 1996). Stimulation of PKC is generally thought to be mediated through PLC signaling; however, other data indicate that determinants of PLC activation reside at the amino terminus of PTH. Thus, even minor N-terminal truncations, as in [desNH_2-Gly^1]PTH(1-34), PTH(2-34), or PTH(3-34), severely diminish the capacity of the peptide to stimulate inositol polyphosphate (IP) production via PLC in porcine kidney LLC-PK1 cells transfected with the human PTH-1 receptor (Takasu *et al.,* 1999a). In addition, the activity-enhanced PTH(1-14) analogs mentioned above stimulate IP production in transfected COS-7 cells, indicating that residues in this N-terminal portion of the ligand are sufficient for PLC signaling (Shimizu *et al.,* 2000b). One possible explanation for the apparent discrepancy in the mapping of PKC and PLC activation determinants is that residues (29-32) of PTH mediate PKC activation via a phospholipase other than PLC. In support of this possibility, Friedman and co-workers (1999) have shown that in the distal tubule cells of the kidney, the PTH-1 receptor couples to phospholipase D, whereas in the proximal tubule cells it couples to phospholipase C; moreover, distinct structural components of the ligand were required for the altered signaling responses in the two different cell types. The PTH-1 receptor may therefore be capable of recognizing different portions of the ligand as activation determinants for various phospholipases, a capacity that may be modulated by the cellular milieu (Whitfield *et al.,* 2001). While these possibilities need further investigation, current data suggest that it should be possible to develop signaling-selective PTH analogs that could be used to dissect the metabolic pathways by which PTH exerts its biological effects. As examples, PTH(1-31) (Whitfield and Morley, 1995) and a conformationally constrained PTH(1-28) analog (Whitfield *et al.,* 2000) have been shown to be osteogenic in a rat model of osteoporosis, thus demonstrating that the bone anabolic effect of PTH is not dependent on the PKC response induced by PTH residues 29-32. The amino-terminally substituted analog [Gly^1]PTH(1-28), in which PLC signaling, but not AC/cAMP signaling, is severely impaired (Takasu *et al.,* 1999a) could similarly be used to examine the role of PLC in the PTH-induced bone formation response. There is interest in whether signaling-selective PTH analogs could be developed as more effective PTH-based therapies for osteoporosis (Neer *et al.,* 2000; Whitfield *et al.,* 2001; Whitfield *et al.,* 2000).

Ligand Determinants of PTH Receptor Binding

For both PTH and PTHrP, the (15-34) fragment can inhibit the binding of either radiolabeled PTH(1-34) or PTHrP(1-34) to the PTH-1 receptor with an IC_{50} in the micromolar range, thus demonstrating that the (15-34) domain contains the principal determinants of receptor-binding affinity (Abou-Samra *et al.,* 1989; Caulfield *et al.,* 1990). The (15-34) domains of both ligands are predicted to form amphiphilic α helices with the hydrophobic face of PTH being formed principally by Trp-23, Leu-24, and Leu-28 (Epand *et al.,* 1985; Neugebauer *et al.,* 1992). Substitution of Leu-24 or Leu-28 in PTH(1-34) by glutamate results in 100-fold reductions in binding affinity, consistent with the view that the hydrophobic face plays a key role in

Figure 2 Ligand sequences and specifity profiles for the PTH receptor subtypes. (A) An alignment of human PTH(1-37), human PTHrP(1-37), and human TIP39. Homologous residues are in boldface type. (B) Ligand selectivities of the human PTH1R, human PTH2R, and zebrafish PTH3R. A minus sign indicates negligable activity; a plus sign indicates high affinity (low nanomolar K_d) or high potency for cAMP generation ($EC_{50} < 10$ n*M*); a plus sign in parentheses indicates low-binding affinity (K_d ~100 to ~1 μM). Note that the rat PTH2R (not shown) responds poorly to PTH(1-34) (EC_{50} 140 n*M*, $E_{max} = 43\%$) as well as PTHrP (Hoare *et al.,* 1999a).

receptor binding (Gardella *et al.,* 1993). It has been suggested for PTH (Epand *et al.,* 1985; Neugebauer *et al.,* 1992; Rölz *et al.,* 1999) that this role involves nonspecific interaction of the hydrophobic surface of the peptide with the phospholipid bilayer of the cell membrane, which then facilitate a two-dimensional diffusion of the hormone to the receptor. Such a model has been suggested for other peptide hormones (Sargent and Schwyzer, 1986). However, it seems likely that the hydrophobic surface of the (15-34) domain directly contacts the receptor. The cross-linking of a PTHrP(1-36) analog having tryptophan-23 replaced by the photolabile benzophenone-containing amino acid analog benzoylphenylalanine (Bpa) to a 16 amino acid segment at the extreme amino terminus of the PTH-1 receptor suggests that at least some residues in the (15-34) domain of the ligand interact with the amino-terminal domain of the receptor (Mannstadt *et al.,* 1998).

TIP39 and the PTH-2 Receptor

The PTH-2 receptor subtype was initially identified through hybridization cloning methods in a human brain cDNA library. At the amino acid level, this receptor is 51% identical to the human PTH-1 receptor (Usdin *et al.,* 1995). The cloning of the PTH-2 receptor prompted a search for a peptide ligand that is its naturally occurring agonist and would selectively activate the PTH-2 receptor. The effort resulted in the discovery of a peptide of 39 amino acids that potently activates both rat and human PTH-2 receptor subtypes without activating the PTH-1 receptor (Usdin, 1999). The human PTH-2 receptor responds to PTH but not to PTHrP, whereas the rat PTH-2 receptor responds to neither PTH nor PTHrP (Hoare *et al.,* 1999a). The newly discovered peptide, called TIP39 (tuberoinfundibular peptide of 39 amino acids), was initially purified from bovine hypothalamus extracts and was shown to be only weakly homologous to PTH and PTHrP (Usdin, 1999). Although TIP39 fails to activate the PTH-1 receptor, it binds to it with moderate affinity (~100 n*M*) (Hoare *et al.,* 2000a). Interestingly, TIP(7-39) and TIP(9-39) bind with higher affinity to the PTH-1 receptor than TIP39 and the truncated peptides function as PTH-1 receptor-specific antagonists (Hoare and Usdin, 2000; Jonsson *et al.,* 2001). Figure 2 illustrates the structural features of the three ligands and their respective binding to and activation of the type 1 and type 2 PTH receptors, as well as to the type 3 PTH receptor identified in zebrafish. The physiological role of TIP39 and the PTH-2 receptor has not yet been identified, but their abundant expression in the central nervous system suggests a possible neuroendocrine function (Usdin, 2000) that is apparently preserved in evolution, as the PTH-2 receptor is found in zebrafish (Rubin and Jüppner, 1999).

Mechanisms of PTH-1 Receptor Function

Role of the Amino-Terminal Receptor Domain

The large glycosylated amino-terminal extracellular domain of the PTH1R contains six highly conserved cysteine residues that are likely to form an intramolecular network of disulfide bonds. A possible arrangement of these disulfide bonds has been suggested from a biochemical study on a recombinant protein corresponding to the amino-terminal domain of the PTH1R (Tyr^{23}-Ile^{191}) that was overproduced

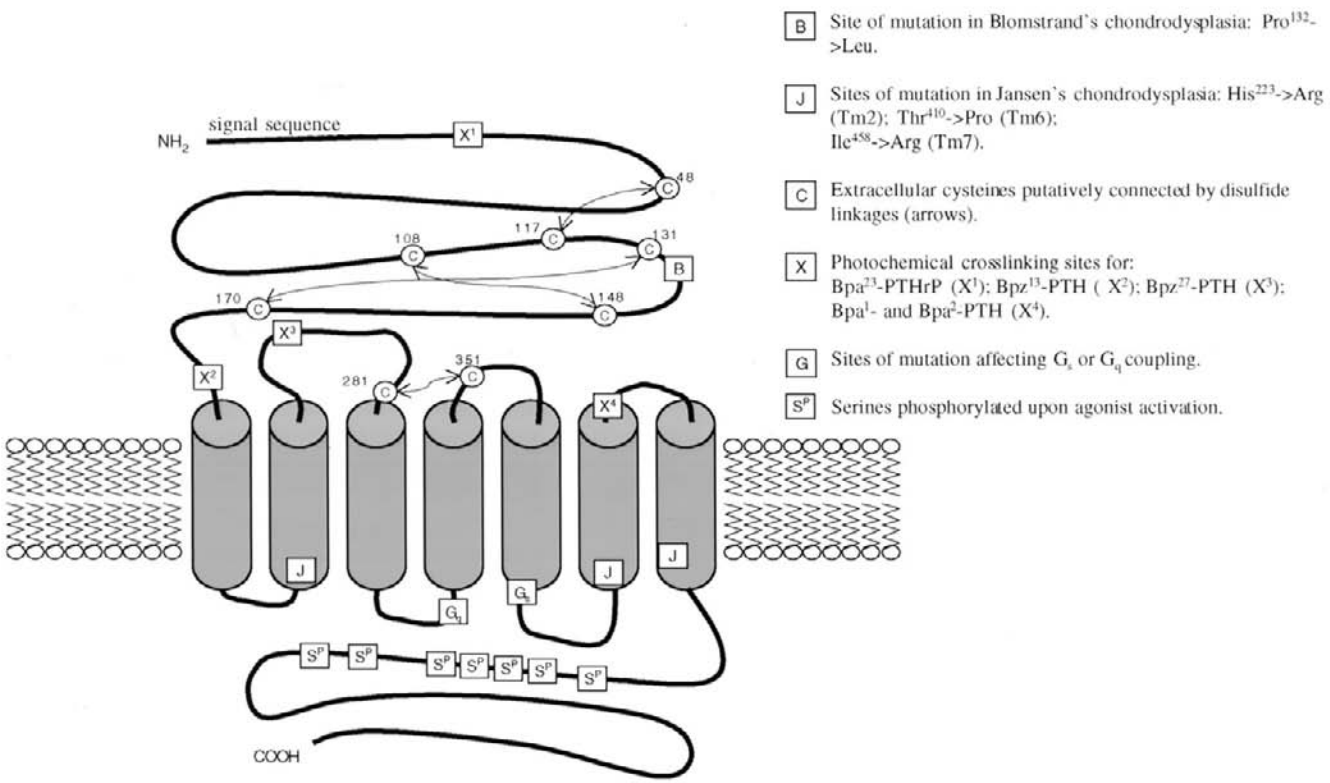

Figure 3 Schematic of the human PTH-1 receptor. The human PTH-1 receptor (591 amino acids) is displayed to illustrate its relative domain organization and the location of selected key residues. A possible arrangement of disulfide bonds involving the eight extracellular cysteines is illustrated by the connecting dotted lines with arrows; this putative arrangement is based on biochemical studies of a purified refolded protein corresponding to the amino-terminal domain of the hPTH1R receptor that was produced in *E.coli* (Grauschopf *et al.,* 2000). As indicated in the figure key, sites of photochemical cross-linking for PTH or PTHrP analogs modified with a benzophenone moiety, either in the form of *p*-benzoyl-*L*-phenylalanine (Bpa) or attached to the ε amino group of a lysine side chain (Bpz), are represened by boxed Xs; sites of mutations in the human skeletal diseases of Blomstrand's chondrodysplasia (receptor inactivity) and Jansen's chondrodysplasia (receptor constitutive activity) are marked by a boxed B and boxed Js, respectively. Serines that are phosphorylated upon agonist activation of the receptor are also shown.

in *Escherichia coli* (Grauschopf *et al.,* 2000). The purified protein was refolded in a glutathione-containing redox buffer system to a homogeneous state and was shown to retain specific, but predictably weak ($K_d \sim 4\ \mu M$), binding affinity for PTH(1-34). The biochemical behavior of this protein suggests that the observed disulfide bond pattern, illustrated in Fig. 3, may faithfully replicate that which occurs in native PTH-1 receptors expressed in eukaryotic cells, although this remains to be verified.

Functional studies on PTH receptor chimeras and mutants generated by site-directed mutagenesis and expressed in COS-7 cells have shown that the amino-terminal domain of the receptor provides important contact sites for at least some residues in the C-terminal-binding domains of PTH(1-34) and PTHrP(1-34) (Bergwitz *et al.,* 1996; Jüppner *et al.,* 1994). The cross-linking studies with [Bpa^{23}]PTHrP(1-36) mentioned earlier support this conclusion (Mannstadt *et al.,* 1998) (see also Chapter 26) Within the 17 amino acid interval identified with the Bpa-23 analog, the specific residues of threonine-33 and glutamine-37 were shown by functional methods to be determinants of PTH(7-34) binding affinity (Mannstadt *et al.,* 1998). A second segment of the amino-terminal extracellular domain involved in ligand interaction maps to the boundary of the amino-terminal domain and the first transmembrane helix. A PTH(1-34) analog having the benzophenone photophore attached to the ε amino group of lysine 13 cross-linked to this region, most likely at Arg-186 (Adams *et al.,* 1998) (Fig. 3), and point mutations at the neighboring hydrophobic residues of Phe-184 and Leu-187 and Ile-190 impaired interaction with PTH(3-34) and PTH(1-14) but not PTHrP(15-36) (Carter *et al.,* 1999b). Residues in this segment of the receptor thus appear to be important interaction determinants for residues in the (3-14) region of the ligand.

Residues in the midportion of the amino-terminal domain of the PTH-1 receptor are also likely to contribute to ligand interaction, but candidate contact points have not been identified. Blomstrand's chondrodysplasia is a human neonatal lethal disorder characterized by dramatically advanced endochondral bone maturation. Investigations into the underlying

molecular defects of this disease revealed that proline-132 in the PTH-1 receptor was mutated on both alleles to leucine (Fig. 3), and the same receptor mutation, when analyzed in transfected COS-7 cells, yielded a loss-of-function phenotype (Karaplis *et al.,* 1998; Zhang *et al.,* 1998). Whether this proline, which is located in the middle of the amino-terminal extracellular domain of the receptor, is directly involved in ligand interaction or provides a more general scaffolding function, as might be inferred from its preservation in all class II receptors, remains to be determined.

Juxtamembrane Region

A number of studies have indicated that interactions between the amino-terminal portion of PTH and the juxtamembrane region of the PTH receptor are important for inducing receptor activation. One such study that utilized PTH-1 receptor/calcitonin receptor chimeras and PTH/calcitonin hybrid ligands showed that efficient functional responses were obtained only when a chimeric receptor was paired with a hybrid ligand such that the amino-terminal portion of the ligand was cognate to the juxtamembrane region of the receptor (Bergwitz *et al.,* 1996). Some specific residues in the juxtamembrane region have been identified as candidate interaction sites for the amino-terminal residues of PTH, such as Ser-370 and Leu-427 at the extracellular ends of transmembrane domain(TM)5 and 6, respectively, which determine the agonist/antagonist response profile observed with [Arg^2]PTH(1-34) (Gardella *et al.,* 1994), and Trp-437 and Gln-440 in the third extracellular loop, at which mutations impair the binding of PTH(1-34) but not PTH(3-34) (implying an interaction site for ligand residues 1 and 2) (Lee *et al.,* 1995). Consistent with these mutational data, the receptor cross-linking sites for [Bpa^1]PTH(1-34) (Bisello *et al.,* 1998) and [Bpa^2]PTHrP(1-36) (Behar *et al.,* 1999) were mapped to the extracellular end of TM6 (Behar *et al.,* 1999). Interestingly, both of these ligands utilized Met-425 for covalent attachment, although [Bpa^2]PTHrP(1-36), an antagonist, utilized an additional second site in TM6, whereas [Bpa^1]PTH(1-34), an agonist, utilized only the methionine. These results raise the possibility that the photochemical cross-linking approach can be used to discern differences in the active and inactive states of the PTH-1 receptor (Behar *et al.,* 1999).

Other receptor residues involved in interactions with the amino-terminal portion of the ligand have been identified in studies aimed at elucidating the molecular basis by which the human PTH-2 receptor discriminates between PTH and PTHrP, an effect that is largely due to the amino acid divergence at position 5 in these ligands (Ile in PTH and His in PTHrP) (Behar *et al.,* 1996; Gardella *et al.,* 1996c). Four PTH-2 receptor residues involved in this specificity were identified at the extracellular ends of several of the TM helices: Ile-244 in TM3, Tyr-318 in TM5, and Cys-397 and Phe-400 in TM7, corresponding to Leu-289, Ile-363, Tyr-443, and Leu-446, respectively, in the human PTH-1 receptor (Bergwitz *et al.,* 1997; Turner *et al.,* 1998). Other residues in the TM domains that have been identified as determinants of PTH(1-34) agonist responsiveness include Ser-229, Arg-233, Ser-236, which may form a hydrophilic surface on TM2 (Turner *et al.,* 1996), and the conserved Gln451 in TM7 (Gardella *et al.,* 1996a).

A series of studies conducted with a truncated PTH-1 receptor (P1R-delNt) that lacks most (residues 24-181) of the amino-terminal extracellular domain has helped discern the role of interactions between the N-terminal residues of PTH and the juxtamembrane region of the receptor in mediating signal transduction. Thus, the modified PTH(1-14) peptides described earlier stimulate cAMP formation with this truncated receptor nearly as effectively as they do with the intact wild-type receptor (Shimizu *et al.,* 2000b, 2001) (Fig 4). The near-full activity of the PTH(1-14) analogs with P1R-delNt stands in dramatic contrast to the markedly (approximately 1000-fold) reduced activity that unmodified PTH(1-34) exhibits with P1R-delNt, as compared to the intact receptor (Fig 4). The weak activity of PTH(1-34) on P1R-delNt highlights the importance of interactions between the (15-34) domain of PTH(1-34) and the N-terminal extracellular domain of the receptor in stabilizing the native hormone–receptor complex (see later), whereas the potent activity of modified PTH(1-14) on P1R-delNt indicates that most, if not all, of the key functional residues in the amino-terminal peptide interact primarily, if not exclusively, with the juxtamembrane region of the recepter.

Studies with conformationally constrained PTH peptides have yielded PTH(1-14) analogs that exhibit full cAMP efficacy and low nanomolar potency on both the intact wild-type PTH-1 receptor and on P1R-delNt (N. Shimizu and T. J. Gardella, unpublished data). Presumably, the modifications in these peptides stabilize a ligand conformation that has high affinity for the juxtamembrane region of the receptor. Most likely, this conformation is α helical, as has been suggested by both nuclear magnetic resource (Rölz *et al.,* 1999) and X-ray crystallographic (Jin *et al.,* 2000) studies of PTH(1-34) and the accompanying computer models of the ligand–receptor complex. At least some of the substitutions in the multisubstituted PTH(1-14) analogs described by Shimizu *et al.* (2000b, 2001), are likely to provide new and favorable interactions with the receptor that compensates for the loss of binding energy that normally derives from residues in the (15-34) domain of PTH, but some may directly facilitate the receptor activation process without affecting binding affinity. One of the goals of the research on these short N-terminal PTH peptides is to discern how individual key residues in the ligand contribute to binding affinity and receptor activation. Such work will most likely require the use of membrane-based pharmacological and kinetic methods, such as those already employed by Hoare and co-workers (1999b, 2001) in their studies on the PTH receptor system.

Data so far on the PTH(1-14) analogs demonstrate that it is possible to achieve full potency and efficacy with a peptide ligand as short as 14 amino acids, and also that

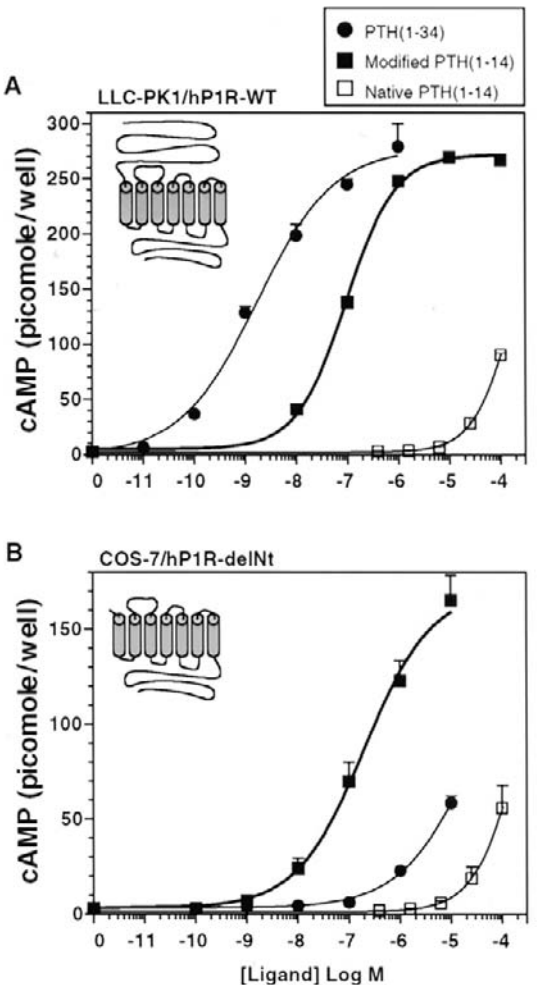

Figure 4 cAMP-stimulating activity of modifed PTH(1-14) and control analogs in cells transfected with wild-type or N-terminally truncated PTH1 receptors. (A) The modified PTH(1-14) analog [$Ala^{3,12}$,Gln^{10},Har^{11},Trp^{14}]-PTH(1-14)amide is shown to stimulate cAMP formation in the porcine kidney cell line LLC-PK1 transfected stably with the wild-type human PTH-1 receptor [HKRK-B28 cells in reference (Takasu *et al.*, 1999b)] with a potency that is 2000-fold greater than that of native PTH(1-14) and only 60-fold weaker than that of PTH(1-34). (B) The same modified PTH(1-14) analog [as well as the native PTH(1-14) peptide] is shown to exhibit nearly the same potency in COS-7 cells transfected transiently with a truncated human PTH1R lacking most of the amino-terminal extracellular domain, hP1R-delNt, as it does with hP1R-WT in A. In contrast, PTH(1-34) is ~20,000-fold weaker with hP1R-delNt than it is with hP1R-WT. The results are excerpted from Shimizu *et al.* (2001) and serve to illustrate three points: (1) the interaction between the N-terminal domain of the intact receptor and the (15-34) domain of the intact ligand is important for the stability of the native hormone–receptor complex; (2) PTH(1-14) peptides can be modified to achieve substantial gains in potency; and (3) full receptor activation can be induced by peptide ligands as short as 14 amino acids that interact solely with the juxtamembrane region of the receptor.

a relatively small agonist ligand can fully activate the PTH receptor by interacting solely with the juxtamembrane region of the receptor. As an extension of these studies, a PTH-1 receptor mutant was constructed in which residues (1-9) or (1-11) of PTH were tethered directly to the juxtamembrane region of the receptor (at Glu-182). When expressed in COS-7 cells, these constructs resulted in basal cAMP levels that closely approached the cAMP level seen with the wild-type PTH-1 receptor fully stimulated with the PTH(1-34) agonist ligand (Shimizu *et al.,* 2000a). A similar result has been reported for corticotropin-releasing factor (CRF) and its class II GPCR (Nielsen *et al.,* 2000).

Two-Site Model of PTH/PTH Receptor Interaction

Combined functional and cross-linking data are consistent with a mechanism for the PTH–PTH receptor interaction that involves two principal components: (1) an interaction between the C-terminal domain of the ligand and the amino-terminal domain of the receptor, which contributes predominantly to binding affinity, and (2) an interaction between the amino-terminal portion of the ligand and the juxtamembrane region of the receptor, which contributes to signaling (Fig. 5). This general interaction model is likely to apply to at least some of the other class II receptors, including those for CRF, calcitonin, secretin, and glucagon (Bergwitz *et al.,* 1996; Nielsen *et al.,* 2000; Stroop *et al.,* 1995; Turner *et al.,* 1998). It has been proposed that the interactions at the two receptor domains occur in a sequential manner (Hoare *et al.,* 2001; Ji *et al.,* 1998) (Fig. 5). There is also the possibility that a higher order of folding is involved. In support of this possibility is the cross-linking study showing that a PTH(1-34) agonist analog having a benzophenone group attached to lysine-27 contacts the first extracellular loop of the PTH-1 receptor (Greenberg *et al.,* 2000) (Fig. 3); thus the amino-terminal extracellular domain of the receptor [and (15-34) portion of the ligand] must be close to the juxtamembrane region of the receptor, at least in the agonist bound state (Piserchio *et al.,* 2000). The model proposed in Fig. 5, based on binding of modified short amino-terminal PTH(1-14) sequences versus the amino-terminally truncated PTH(3-34) antagonist peptide, suggests that the binding steps may even be independent such that the binding of PTH(1-14) analogs to the juxtamembrane regions cannot be blocked by binding of the carboxyl portion of PTH(3-34) to the extracellular domain of the receptor (Hoare *et al.,* 2001). This finding, demonstrated in membrane preparations of receptors, is not seen in cell-based assays that have higher receptor number and differ in other respects (internalization, phosphorylation, etc.) (Shimizu *et al.,* 2000b).

Data seen and the models proposed regarding PTH/PTH-1 receptor interaction mechanisms have clear implications for drug discovery efforts aimed at finding new PTH receptor agonists. Clinical trial data showing that PTH (given as daily subcutaneous injections) can effectively treat osteoporosis (Neer *et al.,* 2000) are likely to heighten interest in developing orally available nonpeptide mimetics for this receptor. So far, however, no such compounds have been reported. Although it is possible that the agonist-dependent activation of the PTH-1 receptor requires multiple ligand contacts to a large and diffuse surface of the receptor,

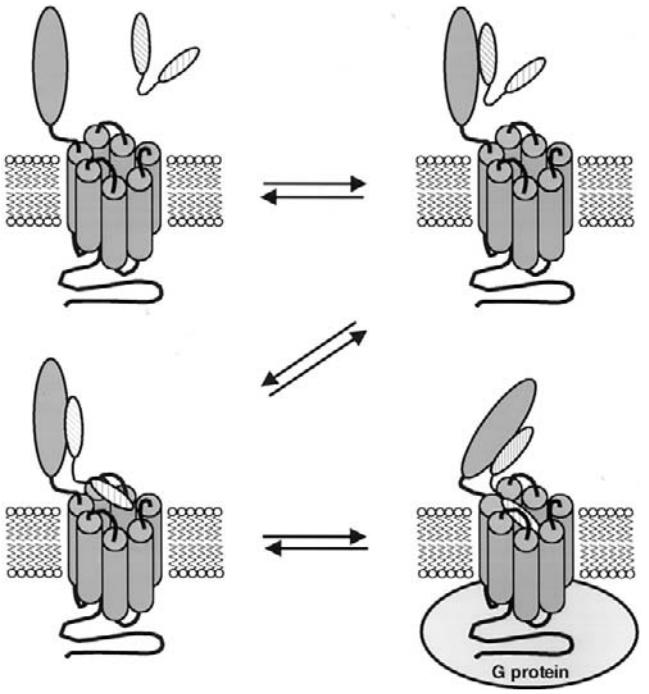

Figure 5 Hypothetical model of the PTH–PTH receptor interaction mechanism. The schematic illustrates current hypotheses regarding the mechanism by which PTH binds to the PTH1 receptor and induces G protein coupling. The interaction with PTH(1-34) (hatched ovals) involves two principal components: (1) binding of the C-terminal domain of PTH(1-34) to the amino-terminal extracellular domain of the receptor and (2) the association of the amino-terminal domain of PTH with the juxtamembrane region of the receptor. These two components of the interaction contribute predominantly to affinity and activation, respectively, and may occur in a sequential manner, as depicted. Upon association of the N-terminal portion of the ligand with the juxtamembrane region, a conformational change occurs, which results in the formation of a "closed" high-affinity ligand–receptor complex that is coupled to G protein. This hypothetical model is adapted from and discussed further in Hoare *et al.* (2001).

including the amino-terminal extracellular domain, the finding that short peptide sequences [modified PTH(1-11) and (1-14), as well as PTH(1-9) in a tethered construct] can activate the receptor (Shimizu *et al.,* 2000a) suggests, as the model in Fig. 5 predicts, that it should be possible for a small nonpeptide molecule that interacts only with the juxtamembrane region of the receptor to function as a potent PTH-1 receptor agonist.

Conformational Changes in the PTH-1 Receptor

As for all GPCRs, the binding of an agonist peptide to the PTH-1 receptor is thought to induce conformational changes in the receptor, including movements of the TM domains that render the cytoplasmic loops more accessible to G proteins (Gether, 2000). The model shown in Fig. 5 deduced from kinetic data (Hoare *et al.,* 2001) that G protein association by a ligand-bound receptor results in a "tightening" of the receptor/ligand complex reflects this proposed conformational change. An agonist-induced movement of TM3 away from TM6 has been demonstrated for the PTH-1 receptor by Sheikh *et al.* (1999), who showed that the chelation of zinc between histidine residues (native or introduced) at the intracellular ends of TM3 and TM6 blocked receptor-mediated G protein activation. An analogous movement was also shown in the β_2-adrenergic receptor, suggesting that the mechanisms of activation for the class I and class II GPCRs are fundamentally similar (Sheikh *et al.,* 1999). Several residues on the cytoplasmic surface of the PTH-1 receptor have been identified within regions that are candidate G protein interaction sites (Fig. 3). In intracellular loop 3, these include Val-384 and Leu-385 (PLC coupling), Thr-387 (AC coupling), and Lys-388 (AC and PLC coupling) (Huang *et al.,* 1996). In intracellular loop 2, Lys-319 has been implicated in PLC signaling (Iida-Klein *et al.,* 1997).

Three different activating mutations in the PTH-1 receptor have been identified in patients with Jansen's metaphyseal chondrodsyplasia, a rare form of dwarfism associated with hypercalcemia (Calvi and Schipani, 2000). These mutations occur at the cytoplasmic termini of TM2 (Arg-233 → His), TM6 (Thr-410 → Pro), and TM7 (Ile-458 → Arg) (Fig. 3) and each results in agonist-independent cAMP signaling. Whether the conformational changes induced by the activating mutations are the same as those that occur in the agonist occupied wild-type PTH receptor is unknown, but the study of these mutant PTH-1 receptors, along with certain peptide ligand analogs, such as [Leu^{11}, D-Trp^{12}]PTHrP(7-34), that behave as inverse agonists with the mutant receptors and depress their basal signaling (Carter *et al.,* 2001; Gardella *et al.,* 1996b), is likely to provide insights into the conformational states that are possible for active and inactive PTH-1 receptors.

PTH-1 Receptor Regulation

The agonist-dependent response capacity of the PTH-1 receptor is diminished markedly within minutes following an initial exposure to agonist (Bergwitz *et al.,* 1994; Fukayama *et al.,* 1992). This desensitization is accompanied by rapid internalization of the PTH–PTH-1 receptor complex (Ferrari *et al.,* 1999; Huang *et al.,* 1999; Malecz *et al.,* 1998). Phosphorylation of other G protein-coupled receptors on cytoplasmic domains is known to play an important role in the internalization/desensitization process (Lefkowitz, 1998). The PTH-1 receptor is phosphorylated on its cytoplasmic tail immediately following agonist activation (Blind *et al.,* 1996), specifically on as many as seven serine residues that cluster to within the midregion of the cytoplasmic tail (Malecz *et al.,* 1998; Qian *et al.,* 1998) (Fig. 3). The second messenger–activated kinases PKA and PKC both appear to contribute to PTH-1 receptor phosphorylation, as both forskolin and phorbol 12-myristate 13-acetate increase PTH-1 receptor phosphorylation (Blind *et al.,* 1995). The inhibitory effect of staurosporine on PTH-1 receptor phosphorylation (Qian *et al.,* 1998) and internalization (Ferrari *et al.,* 1999) supports a role for PKC, and potentially other kinases, in these processes.

Cotransfection experiments have indicated that the G protein receptor kinase-2 (GRK-2) also contributes to PTH-1 receptor phosphorylation (Dicker *et al.,* 1999; Malecz *et al.,* 1998).

With other G protein-coupled receptors, receptor phosphorylation enables the binding of β-arrestin2 (β-Arr2), which then interferes sterically with G protein coupling and, in an adapter role, binds the receptor directly to clatherin (Lefkowitz, 1998). PTH-1 receptor endocytosis occurs largely via a clatherin-coated vesicle-mediated process (Huang *et al.,* 1995). By expressing moderate levels of a phosphorylation-deficient PTH-1 receptor mutant having the clustered serines of the C-tail replaced by alanine, Qian *et al.* (1999) found that agonist-induced internalization in LLC-PK1 cells was reduced markedly in comparison to the wild-type receptor. There does not appear to be a simple relationship between phosphorylation of the C-terminal tail of the PTH-1 receptor and receptor internalization/desensitization, however. Thus, Malecz *et al.* (1998) found that a similar alanine-substituted phosphorylation-deficient PTH-1 receptor mutant expressed at high levels in HEK-293 cells was internalized upon agonist binding just as efficiently as the wild-type receptor; in cotransfection experiments, Dicker *et al.* (1999) found that GRK-2 efficiently cross-linked to, coimmunoprecipitated with, and inhibited agonist-induced PLC signaling by a PTH-1 receptor mutant deleted for the C-terminal tail; and finally, using fluorescent confocal microscopy methods, Ferrari and Bisello (2001) found that a PTH-1 receptor deleted for the C-tail was internalized upon agonist binding just as efficiently as the intact receptor. This latter study also showed that, like the intact receptor, the agonist-occupied C-terminally truncated receptor recruited β-Arr2 tagged with green fluorescent protein (GFP) from the cytosol to the membrane, but where the GFP-β-Arr2 remained associated with the internalized intact receptor, it dissociated rapidly from the internalized truncated receptor. Thus, phosphorylation of the C-terminal tail of the PTH-1 receptor appears to play a role in stabilizing the complex formed with the intracellular trafficking and regulatory proteins, but these proteins must also utilize other cytoplasmic components of the receptor for additional docking interactions.

Studies with the constitutively active mutant PTH receptors of Jansen's disease have begun to shed light on how conformational changes in the receptor might play a role in the internalization process. Both the H223R and the T410P mutant receptors spontaneously recruit β-Arr2 from the cytosol to the membrane (Ferrari and Bisello, 2001), but where the H223R mutant, as well as the wild-type receptor, exhibited little or no internalization of antagonist ligands, the T410P mutant internalized antagonist ligands to levels comparable to those seen with the agonist-occupied wild-type receptor (Carter *et al.,* 2001; Ferrari and Bisello, 2001). Thus, cAMP signaling and β-Arr2 binding by the PTH-1 receptor are not sufficient to induce internalization. In addition, it appears that a specific receptor conformation, which is presumably induced by agonist binding (or in some way mimicked by the T410P mutation), must be accessed for this process to occur. Further investigation with these PTH-1 receptor mutants, new ligand analogs, and fluorescently labeled regulatory proteins should help to elucidate further the molecular mechanisms involved in regulating the PTH-1 receptor-mediated signaling response, a possibly important feature of overall physiological regulation of PTH action and its pharmacological use.

Other Receptors for PTH and/or PTHrP

Receptors for Mid- and Carboxy-Terminal Portions of PTH and PTHrP

There is a substantial amount of pharmacological evidence in the literature for additional nonclassical receptors for PTH and PTHrP (Jüppner *et al.,* 2001). Competition binding studies and other functional assays have suggested that distinct receptors exist for midregional and carboxy-terminal fragments of PTH or PTHrP, although the biological importance of such receptors remains to be established. For example, intact PTH and/or larger carboxyl-terminal PTH fragments have been shown to interact with a novel cell surface receptor (see later). Other receptors appear to mediate the effects of midregional PTHrP on placental calcium transport (Kovacs *et al.,* 1996; Wu *et al.,* 1996) and in the skin (Orloff *et al.,* 1996). Carboxy-terminal portions of PTHrP also have effects on osteoblasts (Cornish *et al.,* 1997, 1999; Fenton *et al.,* 1991a,b), as well as the central nervous system (Fukayama *et al.,* 1995). A novel receptor that interacts with the amino-terminal portion of PTHrP, but not the amino-terminal portion of PTH, has been characterized in the rat supraoptic nucleus, and this PTHrP-selective receptor can regulate the synthesis and release of arginine vasopressin (Yamamoto *et al.,* 1998). Still other receptors that interact with amino-terminal portions of PTH and PTHrP have been identified pharmacologically that signal through changes in intracellular-free calcium but not through increases in cAMP (Gaich *et al.,* 1993; Orloff *et al.,* 1995; Soifer *et al.,* 1992). Clearly there is strong interest in isolating complementary cDNAs, which encode such nonclassical receptors for PTH and PTHrP, but so far none have been identified. Such interest is highlighted by studies on the carboxyl-terminal portion of PTH.

Receptors Specific for Carboxyl-Terminal PTH in Bone (CPTHR)

The traditional view of PTH biology has been that the major biologic actions of PTH on bone, cartilage, and kidney result from activation of PTH1R, which is fully achieved by the N-terminal sequence PTH(1-34) (or the homologous N-terminal portion of PTHrP). This concept has derived largely from a heavy focus in the years following the isolation and structural identification of PTH on the use of cAMP production and of biologic responses now known to be

largely cAMP dependent. These include calcemia and phosphaturia, as indices of PTH action *in vivo* and *in vitro,* although, as reviewed earlier, it is now known that PTH1R can also trigger cAMP-independent signaling events, including activation of PLC, PLD, PLA2, PKC, and increased cytosolic calcium, and that the structural determinants within both the PTH(1-34) ligand and the PTH1R itself that are required for these activities are not fully congruent.

Until very recently, the possibility that the C-terminal portion of the intact PTH(1-84) molecule might be physiologically important has received inadequate attention in part because (a) peptides such as PTH(39-84) or PTH(53-84) cannot be shown to bind or activate PTH1Rs; (b) the expressed PTH1R interacts equivalently with PTH(1-34) and PTH(1-84); (c) even minimal truncation at the N terminus of PTH(1-34) ablates PTH1R activation; and (d) differences in the bioactivity of PTH(1-34) and PTH(1-84) have not been demonstrated consistently in the usual "PTH bioassays" *in vitro* or *in vivo* (Potts and Jüppner, 1998). Moreover, the rapid production of C-terminal PTH fragments via endopeptidic cleavage of intact PTH *in vivo* (mainly in liver and kidney) has been regarded as the major route of metabolic clearance of active PTH, whereby the active N terminus of the molecule is destroyed *in situ* and long-lived C fragments are released back into the circulation (Potts and Jüppner, 1998). However, large portions of the C-terminal sequence of PTH(1-84) have been tightly conserved during evolution, active N-terminal fragments of PTH have not been demonstrated convincingly in blood of normal subjects, and C fragments of PTH (with N termini between residues 24 and 43) are cosecreted with intact hormone by the parathyroid glands in a manner whereby the ratio of intact fragments to C fragments is subject to regulation by blood calcium (Potts and Jüppner, 1998). Uncertainty regarding the potential importance of these observations, vis-à-vis a possible physiologic role for circulating C-terminal PTH peptides (CPTH), resulted mainly from a lack of evidence for specific receptors, distinct from the PTH1R (upon which all major PTH bioassays have been based), at which these peptides might act.

Initial indications that receptors for CPTH (CPTHRs) might exist actually appeared in the 1980s, when techniques were first developed to radiolabel intact PTH(1-84) in a biologically active form. At that time, careful analysis of ^{125}I-bPTH(1-84) binding to renal membranes and intact osteoblastic cells provided clear evidence of a second binding site that had a 10-fold lower affinity than that now known to pertain to the PTH1R and was specifically displaced by CPTH peptides (Demay *et al.,* 1985; Rao and Murray, 1985; Rao *et al.,* 1983). More recently, Inomata *et al.* reported the first direct measurements of CPTHR binding in ROS 17/2.8 rat osteosarcoma cells and rat parathyroid-derived cells, using radioiodinated recombinant peptides ^{125}I-[Tyr^{34}]hPTHrP(19-84) and ^{125}I-[Leu^{8,18}, Tyr^{34}]hPTHrP(1-84) as tracers (Inomata *et al.,* 1995). These two radioligands, which bind minimally, if at all, to the PTH1R, exhibited binding affinity comparable to that of hPTH(1-84) itself. These results suggested that all of the binding determinants of intact PTH(1-84) for the CPTHR reside within the PTH(19-84) sequence. Specific CPTHR binding was observed for hPTH(53-84), hPTH(39-94), and hPTH(1-84) but not hPTH(44-68) or hPTH(1-34); chemical cross-linking demonstrated a predominant 90-kDa receptor band (Inomata *et al.,* 1995). Unequivocal evidence that these CPTHR sites are distinct from the PTH1R subsequently was obtained via the demonstration of specific ^{125}I-[Tyr^{34}]hPTHrP(19-84) binding to clonal osteoblasts and osteocytes in which both PTH1R alleles had been ablated by gene targeting (Divieti *et al.,* 2001). The apparent binding affinity of these CPTHR sites for intact PTH and longer CPTH fragments (K_d = 10–20 n*M*) was 10-fold lower than that of the PTH1R for PTH(1-84) or PTH(1-34) (1-2 n*M*). Interestingly, this difference in affinity of PTH1Rs and CPTHRs for intact PTH and CPTH fragments, respectively, mirrors their relative levels in blood, where evidence suggests a 5- to 10-fold higher concentration of CPTH peptides than intact hormone.

Early work in several laboratories documented increased alkaline phosphatase expression following exposure of rat of human osteosarcoma cells to CPTH peptides, and subsequent research has identified a variety of biologic effects of CPTH fragments, including regulation of collagen and IGFBP-5 mRNA in UMR-106 rat osteosarcoma cells, stimulation of ^{45}Ca uptake in SaOS-2 cells, promotion of osteoclast formation in primary murine bone and marrow cell cultures, regulation of collagen II and X mRNA in primary fetal bovine hypertrophic chondrocytes, induction of cytosolic calcium transients in human primary fetal hypertrophic chondrocytes, and control of dentin and enamel formation in organ-cultured embryonic mouse tooth germ (Erdmann *et al.,* 1996, 1998; Fukayama *et al.,* 1994; Kaji *et al.,* 1994; Murray *et al.,* 1991; Nakamoto *et al.,* 1993; Nasu *et al.,* 1998; Sutherland *et al.,* 1994; Takasu *et al.,* 1996; Tsuboi and Togari, 1998). Most often, these effects of CPTH peptides were different from, if not opposite to, those of PTH(1-34), although mediation by PTH1Rs could not be definitely excluded because all of the cells studied were known, or could be assumed, to express PTH1Rs. More recent work, however, using cells genetically devoid of functional PTH1Rs, has clearly documented biologic responses to CPTHRs that must be distinct from the PTH1R (Divieti *et al.,* 2001). The structural features of the PTH ligand required for CPTHR activation have yet to be fully defined, although the importance of an intact C terminus for some, but not all, responses has been emphasized (Takasu *et al.,* 1996).

It is of interest that CPTHRs have been identified so far primarily in cells of skeletal origin, i.e., marrow stromal cells, osteoblasts, osteocytes, and chondrocytes. However, CPTHRs were also described for cells derived from rat parathyroid cells (rPTs), which have characteristics of fibroblasts (Potts and Jüppner, 1998). The highest levels of CPTHR expression reported to date ($2-3 \times 10^6$/cell) were observed in clonal cell lines, conditionally transformed by

a temperature-sensitive SV40 transgene and isolated from embryonic PTH1R-null mice, with phenotypic features of osteocytes (i.e., a dendritic morphology and abundant expression of osteocalcin and connexin-43 but not of alkaline phosphatase or cbfa-1) (Divieti *et al.,* 2001). In such cells, genetically devoid of PTH1Rs, PTH(1-84) could not elicit cAMP generation and, as expected, no binding of ^{125}I-[Tyr^{34}]hPTHrP(1-36) could be detected (Divieti *et al.,* 2001). Analysis of the structural requirements for CPTHR ligand binding in these cells, using the ^{125}I-[Tyr^{34}]hPTH(19-84) radioligand, demonstrated equivalent affinity of hPTH(1-84), [Tyr^{34}]hPTH(19-84), and hPTH(24-84) (IC_{50} = 20-50 n*M*) that declined substantially with further truncation to hPTH(39-84) (IC_{50} = 20–50 n*M*), indicating the presence of important binding determinants within the sequence hPTH(24-38). Interestingly, hPTH(1-34), which contains most of this region, also weakly displaced the CPTHR radioligand (IC_{50} > 10,000 n*M*). These key features of ligand recognition were shared in common with PTH1R-null chondrocytes, marrow stromal cells, osteoblasts, and osteocytes (P. Divieti, and F. R. Bringhurst, unpublished data), suggesting that these various cell types may express structurally identical CPTHRs.

A possible physiologic role for CPTHRs expressed by cells of the osteoblast lineage was suggested by observations that, in PTH1R-null clonal osteocytes, intact PTH, as well as CPTH fragments, such as hPTH(39-84) and hPTH(53-84), promote apoptosis. This contrasts with the antiapoptotic effect of PTH1R activation in such cells (Jilka *et al.,* 1998) and suggests that the PTH1R and the still-uncloned CPTHR may exert functionally antagonistic actions upon osteoblastic cells *in vivo*. CPTHR activation in clonal osteocytes also modified expression of connexin-43, suggesting a possible role in the regulation of cell-to-cell communication via gap junctions. The signal transduction mechanisms that may underlie these CPTHR effects remain unknown, although, as noted earlier, coupling to G_s is unlikely.

In summary, evidence that receptors with specificity for the carboxyl-terminal portion of intact PTH(1-84) (i.e., CPTHRs) exist in bone is now unequivocal (Divieti *et al.,* 2001). These receptors, most clearly defined *in vitro* using cell systems genetically devoid of PTH/PTHrP receptors (PTH1Rs), can bind and be activated by intact PTH(1–84) and various synthetic CPTH fragments, such as hPTH(19-84), hPTH(39-84), and hPTH(53-84) (Divieti *et al.,* 2001; Murray *et al.,* 1991). Numerous biologic responses to CPTHR activation have been identified, including regulation of calcium transients, alkaline phosphatase, collagen gene expression, osteoclast formation, connexin-43 expression, and apoptosis (Demay *et al.,* 1985; Divieti *et al.,* 2001; Erdmann *et al.,* 1996, 1998; Fukayama *et al.,* 1994; Kaji *et al.,* 1994; Murray *et al.,* 1991; Nakamoto *et al.,* 1993; Nasu *et al.,* 1998; Rao and Murray, 1985; Rao *et al.,* 1983; Sutherland *et al.,* 1994; Takasu *et al.,* 1996; Tsuboi and Togari, 1998). Observations *in vivo* indicate that the fragment hPTH(7-84), which may exist normally *in vivo* but which clearly can bind CPTHRs with high affinity, antagonizes the PTH1R-mediated calcemic effect of PTH *in vivo* (Nguyen-Yamamoto *et al.,* 2000; Slatopolsky *et al.,* 2000). This *in vivo* action is mirrored in *in vitro* studies showing antagonism by hPTH(7-84) but not by hPTHrP(7-34) of calvarial bone resorption induced by PTH(1-34), suggesting a possible role for CPTHR activation in blocking the bone resorption (P. Divieti and F. R. Bringhurst, unpublished data). Finally, evidence that CPTHR activation promotes apoptosis in cells of the osteoblast lineage, an effect opposite that of PTH(1-34) in such cells, points to a potentially important interaction of PTH1Rs and CPTHRs in control of osteoblast and osteocyte number (Divieti *et al.,* 2001).

Carboxyl fragments of intact PTH are secreted in a calcium-regulated manner by the parathyroid glands, are generated rapidly from secreted or injected PTH(1-84) via peripheral metabolism in liver and kidney, circulate normally at molar levels 5- to 10-fold higher than those of intact PTH(1-84), and accumulate to much higher concentrations in renal failure (Potts and Jüppner, 1998). The possibility that CPTHR activation may play a role in modulating osseous responses to full-length (versus N-terminal) PTH administered as a therapeutic for osteoporosis or in the pathogenesis of currently unexplained features of renal osteodystrophy clearly is worthy of further investigation in light of all the accumulating evidence about high concentrations of CPTH fragments, the distinct CPTHR, and the variety of biological effects seen *in vitro* following the interactions of C fragments with the CPTHR.

The Parathyroid Hormone Gene

Chromosomal Location

The human parathyroid hormone (PTH) gene is localized on the short arm of chromosome 11 and is only present once in the genomes of humans, rats, and cows (Antonarakis *et al.,* 1983; Naylor *et al.,* 1983; Mayer *et al.,* 1983). The PTH gene is closely linked to the calcitonin gene. Zabel *et al.* (1985) performed chromosomal *in situ* hybridization studies, which further localized the gene to the region 11p15. Restriction enzyme analysis of the human PTH gene, as well as the use of denaturing gradient gel electrophoresis, demonstrated polymorphism in their cleavage products in different individuals (Antonarakis *et al.,* 1983; Schmidtke *et al.,* 1984; Miric and Levine, 1992). These genetic polymorphisms are useful for genetic analysis and for relating parathyroid disease to structural alterations in the PTH gene.

PTH Gene

Complementary DNA encoding for human (Hendy *et al.,* 1981; Vasicek *et al.,* 1983), bovine (Kronenberg *et al.,* 1979; Weaver *et al.,* 1982), rat (Schmelzer *et al.,* 1987), mouse, pig (Schmelzer *et al.,* 1987), chicken (Khosla *et al.,* 1988; Russell and Sherwood, 1989), dog (Rosol *et al.,* 1995), cat, and horse PTH have all been cloned. Corresponding genomic DNA has also been cloned from human (Vasicek *et al.,* 1983), bovine (Weaver *et al.,* 1984), and rat (Heinrich *et al.,* 1984). The genes all have two introns or intervening sequences and three exons (Kronenberg *et al.,* 1986). The primary RNA transcript consists of RNA transcribed from both introns and exons, and then RNA sequences derived from the introns are spliced out. The product of this RNA processing, which represents the exons, is the mature PTH mRNA, which will then be translated into preproPTH. The first intron separates the 5′-untranslated region of the mRNA from the rest of the gene, and the second intron separates most of the sequence encoding the precursor-specific "pre-pro" region from that encoding mature PTH. The three exons that result are thus roughly divided into functional domains. The large first intron in the human gene (3400 bp) is much larger than that in the rat and bovine. The second intron is about 100 bp in the three species. There is considerable identity among mammalian PTH genes, which is reflected in an 85% identity between human and bovine proteins and 75% identity between human and rat proteins. There is less identity in the 3′-noncoding region. Human and bovine genes have two functional TATA transcription start sites, and the rat only one. The two homologous TATA sequences flanking the human PTH gene direct the synthesis of two human PTH gene transcripts both in normal parathyroid glands and in parathyroid adenomas (Igarashi *et al.,* 1986). The termination codon immediately following the codon for glutamine at position 84 of PTH indicates that there are no additional precursors of PTH with peptide extensions at the carboxyl position.

Tissue-Specific Expression of the PTH Gene

One of the factors that may be related to tissue specificity of the expression of a gene in a particular tissue is decreased methylation of cytosine at particular sites of the gene.

Levine *et al.* (1986) demonstrated that DNA from parathyroid glands is hypomethylated at CpG sequences in the neighborhood of the PTH gene, but not in DNA from control tissues. There was no correlation between the degree of hypomethylation of the PTH gene and the level of parathyroid gland secretory activity. The PTH gene is a typical eukaryotic gene with consensus sequences for initiation of RNA synthesis, RNA splicing, and polyadenylation.

Genetic studies have demonstrated the role of different genes to the development of the parathyroid. Gunther *et al.* (2000) studied Glial cells missing2 (Gcm2), a mouse homologue of *Drosophila* Gcm, a transcription factor whose expression is restricted to the parathyroid glands. They showed that Gcm2-deficient mice lacked parathyroid glands and exhibited hypoparathyroidism, identifying Gcm2 as a master regulatory gene of parathyroid gland development. However, Gcm2-deficient mice were viable and fertile and had only a mildly abnormal bone phenotype. Despite their lack of parathyroid glands, Gcm2-deficient mice had PTH serum levels identical to those of wild-type mice, as did parathyroidectomized wild-type mice. Expression and ablation studies identified the thymus, where Gcm1, another Gcm homologue, is expressed, as the additional, downregulatable source of PTH. Thus, Gcm2 deletion uncovered an auxiliary mechanism for the regulation of calcium homeostasis in the absence of parathyroid glands. It would be interesting to know if these findings are restricted to the mouse or have a wider physiological relevance. A human patient with a defective Gcm B gene, the human equivalent of Gcm[2], exhibited hypoparathyroidism and complete absence of PTH from the bloodstream (Ding *et al.,* 2000).

The thymus, thyroid, and parathyroid glands in vertebrates develop from the pharyngeal region, with contributions both from pharyngeal endoderm and from neural crest cells in the pharyngeal arches. Hoxa3 mutant homozygotes have defects in the development of all three organs and are completely missing parathyroid glands (Manley and Capecchi, 1998). Pax 9 mouse mutants are similarly missing parathyroid glands and other pharyngeal pouch structures (Peters *et al.,* 1998). Humans with one mutated copy of the GATA3 transcription factor exhibit hypoparathyroidism, sensorineural deafness, and renal anomalies (Van Esch *et al.,* 2000). The specific gene causing the hypoparathroidism found in the CATCH-22 syndrome (cardiac defects, abnormal facies, thymic hypoplasia, cleft palate, hypocalcemia, associated with chromosome 22 microdeletion) and the associated DiGeorge syndrome has not yet been identified.

Promoter Sequences

Regions upstream of the transcribed structural gene often determine tissue specificity and contain many of the regulatory sequences for the gene. For PTH, analysis of this region has been hampered by the lack of a parathyroid cell line. Arnold's group has demonstrated, however, that the 4 kb of DNA upstream of the start site of the human PTH gene was able to direct parathyroid gland-specific expression in transgenic mice (Hosokawa *et al.,* 1997). Rupp *et al.* (1990) analyzed the human PTH promoter region up to position -805 and identified a number of consensus sequences by computer analysis. These included a sequence resembling the canonical cAMP-responsive element 5′-TGACGTCA-3′ at position -81 with a single residue deviation. This element was fused to a reporter gene (CAT) and then transfected into different cell lines. Pharmacological agents that increase cAMP led to an increased expression of the CAT gene, suggesting a functional role for the cAMP responsive element (CRE). The role of this possible CRE in the context of the PTH gene in the parathyroid remains to be established.

Several groups have identified DNA sequences that might mediate the negative regulation of PTH gene transcription by 1,25-dihydroxyvitamin D [$1,25(OH)_2D_3$]. Demay *et al.* (1992) identified DNA squences in the human PTH gene that bind the $1,25(OH)_2D_3$ receptor. Nuclear extracts containing the $1,25(OH)_2D_3$ receptor were examined for binding to sequences in the 5′-flanking region of the hPTH gene. A 25-bp oligonucleotide containing sequences from -125 to -101 from the start of exon 1 bound nuclear proteins that were recognized by monoclonal antibodies against the $1,25(OH)_2D_3$ receptor. The sequences in this region contained a single copy of a motif (AGGTTCA) that is homologous to the motifs repeated in the upregulatory $1,25(OH)_2D_3$ response element of the osteocalcin gene. When placed upstream to a heterologous viral promoter, the sequences contained in this 25-bp oligonucleotide mediated transcriptional repression in response to $1,25(OH)_2D_3$ in GH4C1 cells but not in ROS 17/2.8 cells. Therefore, this downregulatory element differs from upregulatory elements both in sequence composition and in the requirement for particular cellular factors other than the $1,25(OH)_2D_3$ receptor (VDR) for repressing PTH transcription (Demay *et al.,* 1992). Farrow *et al.* (1990) and Hawa *et al.* (1994) have identified DNA sequences upstream of the bovine PTH gene that bind the $1,25(OH)_2D_3$ receptor. Russell *et al.* (1999) have shown that there are two negative VDREs in the rat PTH gene. One is situated at -793 to -779 and bound a VDR/RXR heterodimer with high affinity and the other at -760 to -746 bound the heterodimer with a lower affinity. Transfection studies with VDRE-CAT constructs showed that they had an additive effect. Liu *et al.* (1996) have identified such sequences in the chicken PTH gene and demonstrated their functionality after transfection into the opossum kidney (OK) cell line. They converted the negative activity imparted by the a PTH VDRE to a positive transcriptional response through selective mutations introduced into the element. They showed that there was a p160 protein that specifically interacted with a heterodimer complex bound to the wild-type VDRE, but was absent from complexes bound to response elements associated with positive transcriptional activity. Thus, the sequence of the individual VDRE appears to play an active role in dictating transcriptional responses that may be mediated by altering the ability of a vitamin D receptor heterodimer to interact with accessory factor proteins. Further work is needed to demonstrate that any of these differing negative VDREs function in this fashion in parathyroid cells.

Mutations in the PTH Gene

Rare patients have been found with abnormal parathyroid hormone genes that result in hypoparathyroidism. The PTH gene of a patient with familial isolated hypoparathyroidism (Ahn *et al.,* 1986) has been studied by Arnold *et al.* (1990), and a point mutation in the hydrophobic core of the signal peptide-encoding region of preproPTH was identified. This T-to-C point mutation changed the codon for position 18 of the 31 amino acid prepro sequence from cysteine to arginine, and in functional studies the mutant protein was processed inefficiently. The mutation impaired interaction of the nascent protein with signal recognition particle and the translocation machinery, and cleavage of the mutant signal sequence by solubilized signal peptidase was slow (Karaplis *et al.,* 1995). Sunthornthepvarakul *et al.* (1999) reported a novel mutation of the signal peptide of the prepro-PTH gene associated with autosomal recessive familial isolated hypoparathyroidism. The affected members in this family presented with neonatal hypocalcemic seizures. Their intact PTH levels were undetectable during severe hypocalcemia. A replacement of thymine with a cytosine was found in the first nucleotide of position 23 in the 25 amino acid signal peptide. This results in the replacement of the normal Ser (TCG) with a Pro (CCG). Only affected family members were homozygous for the mutant allele, whereas the parents were heterozygous, supporting autosomal recessive inheritance. Because this mutation is at the -3 position in the signal peptide of the prepro-PTH gene, the authors hypothesized that the prepro-PTH mutant might not be cleaved by signal peptidase at the normal position and might be degraded in the rough endoplasmic reticulum. Parkinson and Thakker (1992) studied one kindred with autosomal recessive isolated hypoparathyroidism and identified a G-to-C substitution in the first nucleotide of intron 2 of the parathyroid hormone gene. Restriction enzyme cleavage revealed that the patients were homozygous for mutant alleles, unaffected relatives were heterozygous, and unrelated normals were homozygous for the wild-type alleles. Defects in messenger RNA splicing were investigated by the detection of illegitimate transcription of the PTH gene in lymphoblastoid cells. The mutation resulted in exon skipping with a loss of exon 2, which encodes the initiation codon and the signal peptide, thereby causing parathyroid hormone deficiency. Somatic mutations identified in the PTH gene in some parathyroid adenomas are discussed in Chapter 56.

Regulation of PTH Gene Expression

1,25-Dihydroxyvitamin D

PTH regulates serum concentrations of calcium and phosphate, which, in turn, regulate the synthesis and secretion of PTH. 1,25-Dihydroxyvitamin D or calcitriol has independent effects on calcium and phosphate levels and also participates in a well-defined feedback loop between calcitriol and PTH.

PTH increases the renal synthesis of calcitriol. Calcitriol then increases blood calcium largely by increasing the efficiency of intestinal calcium absorption. Calcitriol also potently decreases transcription of the PTH gene. This action was first demonstrated *in vitro* in bovine parathyroid cells in primary culture, where calcitriol led to a marked decrease in PTH mRNA levels (Silver *et al.,* 1985; Russell *et al.,* 1984) and a consequent decrease in PTH secretion (Cantley *et al.,* 1985; Karmali *et al.,* 1989; Chan *et al.,* 1986). The physiological relevance of these findings was established by *in vivo* studies in rats (Silver *et al.,* 1986). The localization of $1,25(OH)_2D_3$ receptor mRNA (VDR mRNA) to parathyroids was demonstrated by *in situ* hybridization studies of the thyroparathyroid and duodenum. VDR mRNA was localized to the parathyroids in the same concentration as in the duodenum, the classic target organ of calcitriol (Fig. 1) (Naveh-Many *et al.,* 1990). Rats injected with amounts of calcitriol that did not increase serum calcium had marked decreases in PTH mRNA levels, reaching <4% of control at 48 hr (Fig. 2). This effect was shown to be transcriptional both in *in vivo* studies in rats (Silver *et al.,* 1986) and in *in vitro* studies with primary cultures of bovine parathyroid cells (Russell *et al.,* 1986). When 684 bp of the 5′-flanking region of the human PTH gene was linked to a reporter gene and transfected into a rat pituitary cell line (GH4C1), gene expression was lowered by $1,25(OH)_2D_3$ (Okazaki *et al.,* 1988). These studies suggest that $1,25(OH)_2D_3$ decreases PTH transcription by acting on the 5′-flanking region of the PTH gene, probably at least partly through interactions with the vitamin D-binding sequence noted earlier. The effect of $1,25(OH)_2D_3$ may involve heterodimerization with the retinoid acid recptor. This is because 9 *cis*-retinoic acid, which binds to the retinoic acid receptor, when added to bovine parathyroid cells in primary culture, led to a decrease in PTH mRNA levels (MacDonald *et al.,* 1994). Moreover, combined treatment with $1 \times 10^{-6}\,M$ retinoic acid and $1 \times 10^{-8}\,M$ $1,25(OH)_2D_3$ decreased PTH secretion and preproPTH mRNA more effectively than either compound alone (MacDonald *et al.,* 1994). Alternatively, retinoic acid receptors might synergize with VDRs through actions on distinct sequences.

A further level at which $1,25(OH)_2D_3$ might regulate the PTH gene would be at the level of the $1,25(OH)_2D_3$ receptor. $1,25(OH)_2D_3$ acts on its target tissues by binding to the $1,25(OH)_2D_3$ receptor, which regulates the transcription of genes with the appropriate recognition sequences. Concentration of the $1,25(OH)_2D_3$ receptor in $1,25(OH)_2D_3$ target sites could allow a modulation of the $1,25(OH)_2D_3$ effect, with an increase in receptor concentration leading to an amplification of its effect and a decrease in receptor concentration dampening the $1,25(OH)_2D_3$ effect.

Naveh-Many *et al.* (1990) injected $1,25(OH)_2D_3$ into rats and measured the levels of $1,25(OH)_2D_3$ receptor mRNA and PTH mRNA in the parathyrothyroid tissue. They showed that $1,25(OH)_2D_3$ in physiologically relevant

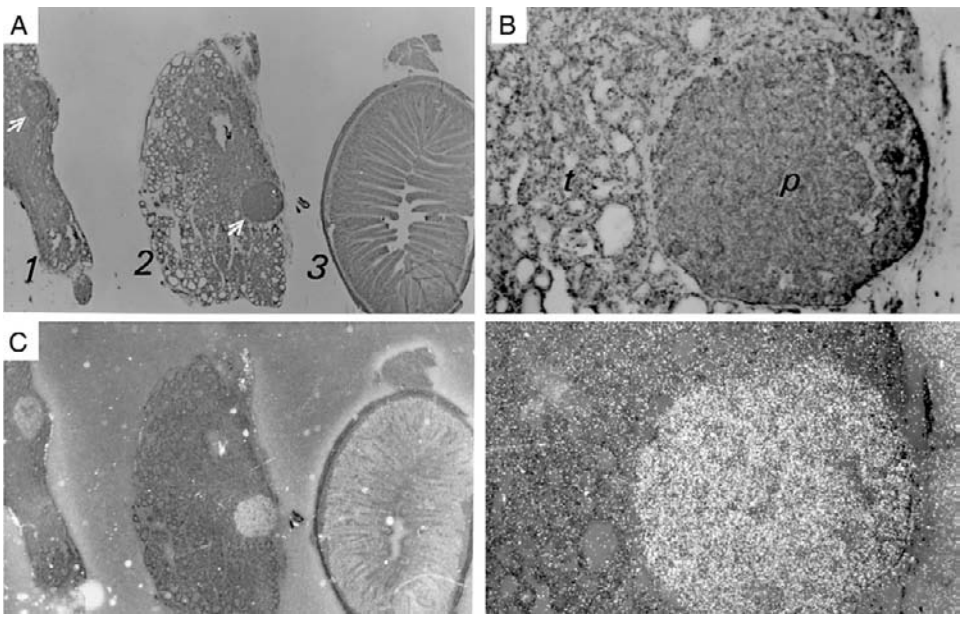

Figure 1 The $1,25(OH)_2$vitamin D receptor (VDR) is localized to the parathyroid in a similar concentration to that found in the duodenum, indicating that the parathyroid is a physiological target organ for $1,25(OH)_2D$. *In situ* hybridization with the VDR probe in rat parathyroid–thyroid and duodenum sections. (A1) Parathyroid–thyroid tissue from a control rat. (A2) Parathyroid–thyroid from a $1,25(OH)_2D_3$-treated rat (100 pmol at 24 hr). (A3) Duodenum from a $1,25(OH)_2D_3$-treated rat. doses led to an increase in VDR mRNA levels in the parathyroid glands in contrast to the decrease in PTH mRNA levels (Fig. 2). This increase in VDR mRNA occurred after a time lag of 6 hr, and a dose response showed a peak at 25 pmol. Weanling rats fed a diet deficient in calcium were markedly hypocalcemic at 3 weeks and had very high serum $1,25(OH)_2D_3$ levels. Despite the chronically high serum $1,25(OH)_2D_3$ levels, there was no increase in VDR mRNA levels; furthermore, PTH mRNA levels did not fall and were increased markedly. The low calcium may have prevented the increase in parathyroid VDR levels, which may partially explain PTH mRNA suppression. Whatever the mechanism, the lack of suppression of PTH synthesis in the setting of hypocalcemia and increased serum $1,25(OH)_2D_3$ is crucial physiologically because it allows an increase in both PTH and $1,25(OH)_2D_3$ at a time of chronic hypocalcemic stress. Russell *et al.* (1993) studied the parathyroids of chicks with vitamin D deficiency and confirmed that $1,25(OH)_2D_3$ regulates PTH and VDR gene expression in the avian parathyroid gland. Chicks in this study were fed a vitamin D-deficient diet from birth for 21 days and had established secondary hyperparathyroidism. These hypocalcemic chicks were then fed a diet with different calcium contents (0.5, 1.0, and 1.6%) for 6 days. The serum calciums were all still low (5, 6, and 7 mg/dl) with the expected inverse relationship between PTH mRNA and serum calcium. There was also a direct relationship between serum calcium and VDR mRNA levels. This result suggests either that VDR mRNA was not upregulated in the setting of secondary hyperparathroidism or that calcium directly regulates the VDR gene. Brown *et al.* (1995) studied vitamin D-deficient rats and confirmed that calcitriol upregulated parathyroid VDR

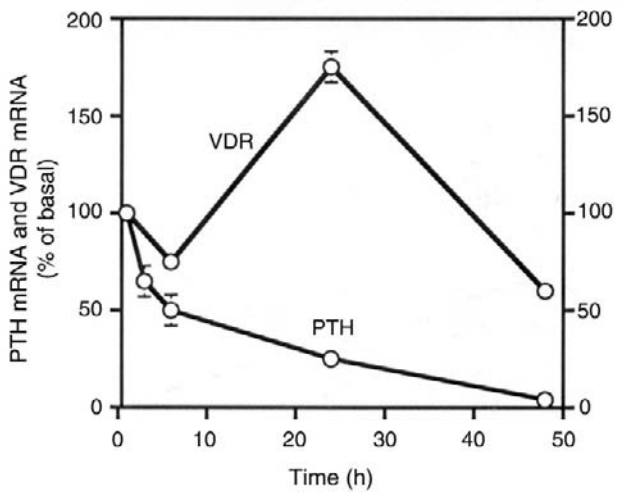

Figure 2 Time course for the effect of $1,25(OH)_2D_3$ on mRNA levels for PTH and the $1,25(OH)_2D_3$ receptor (VDR) in rat thyroparathyroid glands. Rats were injected with a single dose of either 100 or 50 pmol $1,25(OH)_2D_3$ at 0 and 24 hr. Data represent the mean ± SE of four rats. From Naveh-Many *et al.* (1990). By copyright permission of the American Society for Clinical Investigation.

mRNA and that in secondary hyperparathyroidism with hypocalcemia, PTH mRNA was upregulated without a change in VDR mRNA (Naveh-Many *et al.,* 1990).

All these studies show that $1,25(OH)_2D_3$ increases the expression of its receptor's gene in the parathyroid gland, which would result in increased VDR protein synthesis and increased binding of $1,25(OH)_2D_3$ (Fig. 3). This ligand-dependent receptor upregulation would lead to an amplified effect of $1,25(OH)_2D_3$ on the PTH gene and might help explain the dramatic effect of $1,25(OH)_2D_3$ on the PTH gene.

The use of calcitriol is limited by its hypercalcemic effect, and therefore a number of calcitriol analogs have been synthesized that are biologically active but are less hypercalcemic than calcitriol. These analogs usually involve modifications of the calcitriol side chain, such as 22-oxa-$1,25(OH)_2D_3$, which is the chemical modification in oxacacitriol (Nishii *et al.,* 1991), or a cyclopropyl group at the end of the side chain in calcipotriol (Kissmeyer and Binderup, 1991; Evans *et al.,* 1991). Brown *et al.* (1989b) showed that oxacalcitriol *in vitro* decreased PTH secretion from primary cultures of bovine parathyroid cells with a similar dose response to that of calcitriol. *In vivo* the injection of both vitamin D compounds led to a decrease in rat parathyroid PTH mRNA levels (Brown *et al.,* 1989b). However, detailed *in vivo* dose–response studies showed that *in vivo* calcitriol is the most effective analog for decreasing PTH mRNA levels, even at doses that do not cause hypercalcemia (Naveh-Many and Silver, 1993). Oxacalcalcitriol and calcipotriol are less effective for decreasing PTH RNA levels but have a wider dose range at which they do not cause hypercalcemia; this property might be useful clinically. The marked activity of calcitriol analogs *in vitro* as compared to their modest hypercalcemic actions *in vivo* probably reflects their rapid clearance from the circulation (Bouillon *et al.,* 1991). There much interest in the development and marketing of new calcitriol analogs to decrease PTH gene expression and serum PTH levels without causing hypercalcemia, but there have been few rigorous comparisons of their biological effects compared to those of calcitriol itself (Brown, 1998; Verstuyf *et al.,* 1998). The ability of calcitriol to decrease PTH gene transcription is used therapeutically in the management of patients with chronic renal failure. They are treated with calcitriol in order to prevent the secondary hyperparathyroidism of chronic renal failure. The poor response in some patients who do not respond may well result from poor control of serum phosphate, decreased vitamin D receptor concentration (Fukuda *et al.,* 1993), an inhibitory effect of a uremic toxin(s) on VDR-VDRE binding (Patel *et al.,* 1995), or tertiary hyperparathyroidism with monoclonal parathyroid tumors (Arnold *et al.,* 1995).

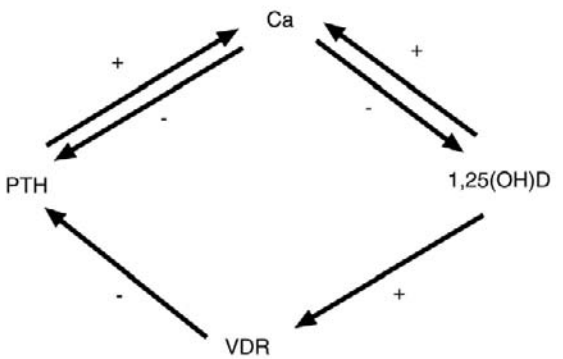

Figure 3 Interrelationships of calcium, $1,25(OH)_2D_3$, the vitamin D receptor (VDR), and PTH.

Calreticulin and the Action of $1,25(OH)_2D_3$ on the PTH Gene

Another possible level at which $1,25(OH)_2D_3$ might regulate PTH gene expression involves calreticulin. Calreticulin is a calcium-binding protein present in the endoplasmic reticulum of the cell and may also have a nuclear function. It regulates gene transcription via its ability to bind a protein motif in the DNA-binding domain of nuclear hormone receptors of sterol hormones. It has been shown to prevent vitamin D's binding and action on the osteocalcin gene *in vitro* (Wheeler *et al.,* 1995). Sela-Brown *et al.* (1998) showed that calreticulin might inhibit the action of vitamin D on the PTH gene. Both rat and chicken VDRE sequences of the PTH gene were incubated with recombinant VDR and retinoic acid receptor (RXR) proteins in a gel retardation assay and showed a clear retarded band. Purified calreticulin inhibited binding of the VDR–RXR complex to the VDREs in gel retardation assays. This inhibition was due to direct protein–protein interactions between VDR and calreticulin. OK cells were transiently cotransfected with calreticulin expression vectors (sense and antisense) and either rat or chicken PTH gene promoter–CAT constructs. The cells were then assayed for $1,25(OH)_2D_3$-induced CAT gene expression. $1,25(OH)_2D_3$ decreased PTH promoter–CAT transcription. Cotransfection with sense calreticulin, which increases calreticulin protein levels, completely inhibited the effect of $1,25(OH)_2D_3$ on the PTH promoters of both rat and chicken. Cotransfection with the antisense calreticulin construct did not interfere with the effect of vitamin on PTH gene transcription. Sense calreticulin expression had no effect on basal CAT mRNA levels. In order to determine a physiological role for calreticulin in regulation of the PTH gene, levels of calreticulin protein were determined in the nuclear fraction of rat parathyroids. The rats were fed either a control diet or a low calcium diet, which leads to increased PTH mRNA levels, despite high serum $1,25(OH)_2D_3$ levels that would be expected to inhibit PTH gene transcription (Sela-Brown *et al.,* 1998). It was postulated that high calreticulin levels in the nuclear fraction would prevent the effect of $1,25(OH)_2D_3$ on the PTH gene. In fact, hypocalcemic rats had increased levels of calreticulin protein, as measured by Western blots, in their parathyroid nuclear faction. This may help explain why hypocalcemia leads to increased PTH gene expression, despite high serum $1,25(OH)_2D_3$

levels, and may also be relevant to the refractoriness of the secondary hyperparathyroidism of many chronic renal failure patients to $1,25(OH)_2D_3$ treatment. These studies, therefore, indicate a role for calreticulin in regulating the effect of vitamin D on the PTH gene and suggest a physiological relevance to these studies (Sela-Brown *et al.,* 1998).

Calcium

In Vitro Studies

A remarkable characteristic of the parathyroid is its sensitivity to small changes in serum calcium, which leads to large changes in PTH secretion. This calcium sensing is also expressed at the levels of PTH gene expression and parathyroid cell proliferation. *In vitro* and *in vivo* data agree that calcium regulates PTH mRNA levels, but data differ in important ways. *In vitro* studies with bovine parathyroid cells in primary culture showed that calcium regulated PTH mRNA levels (Russell *et al.,* 1983; Brookman *et al.,* 1986), with an effect mainly of high calcium to decrease PTH mRNA. These effects were most pronounced after more prolonged incubations, such as 72 hr. The physiologic correlates of these studies in tissue culture are hard to ascertain, as the parathyroid calcium sensor might well have decreased over the time period of the experiment (Mithal *et al.,* 1995). This may explain why the dose response differs from *in vivo* data, but the dramatic difference in time course suggests that *in vivo* data reflect something not seen in cultured cells.

In Vivo Studies

Calcium and phosphate both have marked effects on the levels of PTH mRNA *in vivo.* The major effect is for low calcium to increase PTH mRNA levels and low phosphate to decrease PTH mRNA levels (Fig. 4). Naveh-Many *et al.* (1989) studied rats *in vivo.* They showed that a small decrease in serum calcium from 2.6 to 2.1 mmol/liter led to large increases in PTH mRNA levels, reaching threefold that of controls at 1 and 6 hr. A high serum calcium had no effect on PTH mRNA levels even at concentrations as high as 6.0 mmol/liter. Interestingly, in these same thyroparathyroid tissue RNA extracts, calcium had no effect on the expression of the calcitonin gene. Thus, while a high calcium is a secretagogue for calcitonin, it does not regulate calcitonin gene expression. Yamamoto *et al.* (1989) also studied the *in vivo* effect of calcium on PTH mRNA levels in rats. They showed that hypocalcemia induced by a calcitonin infusion for 48 hr led to a seven-fold increase in PTH mRNA levels. Rats made hypercalcemic (2.9–3.4 m*M*) for 48 hr had the the same PTH mRNA levels as controls that had received no infusion (2.5 m*M*); these levels were modestly lower than those found in rats that had received a calcium-free infusion. In further studies, Naveh-Many *et al.* (1992b) transplanted Walker carcinosarcoma 256 cells into rats. Serum calciums increased to 18 mg/dl at day 10 after transplantation. There was no change in PTH mRNA levels in these rats with marked chronic hypercalcemia (Naveh-Many *et al.,* 1992b). Differences between *in vivo* and *in vitro* results probably reflect the instability of the *in vitro* system, but it is also impossible to eliminate the possibility that *in vivo* effects are influenced by indirect effects of a high or low serum calcium or by other variables changed in the *in vivo* protocols. Nevertheless, the physiological conclusion is that common causes of hypercalcemia *in vivo* do not importantly decrease PTH mRNA levels; these results emphasize that the gland is geared to respond to hypocalcemia and not hypercalcemia.

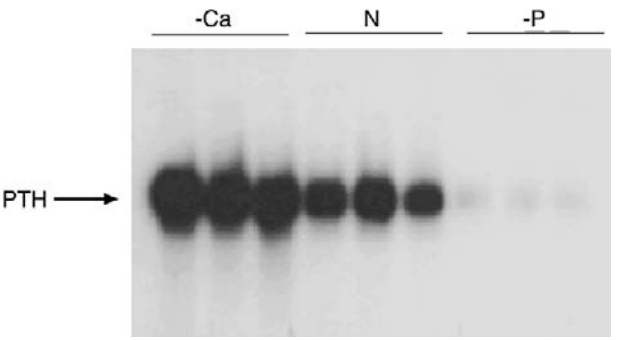

Figure 4 The effect of dietary phosphate and calcium on PTH mRNA levels. PTH mRNA levels are shown for individual rats fed diets for 3 weeks containing low phosphate; control; high phosphate; low calcium.

Mechanisms of Regulation of PTH mRNA by Calcium

The mechanism whereby calcium regulates PTH gene expression is particularly interesting. Changes in extracellular calcium are sensed by a calcium sensor that then regulates PTH secretion (Brown *et al.,* 1993). Signal transduction from the CaSR involves activation of phospholipase C, D, and A_2 enzymes (Kifor *et al.,* 1997). It is not known what mechanism transduces the message of changes in extracellular calcium leading to changes in PTH mRNA. Okazaki *et al.* (1992) identified a negative calcium regulatory element (nCaRE) in the atrial natiuretic peptide gene, with a homologous sequence in the PTH gene. They identified a redox factor protein (ref1), which was known to activate several transcription factors via alterations of their redox state, which bound a nCaRE, and the level of ref1 mRNA and protein were elevated by an increase in extracellular calcium concentration (Okazaki *et al.,* 1994). They suggested that ref1 had transcription repressor activity in addition to its function as a transcriptional auxiliary protein (Okazaki *et al.,* 1994). Because no parathyroid cell line is available, these studies were performed in nonparathyroid cell lines, so their relevance to physiologic PTH gene regulation remains to be established.

We have performed *in vivo* studies on the effect of hypocalcemia on PTH gene expression. The effect is posttranscriptional *in vivo* and involves protein–RNA interactions at the 3′-untranslated region of the PTH mRNA (Moallem *et al.,* 1998). A similar mechanism is involved in the effect of phosphate on PTH gene expression so the

mechanisms involved will be discussed after the independent effect of phosphate on the PT is considered.

Phosphate

A Specific Parathyroid Cell Sodium–Phosphate Cotransporter

The rat parathyroid harbors a type III Na^+-P_i cotransporter whose mRNA was increased by a low P_i diet and increased by vitamin D treatment (Tatsumi *et al.,* 1998). This transporter may contribute to the effects of P_i and vitamin D on parathyroid function.

Phosphate Regulates the Parathyroid Independently of Calcium and $1,25(OH)_2D_3$

The demonstration of a direct effect of high phosphate on the parathyroid *in vivo* has been difficult. One of the reasons is that the various maneuvers used to increase or decrease serum phosphate invariably lead to a change in the ionized calcium concentration. In moderate renal failure, phosphate clearance decreases and serum phosphate increases; this increase becomes an important problem in severe renal failure. Hyperphosphatemia has always been considered central to the pathogenesis of secondary hyperparathyroidism, but it has been difficult to separate the effects of hyperphosphatemia from those of the attendant hypocalcemia and decrease in serum $1,25(OH)_2D_3$ levels. In the 1970s, Slatopolsky and Bricker (1973) showed in dogs with experimental chronic renal failure that dietary phosphate restriction prevented secondary hyperparathyroidism. Clinical studies (Portale *et al.,* 1984) demonstrated that phosphate restriction in patients with chronic renal insufficiency is effective in preventing the increase in serum PTH levels (Lucas *et al.,* 1986; Portale *et al.,* 1984; Lafage *et al.,* 1992; Combe and Aparicio, 1994; Aparicio *et al.,* 1994). The mechanism of this effect was not clear, although at least part of it was considered to be due to changes in serum $1,25(OH)_2D_3$ concentrations. *In vitro* (Tanaka and DeLuca, 1973; Condamine *et al.,* 1994) and *in vivo* (Portale *et al.,* 1984; Portale *et al.,* 1989) phosphate directly regulated the production of $1,25(OH)_2D_3$. A raised serum phosphate decreases serum $1,25(OH)_2D_3$ levels, which then leads to decreased calcium absorption from the diet and eventually a low serum calcium. The raised phosphate complexes calcium, which is then deposited in bone and soft tissues and, thereby, decreases serum calcium. However, a number of careful clinical and experimental studies suggested that the effect of phosphate on serum PTH levels was independent of changes in both serum calcium and $1,25(OH)_2D_3$ levels. In dogs with experimental chronic renal failure, Lopez-Hilker *et al.* (1990) have shown that phosphate restriction corrected their secondary hyperparathyroidism independent of changes in serum calcium and $1,25(OH)_2D_3$ levels. They did this by placing the uremic dogs on diets deficient in both calcium and phosphate. This led to lower levels of serum phosphate and calcium, with no increase in the low levels of serum $1,25(OH)_2D_3$. Despite this, there was a 70% decrease in PTH levels. This study suggested that, at least in chronic renal failure, phosphate affected the parathyroid cell by a mechanism independent of its effect on serum $1,25(OH)_2D_3$ and calcium levels (Lopez-Hilker *et al.,* 1990). Therefore, phosphate plays a central role in the pathogenesis of secondary hyperparathyroidism, both by its effect on serum $1,25(OH)_2D_3$ and calcium levels and possibly independently.

Kilav *et al.* (1995) were the first to establish that the effects of serum phosphate on PTH gene expression and serum PTH levels were independent of any changes in serum calcium or $1,25(OH)_2D_3$. In a particularly informative experiment, they bred second-generation vitamin D-deficient rats and then placed the weanling vitamin D-deficient rats on a diet with no vitamin D, low calcium, and low phosphate. After 1 night of this diet, serum phosphate had decreased markedly with no changes in serum calcium or $1,25(OH)_2D_3$. These rats with isolated hypophosphatemia had marked decreases in PTH mRNA levels and serum PTH. However, the very low serum phosphates in these *in vivo* studies may have no direct relevance to possible direct effects of high phosphate in renal failure. It is necessary to separate nonspecific effects of very low phosphate from true physiologic regulation. To establish that the effect of serum phosphate on the parathyroid was indeed a direct effect, *in vitro* confirmation was needed, which was provided by three groups. Rodriguez was the first to show that increased phosphate levels increased PTH secretion from isolated parathyroid glands *in vitro;* the effect required maintainenance of tissue architecture (Almaden *et al.,* 1996). The effect was found in whole glands or tissue slices but not in isolated cells. This result was soon confirmed by Slatopolsky *et al.* (1996). Olgaard's laboratory provided elegant further evidence of the importance of cell–cell communication in mediating the effect of phosphate on PTH secretion (Nielsen *et al.,* 1996). The requirement for intact tissue suggests either that the sensing mechanism for phosphate is damaged during the preparation of isolated cells or that the intact gland structure is important to the phosphate response.

Parathyroid responds to changes in serum phosphate at the level of secretion, gene expression, and cell proliferation, although the mechanism of these effects is unknown. The effect of high phosphate to increase PTH secretion may be mediated by phospholipase A_2-activated signal transduction. Bourdeau *et al.* (1992, 1994) showed that arachidonic acid and its metabolites inhibit PTH secretion. Almaden *et al.* (2000) showed *in vitro* that a high phosphate medium increased PTH secretion, which was prevented by the addition of arachidonic acid. When dog parathyroid tissue was cultured in a high calcium and normal phosphate medium, there was an increase in arachidonic acid production at 30 and 45 min, returning to baseline at 60 min. A high phosphate medium prevented the increase in arachidonic acid production at 30 and 45 min, and there was a modest increase in PTH secretion only after 2 and 3 hr incubation. These results suggest that phosphate decreases the production of

arachidonic acid in the parathyroid and that arachidonic acid decreases PTH secretion, but it is less clear to what extent the effect of phosphate on PTH secretion is dependent upon this pathway. The use of inhibitors of the phospholipase A_2 pathway may help clarify this question. We can now provide some of the answers for the effect of phosphate and calcium on PTH gene expression.

Protein–RNA Interaction at PTH mRNA

Protein–RNA Binding to the PTH mRNA 3′-Untranslated Region (*3′-UTR*) and Its Regulation by Calcium and Phosphate

The clearest rat *in vivo* models for effects of calcium and phosphate on PTH gene expression are diet-induced hypocalcemia with a large increase in PTH mRNA levels and diet-induced hypophosphatemia with a large decrease in PTH mRNA levels. In both instances the effect was post-transcriptional, as shown by nuclear transcript run-on experiments. Parathyroid cytosolic proteins were found to bind *in vitro*-transcribed PTH mRNA, with three bands at about 50, 60, and 110 kDa (Moallem *et al.,* 1998). Interestingly, this binding was increased with parathyroid proteins from hypocalcemic rats (with increased PTH mRNA levels) and decreased with parathyroid proteins from hypophosphatemic rats (with decreased PTH mRNA levels). Proteins from many tissues bound to PTH mRNA, but this binding is regulated by calcium and phosphate only with parathyroid proteins. Intriguingly, binding requires the presence of the terminal 60 nucleotides of the PTH transcript.

PTH mRNA Is Degraded *in Vitro* by Parathyroid Cytosolic Proteins, Which Is Regulated by Calcium and Phosphate

Naveh-Many and colleagues utilized an *in vitro* degradation assay to study the effects of hypocalcemic and hypophosphatemic parathyroid proteins on PTH mRNA stability (Moallem *et al.,* 1998). In this assay, control rats' parathyroid cytosolic proteins led to the degradation of a radiolabeled PTH transcript in about 40–60 min. Hypocalcemic parathyroid proteins degraded the transcript only in 180 min, whereas hypophosphatemic parathyroid proteins degraded the transcript within 5 min. Moreover, the rapid degradation of PTH mRNA by hypophosphatemic proteins was totally dependent on an intact 3′-untranslated region (UTR) and, in particular, on the terminal 60 nucleotides (Fig. 5). Proteins from other tissues in these rats were not regulated by calcium or phosphate. Therefore, calcium and phosphate change the properties of parathyroid cytosolic proteins, which bind specifically to the PTH mRNA 3′-UTR and determine its stability (Fig. 5). What are these proteins?

Identification of AUF1 as a PTH mRNA 39-UTR Binding Protein That Determines PTH mRNA Stability

Sela-Brown *et al.* (2000) have utilized affinity chromatography to isolate these RNA-binding proteins. The proteins, which bind the PTH mRNA, are also present in other tissues, such as brain, but only in the parathyroid is their binding regulated by calcium and phosphate. The function of PTH mRNA 3′-UTR binding proteins was studied using the *in vitro* degradation assay. Competition for parathyroid-binding proteins by excess unlabeled 3′-UTR destabilized the full-length PTH transcript in this assay, indicating that these proteins protect the RNA from RNase activity (Fig. 6). The PTH RNA 3′-UTR binding proteins were purified by PTH 3′-region RNA affinity chromatography of rat brain S-100 extracts. The eluate from the column was enriched in PTH RNA 3′-UTR binding activity. Addition of eluate to the *in vitro* degradation assay with parathyroid protein extracts stabilized the PTH

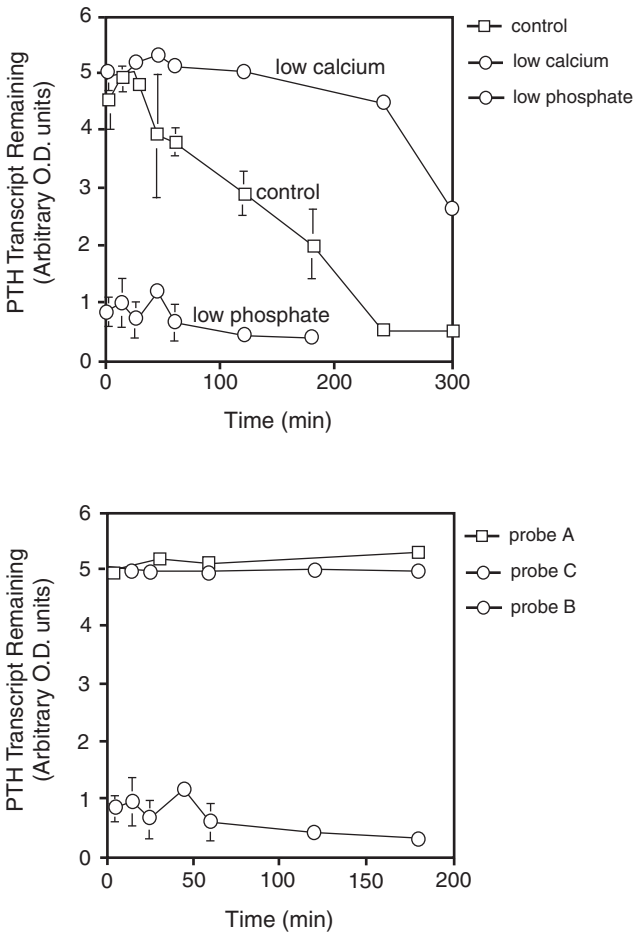

Figure 5 *In vitro* degradation of PTH mRNA by parathyroid cytosolic proteins. (Top) Time – response curves of intact full-length PTH mRNA after incubation with parathyroid cytosolic proteins. Each point represents the mean ± SE of three to four different experiments, apart from -Ca at 240 and 300 min, which is the mean of two experiments. At some points the SE is less than the size of the graphic symbols. The PTH transcript was degraded very rapidly by proteins from -P rats and remained intact for a longer time period with proteins from -Ca rats. (Bottom) Mapping a region in the PTH 3′-UTR that mediates degradation by proteins from -P rats. PTH mRNA probes used were intact PTH mRNA (probe A), without the 3′-UTR (probe C), and without the 3′-terminal 60 nucleotides of the 3′-UTR (probe B). Reproduced with permission from Moallem *et al.* (1998).

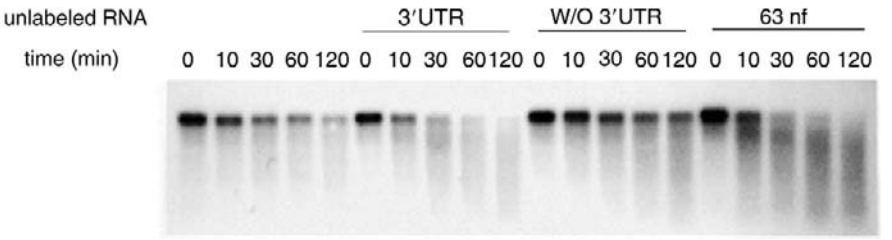

Figure 6 Competitor PTH RNA 3′-UTR accelerates PTH RNA degradation *in vitro*. The full-length PTH mRNA transcript was incubated with cytosolic parathyroid protein extracts (10 μg). At timed intervals, samples were extracted, run on agarose gels, and autoradiographed to measure the intact transcript remaining. The degradation assay was performed in the presence of PT extracts without competitor, with 25 ng of unlabeled PTH RNA 3′-UTR, with unlabeled PTH RNA excluding the 3′-UTR (without 3′-UTR), or with a 63 nucleotide unlabeled transcript comprising the sequences necessary for binding of proteins to the PTH RNA 3′-UTR. Excess 3′-UTR or the 63 nucleotide transcripts led to an accelerated decay of the full-length PTH transcript by PT proteins. The transcript that did not contain 3′-UTR had no effect. Reproduced with permission from Sela-Brown *et al.* (2000).

transcript. A major band from the eluate at 50 kDa was sequenced and was identical to AU-rich binding protein (AUF1). Recombinant AUF1 bound the full-length PTH mRNA and the 3′-UTR. Added recombinant AUF1 also stabilized the PTH transcript in the *in vitro* degradation assay. These results showed that AUF1 is a protein that binds to the PTH mRNA 3′-UTR and stabilizes the PTH transcript. This observation should now be supplemented by identification of the other protein(s) (60 and 110 kDa), which forms the protein complex on the PTH mRNA 3′-UTR. It might then be possible to understand how the different messages of changes in serum calcium and phosphate are transduced to the parathyroid cytosol. These proteins then bind to the PTH mRNA 3′-UTR and, in particular, the terminal 60 nucleotides and determine its stability. A stable transcript, e.g., after hypocalcemia, would then be translated into the hormone and available for rapid secretion. An unstable transcript, such as after hypophosphatemia, would be degraded rapidly and less PTH translated and secreted.

In vitro studies by Hawa *et al.* (1993) have also suggested a posttranscriptional effect of calcium on PTH gene expression. They incubated bovine parathyroid cells for 48 in 0.4 m*M* calcium. This did not increase PTH mRNA levels as compared to controls, but did increase the membrane-bound polysomal content of PTH mRNA twofold. It remains to be determined whether this *in vitro* translational effect involves the binding of parathyroid cytosolic proteins to the PTH mRNA 5′-UTR.

A Conserved Sequence in PTH mRNA 3′-UTR Binds Parathyroid Cytosolic Proteins and Determines RNA Stability in Response to Changes in Calcium and Phosphate

Kilav *et al.* (2001) have identified the minimal sequence for protein binding in the PTH mRNA 3′-UTR and determined its functionality. RNA transcripts of different regions in the 3′-UTR were assayed for their binding to parathyroid proteins by REMSA assays, and the specificity was determined by competition experiments. A minimum sequence of 26 nucleotides was sufficient for PTH RNA–protein binding and competition. Binding interference with antisense DNA oligonucleotides to different regions of the conserved RNA element further identified this 26 nucleotide element. Significantly, this sequence was preserved among species. To study the functionality of the sequence in the context of another RNA, a 63-bp cDNA PTH sequence consisting of the 26 nucleotide and flanking regions was fused to growth hormone (GH) cDNA. There is no parathyroid cell line and therefore an *in vitro* degradation assay was used. In this assay the effect of parathyroid cytosolic proteins on the stability of RNA transcripts for PTH, GH, and a chimeric GH-PTH 63 nucleotide was studied. The PTH transcript was stabilized by parathyroid proteins from rats fed a low calcium diet and destabilized by proteins from rats fed a low phosphate diet, correlating with PTH mRNA levels *in vivo*. The GH transcript was more stable than PTH RNA and was not affected by parathyroid proteins from rats fed the different diets. The chimeric GH transcript was stabilized by low calcium parathyroid proteins and destabilized by low phosphate parathyroid proteins, similar to the PTH full-length transcript. Therefore, the conserved PTH RNA protein-binding region confers responsiveness to calcium and phosphate and determines PTH mRNA stability and levels.

Dynein Light Chain (M_r 8000) Binds the PTH mRNA 3′-Untranslated Region and Mediates Its Association with Microtubules

To isolate other proteins binding to the 3′-UTR of parathyroid hormone, mRNA expression cloning was used. Epstein *et al.* (2000) screened an expression library for proteins that bound the PTH mRNA 3′-UTR, and the sequence of one clone was identical to dynein light chain (M_r 8000) (LC8). LC8 is part of the cytoplasmic dynein complexes that function as molecular motors that translocate along microtubules. Recombinant LC8 bound PTH mRNA 3′-UTR

by the RNA mobility shift assay. PTH mRNA colocalized with polymerized microtubules in the parathyroid gland, as well as with a purified microtubule preparation from calf brain, and this was mediated by LC8 (Fig. 7). This was the first report of a dynein complex protein binding a mRNA. Dynein light chain is also involved in targeting Swallow and *bicoid* RNA to the anterior pole of *Drosophila* oocytes (Schnorrer *et al.,* 2000). Therefore, the dynein complex may be the motor for the transport and localization of mRNAs in the cytoplasm and the subsequent asymmetric distribution of translated proteins in the cell.

Secondary Hyperparathyroidism and Parathyroid Cell Proliferation

Chronic changes in the physiologic milieu often lead to changes in both parathyroid cell proliferation and parathyroid hormone gene regulation. In such complicated settings, the regulation of PTH gene expression may well be controlled by mechanisms that differ from those in nonproliferating cells. Further, the effects of change in cell number and activity of individual cells can be complicated to dissect. Nevertheless, such chronic changes represent commonly observed clinical circumstances that require examination. Secondary parathyroid hyperplasia is a complication of chronic renal disease (Castleman and Mallory, 1932, 1937; Drueke, 1995) or vitamin D deficiency and may lead to disabling skeletal complications. The expression and regulation of the PTH gene have been studied in two models of secondary hyperparathyroidism: (1) rats with experimental uremia due to 5/6 nephrectomy and (2) rats with nutritional secondary hyperparathyroidism due to diets deficient in vitamin D and/or calcium.

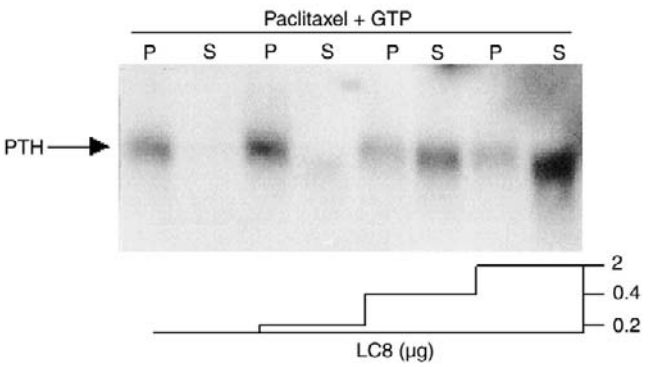

Figure 7 PTH mRNA colocalizes with microtubules. Purified calf brain microtubule preparations, which contained microtubule associated proteins (MAPs), were assembled in the presence of paclitaxel and GTP and incubated with total RNA from rat thyroparathyroid tissue. Polymerized microtubules were sedimented, and the RNA, which was extracted from both supernatants (S) and pellets (P), was assayed for PTH mRNA by Northern blot. PTH mRNA was present in the polymerized microtubule pellet and not in the supernatant. When increasing concentrations of LC8 were added to the RNA-microtubule preparation there was a shift of PTH mRNA from the pellet to the supernatant, indicating that LC8 mediates the association of PTH mRNA to microtubules. From Epstein *et al.* (2000). By copyright permission of the American Society for Clinical Investigation.

5/6 nephrectomy rats had higher serum creatinines and also appreciably higher levels of parathyroid gland PTH mRNA (Shvil *et al.,* 1990). Their PTH mRNA levels decreased after single injections of $1,25(OH)_2D_3$, a response similar to that of normal rats (Shvil *et al.,* 1990). Interestingly, secondary hyperparathyroidism was characterized by an increase in parathyroid gland PTH mRNA but not in VDR mRNA (Shvil *et al.,* 1990). This suggests that in 5/6 nephrectomy rats there was relatively less VDR mRNA per parathyroid cell or a relative downregulation of the VDR, as has been reported in VDR-binding studies (Brown *et al.,* 1989a,b; Korkor, 1987; Merke *et al.,* 1987). Yalcindag *et al.* (1999) showed by the *in vitro* degradation assay that the increase in PTH mRNA levels in uremic rats was due to a decrease in degradation by uremic parathyroid proteins. These results suggested that a decrease in parathyroid cytosolic endonuclease activity in uremia resulted in a more stable PTH transcript. Fukagawa *et al.* (1991) also studied 5/6 nephrectomized rats and confirmed that calcitriol decreased PTH mRNA levels, as did the calcitriol analog 22-oxacalcitriol.

The second model of experimental secondary hyperparathyroidism studied was that due to dietary deficiency of vitamin D (-D) and/or calcium (-Ca), as compared to normal vitamin D (ND) and normal calcium (NCa) (Naveh-Many and Silver, 1990). These dietary regimes were selected to mimic secondary hyperparathyroidism in which stimuli for the production of hyperparathyroidism are the low serum levels of $1,25(OH)_2D_3$ and ionized calcium. Weanling rats were maintained on these diets for 3 weeks and then studied. Rats on diets deficient in both vitamin D and calcium (-D-Ca) had a 10-fold increase in PTH mRNA as compared to controls (NDNCa), together with much lower serum calciums and also lower serum $1,25(OH)_2D_3$ levels. Calcium deficiency alone (-Ca ND) led to a 5-fold increase in PTH mRNA levels, whereas a diet deficient in vitamin D alone (-DNCa) led to a 2-fold increase in PTH mRNA levels.

Because renal failure and prolonged changes in blood calcium and $1,25(OH)_2D_3$ can affect both parathyroid cell number and the activity of each parathyroid cell, a change in parathyroid cell number must be assessed in each model to understand the various mechanisms of secondary hyperparathyroidism. Parathyroid cell number was determined in thyroparathyroid tissue of normal rats and -D-Ca rats. To do this, the tissue was digested enzymatically into an isolated cell population, which was then passed through a flow cytometer (FACS) and separated by size into two peaks. The first peak of smaller cells contained parathyroid cells as determined by the presence of PTH mRNA, and the second peak contained thyroid follicular cells and calcitonin-producing cells, which hybridized positively for thyroglobulin mRNA and calcitonin mRNA, but not PTH mRNA. There were 1.6-fold more cells in -D-Ca rats than in normal rats, as compared to the 10-fold increase in PTH mRNA. Therefore, this model of secondary hyperparathyroidism is characterized by increased gene expression per cell, together with a smaller increase in cell number (Naveh-Many and Silver,

1990). Wernerson has studied parathyroid cell number in dietary secondary hyperparathyroidism (ND-Ca) using stereoscopic electron microscopy and has shown that the cells are markedly hypertrophic without an increase in cell number (Wernerson *et al.,* 1989; Svensson *et al.,* 1988). Thus, in models of secondary parathyroid enlargement such as this one, parathyroid cell hypertrophy can precede the development of parathyroid cell hyperplasia. Further studies by Naveh-Many *et al.* (1995) have clearly demonstrated that hypocalcemia is a stimulus for parathyroid cell proliferation. They studied parathyroid cell proliferation by staining for proliferating cell nuclear antigen (PCNA) and found that a low calcium diet led to increased levels of PTH mRNA (Fig. 4) and a 10-fold increase in PT cell proliferation (Fig. 8) (Naveh-Many *et al.,* 1995). The secondary hyperparathyroidism of 5/6 nephrectomized rats was characterized by an increase in both PTH mRNA levels and PCNA-positive PT cells. Therefore, hypocalcemia and uremia induce PT cell proliferation *in vivo.* $1,25(OH)_2D_3$ decreases PT cell proliferation (Szabo *et al.,* 1989; Nygren *et al.,* 1988). Wada *et al.* (1997) showed that a calimimetic drug (NPS R-568) that acts on the parathyroid CaSR was able to suppress parathyroid cell proliferation in rats with experimental uremia, indicating a role for CaSR in the parathyroid hyperplasia of chronic renal failure. These findings emphasize the importance of normal calcium in the prevention of parathyroid cell hyperplasia, as well as the role of $1,25(OH)_2D_3$ in the management of parathyroid cell proliferation. The important role of calcium in regulating parathyroid cell number was also illustrated in the vitamin D receptor knockout mouse. These mice become hypocalcemic after weaning, with large parathyroid glands. The increase in cellular proliferation and the increase in parathyroid gland size are completely prevented when these mice are treated with a diet that maintains normal calcium and phosphate levels (Li *et al.,* 1998). Thus, these mice, which cannot respond to $1,25(OH)_2$ vitamin D_3, have parathyroid glands of normal size when levels of blood calcium are controlled.

A further mechanism by which calcium might regulate parathyroid cell number is by inducing apoptosis. This has been studied in the parathyroids of hypocalcemic rats, as well as rats with experimental uremia fed different diets (Naveh-Many *et al.,* 1995). Apoptosis was determined by the TUNEL method, which detects nuclear DNA fragmentation *in situ.* In no situation were apoptotic cells detected in the parathyroids. Wang *et al.* (1996a) studied mature rats by the TUNEL method and also could not detect apoptotic cells. In the absence of detectable apoptosis, it is unlikely that PT cells are normally proliferating. However, in human PT adenomas, apoptotic cells were demonstrated and this apoptosis correlated with the number of cells proliferating, as measured by Ki 67 immunoreactivity (Wang *et al.,* 1996b). Moreover, in a study of parathyroids of uremic patients with secondary hyperparathyroidism, convincing evidence of apoptosis was documented (Zhang *et al.,* 2000; Drueke, 2000). Therefore, it is likely that PT cells have the latent ability not only to proliferate, but also to apoptose.

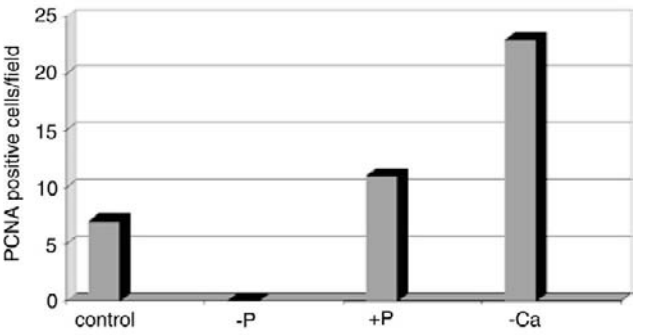

Figure 8 Dietary phosphate and calcium regulate parathyroid cell proliferation. Weanling rats were fed different diets for 10 or 21 days, and the number of proliferating cells was determined by PCNA staining. Diets were control, low calcium (0.02%), low phosphate (0.02%), or high phosphate (1.2%). Results are expressed as PCNA-positive cells per microscope field, as mean ± SE for four different rats and compared to rats fed the control diet.* $p < 0.05$; ** $p < 0.01$. From Naveh-Many *et al.* (1995). By copyright permission of the American Society for Clinical Investigation.

These experimental findings are relevant to the management of patients with secondary hyperparathyroidism. Increased transcription of the PTH gene is readily reversible, but the regulated reversibility of an increased number of parathyroid cells by accelerating cell death has not yet been demonstrated.

Sex Steroids

PTH is anabolic to bone and is an effective means of treating postmenopausal osteoporosis (Finkelstein *et al.,* 1994; Dempster *et al.,* 1993). In postmenopausal women with osteoporosis time series, analysis has shown that there is a loss in the periodicity of PTH secretion (Prank *et al.,* 1995; Fraser *et al.,* 1998). This suggests that estrogens may have an effect on the parathyroid. Estradiol and progesterone both increased the secretion of PTH from bovine parathyroid cells in primary culture (Greenberg *et al.,* 1987). However, transdermal estrogen did not increase serum PTH levels in postmenopausal patients (Prince *et al.,* 1990). Estrogen receptors were not detected in parathyroid tissue by a hormone-binding method (Prince *et al.,* 1991), but were detected by immunohistochemistry and PCR for the estrogen receptor mRNA (Naveh-Many *et al.,* 1992a). *In vivo* in ovariectomized rats, both estrogen and progestins regulated PTH gene expression.

Rats were ovariectomized and after 2 weeks were treated with estradiol or vehicle. PTH gene expression was increased markedly by 17β-estradiol given as a single injection of 37,73, and 145 nmol or by osmotic minipumps at a dose of 12 pmol/day for 7 or 14 days (Naveh-Many *et al.,* 1992a). Serum Ca^{2+} and vitamin D levels did not change. Another parameter of estrogen activity, namely uterus weight, was measured in these rats. Ovariectomy led to a large decrease in uterus weight. One and seven daily injections of 73 nmol 17β-estradiol increased uterus weight.

The much smaller dose of 12 pmol/day by constant infusion for 7 or 14 days did not increase uterus weight, despite its marked effect on PTH mRNA levels. This small dose successfully separated an estrogen effect on the Ca^{2+}-regulating hormones from that on the uterus. This may be important in searching for estrogen analogs or dose regimes that will affect these hormones and through them bone and not other organs, such as breast and uterus. Estrogen receptor mRNA and protein were shown to be present in the parathyroid. These results demonstrate that the ER gene and protein are expressed in parathyroid cells, suggesting that these are target organs for estrogen.

Further studies were performed on the effect of progestins on PTH gene expression (Epstein *et al.,* 1995). The 19-nor progestin R5020 given to weanling rats or mature ovariectomized rats led to a twofold increase in thyroparathyroid PTH mRNA levels. In addition, *in vitro,* in primary cultures of bovine parathyroid cells, progesterone increased PTH mRNA levels. The progesterone receptor (PR) mRNA was demonstrated in rat parathyroid tissue by *in situ* hybridization and in human parathyroid adenoma by immunohistochemistry. Changes in PTH mRNA levels during the rat estrous cycle were also studied. At proestrus and estrus, PTH mRNA levels were increased significantly by three- and fourfold as compared to diestrus (Epstein *et al.,* 1995). These results confirm that the parathyroid gland is a target organ for the ovarian sex steroids estrogen and progesterone and are of physiological relevance, as shown by the changes during estrus.

Therefore, *in vitro* progesterone has been shown to increase PTH mRNA levels, but the same effect *in vitro* has not been shown for estrogen. *In vivo,* both estrogens and progestins increased PTH mRNA levels.

Protein Kinase A and C

CaSR activates phospholipase A_2, C, and D pathways, which are relevant to the regulation of PTH secretion (Kifor *et al.,* 1997). Moallem *et al.* (1995) showed that protein kinases A and C regulate PTH mRNA levels *in vitro* in dispersed bovine parathyroid cells. Activation of protein kinase A by cholera toxin increased PTH mRNA levels about twofold after 3 and 7 hrs of incubation. Incubation with pertussis toxin increased PTH mRNA at low (0.7 m*M*) (four fold increase) and normal (1.25 m*M*) (four fold increase) extracellular Ca^{2+} concentrations and reversed the decrease in PTH mRNA levels caused by high Ca^{2+} (2.0 m*M*), leading to a large increase in PTH mRNA. Inhibition of protein kinase C both by staurosporine and by prolonged incubation with the phorbol ester phorbol 12-myristate 13-acetate (PMA), which then also decreases protein kinase C, decreased PTH mRNA levels at 24 hrs, reaching approximately 40 and 5% of control, respectively. A short-term incubation with PMA (3 hr), which stimulates the protein kinase C pathway, had no effect on PTH mRNA levels. These results show that both protein kinases A and C are involved in the regulation of PTH gene expression. Stimulators of protein kinase A increased PTH mRNA levels. Hypocalcemia is the major stimulus to increased PTH mRNA, and the marked increase after pertussis toxin raises the question as to whether G_i is involved in the signal transduction of hypocalcemia. Downregulation of protein kinase C activity decreased PTH mRNA levels, suggesting that protein kinase C may be necessary for normal PTH gene expression.

Summary

The PTH gene is regulated by a number of factors. Calcitriol acts on the PTH gene to decrease its transcription, and this action is used in the management of patients with chronic renal failure. The main effect of calcium on PTH gene expression *in vivo* is for hypocalcemia to increase PTH mRNA levels, and this seems likely to be posttranscriptional, but an *in vitro* transcriptional mechanism has been described whose physiological relevance remains to be determined. Phosphate also regulates PTH gene expression *in vivo,* and this effect appears to be independent of the effect of phosphate on serum calcium and $1,25(OH)_2D_3$. The effect of phosphate is posttranscriptional. *trans*-acting parathyroid cytosolic proteins bind to a defined *cis* element in the PTH mRNA 3′-UTR, which determine the degradation of PTH mRNA by degrading enzymes and thereby the PTH mRNA half-life. The posttranscriptional effects of calcium and phosphate are the result of changes in the balance of these stabilizing and degrading factors on PTH mRNA. PTH mRNA binds to LC8, a member of the dynein family, which mediates the binding of mRNA to the microtubule apparatus of the parathyroid and may be important to the localization of PTH mRNA in the cell. Estradiol and progestins increase PTH mRNA levels, and their specific receptors are present in the parathyroids. There are changes in PTH mRNA levels during the rat estrous cycle that suggests a physiological relevance for these findings.

In diseases such as chronic renal failure, secondary hyperparathyroidism involves abnormalities in PTH secretion and synthesis. An understanding of how the parathyroid is regulated at each level will help devise rational therapy for the management of such conditions, as well as treatment for diseases, such as osteoporosis, in which alterations in PTH may have a role.

CHAPTER 26

Parathyroid Hormone–Receptor Interactions

Michael Chorev and Michael Rosenblatt

Division of Bone and Mineral Metabolism, Charles A. Dana and Thorndike Memorial Laboratories, Department of Medicine, Beth Israel Deaconess Medical Center and Harvard Medical School, Boston, Massachusetts 02215

Introduction

Investigating structure–function–conformation relations is driven by the desire to advance our understanding of the fundamental nature of ligand–receptor interactions and the molecular recognition events leading to signal transduction. For the parathyroid hormone (PTH)–receptor system, the growing interest in providing osteoporosis patients with a true anabolic therapeutic agent is another driving force in stimulating research in this area. Currently, the field of bone biology is experiencing a period of growth and integration among biology, chemistry, molecular biology, pharmacology, and medicine. Many researchers share the belief that disease-oriented research must be approached in a collaborative and interdisciplinary manner.

The PTH–PTH receptor field is studied today in a wider context than before. Additional PTH receptor subtypes have been discovered and novel cognate ligands identified for these receptors. The family of class II G protein-coupled receptors (GPCRs) is growing steadily. Understanding of ligand–receptor interactions is advancing simultaneously for several hormone–receptor systems belonging to this class. As a result, we can generate hybrid ligands and chimera receptors, thus expanding our repertoire of tools to study functional as well as structural relatedness. Molecular biology is instrumental in providing powerful techniques for the study of receptors: cloning and expressing, adding tags to macromolecular entities, and labeling signaling and adapter molecules with green fluorescent protein (GFP). This "tagging" of proteins allows monitoring of the temporal changes in expression levels and cellular distribution of receptors and their ligands.

This chapter summarizes PTH/PTH-related protein (PTHrP)–receptor interactions in a broad sense. It addresses the traditional approaches, which focus on either the ligand or the receptor, and the more recent integrated approach that examines directly the ligand–receptor bimolecular complex. We provide information on PTH2 and PTH3 receptors (PTH2- and PTH3-Rc), which are structurally related to the classical PTH1 receptor, knowing that they may have no role in normal bone physiology. Nevertheless, their interactions with ligands recognized by the PTH1-Rc make them important tools for gaining important insight into structure–function relations. For the same reason, we also discuss the tuberoinfidibular peptide of 39 amino acid residues (TIP39). In some cases, when there is more than one way of studying a problem or different interpretations of similar results, we present the controversy so that the reader may use his/her own judgement. Such is the case with the debate whether PTH and PTHrP have a stable tertiary structure and its relevance to the biology of the hormones.

Recent results and conclusions from investigations of PTH–receptor interactions are reviewed. Delineation of contact sites, sometimes in atomic detail, between ligand and receptor allow for the first time the generation of an experimentally based model for the PTH–PTH1-Rc complex. This model serves as a testing ground to understand functional consequences of structural modifications in the ligand and the receptor. Moreover, it provides insight for understanding disease-related mutations in the receptor and related intracellular signaling events. Development of signaling-selective PTH analogs not only opens new opportunities for studying the heterogeneous signaling pathway system,

but also generates leads to test new therapeutic paradigms for osteoporosis. Minimization of the size of a ligand and better understanding of its dynamic mode of interaction with the receptor in either the G protein-coupled or -uncoupled states are concepts also described in this chapter.

The Ligand: New Insights into Structure and Function

Early work on the structure–activity relations of PTH and PTHrP has been covered in extensive reviews (Chorev and Rosenblatt, 1994, 1996; Potts *et al.,* 1997). It established that the N-terminal 1-34 amino acid sequence of both calciotropic hormones is sufficient to induce the entire spectrum of *in vitro* and *in vivo* PTH1-Rc-mediated activities (Dempster *et al.,* 1993; Whitfield and Morley, 1995). Both PTH-(1-34) and PTHrP-(1-36) have similar affinities to PTH1-Rc and are equipotent in stimulating adenylyl cyclase (AC) and intracellular Ca^{2+} transients in cells expressing PTH1-Rc. Significant sequence homology between PTH and PTHrP is limited to the first 13 residues, of which 8 are identical (Fig. 1). The molecular architecture consists of two functional domains. The "activation domain" is assigned to the homologous N-terminal sequences, and the principal "binding domain," located at the structurally divergent mid- and C-terminal sequences, contains the "binding domain" assigned to residues 14-34 (Abou-Samra *et al.,* 1989; Caulfield *et al.,* 1990; Gardella *et al.,* 1993; Nussbaum *et al.,* 1980). Truncation of 2-6 residues from the N terminus converts the 1-34/36 agonists into potent antagonists (Rosenblatt, 1986; Rosenblatt *et al.,* 1993, 1997). The architecture similarity of the functional domains in two hormones that also share a common receptor has promoted the hypothesis that they have similar conformations, despite their limited sequence homology (Caulfield *et al.,* 1990; Mierke *et al.,* 1997).

The new challenges facing structural studies of PTH- and PTHrP-derived ligands originate from advances along several avenues of PTH-related biology. Subtype receptor multiplicity raised the need for receptor subtype- or target-specific ligands. Exploring the multiplicity of signaling pathways and their relevance to physiological and pathophysiological processes required the development of signaling selective analogs. The interest in developing a more clinic-friendly PTH-like drug with a better therapeutic window than PTH, i.e., a more favorable ratio of catabolic to anabolic activities, has intensified markedly. There is still a strong feeling that knowing the bioactive conformation will help in understanding structure–function relations and guide the rational design of novel PTH/PTHrP analogs and nonpeptide PTH mimetics. Moreover, for the purpose of drug development, reducing ligand size by introducing affinity and potency enhancing substitutions is a new field of growing interest.

Probing the Primary Structure

A wealth of corroborating data has been generated by exhaustively scanning either the entire sequence of PTH-(1-34/36) or portions of it. These studies employ both synthetic and biosynthetic methodologies to generate new insights into the tolerance and significance of certain residues with regard to bioactivity (Gardella *et al.,* 1991; Gombert *et al.,* 1996; Oldenburg *et al.,* 1996). Both Gardella and Oldenburg and their coworkers used recombinant DNA methodologies to generate analogs, either by randomly mutating codons coding for positions 1-4 in hPTH (Gardella *et al.,* 1991) or by replacing individual codons with [(A/G)(A/G)G] (coding for Lys, Arg, Glu, or Gly) (Oldenburg *et al.,* 1996). Conversely, Gombert *et al.* (1995) used a parallel multisynthesis approach to generate D-Ala, L-Ala and D-Xxx scans of hPTH-(1-36), where D-Xxx is the enantiomeric form of the native amino acid residue in the particular position.

The D-Ala scan reveals segments 2-8 and 20-28 to be the least tolerant. Substitutions with D-Ala within these segments result in large decreases in binding affinity and are accompanied by a large loss in ligand-stimulated AC activity. The latter is most pronounced for substitutions of Arg^{20}, Trp^{23}, Leu^{24}, and Leu^{28} in the sequence (20-28), which overlaps with the principal binding domain (Gombert *et al.,* 1995). A high correlation between binding and AC activation was observed in the L-Ala scan. The largest loss in AC activity occurs when the substitutions are

Figure 1 Alignment of human PTH-(1-40) with human PTHrP-(1-39), bovine PTH-(1-40), and bovine TIP39 sequences. Amino acid residues in bold indicate direct homology. Gaps in the sequences of PTHrP and TIP are introduced to maximize homology. Numbering at the top and bottom refers to mature PTH and mature TIP39, respectively. The wavy line indicates C-terminal truncated sequences. It can be appreciated that the highest homology observed is between human and bovine PTH. There is much less homology between human PTH and human PTHrP. The homology among TIP39 and PTH or PTHrP is very limited.

within the activation domain (residues 2-8) (Gombert *et al.,* 1995). Only substituting L-Ala for Lys^{13}, Asn^{16}, or Glu^{19} yielded slightly more active analogs. The D-Xxx scan resulted in an overall loss of affinity and efficacy. The most affected region was the putative amphiphilic helical domain (residues 23-29) and, to a lesser extent, the C-terminal segment (32-36) (Gombert *et al.,* 1995).

Gardella and co-workers (1991) focused on the evolutionarily conserved, first four N-terminal residues in PTH. Residues Glu^4 and Val^2 are less tolerant to substitution than the other two positions, suggesting an important role in receptor binding and activation (Gardella *et al.,* 1991). The most intriguing finding of this study was the divergent activity displayed by [Arg^2,Tyr^{34}]PTH-(1-34)NH_2 in two different cell lines expressing the wild-type PTH1-Rc: ROS 17/2.8, a rat osteosarcoma cell line, and OK, an opossum kidney cell line (Gardella *et al.,* 1991). This analog is a weak partial agonist for stimulation of AC in ROS 17/2.8 cells, whereas it is a full agonist for cAMP increases in the OK cell system (Gardella *et al.,* 1991). Gardella and co-workers (1994) further analyzed the activities of [Arg^2,Tyr^{34}]PTH-(1-34)NH_2 in COS-7 cells transfected with rat or opossum PTH1-Rc or rat/opossum PTH1-Rc chimeras. They demonstrated that the differences in activity in ROS and OK cells are due to differences in the interaction of the receptors (rat vs opossum) with the amino terminus of the ligand and not to tissue-specific (bone vs kidney) effects.

Cohen and co-workers (1991) reported that the highly conserved PTH and PTHrP residues, Ser^3 and Gln^6, make important contributions to the binding to and activation of PTH1-Rc. Substituting of Phe or Tyr for Ser^3, and Phe or Ser for Gln^6, generates partial agonists. Both [Phe^3]hPTH-(1-34) and [Phe^6]hPTH-(1-34) competitively inhibit bPTH-(1-34)- and PTHrP-(1-34)-stimulated AC activity. Taken together, the finding that specific substitutions within the "activation domain" may convert full agonists into partial antagonists provides new tools for designing potent, full-length antagonists (1-34). It also suggests that structural perturbation of ligand–receptor bimolecular interactions at the N terminus of PTH-(1-34) can interfere preferentially with the induction of conformational changes, and therefore inhibit intracellular signaling. Such conformational changes are required for the effective coupling of the ligand-occupied receptor to G proteins, but are not important for ligand recognition and binding.

Oldenburg and co-workers (1996) conducted an extensive study in which they introduced single, nonconservative point mutations in PTH-(1-34) and characterized them in UMR106, rat osteosarcoma cells. These mutations, which span the mid- and C-terminal regions, namely, the 11-34 sequence, generated several analogs more potent than the parent peptide. One of the more interesting analogs is [$Arg^{19,22,30}$,Lys^{29},Hse^{34}]hPTH-(1-34), which is equipotent to bPTH (EC_{50} ~ 0.9 and K_d ~ 1.5 n*M*). The high potency of this analog is attributed to the presence and disposition of the seven positive charges in the C-terminal helix and not to its amphiphilic nature. The positive charges may play a critical role in intramolecular, ligand–receptor or ligand–lipid interactions (Oldenburg *et al.,* 1996).

Although amino-terminal fragments of PTH and PTHrP shorter than 1-27 were previously reported devoid of biological activity (Azarani *et al.,* 1996; Kemp *et al.,* 1987; Rosenblatt, 1981; Tregear *et al.,* 1973), the efforts of Gardella and co-workers focused on the isolated activation domain represented by the amino terminus, PTH-(1-14) (Carter and Gardella, 1999; Luck *et al.,* 1999; Shimizu *et al.,* 1999). In the search for small peptide and nonpeptide PTH-mimicking molecules as potential therapies for bone metabolic disorders, the marginally active PTH-(1-14) was used as the starting point for structural manipulations in an effort to optimize its activity. Numerous studies employing site-directed mutagenesis and chimera studies of PTH1-Rc (Bergwitz *et al.,* 1996; Gardella *et al.,* 1994; Juppner *et al.,* 1994; Lee *et al.,* 1995a; Turner *et al.,* 1996), as well as photoaffinity cross-linking studies between photoreactive PTH and PTHrP analogs and PTH receptors (Adams *et al.,* 1995; Behar *et al.,* 1999, 2000; Bisello *et al.,* 1998; Mannstadt *et al.,* 1998; Zhou *et al.,* 1997), support the paradigm that the activation domain of PTH interacts with the extracellular loops (ECLs) and the juxtamembrane portions of the TMs. These receptor sites are different from those involved in interacting with the binding domain of PTH, which are located primarily within the N-terminal extracellular domain of the receptor (N-ECD). Similar observations were reported for secretin (Dong *et al.,* 1999; Holtmann *et al.,* 1996), vasoactive intestinal peptide (VIP) (Holtmann *et al.,* 1996a,b), calcitonin (CT) (Stroop *et al.,* 1996), and CT/glucagon chimera (Stroop *et al.,* 1995) receptors, all belonging to class II GPCRs.

Luck and co-workers (1999) reported that PTH-(1-14) is equipotent in stimulating increased cAMP levels (EC_{50} 100 μM) via the intact rat (r) PTH1-Rc and the *N*-terminal truncated receptor (rΔNt) missing N-ECD residues 26-181, both transiently expressed in COS-7 cells. In contrast, PTH-(1-34) is two orders of magnitude less potent in stimulating AC via the rΔNt than through the intact rPTH1-Rc (Luck *et al.,* 1999). In addition, the "Ala scan" of PTH-(1-14) revealed that the first nine of the N-terminal residues forming the critical activation domain are involved in ligand–receptor interaction, rather than in an intramolecular interaction with the C-terminal domain PTH(15-34) as suggested previously (Cohen *et al.,* 1991; Gardella *et al.,* 1995; Marx *et al.,* 1995). This study reinforced the paradigm that the N terminus of PTH interacts with binding determinants within both ECLs and the juxtamembranal portions of the TMs of the PTH1-Rc.

Shimizu and co-workers (1999) identified some substitutions in the 10–14 sequence of the hormone that are not only compatible with function, but also result in more potent peptides. The peptides [$Ala^{3,10,12}$,Arg^{11}]PTH-(1-14) and [$Ala^{3,10}$,Arg^{11}]PTH-(1-11) are, respectively, 100- and 500-fold more active than PTH-(1-14) (Fig. 2). In addition, insertion of His, a "Zn^{2+} switch," into some positions in the 10-13 sequence of PTH-(1-14) led to increases in ligand-stimulated cAMP levels in the presence of Zn^{2+} (Carter and

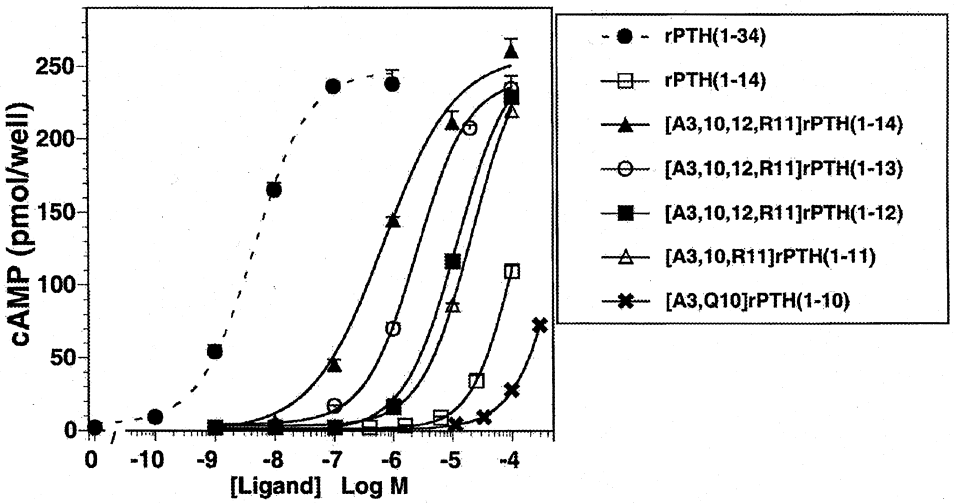

Figure 2 Dose–response analysis of PTH C-terminal truncated sequences in LLC-PK1 cells stably transfected with PTH1-Rc. Dose–response curves for AC activity by control peptide, [Nle^{8,21},Tyr^{34}]rPTH-(1-34)NH_2 [rPTH(1-34)] and the native or modified amino-terminal fragment analogs of rPTH in HKRK-B7 cells (Shimizu *et al.,* 2000b).

Gardella, 1999). This result was interpreted by Carter and co-workers (1999) to suggest that the C-terminal portion of PTH-(1-14) contributes important interactions with the ECLs and TM domains. A particular ternary metal–ligand–receptor complex, in which the histidine residues in the ligand and the receptor participate in the coordination sphere around the Zn^{2+}, stabilizes these interactions. However, in the absence of demonstrable specific binding, it is unclear whether the extremely low levels of ligand-induced cAMP increases result from nonspecific interactions between PTH-(1-14) and PTH1-Rc or from interactions at sites different from the ones used by the 1-34 sequence.

Receptor Subtype Specificity Switch

The finding that the N-truncated sequence, PTHrP-(7-34), can bind and weakly activate the PTH2-Rc, which selectively binds PTH but not PTHrP (Behar *et al.,* 1996b; Usdin *et al.,* 1995), suggested to Behar and co-workers (1996a) that the N-terminal sequence 1-6 of PTHrP must contain a structural element that disrupts the PTHrP-(1-34)–PTH2-Rc interaction. The single-point hybrid ligands, [His^5,Nle^{8,18},Tyr^{34}]bPTH-(1-34)NH_2 and [Ile^5]PTHrP-(1-34)NH_2, were generated by swapping the nonconserved residues in position 5 between PTH-(1-34), which binds and activates both PTH1- and PTH2-Rc, and PTHrP-(1-34) (Behar *et al.,* 1996a). Indeed, in HEK293 cells stably transfected with either hPTH1-Rc or hPTH2-Rc, the receptor specificity of these point-hybrid ligands is reversed when compared with their parent compounds. Therefore, His^5, a single residue within the activation domain of the ligands, acts as a specificity "switch" between these two highly homologous receptor subtypes (Behar *et al.,* 1996a).

A similar study conducted by Gardella and colleagues (1996a) in COS-7 cells transiently expressing PTH1-Rc and PTH2-Rc arrived at a somewhat different conclusion. According to their study, two sites are responsible for the divergent specificity of PTH and PTHrP: position 5 determines signaling and position 23 determines receptor-binding affinity. Simultaneously swapping the residues in positions 5 and 23 between PTH and PTHrP results in [His^5,Phe^{23},Tyr^{34}]PTH-(1-34)NH_2 ($IC_{50} > 10{,}000$ n*M* for both PTH1- and PTH2-Rc, and $EC_{50} = 1.18$ and > 1000 n*M* for PTH1- and PTH2-Rc, respectively) and [Ile^5, Trp^{23},Tyr^{36}]PTHrP-(1-36)NH_2 ($IC_{50} = 16$ and 10 n*M,* and $EC_{50} = 0.21$ and 0.5 n*M* for PTH1- and PTH2-Rc, respectively). In their hands, [Trp^{23},Tyr^{36}]PTHrP-(1-36)NH_2 is an antagonist for the PTH2-Rc, but a full agonist for the PTH1-Rc.

Studies by Behar and Gardella agree in identifying position 5 as a signaling switch between PTH1- and PTH2-Rc (Behar *et al.,* 1996a; Gardella *et al.,* 1996a). They differ in the assigning of the affinity switch to two different residues. Whereas Behar and co-workers (1996a) do not identify distinct affinity determinants unique to each of the receptor subtypes, Gardella and colleagues (1996a) attribute the affinity switch to a distinct residue at position 23. These discrepancies may be related to differences in the experimental systems employed, as they vary in a number of ways: the use of stable vs transient transfections, homologous vs heterologous receptor–cell systems, and radioligands (rat- vs bovine-derived peptides).

TIP39, a Putative Endogenous Ligand of PTH2-Rc

Usdin and co-workers (1999b) have purified an endogenous ligand selective for PTH2-Rc, a tuberoinfundibular peptide of 39 amino acids (bTIP39), from bovine hypothalamic extracts. A homology search reveals that 9 out of the 39 residues of bTIP39 are identical to bPTH (Fig. 1).

Interestingly, TIP39 does not appreciably activate AC in COS-7 cells transfected with either human or rat PTH1-Rc (Usdin *et al.,* 1999b), although it binds to the receptor with moderate affinity [IC_{50} = 59 n*M,* displacing ^{125}I-bPTH-(3-34)] (Hoare *et al.,* 2000a). Jonsson and co-workers (2001) reported that TIP39 binds with weak affinity (~200 n*M*) to hPTH1-Rc stably expressed in $LLCPK_1$ cells (HKrk-B7 cells) and failed to stimulate AC activity. The truncated peptides, TIP-(3-39) and TIP-(9-39), which display 3- and 5.5-fold higher affinity than the intact peptide, are similarly devoid of any AC activity. Moreover, while TIP39 is a weak antagonist, both of the TIP39-derived N-terminal truncated peptides inhibit PTH-(1-34)- and PTHrP-(1-36)-stimulated AC with efficiencies similar to a highly potent PTH1-Rc antagonist, [Leu^{11},D-Trp^{12},Trp^{23}, Tyr^{36}]PTHrP-(7-36)NH_2 (Jonsson *et al.,* 2001).

Additional work with the hybrid PTHrP/TIP39 peptide and PTH1-Rc/PTH2-Rc chimeras provides some insight into TIP39–receptor interactions (Hoare *et al.,* 2000; Jonsson *et al.,* 2001). Jonsson and co-workers (2001) reported that the hybrid peptide PTHrP-(1-20)-TIP39-(23-39) binds effectively (IC_{50} = 8–11 n*M*) and stimulates cAMP efficaciously in HKrk-B7 and SaOS-2 cells (EC_{50} = 1.4 and 0.38 n*M,* respectively). Hoare and co-workers (2000) reported that the juxtamembrane domains (JMD) of the PTH2-Rc, which include ECL's 1-3, determine binding and signaling selectivity of TIP39 for PTH2-Rc over PTH1-Rc. This was established by studying TIP39 interactions with the reciprocal chimeric PTH1-Rc/PTH2-Rc, in which the N-ECD domains were exchanged. TIP39 fully activated [N-ECD]PTH1-Rc/[JMD]PTH2-Rc (EC_{50} = 2 n*M*) and bound to it with affinity equal to wild-type PTH2-Rc (IC_{50} = 2.3 and 2 n*M,* respectively) (Hoare *et al.,* 2000). However, the reciprocal chimeric receptor, ([N-ECD]PTH2-Rc/[JMD]PTH1-Rc), is not activated by TIP39 and binds it with affinity similar to that of PTH1-Rc. Truncation of the first six amino acid residues from the N terminus of TIP39 results in a 10-fold increase in binding affinity for PTH1-Rc (IC_{50} = 6 n*M*), making it a potent, selective antagonist of this receptor (Hoare *et al.,* 2000). At the same time, TIP39-(7-39) does not activate PTH2-Rc and has a 70-fold lower affinity to it than the intact hormone (IC_{50} = 370 and 5.2 n*M,* respectively). Jonsson and colleagues (2001) concluded from their studies with amino-terminal truncated TIP39 and PTHrP/TIP39 hybrid peptides (see earlier discussion) that the carboxyl-terminal portion of TIP39 interacts with PTH1-Rc very similarly to the analogous domains in PTH-(1-34) and PTHrP-(1-36). At the same time, the amino-terminal portion has destabilizing interactions with this receptor that result in poor affinity and are therefore unproductive (Jonsson *et al.,* 2001).

Taken together, these studies suggest that the dominating molecular determinants of the binding selectivity of TIP39 to PTH2-Rc are different from those identified for PTH and PTHrP binding to PTH1-Rc. While in the TIP39/PTH2-Rc system, binding specificity is assigned to the JMD and the N-terminal of the ligand (Hoare *et al.,* 2000), the binding selectivity in the PTH-PTHrP/PTH1-Rc system is specified by the N-ECD in the receptor and the C-terminal portion of the ligands (Bergwitz *et al.,* 1996; Gardella *et al.,* 1994, 1996a; Rosenblatt *et al.,* 1978). Although these findings are of major significance for understanding bimolecular ligand–receptor interactions, the physiological role of the TIP39/PTH2-Rc system remains to be established (Usdin *et al.,* 2000).

Dual Intracellular Signaling Pathways

Activation of PTH1-Rc by either PTH or PTHrP stimulates multiple intracellular signaling pathways via coupling to multiple G proteins (Abou-Samra *et al.,* 1992; Bringhurst *et al.,* 1993; Juppner *et al.,* 1991; Lee *et al.,* 1995b; McCuaig *et al.,* 1994; Pines *et al.,* 1994, 1996; Schwindinger *et al.,* 1998; Segre and Goldring, 1993; Segre, 1996; Takasu *et al.,* 1999b). PTH increases intracellular cAMP via G_s. PTH also activates phospholipase C (PLC), leading to the accumulation of IP_3 (Schneider *et al.,* 1994), which stimulates the release of Ca^{2+} from intracellular stores (Pines *et al.,* 1996) via pertussis toxin-insensitive G_q, as well as the accumulation of diacylglycerols, which stimulate membrane-associated protein kinase C (PKC) (Gagnon *et al.,* 1993; Janulis *et al.,* 1992, 1993; Jouishomme *et al.,* 1992; Massry, 1983). While the cAMP–protein kinase A (PKA) signaling pathway seems to be responsible for almost all of the calciotropic and skeletal actions of PTH and PTHrP, the physiological role of the PKC signaling pathway is not yet fully understood (Goltzman, 1999). For example, PTH/PTHrP regulation of mineralization or alkaline phosphatase activity in hypertrophic chondrocytes is PLC independent (Guo *et al.,* 2001). It has been suggested that the relative intensity of AC and PLC signaling via the PTH1-Rc is differentially regulated by the density of receptors expressed on the cell surface (Schwindinger *et al.,* 1998; Takasu *et al.,* 1999). In LLC-PK1 (porcine renal epithelial cells), maximal AC stimulation is achieved at levels of stably expressed recombinant hPTH1-Rc (≥90,000 Rc/cell) that are much lower than those required for detectable activation of PLC (≥600,000 Rc/cell) (Takasu *et al.,* 1999b). According to Schwindinger and co-workers (1998), the differential coupling efficacy of PTH1-Rc to different G protein α subunits may provide some explanation to the lower response of the PLC pathway. PLC activation was observed in COS-7 cells transiently transfected with PTH1-Rc (Schipani *et al.,* 1995; Schneider *et al.,* 1994), but was barely detected in stably transfected HEK-293 cells (Jobert *et al.,* 1997; Pines *et al.,* 1996; Tong *et al.,* 1996). PTH-(1-34)-induced release of free intracellular Ca^{2+} in parental HEK-293 cells (Jobert *et al.,* 1997) or in cells stably transfected with recombinant PTH1-Rc (Pines *et al.,* 1996; Seuwen and Boddeke, 1995) may involve PTH1-Rc-mediated, PLC-independent PKC activation (Tong *et al.,* 1996), such as stimulation of PLD (Friedman *et al.,* 1999; Singh *et al.,* 1999) or phospholipase A_2 (Ribeiro *et al.,* 1994). Alternatively, receptor subtypes other

than PTH1-Rc may mediate these PKC activities. These putative yet unidentified receptors, for example, may fail to increase cAMP in response to PTH and PTHrP in otherwise AC-competent cells (Atkinson *et al.,* 1987; Orloff *et al.,* 1992, 1995) or may display PTHrP-(1-34)- but not PTH-(1-34)-stimulated release of vasopressin from the rat supraoptic nucleus cells, *in vitro* (Yamamoto *et al.,* 1997).

One interesting proposition is that cell surface density of the PTH1-Rc is a key determinant, independent of ligand concentration, for both AC and PLC signaling pathways in response to PTH-(1-34), with the latter functioning only at high receptor density. It may imply the dissociation between structural determinants in PTH1-Rc involved in agonist recognition and signal transduction and those involved in G protein–effector interaction (Takasu *et al.,* 1999b). The potential physiological relevance of this hypothesis is supported by findings such as the wide range in expression levels of the endogenous PTH1-Rc in different cell systems, e.g., rat calvaria cells and chondrogenically differentiating mouse embryonic carcinoma-derived clonal cells (Bos *et al.,* 1996; Shukunami *et al.,* 1996), and the desensitization/downregulation observed in response to prolonged or repetitive exposure to PTH (Bellorin-Font *et al.,* 1995; Fukayama *et al.,* 1994; Mitchell and Goltzman, 1990; Shukunami *et al.,* 1996).

Downstream Signaling Activities

Mitogen-activated protein kinases (MAPKs) are a group of protein serine and threonine kinases that are important regulators of cell growth and differentiation. Many of the MAPKs are regulated by agonist-activated GPCRs and growth factor receptor tyrosine kinases (RTKs). Several studies have reported that PTH regulates the activity of some members of the MAPK family, such as p44/ERK2, p42/ERK1, and p38, in a cell-specific and G protein type-dependent manner (Chaudhary and Avioli, 1998; Cole, 1999; Sneddon *et al.,* 2001; Verheijen and Defize, 1995, 1997; Zhen *et al.,* 2001). Sneddon and co-workers (2001) observed that PTH activates MAPK in a PKC-dependent manner, causing phosphorylation and activation of extracellular-regulated kinase 2 (ERK2) in both distal and proximal renal tubule cells. In contrast to distal renal tubule cells, where Ca^{2+} transients are ERK2 activation dependent and therefore depend on MAPK activation, the increase in $[Ca^{2+}]_i$ in proximal renal tubule cells is independent of ERK2 phosphorylation (Sneddon *et al.,* 2001). This differential signaling pathway mediated by a common PTH1-Rc results in inhibition of phosphate absorption by the proximal tubules, while stimulating calcium transport by the distal tubules (Sneddon *et al.,* 2001). In OK cells, PTH activation of p42 and p44 MAPKs (ERK1 and ERK2, respectively) is mediated by both PKA and PKC in a time- and concentration-dependent manner (Cole, 1999). MAPK activation is preceded by PTH-induced phosphorylation of the EGFR, suggesting that the latter is involved in PTH signaling (Cole, 1999). PTH regulation of chondrocyte differentiation from prehypertrophic to hypertrophic condrocytes is mediated by PKC inhibiting p38 MAPK, leading to upregulation of Bcl-2, an antiapoptotic molecule, and delayed endochondral ossification (Zhen *et al.,* 2001).

Interestingly, PTH has an inhibitory EGF-induced activation of p42 MAPK in osteoblastic UMR 106 osteosarcoma cells in a PKA-dependent manner (Verheijen and Defize, 1995), and it also inhibits bFGF- and PDGF-induced activation of ERK2 in osteoblastic cells (Chaudhary and Avioli, 1998). At the same time, however, it transiently activates MAPK in CHO-R15 stably transfected with rPTH1-Rc in a PKA-dependent and Ras-independent manner (Verheijen and Defize, 1997). Swarthout and co-workers (2001) reported activation of ERK1 and ERK2 and proliferation of UMR106-01 following continuous treatment with very low concentrations of PTH (10^{-12}–10^{-11} *M*). This proliferation is PKC dependent, but stimulation of MAPKs does not require the activation of small G protein Ras or phosphorylation of epidermal growth factor receptor (EGF). The biphasic effect of PTH on DNA synthesis in OK cells (Cole, 1999) and the opposing effects of PTH on MAPK activity in UMR 106 and CHO-R15 cells (Verheijen and Defize, 1995, 1997) suggest that the effect of cAMP increase on MAPK-induced proliferation and differentiation is cell-signaling dependent. Alternatively, sustained activation of MAPK by PTH-dependent PKC activation will induce proliferation, whereas short-lived activation of MAPK by PTH-dependent PKA activation may result in growth arrest and inhibition of cellular differentiation (Cole, 1999).

PTH regulation of cell growth, proliferation, and differentiation of osteoblasts is due to the modulation of downstream activities (Majeska and Rodan, 1981; Nijweide *et al.,* 1986). PTH affects osteoclasts indirectly through its direct action on osteoblasts (McSheehy and Chambers, 1986). Subcutaneous administration of PTH results in an immediate and transient expression of c-fos mRNA in PTH1-Rc-bearing cells (chondrocytes, osteoblasts, and spindle-shaped stromal cells), followed by a delayed expression in the majority of stromal cells and osteoclasts (Lee *et al.,* 1994b). This observation provides further support for the indirect action of PTH on osteoclasts, which may be mediated by osteoblasts and/or a subpopulation of stromal cells. In UMR cells, PTH rapidly and dose dependently induces transcription of c-fos (Clohisy *et al.,* 1992; Kano *et al.,* 1994). Pearman and colleagues (1996) reported that the cAMP response element (CRE) in the c-fos promoter is required for PTH induction of c-fos in UMR cells and that the CRE-binding protein (CREB) binds to this site, apparently as a homodimer, and is phosphorylated in a PTH-inducible fashion at Ser^{133}. Therefore, c-fos appears to have pleiotropic and essential effects in bone. These include mitogenesis and/or differentiation in the skeletal system, as well as inhibition of osteocalcin expression, which is achieved by binding to the AP-1 site in the osteocalcin promoter and thereby suppressing the mature osteoblast phenotype (Owen *et al.,* 1990). PTH-induced c-fos promoter activity was completely

inhibited in a dose-dependent manner by transfection of a heat-stable inhibitor of PKA (Tyson *et al.,* 1999). This finding provides strong evidence that PKA is the enzyme responsible for the phosphorylation of CREB at Ser^{133} in response to PTH and that PKA activity is required for PTH-induced c-fos expression.

Amling and co-workers (1997) tested the hypothesis that accelerated chondrocyte differentiation in the growth plate of PTHrP knockout mice could be due to an increase in apoptosis. They reported that Bcl-2, a programmed cell death inhibitor, and Bax, a programmed cell death inducer, both members of the Bcl-2 family of proteins whose function involves the regulation of programmed cell death, are expressed in chondrocytes *in vivo.* Both proteins show a characteristic distribution within the developing growth plate. In addition, accelerated endochondrial bone maturation is observed in *bcl-2* knockout mice, whose phenotype resembles that of PTHrP knockout mice (Amizuka *et al.,* 1994). Moreover, using transgenic mice that overexpress PTHrP targeted to chondrocytes, they reported *in vitro* and *in vivo* evidence that Bcl-2 is downstream of PTHrP in a signaling pathway important for normal skeletal development (Amling *et al.,* 1997). Taken together, this study offers a strong link between PTHrP-mediated signaling and apoptosis.

Contrary to numerous reports that have consistently shown PTH treatment to increase the osteoclastogenensis of functional osteoclasts (Cosman *et al.,* 1998; Dempster *et al.,* 1993), Jilka and co-workers (1999) reported that intermittently administered PTH had antiapoptotic activity in mice. The increase in bone formation was accompanied by an increase in the life span of mature osteoblasts. In this study, apoptosis was a rare event, affecting less than 2% of the cells in control experiments. Interesting results were reported by Stanislaus and co-workers (2000), who studied the effect of intermittent PTH treatment on apoptosis in bone cells of the distal metaphysis of young male rats. They observed a 40–60% transient increase in the number of apoptotic osteoblasts in the proliferating zone and apoptotic osteocytes in the terminal trabecular zone within 2–6 days of PTH treatment. This effect subsided to control levels after 21–28 days of treatment. According to Turner and colleagues (2000), PTH-mediated apoptotic activity can also be observed in HEK293 cells stably transfected with oPTH1-Rc. This activity was PKC and caspase dependent. Overexpression of the antiapoptotic protooncogene bcl-2, which acts upstream to caspase 3, did not prevent PTH-induced apoptosis. Taken together, PTH-modulated apoptosis may indeed be one of its downstream signaling activities. Nevertheless, the physiological relevance of apoptosis in osteoblasts and bone metabolism, as well as its role in PTH-induced *in vitro* and *in vivo* activities, remains to be elaborated further.

Signaling-Selective Ligands

The activation of PTH1-Rc evokes dual signaling pathways, increasing both AC/PKA via $G_s\alpha$ and PLC/IP_3-DAG/cytosolic transients of $[Ca^{2+}]_i$/PKC via G_q (Abou-Samra *et al.,* 1992; Bringhurst *et al.,* 1993; Juppner *et al.,* 1991; Lee *et al.,* 1995b; McCuaig *et al.,* 1994; Pines *et al.,* 1994; Schneider *et al.,* 1993; Smith *et al.,* 1996) in homologous as well as heterologous receptor/cell systems. Currently, the relationship between these signaling pathways and the cellular and *in vivo* responses to PTH is not fully established. In general, the role of cellular processes such as receptor inactivation, internalization, trafficking, and recycling in bone metabolism is only beginning to be elucidated. One of the open questions in the development of PTH-based, anabolic anti osteoporotic therapies focuses on understanding the mechanism responsible for catabolic vs anabolic actions of PTH induced by continuous vs intermittent administration of hormone, respectively. The linkage of one or both of these signaling pathways to the anabolic activity of PTH remains to be established.

The development of signaling-selective PTH/PTHrP-derived agonists to dissociate the two major signaling pathways is of great significance for understanding the role of the different pathways in cellular metabolic processes. Studies carried out using osteoblastic cells and organ cultures suggest that PTH residues 1-7 form the cAMP/PKA activation domain (Fujimori *et al.,* 1991), whereas PTH residues 28-34 comprise the PKC activation domain (Jouishomme *et al.,* 1992, 1994). The latter encompasses the region also associated with PTH mitogenic activity in cultured osteoblast-like cells (residues 30-34) (Schluter *et al.,* 1989; Somjen *et al.,* 1990). Cyclic AMP appears to be involved in the bone formation (Rixon *et al.,* 1994) and resorption activities of PTH (Tregear *et al.,* 1973). Although PTH stimulation of bone resorption *in vitro* is mediated primarily through the cAMP-dependent activation of PKA (Kaji *et al.,* 1992), it may not be the sole second messenger pathway involved (Herrmann-Erlee *et al.,* 1988; Lerner *et al.,* 1991). At the same time, stimulation of TE-85 human osteosarcoma cell proliferation by PTH-(1-34) is not associated with an increase in intracellular cAMP (Finkelman *et al.,* 1992). Taken together, PTH analogs that stimulate increases in cAMP levels have been shown to either inhibit (Kano *et al.,* 1991; Reid *et al.,* 1988; Sabatini *et al.,* 1996) or stimulate (McDonald *et al.,* 1986; Sabatini *et al.,* 1996; Van der Plas *et al.,* 1985) osteoblastic cell proliferation, depending on species, cell models used, and experimental conditions.

The search for selective anabolic agents explores N-terminally truncated PTH fragments, e.g., PTH-(3-34) and PTH-(7-34), that selectively activate PKC without affecting cAMP (Chakravarthy *et al.,* 1990; Fujimori *et al.,* 1991, 1992) and are also mitogenic for osteoblastic cells (Somjen *et al.,* 1991). Because these truncated fragments do not stimulate bone resorption (Tregear *et al.,* 1973), they may be more effective "anabolic" agents than peptides with an intact N terminus. Truncation of two amino acids from the N terminus of PTH-(1-34) generates PTH-(3-34), which displays reduced AC activity without significantly affecting PKC activation or the mitogenic response *in vitro* (Fujimori *et al.,* 1992). Therefore, if stimulation of bone formation *in vivo* is related only to the

mitogenic response *in vitro,* the bone formation response should be retained in these amino-truncated PTH fragments that are inactive in stimulating bone resorption *in vitro.* However, N-terminal truncated PTH analogs, such as PTH-(3-34), PTH-(7-34), PTH-(13-34), and PTH(8-84), although capable of stimulating PKC activity, were devoid of any bone anabolic *in vivo* activity (Armamento-Villareal *et al.,* 1997; Hilliker *et al.,* 1996; Jouishomme *et al.,* 1992; Rixon *et al.,* 1994; Schneider *et al.,* 1994; Whitfield *et al.,* 1996; Whitfield and Morley, 1995). Moreover, desamino-hPTH-(1-34), which stimulates PKC as potently as hPTH-(1-34) (Rixon *et al.,* 1994) and is a weak stimulator of AC [at 100 n*M* it has only 40% of maximal AC stimulation by hPTH-(1-34)] (Fujimori *et al.,* 1992; Rixon *et al.,* 1994), is also devoid of any anabolic activity on bone in the OVX rat model (Rixon *et al.,* 1994).

The failure to demonstrate bone-forming activity *in vitro* and bone anabolic effects *in vivo* with PTH analogs in which the capacity to activate AC is severely compromised or completely eliminated turned attention to AC-selective analogs. The AC-selective analog hPTH-(1-31)NH_2 (Ostabolin) is equipotent to PTH-(1-34) in stimulating cAMP production in ROS 17/2 (Jouishomme *et al.,* 1994; Neugebauer *et al.,* 1995) and a potent stimulator of cortical and trabecular bone growth in OVX rats (Armamento-Villareal *et al.,* 1997; Hilliker *et al.,* 1996; Rixon *et al.,* 1994; Whitfield *et al.,* 1996, 2000). By truncating the C terminus up to residue 31, Jouishomme and co-workers (1994) were able to compromise the putative PKC-signaling motif, Gln^{28}-His^{32}, and generate hPTH-(1-31)NH_2, a PKA-selective analog. Whitfield and colleagues (1997) developed *c*[Glu^{22},Lys^{26},Leu^{27}]hPTH (1-31)NH_2, a second-generation PKA signaling-selective analog, in which the helical nature of the C terminus is enhanced by formation of a side-chain to side-chain lactam ring and the introduction of a hydrophobic residue at position 27. The replacement of Lys^{27} with Leu improves the amphiphilicity of the C-terminal helical domain, which interacts with L^{261} in ECL3 of PTH1-Rc (Greenberg *et al.,* 2000; Piserchio *et al.,* 2000a). This analog is only a 1.4- to 2-fold stronger stimulator of femoral trabecular bone formation than the linear parent analog. Both hPTH-(1-31)NH_2 and *c*[Glu^{22},Lys^{26},Leu^{27}]hPTH (1-31)NH_2 have been reported to prevent loss of vertebral and trabecular bone and to raise vertebral and trabecular bone volume and thickness over those of control, vehicle-injected, sham-operated rats (Whitfield *et al.,* 2000). The action of these analogs on vertebral bone was as effective as that of hPTH-(1-34)NH_2. However, unlike hPTH-(1-34)NH_2, their effect on pelvic BMD was equivocal.

Takasu and co-workers (1999a) offered an alternative view regarding the structural determinants associated with signaling pathway activation. They showed that replacement of Glu^{19}→Arg, a receptor-binding and affinity-enhancing modification, generates [Arg^{19}]PTH-(1-28), which is a potent and full stimulator of AC and PKC. Interestingly, they find that substitution of Ala^1 for Gly generates [Gly^1,Arg^{19}]hPTH-(1-28), which is a PKA-selective agonist (Takasu *et al.,* 1999a). This study concludes that the extreme N terminus of hPTH constitutes a critical activation domain for coupling to PLC. The C-terminal region, especially hPTH-(28-31), contributes to PLC activation through receptor binding, but this domain is not required for full PLC activation. Therefore, they suggest that the N-terminal determinants for AC and PLC activation in hPTH(1-34) overlap but are not identical and that subtle modifications in this region may dissociate activation of these two effectors.

In the course of designing photoreactive PTHrP analogs for mapping the bimolecular ligand–receptor interface, Behar and co-workers (2000) generated [Bpa^1,Ile^5,$Arg^{11,13}$,Try^{36}] PTHrP(1-36)NH_2. This analog binds and stimulates AC equipotently to the parent analog [Ile^5,$Arg^{11,13}$,Try^{36}]PTHrP (1-36)NH_2 in HEK-293/C-21 cells overexpressing the recombinant human PTH1-Rc (~ 400,000 receptors/cell), but does not elicit intracellular calcium transients. Moreover, it does not stimulate the translocation of β-arrestin2–GFP fusion protein, an effect that is PKC dependent (Ferrari *et al.,* 1999). It will be very interesting to test this PKA-selective analog for its anabolic activity in animal models of osteoporosis.

Target-Specific Ligands

The wide distribution of PTH1-Rc in tissues other than bone and kidney (Urena *et al.,* 1993), the classical target tissues for PTH, and its physiological activation by locally secreted PTHrP (Philbrick *et al.,* 1996) raise concerns about potential side effects following parenteral administration of therapeutic doses of exogenous PTH. Bone-selective PTH/PTHrP-derived analogs may reduce the activation of PTH1-Rc in kidney and nonosseous tissues and provide better bone anabolic drugs.

To this end, Cohen and co-workers reported that [His^3]- and [Leu^3]hPTH-(1-34) are partial agonists of AC in a kidney cell line (50 and 20%, respectively), but full agonists in UMR-106 rat osteosarcoma cells (Cohen *et al.,* 1991; Lane *et al.,* 1996). *In vivo,* however, both analogs were less potent than PTH in the induction of bone formation.

In summary, the development of an effective and safe therapeutic modality that would stimulate the formation of new, mechanically competent bone and possibly reconstitute trabecular architecture in osteoporotic patients continues to be a worthy goal. This goal may be approached by analogs that interact with the PTH1-Rc in a signaling-selective manner or are targeted specifically to bone to achieve a more favorable therapeutic window.

Putative Bioactive Conformation

Elucidation of the bioactive conformation of peptide ligands, namely, the conformation that is recognized by, binds to, and activates the cognate GPCR, is a major objective in structural biology. The ligand–receptor complex is the definitive system for studying the putative bioactive conformation. Unfortunately, for GPCRs, this is currently

an unattainable goal, as no hormone–GPCR complex has been crystallized, probably because of its size and its location as an integral part of the cell membrane. Inooka and co-workers (2001) reported the first nuclear magnetic resonance (NMR)-based structure of GPCR-bound ligand. They analyzed the conformation of the peptide ligand PACAP-(1-21)NH_2 bound to its cognate GPCR. Because recognition, binding, and signal transduction are carried out by membrane-embedded GPCRs, Schwyzer (1991, 1992, 1995) hypothesized that the initial conformations adapted by a ligand are induced by nonspecific interactions with the membrane. Only some of these membrane-induced conformations are recognized by the membrane-embedded GPCR. Therefore, the study of conformations in the presence of membrane mimetic milieu, like the micellar environment, is probably the best available approximation of the natural state.

Secondary structure prediction methods suggest that the N-terminal 1-34 sequences of both PTH and PTHrP assume helical structures at their N- and C-terminal domains (Chorev *et al.,* 1990; Cohen *et al.,* 1991; Epand *et al.,* 1985). These helical sequences span residues 1-9 and 17-31 in PTH and 1-11 and 21-34 in PTHrP (Cohen *et al.,* 1991). A good correlation between receptor-binding affinity and the extent of helicity was established by circular dichroism (CD), a method spectroscopic that can assess the average conformation of a peptide (Neugebauer *et al.,* 1995). Assessment of helical content by CD estimated PTH-(1-34) to have on the average fewer than 8 residues in helical conformation, which is lower than that estimated for PTHrP-(1-34) (Cohen *et al.,* 1991; Epand *et al.,* 1985; Neugebauer *et al.,* 1992; Willis and Szabo, 1992; Zull *et al.,* 1990). In the presence of 45% trifluoroethanol (TFE), a solvent that promotes secondary structure, the total helical content of bPTH-(1-34) and hPTHrP-(1-34) is about 73% (Cohen *et al.,* 1991). Nevertheless, the relevance of the conformation in TFE to the bioactive conformations is still debated.

According to ^{1}H-NMR studies in water, the structure of PTH-(1-34) is mostly random, except for a short ordered region encompassing residues 20-24 (Bundi *et al.,* 1976, 1978; Lee and Russell, 1989). Pellegrini and co-workers (1998b) reported that hPTH-(1-34) in water is highly flexible, with some evidence of transient helical loops spanning the sequences 21-26 and 7-8. This CD and NMR study was carried out in aqueous solutions, with variable pHs and salt concentrations, and in dodecylphosphocholine (DPC) micelles. The subsequent distance geometry calculations, generated conformations that were refined by molecular dynamic simulations explicitly incorporating solvent (H_2O) (Pellegrini *et al.,* 1998b). This study generated high-resolution conformational preferences of hPTH-(1-34), which were later used in the construction of an experimentally based model of the hormone–receptor complex. Both in aqueous solution and in the presence of DPC micelles, Pellegrini and co-workers (1998b) observed fast conformational averaging on the NMR time scale. As anticipated, the two helical domains observed in aqueous solution — the N-terminal helix, comprising residues 6-14, and the C-terminal helix, comprising residues 19-23 — are extended (4-17 and 21-33, respectively) and stabilized in the presence of DPC micelles. A region of flexibility, which is centered around residues 15-16 in aqueous solutions and around residues 18-19 in the micellar system, separates both helices (Fig. 3). Therefore, in solution, the two helical domains adopt a range of different spatial orientations, none of which corresponds to a tertiary structure in which helix–helix interactions can be observed (Pellegrini *et al.,* 1998b). This observation is in complete accord with conformational studies of lactam-containing PTHrP analogs (Mierke *et al.,* 1997), point-mutated and segment PTH-PTHrP hybrids (Peggion *et al.,* 1999; Schievano, 2000), and a model amphiphilic α-helix-containing PTHrP analog (Pellegrini *et al.,* 1997a).

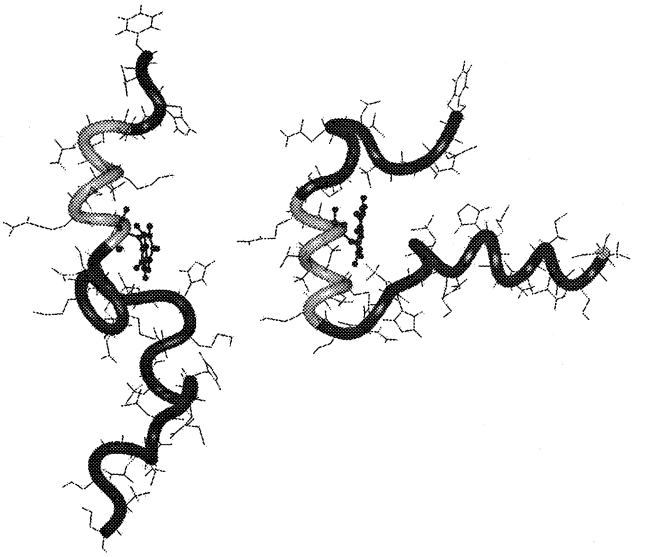

Figure 3 Ribbon diagram of two conformations of hPTH-(1-34) resulting from ensemble-based calculations. Averaging over these two-member ensembles fulfills all of the CD- and NMR-based experimental observations. The different locations and extends of the α helices are highlighted in gray; the side chain of Trp^{23}, used to align the conformations, is shown as a ball-and-stick structure (Pellegrini *et al.,* 1998b).

Weidler and co-workers (1999) studied PTHrP-(1-34) by CD and NMR in what they define as near physiological solution (50 m*M* potassium phosphate, pH 5.1, 250 m*M* NaCl). According to their studies, PTHrP-(1-34) contains two helical domains, His^5-Leu^8 and Glu^{16}-Leu^{27}, which are connected by a flexible linker (Weidler *et al.,* 1999). Similar to Pellegrini and co-workers (1998b), who studied PTH-(1-34), they also could not detect any tertiary structure in PTHrP-(1-34).

The more hydrophobic and amphiphilic C-terminal sequence in PTHrP has a higher propensity for forming a helix than the N-terminal domain, as demonstrated by the higher percentage of TFE needed for nucleation of an N-terminal helix (Mierke *et al.,* 1997). Similar conclusions were reached by adding lipids (Epand *et al.,* 1985; Neugebauer *et al.,* 1992; Willis, 1994) or DPC micelles (Pellegrini

et al., 1997a, 1998b) to PTH- and PTHrP-derived sequences. Taken together, the conformational analyses allow us to postulate a dynamic model for ligand–receptor binding. Binding is initiated by complementary hydrophobic interactions between the hydrophobic face of the amphiphilic C-terminal helical domain of the ligand, including the principal binding domain, and the hydrophobic membrane. This hydrophobic ligand–membrane interaction allows the propagation of the C-terminal helix and the formation of specific interactions with extracellular portions of the PTH receptor. In the membrane environment, nucleation of the N-terminal helix occurs either cooperatively with (in the antagonist) or independently of (in the agonist) the previously formed C-terminal helical domain. Consequently, in the case of PTH/PTHrP agonists, the flexibility around hinges 12-13 and 19-20 allows the membrane-induced "message domain" to be positioned correctly within the receptor. Specific message–receptor interactions leading to the conformational changes required for signal transduction can thus occur. In the case of PTH/PTHrP antagonists, which lack most of the "message" sequence, no conformational change in the receptor occurs and no signal transduction event is triggered. Absence of the critical hinge around positions 19-20, or a shift in register of the hinge region, results in reduced binding affinity and efficacy, as observed for the cyclic PTHrP analogs (Mierke *et al.,* 1997) and point-mutated PTH/PTHrP hybrids (Peggion *et al.,* 1999). This proposed dynamic model for ligand–membrane–receptor interaction provides a testable paradigm for future experiments.

A much debated issue is whether PTH and PTHrP fold into a tertiary structure, in which secondary structural elements interact specifically with each other to form a more stable and higher ordered structure. Cohen and co-workers (1991) suggested that in TFE, the amphiphilic helices located at the N and C termini of bPTH-(1-34) and hPTHrP-(1-34) interact to form a U-shaped tertiary structure, with the hydrophobic residues facing inward to form a hydrophobic core. As a result, the hydrophilic residues are oriented outward, exposing them to the polar solvent (Cohen *et al.,* 1991). However, in light of the lack of compelling spectroscopic evidence for long-range interactions between the two N- and C-terminal helices in both hPTH-(1-34) and PTHrP-(1-34) (Klaus *et al.,* 1991; Strickland *et al.,* 1993; Wray *et al.,* 1994), the notion of a U-shaped tertiary structure remains unsupported. Interestingly, Gronwald and co-workers (1996) reported that in aqueous TFE, the long-range proton–proton correlations (Val^2-to-Trp^{23} and Ile^5-to-Asn^{10}) between the two N-terminal helices (sequences 1-10 and 17-27) in the full-length, recombinant hPTH are dependent on interactions provided by residues in the middle and C-terminal portion of the molecule (sequences 30-37 and 57-62, respectively). They cautiously suggested that the molecule shows a tendency toward tertiary structure. It should be noted that in TFE, the low dielectric constant, which helps stabilize helices, is also supposed to shield the side chains from hydrophobic interactions between the helices and, therefore, destabilizes alleged U-shaped tertiary structures.

Marx and co-workers (1995) suggested that hPTH-(1-37) assumes a U-shaped structure in aqueous solution containing a high salt concentration. However, their reported long-range, proton–proton correlations are limited to side chains of Leu^{15} and Trp^{23} located close to the bend forming the putative U-shaped structure, leaving, therefore, too much flexibility to define a stable U-shaped structure. Others have also assigned a tertiary folded structure to PTH-(1-39), PTH-(1-34), and the osteogenic PTH sequence PTH-(1-31) (Chen *et al.,* 2000; Marx *et al.,* 2000). The same researchers identify a loop region around His^{14}-Ser^{17}, stabilized by hydrophobic interactions, and long-range proton–proton correlations between Leu^{15} and Trp^{23}, which are also found in hPTH-(1-37) and in N-truncated analogs hPTH-(2-37), -(3-47), and -(4-37) (Marx *et al.,* 1998).

Other studies of PTHrP analogs describe interactions between N- and C-terminal helical domains, in the presence of TFE, thus offering support for the U-shaped structure (Barden and Kemp, 1989, 1994, 1995, 1996; Barden *et al.,* 1997). Barden and Kemp mentioned the presence of a hinge at Arg^{19}-Arg^{20} in [Ala^9]PTHrP-(1-34)NH_2 and attributed to it a functional role in signal transduction. They also postulate long-range interactions between side chains located on both sides of the turn, Gln^{16}-Arg^{19}, implicating the presence of a tertiary structure (Barden and Kemp, 1996). The question of tertiary structure in PTHrP-(1-34) was also addressed by Gronwald and co-workers (1997), who studied it in water and in 50% TFE. In the presence of TFE, they observed two stable α-helical regions spanning residues 3 to 12 and 17 to 33, which are connected by a flexible linker. Based on their CD and NMR study, Gronwald and co-workers (1997) concluded that there is no evidence of a stable tertiary structure in PTHrP-(1-34). Taken together, the current and prevailing view is that both PTH- and PTHrP-derived linear peptides in solution do not form an appreciable component of stable tertiary structure. This understanding runs counter to the notion of a folded or U-shaped structure as the predominant bioactive conformation.

The lack of tertiary structure in PTHrP-(1-34) in either aqueous solutions or in the presence of TFE is not limited to the linear parent peptide (Barbier *et al.,* 2000; Maretto *et al.,* 1997; Mierke *et al.,* 1997). Similar conformational behavior was observed in a series of side-chain to side-chain-bridged mono- and bicyclic lactam-containing PTHrP analogs. These conformationally constrained analogs are obtained through cyclization of side-chain pairs, Asp^{13} to Lys^{17}, Asp^{22} to Lys^{26}, Lys^{25} (replacing Arg) to Glu^{29}, and Lys^{26} to Asp^{30}, located at the putative N- and C-terminal helical domains (Barbier *et al.,* 2000; Bisello *et al.,* 1997; Chorev *et al.,* 1991, 1993; Maretto *et al.,* 1997, 1998; Mierke *et al.,* 1997). This i-to-i + 4 side-chain to side-chain cyclization is known to stabilize helical structures in other peptide systems. Bioactivity in the agonist (1-34) and antagonist (7-34) series of lactam-containing analogs requires well-defined N- and C-helical domains that are linked by two flexible hinges located around residues 12-13 and 19-20 (Maretto *et al.,* 1997; Mierke *et al.,* 1997).

Two separate studies suggested that the bioactive conformation of PTH forms an extended helix (Condon *et al.,* 2000; Jin *et al.,* 2000). In a CD study, Condon and co-workers (2000) analyzed a series of lactam-containing PTH-(1-31) analogs that include the tricyclo (Lys^{13}Asp^{17},Lys^{18}Asp^{22},Lys^{26}Asp^{30})-[Ala^{1},Nle^{8},Lys^{18}, Asp^{17,22}, Leu^{27}]hPTH-(1-31)NH_2, a highly potent (EC_{50} = 0.14 n*M*) analog. This analog forms an extended helix-spanning residues 13-30 in aqueous solution and is fully helical in 40% TFE. This tricyclic analog includes a lactam bridge, Lys^{18}-to-Asp^{22}, which engulfs Arg^{19}, a putative hinge site in the bioactive conformation. They concluded, therefore, that PTH binds to its cognate receptor in an extended helical conformation (Fig. 4, see also color plate). A similar conclusion was reached by Jin and co-workers (2000), who reported the crystal structure of hPTH-(1-34). The PTH crystallized in a slightly bent (residues 12-21), long helical antiparallel dimer (Fig. 5, see also color plate). In general, solid-phase structures of short peptides can be very much affected by the intermolecular packing forces stabilizing the crystal structure. In particular, formation of the dimer, as in the PTH crystal, can override other intramolecular interactions. In addition, there is no resemblance between the crystal environment and a membrane-mimicking milieu in which the bimolecular ligand–GPCR interaction takes place. We do not think that these studies contradict previous findings obtained with both PTH and PTHrP in solution, or with analogs more flexible than the tricyclic one. Conformations of the tricyclic analog of PTH in solution or PTH-(1-34) in the solid state may represent only a fraction of the ensemble of fast equilibrating conformations that can generate the putative bioactive conformation. At any rate, the tricyclic analog may retain sufficient structural flexibility to allow optimal interaction with the receptor.

Piserchio and colleagues (2000b) studied bTIP39, the recently identified endogenous ligand for PTH2-Rc, using both high-resolution NMR and CD in the presence of DPC micelles and computer simulation in a water/decane simulation cell. They reported a molecular architecture consisting of two stable α helices, Ala^{5}-Leu^{20} and Leu^{27}-Val^{35}, separated by an unstructured region. This architecture is reminiscent of the structure of PTH-(1-34), with which TIP39 shares only limited sequence homology (Fig. 1). The N-terminal helix in TIP39, important for activation of PTH2-Rc, has a spatial distribution of polar and hydrophobic amino acid residues almost identical to PTH, making it only moderately amphiphilic. Interestingly, in molecular modeling, Asp^{7} in TIP39 is homologous to Ile^{5} in PTH and His^{5} in PTHrP, both of which are crucial for ligand selectivity toward the PTH2-Rc (Behar *et al.,* 1996a; Gardella *et al.,* 1996a). Thus, the putative steric and repulsive interaction between His^{5} in PTHrP and H^{384} in the bottom of the narrow binding pocket of PTH2-Rc, which is responsible for this receptor–ligand selectivity (Rolz *et al.,* 1999), is replaced by an attractive Coulombic interaction and smaller side chain presented by Asp^{7} in TIP39. This complementarity may favorably accommodate the interaction between TIP39 and its cognate PTH2-Rc. Compared to PTH, the N-terminal helix in TIP39 is longer by five residues (Leu^{16}-Leu-Ala-Ala-Leu^{20}), causing a shift in the relative location of the flexible region 21-26. The C-terminal helices in TIP39 and PTH-(1-34) are only slightly amphiphilic and share a lower degree of homology than the one observed for N-terminal helices. Some unique structural features related to the C-terminal portion of TIP39 may explain its weaker

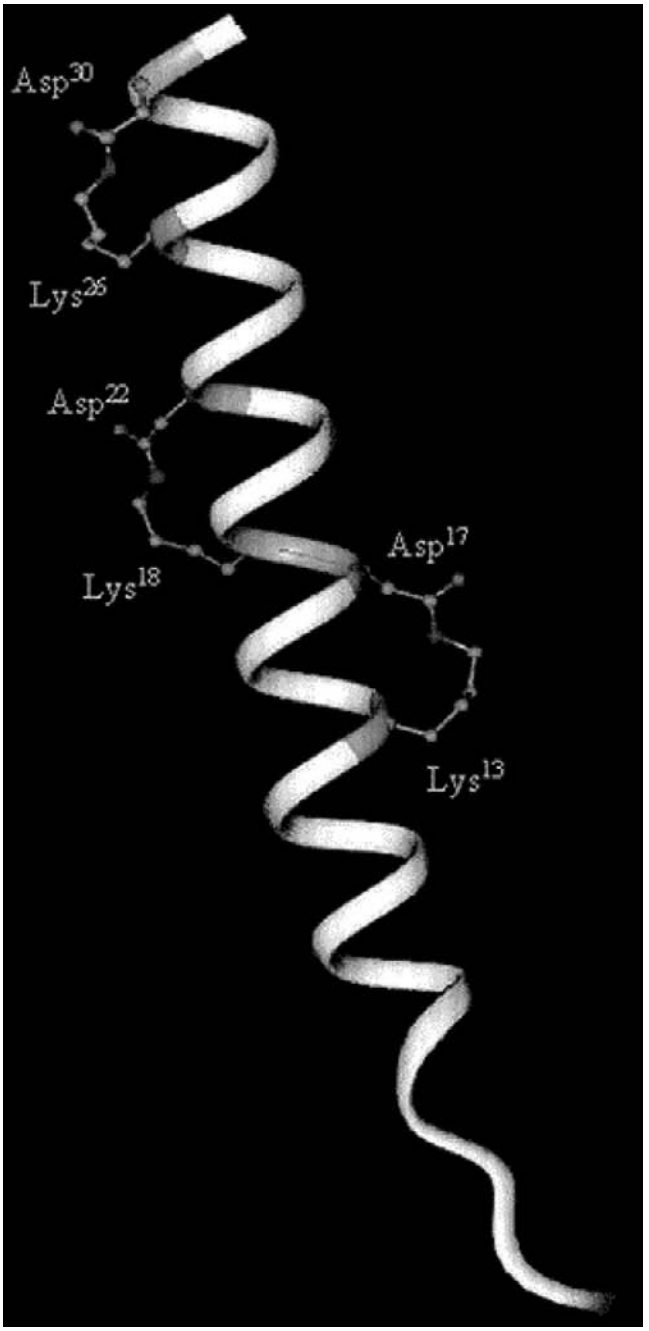

Figure 4 Schematic representation of the tricyclo (Lys^{13}Asp^{30}, Lys^{18}Asp^{22},Lys^{26}Asp^{30})-[Ala^{1},Nle^{8},Lys^{18},Asp^{17,22},Leu^{27}]hPTH-(1–31) NH_2. The peptide backbone is shown as a white ribbon. The three lactam bridges are indicated in orange (Condon *et al.,* 2000). (See also color plate.)

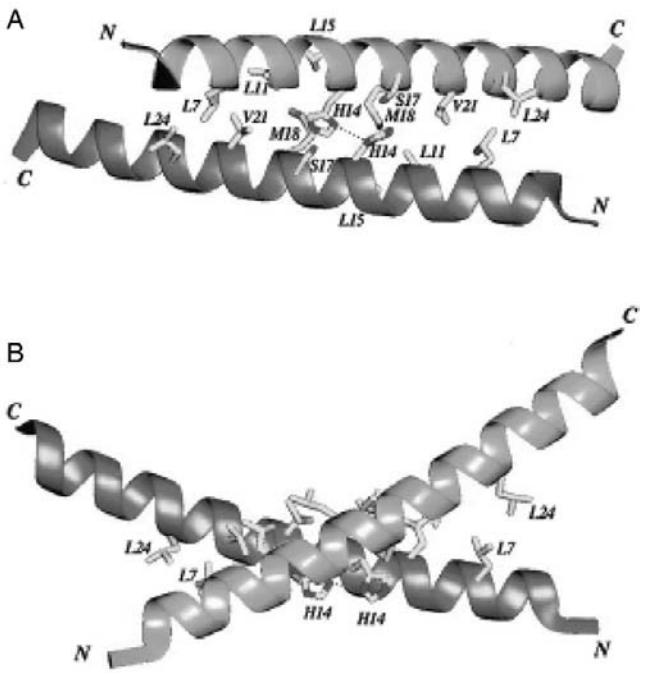

Figure 5 Overall structure of hPTH-(1-34) in the solid state. The monomeric chain is a slightly bent helix presented as green ribbons. At the crossing point of the amphiphilic helices in the dimer, His^{14} from each chain forms a hydrogen bond shown as a dotted line. The dimer interface is mainly hydrophobic. A and B are two different views of the dimer (Jin *et al.,* 2000). (See also color plate.)

interaction with the N-ECD of PTH2-Rc, and therefore its diminished role in recognition and binding (Hoare *et al.,* 2000). Compared to the C-terminal helix in PTH-(1-34), the amphiphilicity of the C-terminal helix of TIP39 is compromised by two factors: the presence of charged residues within the hydrophobic face and the location of Trp^{25} in the unordered region separating the N- and C-helices instead of within the C-terminal helix, as Trp^{23} is in PTH. These experimental and computational results reiterate the significance and relevance of studying structurally related, but functionally distinct ligand–receptor systems to the PTH/PTHrP–PTH1-Rc system.

Conformation-Based Design of PTH/PTHrP Analogs

Enhancing receptor-favored conformations by restricting conformational freedom in a local or global manner may preclude a wide range of nonproductive conformations and will result in more potent analogs. Indeed, one of the goals of searching for the bioactive conformation is to identify structural elements essential for bioactivity and devise ways to stabilize them. Furthermore, enhancing of complementary topological features in the ligand–receptor interface may also contribute to increased potency. For example, enhancement of the amphiphilicity of a helical segment may stabilize a favored bimolecular interaction and lead to a more productive receptor interaction. To this end, several studies have incorporated structural modifications that stabilize an element important in the putative bioactive conformation (Barbier *et al.,* 1997; Bisello *et al.,* 1997; Chorev *et al.,* 1991, 1993; Leaffer *et al.,* 1995; Mierke *et al.,* 1997; Surewicz *et al.,* 1999).

Much attention has been drawn to the amphiphilic nature of the C-terminal helix comprising residues 20-34 of hPTH-(1-34) and its role in receptor binding (Gardella *et al.,* 1993; Neugebauer *et al.,* 1992). A Lys27Leu substitution in PTH-(1-34)NH_2 and PTH-(1-31)NH_2 improved the amphiphilic character of the C-terminal helical sequence and increased AC activity over the corresponding nonsubstituted sequences (Barbier *et al.,* 1997; Surewicz *et al.,* 1999).

Vickery and co-workers (1996) reported a more extensive enhancement of the amphiphilicity of the C-terminal helix of PTHrP. Substitution in PTHrP-(1-34)NH_2 of the sequence 22-31 with a model amphipathic peptide (MAP; Glu^1-Leu-Leu-Glu-Lys-Leu-Leu-Glu-Lys-Leu-Lys^{10}), which is highly α helical when incorporated into short peptides (Krstenansky *et al.,* 1989), generates [$(MAP_{1\text{-}10})^{22\text{-}31}$] hPTHrP-(1-34)$NH_2$ (RS-66271). In this analog, important structural features, such as $Leu^{24 \text{ and } 27}$, are maintained, and $Ile^{22 \text{ and } 31}$ are substituted conservatively by Leu. In aqueous buffer, RS-66271 displays 8- to 9-fold higher helicity than the parent peptide. A detailed conformational analysis of RS-66271 in water, employing CD and ^1H NMR spectroscopy, confirmed the presence of an extensive helical structure encompassing residues 16-32 (Pellegrini *et al.,* 1997a). Nevertheless, the absence of a hinge element around Arg^{19}, considered to contribute to high biological activity, may explain the 6-fold lower AC activity and 10-fold lower binding affinity in ROS17/2.8 cells of RS-66271, compared to the more flexible and less helical PTHrP-(1-34) (Krstenansky *et al.,* 1989, 1994). Importantly, the preservation of significant *in vitro* potency, despite the multitude of substitutions, validates the rationale behind the design of RS-66271.

The discrepancy between the low binding affinity of RS-66271 compared to that of PTH-(1-34), and its PTH-(1-34)-like *in vivo* anabolic activity and *in vitro* activity measured by bone resorption, cAMP accumulation, and inositol phosphate assays, is very intriguing (Frolik *et al.,* 1999; Krstenansky *et al.,* 1994; Vickery *et al.,* 1996). According to Usdin and co-workers, RS-66271 binds selectively to the G protein-coupled PTH1-Rc with high affinity. Therefore, if the PTH1-Rc population in the intact cell is predominantly uncoupled from G protein, the binding affinity of RS-66271 will be markedly low (Hoare *et al.,* 1999b; Hoare and Usdin, 1999, 2000). Using a membrane-based binding assay, they demonstrated that hPTH-(1-34) binds with high affinity ($IC_{50} < 10$ n*M*) to the PTH1-Rc, whether or not it is coupled to G protein (Hoare *et al.,* 1999b). However, RS-66271 binds with high affinity ($IC_{50} = 16$ p*M*) to the coupled receptor, but with much lower affinity ($IC_{50} > 100$ n*M*) to the uncoupled receptor (Hoare and Usdin, 1999). Interestingly, His^5 in RS-66271, which has been implicated previously in specifying the signaling and binding of PTHrP to PTH1-Rc but not to PTH2-Rc (Behar *et al.,* 1996a; Gardella *et al.,* 1996a), is also

implicated as a determinant in G protein-coupled- vs-uncoupled PTH1-Rc selectivity (Hoare *et al.,* 2001). Replacement of His^5 in RS-66271 with Ile reduced selectivity toward the high-affinity G protein-coupled PTH1-Rc by 17-fold and increased the affinity to the uncoupled receptor by 160-fold. The ability of [Ile^5]RS-66271 to restore AC activation in N-ECD-truncated PTH1-Rc, in which RS-66271 failed to stimulate cAMP production, suggests that the residue in position 5 affects receptor selectivity through interactions with the ECLs and the ectopic portions of the TMs (Hoare *et al.,* 2001).

It is generally accepted that PTH-(1-34) and PTHrP-(1-34) contain two helical domains spanning sequences 13-18 and 20-34 (Barden and Cuthbertson, 1993; Barden and Kemp, 1993; Strickland *et al.,* 1993; Wray *et al.,* 1994). Introduction of side-chain to side-chain cyclizations via lactam bond formation between residues that are 4 amino acids apart and located across a single helical pitch (residue i-to-residue i+4) has been demonstrated to be an effective way to stabilize a helical structure (Bouvier and Taylor, 1992; Danho *et al.,* 1991; Felix *et al.,* 1988a,b; Madison *et al.,* 1990). Therefore, we undertook replacement of a potential ion pair participating in α-helical stabilization by a covalent lactam bridge in an attempt to further stabilize the helices in these regions. The initial application of this approach generated *c*[Lys^{13}-Asp^{17}]PTHrP-(7-34)NH_2, which was about 10-fold more potent than the linear parent antagonist (K_b = 18 and 170 n*M* K_i = 17 and 80 n*M,* respectively, in Saos2/B10 cells) (Chorev *et al.,* 1991). Rigidification of the C-terminal helix in *c*[Lys^{26}-Asp^{30}]PTHrP-(7-34)NH_2 did not improve antagonist potency (Bisello *et al.,* 1997), but a combination of two 20-membered lactam bridges, in both N- and C-terminal helices, generated *c*[Lys^{13}-Asp^{17},Lys^{26}-Asp^{30}]PTHrP(7-34)NH_2, a potent (K_b = 95 n*M* and K_i = 130 n*M* in Saos2/B10 cells) (Bisello *et al.,* 1997), highly conformationally constrained, PTHrP-derived antagonist, and a valuable tool for conformational studies (Maretto *et al.,* 1997).

The same approach applied to the agonist PTHrP-(1-34)NH_2 yielded the mono- and bicyclic analogs *c*[Lys^{13}-Asp^{17}]PTHrP-(1-34)NH_2 and *c*[Lys^{13}-Asp^{17},Lys^{26}-Asp^{30}]PTHrP-(1-34)NH_2, which were equipotent to the linear parent compound (K_b = 3.2, 2.1 and 1 n*M,* K_m = 0.17, 0.22, and 0.57 n*M,* respectively, in Saos2/B10 cells) (Bisello *et al.,* 1997). A similar approach was also applied to signaling-selective analogs, hPTH-(1-31)NH_2, and the more potent [Leu^{27}]hPTH-(1-31)NH_2. Both of these analogs stimulate the AC, but not the PLC/PKC signaling pathway (Barbier *et al.,* 1997). Whereas i-to-i+4 lactam bridge formation between Glu^{22} and Lys^{26}, as in *c*[Glu^{22}-Lys^{26},Leu^{27}]hPTH-(1-31)NH_2, results in about a four fold increase in AC activity compared to the linear parent peptide (EC_{50} = 3.3 and 11.5 n*M,* respectively, in ROS 17/2 cells), similar cyclization between Lys^{26} and Asp^{30} or i-to-i+3 lactam bridge formation between Lys^{27} and Asp^{30} results in cyclic analogs less potent than the corresponding linear parent peptides (Barbier *et al.,* 1997).

Interestingly, the higher AC activity *in vitro* observed for *c*[Glu^{22}-Lys^{26},Leu^{27}]hPTH-(1-31)NH_2 compared to the linear peptide results in a higher anabolic effect on trabecular bone growth in ovariectomized rats (Whitfield *et al.,* 1997) and more effective protection than hPTH-(1-34) affords against loss of femoral trabeculae in the same animal model (Whitfield *et al.,* 1998).

The retention of full PKC activity (in ROS 17/2 cells) by the extensively N-terminally truncated linear fragment [Lys^{27}]hPTH-(20-34)NH_2 and the structurally related lactam-bridged analog *c*[Lys^{26}-Asp^{30}]hPTH-(20-34)NH_2 was consistent with the stabilization of the amphiphilic helix at the C terminus and implicated the helix as an important functional motif for binding to the PTH1-Rc (Neugebauer *et al.,* 1994). Taken together, these studies provide important insights regarding the structural nature of the hormones PTH-(1-34) and PTHrP-(1-34) and help to better characterize conformational features important for PTH binding and bioactivity.

PTH Receptors

The physiological and pathophysiological activities of PTH and PTHrP are mediated predominantly by PTH1-Rc. PTH1-Rc is encoded by a single-copy gene expressed primarily in kidney, intestine, and bone, the target tissues for PTH, and the PTH–PTH1-Rc interaction is essential for maintaining mineral ion homeostasis (Schipani *et al.,* 1993). The discovery of receptors for PTH and PTHrP, their functional properties, and biological importance are summarized in some excellent reviews (Juppner, 1995, 1999; Mannstadt *et al.,* 1999).

The expanding pharmacological evidence for actions of PTH on targets other than bone and kidney and the divergence of signaling pathways suggest the presence of a distinct subfamily of cognate receptors for PTH, PTHrP, and other related peptides. Homology-based screen and the exploration of molecular evolution of PTH receptors in various species yielded cDNAs encoding three distinct PTH receptor subtypes (Fig. 6) (Rubin and Juppner, 1999). The potential role of these new receptors in physiological processes and in disease, and their usefulness in drug screening and design drive the search for novel receptor subtypes and their cognate ligands.

PTH1 Receptor

The ~87-kDa N-glycosylated PTH1-Rc is a member of the class II hepta-helical transmembrane domain G protein-coupled receptors. Class II comprises receptors recognizing peptide hormones ranging in size from 27 to 173 amino acid residues and it includes receptors for secretin, glucagon, calcitonin, growth hormone-releasing hormone, corticotropin-releasing hormone, vasoactive intestinal peptide, pituitary AC-activating peptide, gastric inhibitory peptide, and glucagon-like peptide 1 (Juppner, 1994, 1995; Segre and Goldring, 1993). The putative hepta-helical structure, which defines the extracellular, TM, and cytoplasmic

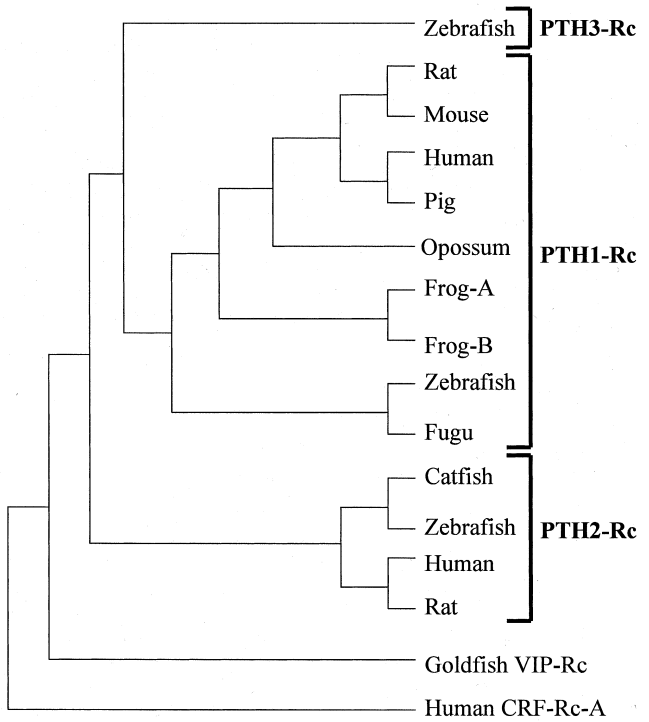

Figure 6 A phylogenic dendogram of PTH receptor subtypes. Analysis was reported by Rubin and Juppner (1999). VIP-Rc, vasoactive intestinal polypeptide receptor; CRF-Rc-A, corticotropin-releasing factor receptor A

domains, was derived from structural homology studies (Abou-Samra *et al.,* 1992; Juppner *et al.,* 1991) and confirmed by epitope tag mapping of the extracellular and cytoplasmic domains (Xie and Abou-Samra, 1998). Class II GPCRs have no significant sequence identity (<12%) with other GPCRs. In addition, only 50 amino acid residues are strictly conserved, indicating their early emergence in evolution. The conserved residues are located predominantly in the N-ECD and the TM domains and must play an important structural and functional role.

The distinct features of the class II GPCRs include an N-ECD of ~160 residues, which is intermediate in length between those of the glycoprotein hormone (~400 residues) and aminergic receptors (~35 residues); a highly conserved pattern of 8 cysteines (6 in the N-ECD, 1 in the ECL1, and 1 in the ECL2); and multiple potential N-glycosylation sites located within the N-ECD.

PTH1-Rc homologues from different mammalian species, such as rat, opossum, pig, human, and mouse, are most divergent within the N-ECD, the ECL1, and the carboxyl-terminal intracellular tail (Abou-Samra *et al.,* 1992; Juppner *et al.,* 1991; Kong *et al.,* 1994; Schipani *et al.,* 1993; Smith *et al.,* 1996). Evidently, the divergence in the response of different PTH1-Rc homologues to truncated sequences and analogs of PTH and PTHrP is instrumental in defining important functional domains within the PTH1-Rc. For example, despite their 91% homology and similar apparent dissociation constant of ~10 n*M* for PTH-(1-34), rat and human PTH1-Rc have very different affinities for the antagonist PTH-(7-34) (K_d = 14 and 4385 n*M,* respectively) (Juppner *et al.,* 1994).

Studying the structure–function relationship of the PTH1-Rc is an important indirect approach to gaining insight into the ligand–receptor bimolecular recognition process and the signal transduction mechanisms. This approach, however, focuses on only one component of the hormone–receptor complex, the receptor, and therefore it is "blind" to the structural information of the ligand. In addition, many of these point mutated, truncated, and hybrid receptors can be affected by long-range structural consequences that are removed from the site of modification, thus making the interpretation of stucture–function relationships quite difficult.

PTH Receptor Subtypes

Two novel PTH receptor subtypes, PTH2- and PTH3-Rc, have been identified (Rubin and Juppner, 1999; Usdin *et al.,* 1995). Their designation as PTH receptor subtypes is based on their high level of sequence homology with PTH1-Rc, their interaction with PTH- and/or PTHrP-derived peptides, and their capacity to stimulate both PKA- and PKC-dependent signaling pathways. However, this designation does not reflect any physiological or functional relationship to the PTH/PTHrP–PTH1-Rc system. Therefore, they are very valuable as natural structure–function experiments that can provide insights into ligand–receptor bimolecular interactions.

PTH2 Receptor Subtype and TIP39

PTH2-Rc, which has been cloned from rat and human cDNA libraries, selectively binds PTH, but not PTHrP (Usdin *et al.,* 1995, 1999). *In situ* hybridization studies have identified a high level of expression of PTH2-Rc in brain and lower levels in the exocrine pancreas, epididymis, artrial and cardiac endothelium, vascular smooth muscle, lung, placenta, and vascular pole of renal glomeruli (Usdin *et al.,* 1995, 1999a). However, little is known about its physiological role in these tissues. While the tissue distribution, and particularly the lack of PTH2-Rc expression in kidney and bone, suggests a limited physiologic role in mineral metabolism, the distinct ligand specificity of PTH2-Rc has provided insight into the current model of PTH ligand–receptor interactions.

Usdin *et al.* (1999b) isolated a novel peptide from bovine hypothalamus, tuberofundibular peptide 39 (TIP39), whose binding affinity and stimulating activity for the PTH2-Rc are similar to those of PTH (Usdin *et al.,* 1995, 1999). In contrast to PTH, TIP39 does not appreciably activate AC in COS-7 cells transiently transfected with either human or rat PTH1-Rc (Usdin *et al.,* 1999b), but instead binds to them with moderate affinity (Hoare *et al.,* 2000). A homology search reveals that 9 out of the 39 residues of TIP39 are

identical to bPTH, and most of them are located in the midregion of the molecule. The physiological role of the TIP39–PTH2-Rc system remains to be established.

Several lines of evidence suggest that PTH is unlikely to be a physiologically important endogenous ligand for PTH2-Rc. These include (1) different ligand rank order of intrinsic activity of a series of PTH analogs in the human and rat PTH2-Rc, (2) considerably lower intrinsic activities and relative potencies of PTH-like ligands at the rPTH2-Rc than at the hPTH2-Rc, (3) the partial agonist effect of PTH-based peptides when compared to bovine hypothalamic extracts (Hoare *et al.,* 1999a), and, last but not least, (4) the discovery that TIP39, a peptide distantly related to either PTH or PTHrP, is a potent and selective activator of the PTH2-Rc (Usdin *et al.,* 2000).

PTH3 Receptor Subtype

Two PTH receptor alleles, one highly homologous to human PTH1-Rc and the other a novel PTH3-Rc, have been cloned by genomic PCR from zebrafish (z) DNA. While these receptors exhibited 69% similarity (61% identity) with each other, neither of them exhibited as great a degree of homology with zPTH2-Rc (Rubin *et al.,* 1999). Zebrafish PTH1-Rc and zPTH3-Rc showed 76 and 67% amino acid sequence similarity with hPTH1-Rc, respectively, but similarity with hPTH2-Rc was 63 and only 59% for both teleost receptors (Rubin and Juppner, 1999). Recombinant zPTH3-Rc, transiently expressed in COS-7 cells, exhibited more efficient AC activity when stimulated by [Ala^{29},Glu^{30},Ala^{34},Glu^{35},Tyr^{36}]fugufish PTHrP-(1-36)NH_2 and [Tyr^{36}]hPTHrP-(1-36)NH_2 (EC_{50} = 0.47 and 0.45, respectively) than by [Tyr^{34}]hPTH-(1-34)NH_2 (EC_{50} = 9.95 n*M*). In addition, zPTH3-Rc showed higher affinity to the PTHrP analogs than to the PTH analog. Finally, zPTH1-Rc activated the inositol phosphate (IP) pathway but zPTH3-Rc did not (Rubin and Juppner, 1999).

When these results are taken together, compared to the nondiscriminatory interaction of PTH1-Rcs with PTH and PTHrP and the selectivity of PTH2-Rc for PTH, zPTH3-Rc emerges as the preferential target for PTHrP-derived agonists. Interestingly, some compelling findings suggest the presence of a PTHrP-selective receptor in rat supraoptic nucleus, which is distinct from PTH1-Rc, whose activation leads to the release of Arg-vasopressin (Yamamoto *et al.,* 1997, 1998). We may speculate that since PTH1-Rc from all known species appear to have similar structural and functional properties, it is likely that the mammalian homologue of zPTH3-Rc, when identified, will interact preferentially with PTHrP.

Receptor Chimera

PTH receptor subtype chimeras, deletion mutation, and point mutations have been used to explore the functional domains in the receptor involved in ligand binding and signal transduction (Gardella *et al.,* 1994; Juppner *et al.,* 1994; Lee *et al.,* 1994a). Rat/human and rat/opossum PTH1-Rc chimeras revealed that the N-ECD plays an important role in binding of the amino-truncated PTH-(1-34)-derived peptides, such as the antagonist PTH-(7-34) (Juppner *et al.,* 1994). Chimeras with the N-ECD of hPTH1-Rc have considerably higher binding affinity for PTH-(7-34), PTH-(10-34), and PTH-(15-34) than the reciprocal chimera where the N-ECD is from the rPTH1-Rc. In addition, deletion of the sequence 61-105 (encoded by exon E2) from the N-ECD did not affect the binding of either PTH-(1-34) or PTH-(7-34) (Juppner *et al.,* 1994). Therefore, this region, which is much more variable among the human, rat, and opossum receptor species than the rest of the N-ECD, does not contribute to the difference in binding affinity of PTH-(7-34) in the rat and human PTH1-Rc. Interestingly, the ectopic regions of TM5 (residues S^{370} and V^{371}) and TM6 (residue L^{427}), which provide important interactions with the extreme amino-terminal residues of PTH and PTHrP, have been found to participate in the binding and signaling of [Arg^2]PTH-(1-34) (Gardella *et al.,* 1994). This analog is a weak partial agonist for cAMP stimulation through rPTH1-Rc and full agonist for cAMP stimulation through the opossum PTH1-Rc (Gardella *et al.,* 1991). Reciprocal specific point mutations of residues in rPTH1-Rc with residues from oPTH1-Rc (S370A, V371I, and L427T) increased binding affinity to the mutated rPTH1-Rc to the level observed for the wild-type opossum receptor, yet without affecting the binding of PTH-(1-34). Only one of these mutations in the rPTH1-Rc (S370A) conferred agonist activity to [Arg^2]PTH-(1-34) (Gardella *et al.,* 1994). The tolerance for the deletion of residues 61-105, which are located in the N-ECD, was utilized to replace it with an epitope tag derived from *Haemophilus influenza* hemagglutinin (HA) without affecting receptor functions, thus generating a powerful tool for monitoring receptor expression levels (Lee *et al.,* 1994a). However, deletions of residues 31-47 near the amino terminus and residues 431-440 in the ECL3 were both detrimental to the efficient binding of PTH-(1-34) (Lee *et al.,* 1994a).

The prevailing paradigm for the global topological organization of the PTH–PTH1-Rc complex suggests two major interdomain interactions. The first is between the N-ECD of PTH1-Rc and the principal binding domain in the ligand, located at its C-terminal portion. The second is between ECLs and juxtamembrane regions of the TMs of the receptor and the activation domain in the ligand, located at the N-terminal portion of the sequence. In line with this paradigm, Luck and co-workers (1999) reported that the amino-terminal fragment PTH-(1-14), which encompasses the principal activation domain, is equally potent in stimulating AC in rPTH1-Rc and in the N-ECD-truncated rPTH1-Rc (Carter *et al.,* 1999b; Luck *et al.,* 1999). In contrast, PTH-(1-34) was ~100-fold weaker in potency with N-ECD-truncated rPTH1-Rc than PTH-(1-14). An alanine scan identified R^{186} in the PTH1-Rc as critical for the cAMP response only in the case of PTH-(1-14) but not for PTH-(1-34) (Luck *et al.,* 1999).

Lack of photocross-linking of fully biologically active ^{125}I-Lys^{13}(*p*Bz$_2$)-PTH-(1-34) to [R186A/K]hPTH1-Rc mutants (Adams *et al.,* 1998) suggests that a contact site in the proximity of R^{186} contributes bimolecular interactions with PTH that are crucial for the signaling activity of PTH-(1-14). In addition, Carter and co-workers, carrying out Ala scan analysis and hydrophylic-to-hydrophobic substitutions in the 182-190 sequence of rPTH1-Rc, identified by homolog-scanning mutagenesis strategy to be a candidate for a ligand-binding site (Lee *et al.,* 1995a), suggest that F^{184} and L^{187} are important deterninants of functional interaction with residues 3-14 in PTH (Carter *et al.,* 1999b).

Homolog-scanning mutagenesis (Cunningham *et al.,* 1989) is a powerful technique. It generates chimeric receptors by systematically replacing segments of the PTH1-Rc with homologous segments of other class II GPCRs and has the potential to maximize surface expression and minimize perturbation of receptor conformation. Exploring the extracellular domains of the rPTH1-Rc by corresponding segments of the homologous rat secretin receptor reveals that the ectopic end of TM1 and the carboxyl-terminal of ECL1, ECL2, and ECL3 are involved in ligand binding (Lee *et al.,* 1995a). In ECL3, two specific residues, W^{437} and Q^{440}, were identified as major contributors to agonist binding. Interestingly, these two mutations did not affect the binding affinity of PTH(3-34), suggesting that these residues are involved in the interaction with the critical amino terminus of the hormone (Lee *et al.,* 1995a). Two chimeric receptors in which the entire amino-terminal domains of corticotropin-releasing receptor 1 and hPTH1-Rc were exchanged bound analogs of their cognate receptors with a specificity determined by the N-ECD (Assil *et al.,* 2001).

While calcitonin (CT) and PTH share little sequence homology, their functional domains have a similar organization. In both hormones the N-terminal portions function as activation domains, whereas the C-terminal portions contain the principal binding determinants. Although similar in structure, CTR and PTH1-Rc class II receptor glycoproteins have only 42% homology and are selectively activated only by their respective ligands. Bergwitz *et al.* (1996) created reciprocal CT-Rc/PTH1-Rc chimeras in which the N-ECD was exchanged between the two receptors. Similarly, chimeric ligands were synthesized in which the activation and binding domains of each ligand were exchanged to create CT/PTH hybrid peptides. Using a COS-7 mammalian expression system to assess ligand binding and cAMP accumulation, it was demonstrated that the reciprocal hybrid ligands [CT-(1-11)/PTH-(15-34) and PTH-(1-13)/CT-(12-32)] do not activate normal CT- or PTH1-Rc; they can, however, activate their respective N-ECD-PTH1-Rc/CT-Rc and N-ECD-CT-Rc/PTH1-Rc chimeras. This interaction was dependent on the receptor cognate N-ECD binding the hybrid with the cognate C-terminal portion. These chimeric receptors were then activated by the amino-terminal portion of the ligand interacting with the membrane-embedded domains of the receptor and the associated ECLs.

The discriminatory domains in PTH2-Rc, which allow response to PTH but not PTHrP, were studied using PTH1-Rc/PTH2-Rc chimeras with reciprocal exchanges among N-ECD, ECLs, and portions of the TMs (Bergwitz *et al.,* 1997; Turner *et al.,* 1998). The chimeric receptor N-ECD-PTH1-Rc/PTH2-Rc responded similarly to PTH and PTHrP (EC_{50} = 1.1 and 1.3 n*M,* respectively). However, this chimera had 100-fold higher apparent affinity for PTH than for PTHrP (Turner *et al.,* 1998). These findings suggest that in addition to the discriminatory role of the N-ECD, which predominantly affects binding, other domains of the PTH2-Rc may contain sites that restrict activation by PTHrP. These sites were located by generating PTH2-Rc mutants in which single or multiple nonconserved TM domain residues were mutated to the corresponding PTH1-Rc residues. Mutations within TM3 and 7 of PTH2-Rc (I244L in TM3 and C397Y, L399M and F400L in TM7) resulted in only partial recovery of affinity toward PTHrP. Turner and co-worker (1998) therefore concluded that the extracellular juxtamembrane portions of the TMs function as a selectivity filter or barrier that discriminates between Ile^5 and His^5 in PTH and PTHrP (Behar *et al.,* 1996a; Gardella *et al.,* 1996a), respectively, by accommodating the first and causing destabilizing interactions with the latter (Turner *et al.,* 1998).

Bergwitz *et al.* (1997) arrived at similar conclusions employing PTH/PTHrP point hybrids, [Trp^{23},Tyr^{36}]- and [Ile^5,Trp^{23},Tyr^{36}]PTHrP-(1-36)NH$_2$. While both analogs were equipotent and had similar affinities to the PTH1-Rc, only the former was an antagonist of PTH2-Rc (Gardella *et al.,* 1996a). Probing the pharmacological properties of these analogs with PTH1-Rc/PTH2-Rc domain, cassette, and point mutated chimeras revealed that I^{244} at the ectopic portion of TM3, as well as Y^{318} near the carboxyl end of ECL2, provide functional interactions with position 5 of the ligands that are involved in the PTH/PTHrP specificity switch (Bergwitz *et al.,* 1997).

Another series of experiments confirms the important role of PTH1-Rc TMs in ligand recognition and receptor structure. Mutation of a single amino acid (N192I) in the TM2 of the secretin receptor to the corresponding residue in the PTH receptor produced PTH binding and functional signaling by the secretin receptor (Turner *et al.,* 1996a). The reciprocal mutation in the PTH1-Rc (I234N) produced a PTH1-Rc that was responsive to secretin. Neither mutation significantly altered the response of the receptors to their own ligands. These results suggest a model of specificity wherein TM residues near the extracellular surface of the receptor function as a selectivity filter that blocks access of the wrong ligands to sites involved in receptor activation (Turner *et al.,* 1996a).

Clark *et al.* (1998) studied PTH1-Rc/PTH2-Rc chimeras in which the N-ECD and ECL3 of the two receptors were interchanged. They found that both domains in both receptors interact similarly with PTH and contribute to the differential interaction with PTHrP. Introduction of the ECL3 of PTH2-Rc into PTH1-Rc increased PTH- and PTHrP-stimulated AC

activity and maintained high binding affinity to PTH but eliminated high-affinity PTHrP binding. Similarly, exchanging ECL3 in PTH2-Rc for the one from PTH1-Rc preserved high-affinity binding but reduced the response to PTH. Interestingly, Q^{440} in the ECL3 of PTH1-Rc is important for PTH-(1-34) binding (Lee *et al.,* 1995a) and is predicted to participate in the binding pocket that accommodates Val^2 in the ligand (Rolz *et al.,* 1999). The corresponding residue in PTH2-Rc is R^{394}. Introduction of the Q440R mutation in the ECL3 derived from PTH1-Rc and the R394Q mutation in the ECL3 derived from PTH2-Rc restored the function of ECL3 chimeric receptors. Moreover, simultaneous interchange of N-ECDs and ECL3s eliminated agonist activation but not binding for both receptors. Simultaneous elimination of the E2-coded sequence (residues 62-106) from the N-ECD of PTH1-Rc and introducing the Q440/R394 mutation into the ECL3 of the PTH1-Rc restored function in the PTH2-Rc chimera. Taken together, these results suggest that interaction between N-ECD and ECL3 in PTH1-Rc is important for PTHrP recognition. To achieve high-affinity binding of PTHrP to the mutated PTH2-Rc, additional high-affinity interaction sites for PTHrP must be identified in PTH1-Rc and introduced to the PTH2-Rc (Clark *et al.,* 1998).

The reciprocal mutations of specific homologous domains and residues identify and delineate potential residues that are critical for local interactions with ligands of different pharmacological profiles and specificities and thus provide important insights into bimolecular ligand–receptor interactions. These studies have pointed to at least two distinct, independently functioning domains on the extracellular surface of the PTH1-Rc: (1) the N-ECD, which largely determines ligand binding specificity by interactions with the C terminus of PTH-(1-34), and (2) the TM5/ECL3/TM6 region of the receptor, which interacts with the N-terminal activation domain in PTH. Taken together, receptor chimera-based studies indicate that class II GPCRs share a similar overall structure with multiple functionally independent, ligand-specific domains. These domains are sufficiently different to permit synthetic hybrid ligands to bind and efficiently activate the complementary receptor chimeras.

Other Site-Directed Mutagenesis Studies

Mutagenesis has been instrumental in identifying polar residues within the hydrophobic TM domains of PTH1-Rc as important determinants of receptor function (Gardella *et al.,* 1996b; Turner *et al.,* 1996a). The polar residues R^{233} and Q^{451} located in TM2 and TM7, respectively, are highly conserved within class II GPCRs. Gardella and co-workers (1996b) found that mutating either R^{233} or Q^{451} resulted in reduced binding affinity and transmembrane signaling by the agonist but did not affect the binding of PTH-(3-34). These findings suggest that R^{233} and Q^{451} play important roles in receptor function by contributing to the interaction with the two critical N-terminal residues in PTH-(1-34) and thus affecting affinity and signaling. Combining both mutations, as in R233Q/Q451K, restored the binding affinity of the agonist almost to the wild-type receptor level but was devoid of activation of PTH-mediated cAMP or inositol phosphate signaling pathways. These results strongly suggest that residues in TM domains 2 and 7 are linked functionally, are proximal to each other, as in the bacteriorodopsin, and are involved in agonist-induced conformational changes affecting coupling to G protein (Gardella *et al.,* 1996). Moreover, mutation of three residues (S^{227}, R^{230}, and S^{233}) predicted to be aligned on the same face of TM2 resulted in blunted PTH-(1-34)-stimulated AC response and lower binding affinity for the agonist despite efficient cell surface expression (Turner *et al.,* 1996a). The same mutation at the corresponding sites in another member of the class II GPCRs, the secretin receptor, resulted in a similar reduction in AC activity. Taken together, these studies led Turner and co-workers (1996a) to propose that this ectopic region in TM2 participates in a signal transduction mechanism common to class II of GPCRs.

Characterization of Cysteins in the Ectopic Domain of PTH1-Rc

Cysteine to serine mutations of any of the six cysteines in the N-ECD severely impaired expression of the mutated receptor (Lee *et al.,* 1994a). However, mutations C281S or C351S, in the ECL1 and ECL2, respectively, resulted in a reduced level of cell surface expression and compromised binding affinity. Nevertheless, the double mutant C281S/C351S, however, had significant improvement in binding affinity, suggesting that these cysteins are involved in a disulfide bridge connecting the first and second ECLs as they are in rhodopsin and βAR (Lee *et al.,* 1994a).

Elucidation of the distinct pattern of the three disulfide bridges formed by the six cysteins in the extracellular N-terminal domain of PTH1-Rc is a major accomplishment (Grauschopf *et al.,* 2000). These six cysteins are highly conserved in class II GPCRs and therefore must contribute critically to receptor function. Bacterial expression of the N-ECD in inclusion bodies was followed by oxidative refolding, which generated stable, soluble, monomeric and functional protein (Grauschopf *et al.,* 2000). The N-ECD binds PTH-(1-34) with an apparent dissociation constant of $3-5\ \mu M$. Analysis of the disulfide bond pattern revealed the following pairwise arrangement: C^{131}-C^{170}, C^{108}-C^{148}, and C^{48}-C^{117} (Grauschopf *et al.,* 2000). This nonsequential pattern has the potential to contribute dramatically to the tertiary structure of the N-ECD and will therefore play an important role in future receptor-modeling studies.

Structure–activity studies of receptors using mutagenic techniques are inferential and cannot conclusively distinguish between direct bimolecular interactions and indirect effects resulting from the modification of local and global conformation. Understanding ligand–receptor interactions at the atomic level requires identifying the contact sites

between specific residues in the ligand and specific residues within the cognate receptor. Mapping this bimolecular interface will identify contact sites that contribute differentially to the bimolecular interaction. In addition to critical sites that contribute primarily either to binding affinity or to the conformational changes leading to signal transduction, there will be bimolecular interactions with less critical roles in both functions. Nevertheless, each additional bimolecular contact site contributes significantly to the identification and characterization of the bimolecular interface and therefore to the understanding of the ligand–receptor interaction.

Mutated Receptor-Based Genetic Disorders

JANSEN'S METAPHYSEAL CHONDRODYSPLASIA

Jansen's metaphyseal chondrodysplasia (JMC) is a rare form of short limb dwarfism associated with abnormalities in endochondral skeletal development, hypercalcemia, and hypophosphatemia, despite normal levels of PTH and PTHrP. Three missense mutations in the PTH1-Rc coding region, H223R, T410P, and I458R, have been discovered in patients with the disease (Schipani *et al.,* 1995, 1996, 1999). PTH1-Rc carrying any one of these mutations display constitutive, ligand-independent activation of the cAMP signaling pathway when tested *in vitro.*

The H223R, T410P, and I458R mutations are located at the cytoplasmic base of TM2, TM6, and TM7, respectively. In COS-7 cells transiently expressing the human I458R PTH1-Rc, basal cAMP accumulation was approximately eight times higher than in cells expressing the recombinant normal receptor. Furthermore, the I458R mutant showed higher activation by PTH than the wild-type receptor in assays measuring the activity of downstream effectors, AC and PLC. Like the H223R and T410P mutants, the I458R mutant does not constitutively activate basal inositol phosphate accumulation. Interestingly, these mutations all occur at TM regions near the intracellular loops of PTH1-Rc that are hypothesized to interact with and activate intracellular G proteins and the subsequent signaling cascade.

These same mutations in PTH1-Rc have also been utilized to identify PTH and PTHrP analogs with inverse agonist activity. Two peptides, [Leu^{11},D-Trp^{12}]hPTHrP-(7-34)NH_2 and [D-Trp^{12},Tyr^{34}]bPTH-(7-34)NH_2, which are highly potent antagonists for the wild-type PTH1-Rc, exhibited inverse agonist activity in COS-7 cells expressing either mutant receptor (H223R or T410P) and reduced cAMP accumulation by 30–50% with an EC_{50} of approximately 50 n*M* (Gardella *et al.,* 1996c). Such inverse agonist ligands may be useful tools for exploring the different conformational states of the receptor, as well as leading to new approaches for treating human diseases with an underlying etiology of receptor-activating mutations.

BLOMSTRAND'S LETAL CHONDRODYSPLASIA

Blomstrand's letal osteochondrodysplasia (BLC) is a rare lethal skeletal dysplasia characterized by accelerated endochondral and intramembranous ossification (Blomstrand *et al.,* 1985; Leroy *et al.,* 1996; Loshkajian *et al.,* 1997; Young *et al.,* 1993). The phenotype of BLC is strikingly similar to PTH1-Rc "knockout" mice, which display prominent pathology in the growth plate (Lanske *et al.,* 1999). In both the human disease and the PTH1-Rc-ablated mouse model, the growth plate is reduced in size because proliferating chondrocytes lack the normal columnar architecture as well as a greatly reduced zone of resting cartilage. This overall similarity of phenotype suggests that an inactivating mutation of PTH1-Rc is the underlying genetic defect in BLC. To date, two types of inactivating mutations have been documented in BLC patients (Karaplis *et al.,* 1998; Zhang *et al.,* 1998). The first is a single homozygous nucleotide exchange in exon E3 of the PTH1-Rc gene. This alteration introduces a P132L mutation in the N-ECD of the receptor (Zhang *et al.,* 1998). Proline 132 is conserved in all mammalian class II GPCRs. COS-7 cells expressing a GFP-tagged mutant receptor do not accumulate cAMP in response to PTH or PTHrP and do not bind radiolabeled ligand, despite being expressed at levels comparable to GFP-tagged wild-type PTH1-Rc. Thus, while full-length PTH1-Rc is being synthesized, it does not bind the ligand and it is functionally inactive.

Another mutation in PTH1-Rc detected in BLC patients results in the synthesis of truncated receptor fragments (Karperien *et al.,* 1999). Sequence analysis of all coding exons of the PTH1-Rc gene identified a homozygous point mutation in exon EL2 with one absent nucleotide (G at position 1122). This missense mutation produces a shift in the open reading frame, leading to a receptor truncated after amino acid 364 located in the ECL2. The mutant receptor, therefore, lacks TMs 5, 6, and 7.

Jobert and co-workers (1998) described a third point mutation in PTH1-Rc associated with BLC. This mutation (G→A at nucleotide 1176) leads to the deletion of 11 amino acids (residues 373-383) in the TM5 of the receptor (Jobert *et al.,* 1998). The mutated receptor is well expressed in COS-7 cells, but does not bind PTH or PTHrP and fails to elevate cAMP and inositol phosphate in response to these ligands.

All three mutations occur precisely at regions thought to be critical for (1) the interaction of PTH1-Rc with the activation domain at the extreme N terminus of PTH and PTHrP and (2) the activation of coupled G proteins at the cytoplasmic side of the receptor. Functional analysis of the mutant receptor in COS-7 cells and of dermal fibroblasts obtained from a BCL patient demonstrated that all of the BLC mutations described earlier are inactivating. Neither the transiently transfected COS-7 cells nor the dermal fibroblasts increased cAMP accumulation in response to PTH or PTHrP.

Integrated Studies of Ligand–Receptor Interactions

One of the most effective ways of characterizing any ligand–acceptor system is to study the intact bioactive bimolecular complex. Routinely, X-ray crystallography and

NMR spectroscopy are the tools of choice for analyzing the structure of bimolecular entities. These methods yield very detailed structural information that has been utilized in rational drug design and generated important leads for the development of novel therapeutic agents. Enzyme inhibitors, such as cathepsin K–inhibitor (Thompson *et al.,* 1997) and HIV protease–inhibitor (Miller *et al.,* 1989), and soluble protein acceptor–ligand systems, such as the human growth hormone (hGH)–extracellular domain of the hGH receptor (de Vos *et al.,* 1992), erythropoietin (EPO)–EPO-receptor (Livnah *et al.,* 1996), and ligand–FK506 binding protein (Shuker *et al.,* 1996), are just a few of a long list of successes demonstrating the power of studying the bimolecular complex and identifying intermolecular interfaces. It is imperative, however, to conduct structural studies under conditions that will not perturb biologically relevant conformations. Unfortunately, membrane-embedded proteins, such as GPCR, are not amenable to either NMR or X-ray analysis because of their large molecular weight, inability to form crystals, and great suceptibility to the manipulations required by these techniques.

Two traditional and indirect approaches, one "ligand centered" and the other "receptor centered," have been pursued to further understand the ligand–PTH Rc interaction and each has made important contributions (see preceding sections). The hormone-centered approach succeeded in mapping functional domains within the hormone that affects receptor binding and activation. In some cases, structural features responsible for biological properties have been identified down to the level of a single amino acid, which sometimes led to the development of important therapeutics. In the PTH/PTHrP field, the identification of the architecture of functional domains and the development of potent antagonists, partial agonists, and inverse agonists, signaling-selective analogs, and potent *in vivo* anabolic agents generate a very impressive list of accomplishments. However, this approach cannot be used to deduce the receptor domains that are in contact with the hormone across the interface. Furthermore, in some cases, modifying the primary structure of the hormone may result in altering the pattern of bimolecular interactions with the receptor. Although some structural modifications of the hormone may directly alter its interaction with an important complementary structural feature of the Rc, others may affect bioactivity through either local or global conformational changes within the hormone that prevent formation of an optimal "bioactive conformation." In essence, the hormone-centered approach is "blind" to the structure of the receptor.

The "receptor-centered" approach has also succeeded in providing valuable insights. Point-mutated and chimeric PTH-Rc — interspecies of PTH1-Rc, such as rat with opossum Rc, or interhormone Rc, such as PTH1-Rc with calcitonin or secretin Rc's — revealed the importance of specific Rc domains and single amino acids necessary for Rc function. However, analysis of the functional consequences that result from modifying the Rc structure alone cannot be used to identify unequivocally the interacting complementary structural elements in the hormone. Furthermore, one usually cannot distinguish Rc modifications that disrupt function as a result of local changes in an important "contact site" or a global conformational change. While local changes affect Rc interaction with a site in the hormone directly, global conformational changes lead to extensive modification of Rc topology, thereby altering interactions with the hormone indirectly. Hence, despite the attractiveness of both lines of investigation and the importance of their contributions, conclusions drawn from the hormone-centered and Rc-centered approaches have inherent limitations and are inferential at best.

In order to study the bimolecular interface of a dynamic system such as the ligand–receptor complex, we need to be able to freeze a bimolecular interaction and identify the interacting site. Photoaffinity labeling has emerged as an effective methodology for studying interactions of biological macromolecules with their ligands (Chowdhry and Westheimer, 1979; Dorman and Prestwich, 1994; Hazum, 1983; Hibert-Kotzyba *et al.,* 1995). The resultant photocross-linked conjugate can serve as a starting point for mapping "contact domains," and even "amino acid-to-amino acid contact points" between a biologically active compound and an interacting macromolecule (Bitan *et al.,* 1999; Blanton *et al.,* 1994; Boyd *et al.,* 1996; Girault *et al.,* 1996; Hadac *et al.,* 1999; Ji *et al.,* 1997; Kage *et al.,* 1996; Keutmann and Rubin, 1993; Kojr *et al.,* 1993; Li *et al.,* 1995; McNicoll *et al.,* 1996; Phalipou *et al.,* 1999; Williams and Shoelson, 1993).

A number of laboratories, including our own, have embarked on a challenging program to map the bimolecular interface between a large peptide hormone and a seven transmembrane-spanning G protein-coupled Rc. The approach, using photoaffinity scanning (PAS) to identify directly contact sites in the hPTH1-Rc responsible for hormone binding and signal transduction, has numerous stringent requirements, the fulfillment of which are crucial for success. Bioactive, specific cleavage-resistant, photoactivable, and radiolabled PTH analogs must be designed and synthesized. A rich and stable source of functional wild-type or mutant PTH-Rc, overexpressed preferentially in a homologous cellular background, must be developed and fully characterized pharmacologically. For purifying either the intact ligand–receptor conjugate or its ligand–receptor conjugated fragments, it will be advantageous to work with epitope-tagged hRc. Although optional, it may be very helpful to have antibodies to various hRc extracellular epitopes for use in purification and analysis. The PAS approach also requires devising an analytic strategy with sequential chemical and enzymatic cleavages; theoretical digestion maps to allow unambiguous identification of hormone-binding sites within the hPTH-Rc; readily available capacity to either synthesize or express receptor domains that contain the identified contact sites for conformational studies; and the capacity to generate site-directed mutated PTH1-Rc, express them stably or transiently, characterize them pharmacologically, and use them in the PAS technology to validate and/or delineate emerging results. Last but not least, this approach requires

access to tools that will allow to integrate cross-linking data with Rc mutagenesis data, and eventually with conformational analysis and molecular modeling data to generate a unified, experimentally based model of the hormone–Rc complex.

In summary, PAS technology is a multidisciplinary, integrated, iterative, and labor-intensive approach. Nevertheless, it is currently the only direct method that yields the best approximation of the actual ligand–receptor complex. Because of the nature of this approach, however it cannot yield molecular structures of the same resolution as those obtained by either X-ray crystallography or NMR analysis.

Photoreactive Analogs

Early efforts to generate a photoreactive, radiolabeled, and biologically active analog of PTH aimed to identify the receptor as a distinct molecular entity (Coltrera *et al.,* 1981; Draper *et al.,* 1982; Goldring *et al.,* 1984; Wright *et al.,* 1987). All of these studies used poorly characterized ligands containing nitroarylazide-based photophores and reported molecular masses ranging between 28 and 95 kDa for the hormone–receptor complex. Shigeno and co-workers (1988a,b) carried out a careful synthesis and characterization of the nitroarylazide-based photoligand and identified it as [$Nle^{8,18}$,Lys^{13}(N^{ε}-(4-N_3-2-NO_2-phenyl),Tyr^{34}]PTH-(1-34)NH_2, a fully active analog in ROS 17/2.8 cells. Using this photoaffinity ligand, they were able to identify in the same cells a plasma membrane glycoprotein corresponding to the PTH receptor that had the apparent molecular mass of 80 kDa (Shigeno *et al.,* 1988a,b).

Introduction of the arylketone-based photoaffinity scanning methodology (Adams *et al.,* 1995; Bisello *et al.,* 1999; Han *et al.,* 2000; Nakamoto *et al.,* 1995; Suva *et al.,* 1997) into the field of calciotrophic hormones and their corresponding receptors is the basis for the current approach to the characterization of the ligand–receptor bimolecular interface (Adams *et al.,* 1998; Behar *et al.,* 1999, 2000; Bisello *et al.,* 1998; Greenberg *et al.,* 2000; Suva *et al.,* 1997; Zhou *et al.,* 1997). Advantages of the benzophenone moiety as a photophore over the aryl azide moiety are numerous. A partial list includes the high efficiency of cross-linking—only a small amount is lost to hydrolysis and, as a result, very little nonspecific cross-linking is observed. Photoactivation is carried out at a wavelengths >330 nm, in which proteins are less susceptible to photodegradation. In addition, there is excellent compatibility with solid-phase peptide synthesis methodology. Furthermore, synthesis, purification, and biological evaluation can be conducted in the laboratory under normal ambient light conditions. This section summarizes major achievements in the design and development of benzophenone-containing PTH and PTHrP ligands and their contribution to the mapping of the bimolecular ligand–receptor interface.

Radioiodination was chosen as the tagging method of choice because of its high specific radioactivity translating into high sensitivity of detection of the radiolabeled conjugated ligand–receptor complex and the fragments derived from it. Therefore, successful PAS analysis requires maintaining the connectivity between the radiotag and the photophore throughout the controlled degradation of the conjugated ligand–receptor complex. Modifications in PTH-(1-34), which include $Met^{8 \text{ and } 18} \rightarrow Nle^{8 \text{ and } 18}$, $Lys^{13,26, \text{ and } 27} \rightarrow Arg^{13,26, \text{ and } 27}$, and $Trp^{23} \rightarrow$2-naphthylalanine^{23} (Nal), render the ligand resistant to the various chemical and enzymatic cleavage agents [i.e. CNBr, lysyl endopeptidase (Lys-C) and BNP-skatole, cleaving at the carboxyl side of Met, Lys, and Trp, respectively].

The fundamental requirement in any photoaffinity cross-linking study is that the photoreactive analogs have the same pharmacological profile as the parent peptide hormone. It will therefore be safe to assume that they share similar bioactive conformations and generate topochemically equivalent ligand–receptor complexes. The photoreactive benzophenone-containing analogs of PTH and PTHrP were designed specifically for PAS studies aimed at investigating the bimolecular interactions of the activation and binding domains of PTH and PTHrP with either PTH1-Rc or PTH2-Rc subtypes.

Identification of Contact Sites

Using PAS methodology, the positions for which contact sites have been identified are positions 1, 13, and 27 in PTH and positions 1, 2, and 23 in PTHrP (Adams *et al.,* 1995; Behar *et al.,* 2000; Bisello *et al.,* 1998; Carter *et al.,* 1999a; Greenberg *et al.,* 2000; Zhou *et al.,* 1997). Two different photophores were used in different studies: *p*-benzoylphenylalanine (Bpa) (Behar *et al.,* 2000; Bisello *et al.,* 1998; Carter *et al.,* 1999a) and the Lys(N^{ε}-*p*-benzoylbenzoyl) [Lys(N^{ε}-*p*Bz_2] (Adams *et al.,* 1995; Behar *et al.,* 2000; Greenberg *et al.,* 2000; Zhou *et al.,* 1997). The former has the benzophenone moiety attached to the peptide backbone through a β carbon, whereas the latter is presented on a relatively long side chain removed by six atoms from the backbone. These different modes of presentation of the benzophenone moiety may play a limited role in selecting cross-linking sites.

Position 1 in PTH Cross-Links to the Ectopic Site in TM6

Photocross-linking [Bpa^1,$Nle^{8,18}$,$Arg^{13,26,27}$,Nal^{23},Tyr^{34}] bPTH-(1-34)NH_2 (Bpa^1-PTH) to the human PTH1-Rc stably overexpressed (~400,000 Rc/cell) in human embryonic kidney cell line 293 (HEK293/C21) generates an 87-kDa photoconjugate (Bisello *et al.,* 1998). Chemical digestions by CNBr and BNPS-skatole, which cleave at the carboxyl end of Met and Trp, respectively, and enzymatic digestions by lysyl endopeptidase (Lys-C) and endoglycosidase F/N-glycosidase F (Endo-F), which cleave at the carboxyl end of Lys and deglycosylate aspargines at concensus glycosylated sites, respectively, generate an array of fragments. These radioiodinated fragments are characterized by SDS-PAGE, and the apparent molecular weights obtained are compared with the theoretic digestion restriction map of the

photoconjugated receptor. Although the resolving power of PAGE is limited, the combination of consecutive cleavages (e.g., Endo-F followed by Lys-C followed by CNBr) carried out in reversed order (e.g., Lys-C followed by BNPS-skatole and BNPS-skatole followed by Lys-C) is extremely powerful. It generates a reproducible pattern of fragments delimited by specific end residues and the presence or absence of glycosylation sites. Comparing the putative digestion map of the hPTH1-Rc with actual fragments identifies the sequence of the smallest radiolabeled ^{125}I-Bpa^{1}-PTH–PTH1-Rc-conjugated fragment (~4 kDa). This fragment consists of the ligand (4489 Da) modified by a very small moiety contributed by a Met residue belonging to the receptor (Bisello *et al.,* 1998). Two Met residues, 414 and 425, present at the mid region and the extracellular end of TM6, emerged as potential contact sites for position 1 in PTH. Contact between residue 1 in PTH and M^{414} requires the N terminus of PTH to protrude into the 7 helical and hydrophobic TMs bundle. In contrast, contact with M^{425} can be achieved while the N terminus is dipping only superficially into the TM bundle.

These biochemical methods are supplemented by molecular biology to provide additional resolving power to the PAS method. Transient expression of two point-mutated hPTH1-Rc, [M414L] and [M425L], generated fully active receptors in COS-7 cells (Bisello *et al.,* 1998). ^{125}I-Bpa^{1}-PTH lost its ability to photocross-link to [M425L] but not to [M414L], thus suggesting that M^{425} is the putative contact site for position 1 in PTH.

Behar and co-workers (2000) reported that radioiodinated PTHrP-based agonist [Bpa^{1},Ile^{5},Tyr^{36}]PTHrP-(1-36) NH_2 (^{125}I-Bpa^{1}-PTHrP), which carries a photophore at the same position as the photoreactive PTH analog ^{125}I-Bpa^{1}-PTH, forms a contact with M^{425} in hPTH1-Rc. This exciting finding confirms that the functional and conformational similarity between PTH and PTHrP extends to a common contact site for the N-terminal residue in the ligand. The location of this site at M^{425} in the ectopic portion of TM6 supports the prevailing view that these two hormones interact very similarly, if not identically, with the PTH1-Rc (Behar *et al.,* 2000).

Position 13 in PTH Cross-Links to a Juxtamembrane Location in N-ECD

Biochemical analysis of the photocross-linking product of radiolabled [Nle^{8,18},Lys^{13}(N$^{\varepsilon}$-*p*(3-I-Bz)Bz),Nal^{23}, Arg^{26,27},Tyr^{34}]bPTH-(1-34)NH_2 [Lys^{13}(*p*Bz$_2$)-PTH] with hPTH1-Rc expressed in HEK293/C-21 cells identifies a glycosylated radioactive band of ~6 kDa, which is delimited by Lys-C and CNBr cleavage sites at the N and C termini, respectively. The theoretical cleavage restriction map of hPTH1-Rc reveals that this minimal radiolabeled ^{125}I-Lys^{13} (*p*Bz$_2$)-PTH–hPTH1-Rc-conjugated fragment corresponds to hPTH1-Rc[173-189] and is located at the juxtamembranal end of the N-ECD (Zhou *et al.,* 1997).

Additional analysis of the 17 amino acid residues composing hPTH1-Rc[173-189] by a combination of site-directed mutagenesis followed by biochemical analysis further delineates the boundaries of the fragment containing the contact site for ^{125}I-Lys^{13}(*p*Bz$_2$)-PTH to obtain hPTH1-Rc [182-189], an 8 amino acid-sequence (Adams *et al.,* 1995). Several R-to-K single site-mutated receptors were generated. These include new Lys-C-susceptible cleavage sites that will allow further delineation of the contact site for position 13. The mutant [R181K]hPTH1-Rc was stably expressed in HEK293 cells (~200,000 Rcs/cell) and was fully functional. Compared to the wild-type receptor, Lys-C cleavage of the ^{125}I-Lys^{13}(*p*Bz$_2$)-PTH–[R181K] photoconjugate produces a smaller conjugated fragment (~18 vs ~9 kDa, respectively), corresponding to a cleavage site upstream to the N-glycosylated N^{176}. Interestingly, the only functional mutations that failed to cross-link to ^{125}I-Lys^{13}(*p*Bz$_2$)-PTH were the [R186K/A] mutants (Adams *et al.,* 1995). However, [R186K]hPTH1-Rc stably expressed in HEK293 cells cross-links effectively to ^{125}I-Bpa^{1}-PTH and displays wild-type receptor-like AC activity and binding affinity similar to that observed in HEK293/C-21 cells. These findings suggest that R^{186} participates in an interaction with the ligand that either provides a contact site for position 13 in the ligand or contributes an interaction that brings the ligand into the close spatial proximity required for cross-linking within the hPTH1-Rc[182-189] contact site (Adams *et al.,* 1995). This interaction does not appear to be essential for a productive ligand–receptor interaction, as [R186K] is fully functional and cross-links effectively with another photoreactive and bioactive analog, ^{125}I-Bpa^{1}-PTH.

Position 27 in PTH Cross-Links to ECL1

The two contact sites described earlier involve residues in the extended activation domain of PTH comprising residues 1-13. Greenberg and co-workers (2000) identified contact sites within the receptor that are involved in the interaction with the principal binding domain of the ligand (residues 24-34). This bimolecular interaction was probed by [Nle^{8,18},Arg^{13,26},L-2-Nal^{23},Lys^{27}(*N*$^{\varepsilon}$-*p*Bz$_2$),Tyr^{34}]bPTH (1-34)NH_2 [Lys^{27}(*p*Bz$_2$)-PTH], a potent agonist, modified by a benzophenone-containing photophore at position 27, and the study employed a combination of biochemical analysis of the photoconjugates and site-directed mutagenesis (Greenberg *et al.,* 2000). Analysis of the ^{125}I-Lys^{27} (*p*Bz$_2$)-PTH–PTH1-Rc photoconjugate by CNBr/Endo-F and BNPS-skatole/Endo-F degradation pathways produced an overlapping sequence of 67 amino acids corresponding to L^{232}-W^{298}. This contact domain includes part of TM2, ECL1, and the entire TM3. Secondary digestions of CNBr- and BNPS-skatole-derived fragments by endoproteinase Glu-C, which predominantly cleaves at the carboxyl side of Glu, converged on an overlapping 38 amino acid sequence corresponding to L^{261}-W^{298}, which includes part of ECL1 and the entire TM3 (Greenberg *et al.,* 2000).

This 38 amino acid contact site was further delineated by analyzing specific single point mutants transiently expressed in COS-7 cells. All three receptor mutants, [R262K], [L261M], and [L261A], were expressed and

displayed characteristic binding affinity and PTH-stimulated AC activity comparable to the wild-type receptor. [R262K] and [L261M] were designed to modify the Lys-C and CNBr cleavage patterns, respectively. The [L261A] was introduced to eliminate a favorable insertion site at position 261. Restriction digestion analysis of the ^{125}I-Lys^{27}(pBz$_2$)-PTH–[R262K] photoconjugate delineated the contact site as hPTH1-Rc[232-262]. Taken together, the minimal contact sites [261-298] and [232-262] obtained from the analysis of the wild-type and mutant [R262K] receptors, respectively, suggest either L^{261} or R^{262} as the contact site for Lys^{27}. Treatment of the ^{125}I-Lys^{27}(pBz$_2$)-PTH–[L261M]PTH1-Rc photoconjugate with CNBr generated a conjugated fragment similar in size to the ligand itself, thus confirming position 261 in the receptor as the contact site for position 27 in the ligand. This was further confirmed by the elimination of effective cross-linking of I^{125}-Lys^{27}(pBz$_2$)-PTH to the mutated receptor [L261A], in which a reactive insertion site, such as Leu, is replaced by Ala, a poor insertion site for the photoactivated benzophenone-derived biradical. Position 261, the contact site for position 27 in PTH, is located near the center of ECL1 (Greenberg *et al.,* 2000).

The identification of L^{261} in hPTH1-Rc as a contact site for Lys^{27} in PTH provides important information for mapping the PTH–PTH1-Rc interface. The ligand–receptor bimolecular interface includes three receptor domains: the juxtamembranal portion of N-ECD, the ectopic portion of TM6, and the ECL1. The remoteness of position 27 from positions 1 and 13 in PTH and that of L^{261} from R^{186} and Met^{425} in hPTH1-Rc generates an important additional structural constraint that can be used to refine the emerging experimentally based model of the PTH–PTH1-Rc complex.

Position 23 in PTHrPc Cross-Links to a Site Located at the Amino-Terminal End

Mannstadt and co-workers (1998) reported that the photoreactive analog of PTHrP, [Ile^5,Bpa^{23},Tyr^{36}]PTHrP-(1-36)NH$_2$ (Bpa^{23}-PTHrP), modified by a benzophenone moiety incorporated at position 23, cross-links to the contact site Y^{23}-L^{40} located at the very N-terminal end of rat PTH1-Rc. CNBr analysis of the ^{125}I-Bpa^{23}-PTHrP–rPTH1-Rc photoconjugate suggests that the contact site resides at the N terminus of the receptor, rPTH1-Rc[23-63]. A combination of CNBr cleavages and site-directed mutagenesis—single point mutation [M63I] and the double mutants [M63I,L40M] and [M63I,L41M])—further delineates the contact site to span the sequence 23-40. Earlier findings reported that the two mutant rPTH1-Rcs with deletions of residues 26-60 or 31-47 transiently expressed in COS-7 cells had little or no capacity to bind ^{125}I-PTH, thus suggesting that these regions are important for ligand binding (Lee *et al.,* 1994a). Further mutational analysis, which included cassette mutagenesis and Ala scan, found that mutants [T33A] and [Q37A] suffered the largest loss in binding affinity for ^{125}I-PTHrP and complete loss of binding affinity toward the antagonist [Leu^{11},D-Trp^{12}]PTHrP-(7-34)NH$_2$. These results led Mannstadt and co-workers (1998) to conclude that the first 18 amino acid residues of the PTH1-Rc include the contact site for position 23 in PTH and that T^{33} and Q^{37} are functionally involved in the binding of the 7-34 region in PTH rather than the 1-6 region.

The location of contact sites for two closely spaced residues in PTH/PTHrP (23 and 13) at both ends of the extracellular amino terminus of the receptor (within the sequence 23-40 and in proximity to R^{186}, respectively) is consistent with the current model of the ligand–receptor binding interface. The extensive length of the putative extracellular amino terminus of PTH1-Rc (~167 residues) may allow the formation of secondary and tertiary structures by the receptor within this domain so that it will be capable of simultaneously accommodating the bimolecular interactions mentioned earlier.

Cross-Linking of Position 1 of Antagonist vs the Same Position in Agonist

A detailed, atomic level understanding of the distinct ligand–receptor interactions that differentiate an agonist from an antagonist is of major importance. Behar and co-workers (2000) made a very interesting observation that directly distinguishes the nature of the bimolecular interactions of agonists and antagonists with PTH1-Rc. Radiolabeled [Bpa^2,Ile^5,Arg^{11,13},Tyr^{36}]PTHrP-(1-36)NH$_2$ (Bpa^2-PTHrP), a highly potent antagonist, was photoconjugated to hPTH1-Rc in HEK293/C-21 cells (Behar *et al.,* 2000). Unlike ^{125}I-Bpa^1-PTH and ^{125}I-Bpa^1-PTHrP, which are derived from potent agonists of PTH1-Rc and cross-link to it at M^{425}, ^{125}I-Bpa^2-PTHrP cross-links to both M^{425} and a proximal site within the receptor domain P415-M425 (Behar *et al.,* 2000). These results may reflect differences in binding modes of agonists and antagonists or in the interaction between the two consecutive positions in the PTHrP-(1-36) sequence and PTH1-Rc.

In an attempt to distinguish between these two possibilities, Behar and co-workers (2000) utilized the analog [Bpa^2,Nle^{8,18},Arg^{13,26,27},Nal^{23},Tyr^{34}]bPTH-(1-34)NH$_2$ (Bpa^2-PTH), which is a full agonist of PTH1-Rc and carries the same photoreactive moiety at the same position as the antagonist Bpa^2-PTHrP (Bisello *et al.,* 1998). Analysis of ^{125}I-Bpa^2-PTH photoconjugates with wild-type and [M414L] or [M425L] mutated hPTH1-Rc indicates that this ligand cross-links only to the ε-methyl of Met^{425}, which is similar to Bpa^1-PTHrP and Bpa^1-PTH cross-linking (Bisello *et al.,* 1998). These results, therefore, provide strong support for the hypothesis that the differences observed between the cross-linking of ^{125}I-Bpa^1- and ^{125}I-Bpa^2-PTHrP may reflect different interaction modes of agonists and antagonists with the PTH1-Rc.

Interestingly, two additional Bpa-containing PTHrP-(1-36) analogs, [Bpa^2,Ile^5,Trp^{23},Tyr^{36}]- and [Bpa^4,Ile^5,Trp^{23},Tyr^{36}]PTHrP-(1-36)NH$_2$, were reported to selectively antagonize and preferentially cross-link to hPTH1-Rc and

hPTH2-Rc stably expressed in LLC-PK_1 cells, respectively (Carter *et al.,* 1999a). However, in homologous systems composed of hPTH1- and hPTH2-Rc expressed in a human cellular background (HEK293/C-21 and HEK293/BP-16, respectively), Bpa^2-PTH is a full agonist and Bpa^4-PTH is a very weak agonist with a slightly better affinity for the hPTH2-Rc (Bisello *et al.,* 1998; Carter *et al.,* 1999a). Similar to [Bpa^4,Ile^5,Trp^{23},Tyr^{36}]PTHrP-(1-36)NH_2 (Carter *et al.,* 1999a), [Bpa^4,Ile^5,$Arg^{11,13}$,Tyr^{36}]PTHrP-(1-36)NH_2 displays poor binding affinity and negligible efficacy in HEK293/C-21 cells expressing the hPTH1-Rc (Behar *et al.,* 2000). Nevertheless, Carter and colleagues (1999a) reiterated the prevailing understanding that individual residues within the 1-5 sequence in PTHrP play distinct roles in modulating the interactions with PTH1- and PTH2-Rc.

Although PTH2-Rc may not be the physiological target for PTH or PTHrP, its structural resemblance to PTH1-Rc, its high-binding affinity, specific cross-linking, and effective coupling to the PTH-induced intracellular signaling pathways make it an attractive target for exploring structure–function relations in the PTH/PTHrP–PTH1-Rc system. Analysis of the photoconjugates obtained upon cross-linking ^{125}I-Bpa^1-PTH and ^{125}I-Lys^{13}($p$$Bz_2$)-PTH to hPTH2-Rc stably expressed in HEK293 cells (HEK293/BP-16, ~160,000 Rc/cell) revealed that both hPTH1-Rc and hPTH2-Rc use analogous sites for interaction with positions 1 and 13 (Behar *et al.,* 1999).

PAS methodology, although not perfect, offers the only readily available experimental approach to studying the bimolecular ligand–GPCR interface directly. To practice this methodology successfully requires introducing benzophenone moieties, radioiodine, and substitutions that provide resistance to specific chemical and enzymatic cleavages. The stringent requirements that a potential candidate molecule must meet to be employed in the PAS methodology result in a limited set of reagents. Photoreactive ligands thus represent only those molecules with the following characteristics. They tolerate the numerous modifications, maintain high-binding affinity, and efficaciously stimulate AC in a PTH-like manner, in the case of agonists, or effectively block agonist-stimulated AC, in the case of antagonists. The photoinsertion site of the benzophenone moiety is dictated by spatial proximity between the photophore and the potential insertion sites and their correct spatial disposition. However, it is also biased toward the more reactive insertion sites within its reactivity sphere. Finally, both the cleavages employed and the level of resolution allowed by SDS-PAGE limit photoconjugate analysis. In this respect, there is ample room for technological enhancements that will include epitope tagging, affinity purification, sequencing, and mass spectroscopic analysis. Validation of a putative contact site by site-directed mutagenesis is not necessarily benign. It generates some degree of perturbation, which we accept as long as the mutated receptor is expressed and functions similarly to the wild-type. Taken together, PAS is not the perfect method, but we believe it is the best available.

Experimentally Based Molecular Modeling

It is safe to assume that contact sites identified by the cross-linking studies described earlier are only a small fraction of the large ensemble that forms the bimolecular interface. It is also possible that not all contact sites revealed by PAS methodology will have the same functional significance. Nevertheless, all these contact sites will be part of the ligand–receptor interface and are therefore indispensable targets in mapping efforts. The ultimate objective of PAS studies is to generate a series of bimolecular structural constraints, which will be used in mapping the bimolecular interface. To this end, merging the information generated by PAS studies with information about the conformations of the ligand and receptor domains, as well as molecular modeling, is an integrated approach that results in an experimentally based ligand–receptor model. It contrasts with the more common approaches that predict conformation and molecular models solely on a theoretical basis.

The model for the PTH–PTH1-Rc complex is steadily evolving as new bimolecular contact sites are identified and additional conformational data on receptor domains are generated (Bisello *et al.,* 1998; Piserchio *et al.,* 2000a; Rolz *et al.,* 1999). Combining hydrophobicity profile analysis with a search of the Brookhaven Protein Data Bank (PDB) employing the Basic Logic Alignment Search Tool (BLAST) first identifies and then refines the location of the TM helices (Altschul *et al.,* 1990; Kyte and Doolittle, 1982). Identification of the TM domains of the PTH1-Rc is in good agreement with respect to those identified in peptides containing TM helical regions as determined by high-resolution NMR in micellar system (Mierke *et al.,* 1996; Pellegrini *et al.,* 1997b, 1998b). Arrangements of the TM heptahelical bundle in rhodopsin and bacteriorhodopsin (Grigorieff *et al.,* 1996; Henderson *et al.,* 1990; Pebay-Peyroula *et al.,* 1997; Schertler *et al.,* 1993; Schertler and Hargrave, 1995) were used as templates for the initial arrangement of the putative TM helical domains of the PTH-Rc and optimized to account for hydrophobic moment toward the membrane environment, helix–helix, helix–core, and helix–membrane interactions (Pellegrini *et al.,* 1997b).

Unlike the high structural similarity in the arrangement of the heptahelical TM domains bundle (Baldwin, 1993), the cytoplasmic and ectopic domains of GPCRs are extensively variable and no *a priori* structural model is available. The loops are constrained to some extent by the TM helical domains to which they are attached. Additional constraints are imposed by the three disulfide bridges at the extracellular N terminus (Grauschopf *et al.,* 2000) and the disulfide bridge connecting the first and second ECL. All of these cysteines are highly conserved in the class II GPCRs of which PTH1-Rc is a member. Therefore, constructing a good model for the ligand–ectopic/juxtamembrane bimolecular interface is a much more complicated endeavor.

A homology search with BLAST (Altschul *et al.,* 1990) has identified the conformational preferences of the C-terminal portion of the N-ECD proximal to TM1 of

PTH1- and PTH2-Rcs and ECL3 of PTH1-Rc (Bisello *et al.,* 1998; Rolz *et al.,* 1999). These homology searches suggest that the ECL3 adopts a helical conformations at T^{435}-Y^{443} (Rolz *et al.,* 1999) and that the juxtamembrane portion of N-ECD in PTH1-Rc and PTH2-Rc contains amphiphatic helices K^{172}-M^{189} and L^{129}-E^{139}, respectively (Bisello *et al.,* 1998; Rolz *et al.,* 1999). Unfortunately, such homology searches may not always result in the assignment of a distinct secondary structure to a specific receptor sequence.

Mierke and Pellegrini (1999) modeled the receptor and receptor–ligand complex in a H_2O/decane/H_2O (40 Å each) simulation cell that mimics the membrane milieu. The molecular simulation is carried out in multiple steps in which the heptahelical bundle and/or the cytoplasmic and extracellular domains are allowed to move freely. PTH, in its membrane-associated conformation, is then added to the receptor model, applying the ligand/receptor distance constraints derived from the cross-linking experiments, and additional simulations are carried out. At this stage, additional constraints obtained via site-directed mutagenesis and chimera receptor studies can be incorporated to enhance the modeling procedure.

The most direct way to identify conformational features of the cytoplasmic and ectopic domains of the GPCR is by generating these receptor fragments and examining them by NMR in a membrane mimetic system. Adding small portions of the corresponding TM(s) to the otherwise flexible receptor-derived termini or loops provides an anchor(s) that partially reproduces the native orientation of the receptor domain relative to the membrane-mimicking milieu. Another design element useful in restraining an excised loop sequence from assuming extended conformations is the covalent binding of both ends of the sequence by a linker of ~12 Å that approximate the distance between two consecutive TM domains (Schertler *et al.,* 1993; Schertler and Hargrave, 1995).

Mierke and co-workers have characterized the conformational features of the following PTH1-Rc domains: the third intracellular loop (ICL3), the C-terminal juxtamembrane portion of the N-ECD, and the ECL3 (Bisello *et al.,* 1998; Mierke *et al.,* 1996; Pellegrini *et al.,* 1997; Piserchio *et al.,* 2000a). These peptides were studied in a micellar system that mimics the cellular membrane and generates a micelle–water interface resembling the membrane–water interface. ICL3 was constructed as a 29 amino acid peptide with Cys residues in positions 1 and 28 (Pellegrini *et al.,* 1997b). Side chains of the two cysteines were bridged by an octamethylene linker to maintain the putative ~12-Å distance between two consecutive TM domains. Analysis of this constrained peptide revealed interesting conformational features that allow insight into ICL3–G protein interactions (Pellegrini *et al.,* 1997b).

More relevant to the ligand–receptor bimolecular interactions are analyses of the two ectopic domains that photocross-link to Lys^{13} and Lys^{27} in PTH-(1-34) (Adams *et al.,* 1998; Bisello *et al.,* 1998; Greenberg *et al.,* 2000). The sequence PTH1-Rc[172-189], which contains the 8 amino acid domain 182-189 identified as a contact site for position 13 in PTH (Adams *et al.,* 1998; Zhou *et al.,* 1997), was subjected to a combination of homology search and molecular dynamic calculations using a two-phase simulation cell consisting of H_2O and CCl_4 to mimic a membrane–water interface (Bisello *et al.,* 1998; Pellegrini *et al.,* 1998a). These analyses suggest that the segment R^{179}-E-R-E-V-F-D-R-L-G-M^{189} forms an amphipathic α helix whose axis is parallel to the membrane surface and points away from the heptahelical bundle (Fig. 7, see also color plate) (Bisello *et al.,* 1998; Pellegrini *et al.,* 1998a). ^{1}H-NMR analysis of the synthetic peptide hPTH1-Rc-[168-198] in the presence of micelles was carried out in combination

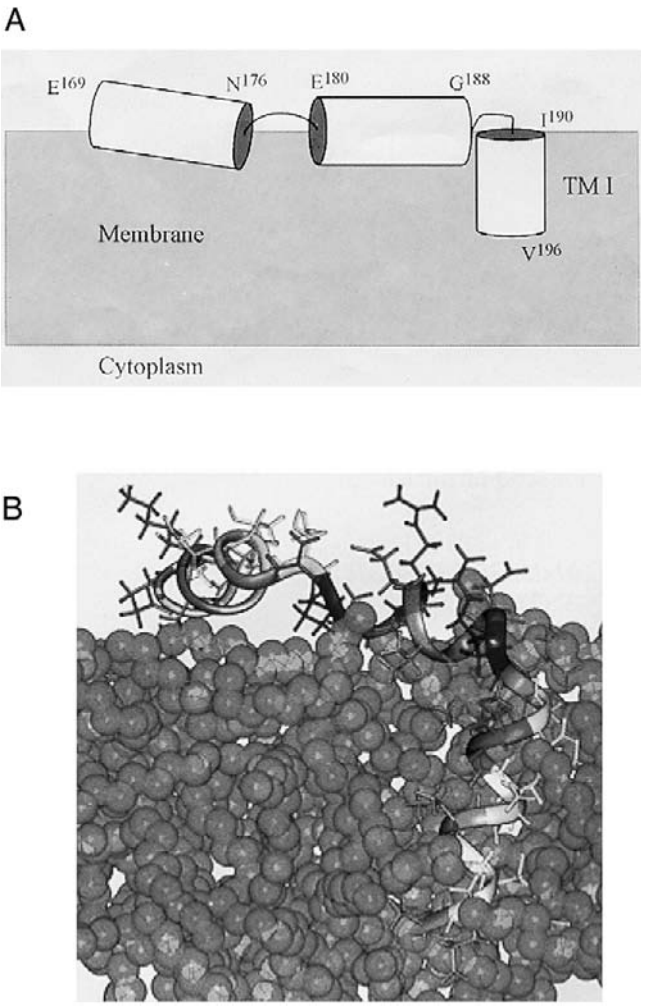

Figure 7 Structural features and topological orientation of PTH1-Rc[168-198], which consists of the juxtamembrane portion of N-ECD and the ectopic portion of TM1 (Pellegrini *et al.,* 1998a). (A) Schematic presentation of the experimentally determined conformation, which consists of three α helices, two of which have been determined to lie on the surface of the membrane; the third, at the top of TM1, is membrane embedded. (B) Molecular simulation of this peptide in a water/decane simulation cell used to refine the structure obtained in the presence of dodecylphosphocholine (DPC) micelles used in the NMR study. Decane molecules are shown in green as CPK space-filling spheres. The peptide molecule is colored according to hydrophobicity (blue, polar; red, hydrophobic). (See also color plate.)

with distance geometry and molecular dynamic simulation (Pellegrini *et al.,* 1998a). The analysis identifies three helical segments: 169-176, 180-188, and 190-196. The C-terminal helix, hPTH1-Rc[190-196], corresponding to the ectopic portion of the first TM helix, is hydrophobic and embeds perpendicularly into the micelle. The other two α helices, [180-188] and [169-176], lie on the membrane surface (Fig. 7). Polar residues in the linker, E^{177} and R^{179}, and in the middle helix, R^{181}, E^{182}, D^{185}, and R^{186}, are exposed to the solvent, whereas the hydrophobic residues, F^{173}, F^{184}, and L^{187}, project toward the hydrophobic membrane (Pellegrini *et al.,* 1998a). It is plausible that the positively charged Lys^{13} in PTH participates in stabilizing the Coulombic interaction with the negatively charged E^{182} and D^{185} located at the solvent-exposed hydrophilic phase of the receptor sequence. Nevertheless, this may not be an essential interaction, as analogs in which the ε amino on Lys^{13} is blocked by acylation maintain high affinity and efficacy. Point mutations replacing negatively charged amino acids with neutral or positively charged ones will help assess this putative interaction further.

Combining the putative TM bundle obtained in the modeling studies with the experimentally derived conformation of the synthetic hPTH1-Rc-[168-198] establishes a partial PTH1-Rc model that can be used to dock hPTH-(1-34) in its experimentally derived putative bioactive conformation (Pellegrini *et al.,* 1998b). This "on silicon" experiment results in the first generation of an experimentally based model of the PTH-hPTH1-Rc complex (Fig. 8, see also color plate) (Bisello *et al.,* 1998). Using cross-linking data as a docking cue places the C-terminal amphiphilic helix of the legand parallel to the membrane-aligned portion of the receptor-derived peptide. This positioning allows the formation of complementary Coulombic interactions between the polar residues in the C-terminal helix, comprising the principal binding domain of the ligand and the polar residues E^{177}, R^{179}, R^{181}, E^{182}, D^{185}, and R^{186} in the receptor-derived peptide. Interestingly, this docking procedure brings only M^{425}, and not M^{414}, into sufficient proximity to permit cross-linking to position 1 in PTH. Therefore, these observations are in complete agreement with the results obtained through cross-linking studies (Bisello *et al.,* 1998).

The contact site between position 27 in PTH and L^{261} in the ECL1 of PTH1-Rc (Greenberg *et al.,* 2000) offers another target for structural studies (Piserchio *et al.,* 2000a). The synthetic peptide hPTH1-Rc[241-285], composed of ECL1 and a few residues from the ectopic portions of TM2 and TM3 at the N and C termini of the loop, respectively, was subjected to detailed conformational analysis. These studies included high-resolution NMR in the presence of dodecylphosphocholine micelles followed by distance geometry calculations and molecular dynamic simulations. Piserchio and co-workers found that this receptor fragment contained three α-helical segments: [241-244], [256-264], and [275-284] (Fig. 9, see also color plate) (Piserchio *et al.,* 2000a). The first and last helices correspond to the ectopic portions of TM2 and TM3, respectively. Hydrophobic amino acids corresponding to the ectopic portion of the TMs are more strongly associated with the lipid micelle and may serve as membranal anchors. Moreover, all of the hydrophobic residues in the partially ordered central helical portion (terminated by the unique helix-breaking sequence P^{258}-P-P-P^{261}) project toward the lipid surface (Piserchio *et al.,* 2000a).

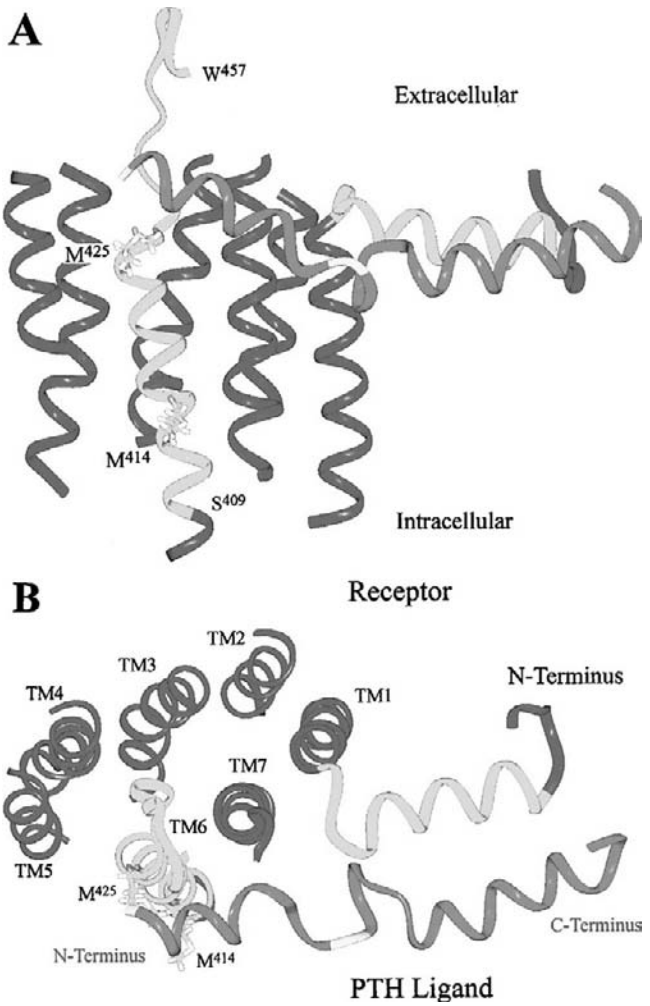

Figure 8 First generation of an experimentally based model of PTH–hPTH1-Rc complex. For clarity, only portions of the TM helices, N terminus, and the third extracellular loop are shown in *blue* (noncross-linked domains) and green (contact domains hPTH1-Rc[173-189] and hPTH1-Rc[409-437]) (A, side view; B, top view). The amphipathic α helix of the extracellular N terminus of the receptor is projecting to the *right*, lying on the surface of the membrane. The high-resolution, low-energy structure of hPTH-(1-34) determined by NMR in a micellar environment is presented in *pink*. Residues in cross-linking positions 1 and 13 of hPTH-(1-34) are denoted in *yellow*. The C-terminal amphipatic α helix of hPTH-(1-34) is aligned in antiparallel arrangement with the amphipatic α helix of the extracellular N terminus hPTH1-Rc[173-189]), contiguous with TM1 and encompassing the 17 amino acid contact domain (in *green*) to optimize hydrophilic interactions. Side chains of residue M^{414} and M^{425} within the "contact domain" comprised of TM6 and the third extracellular loop (hPTH1-Rc[S^{409}-W^{437}]) are shown (Bisello *et al.,* 1998). (See also color plate.)

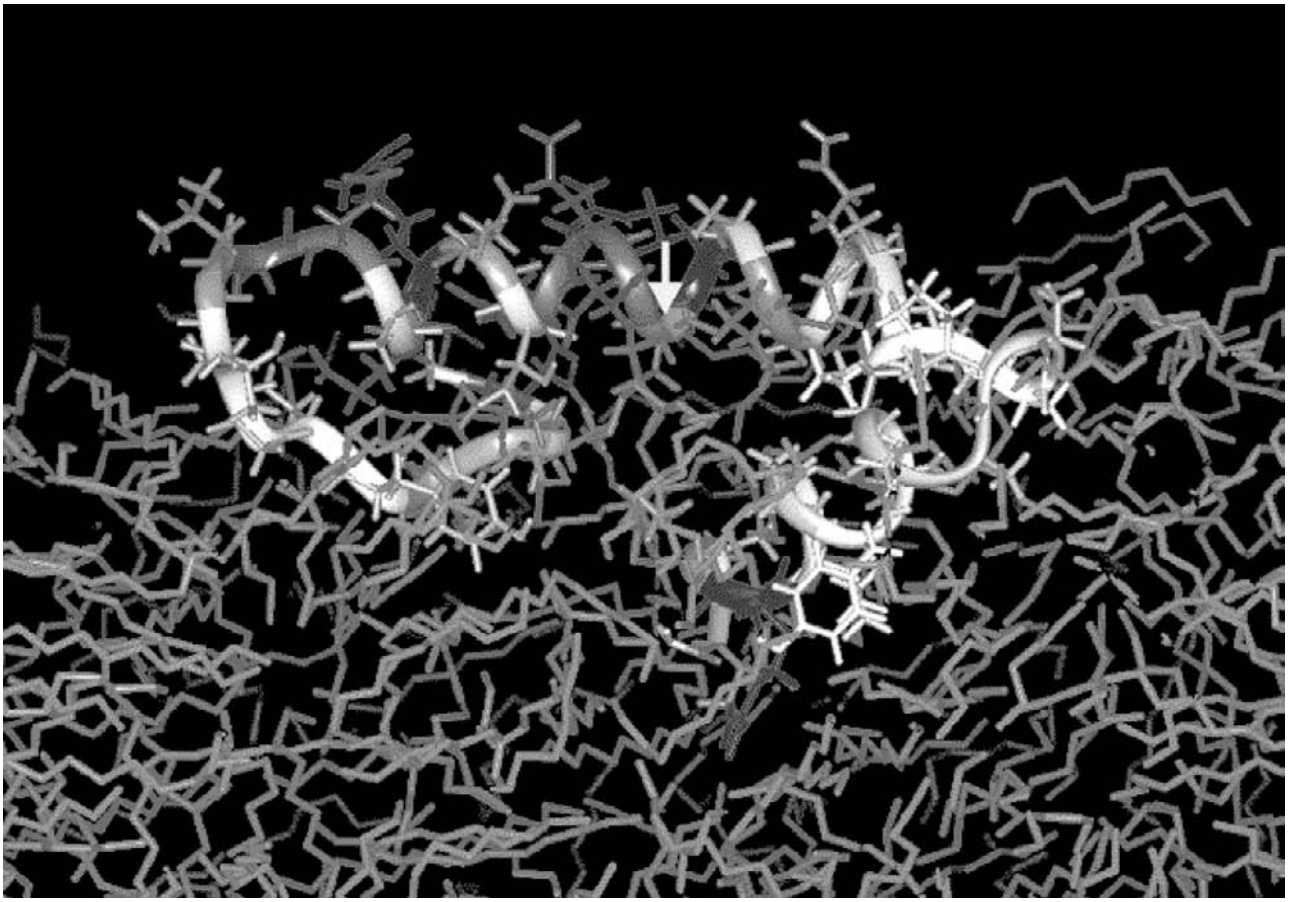

Figure 9 Structure of PTH1-Rc(241-285) comprising the ECL1 from the molecular dynamics simulation in a water/decane simulation cell. Peptide residues are colored according to side chain hydrophobicity (blue, polar; red, hydrophobic). Decane molecules are depicted in green; water molecules are not displayed for clarity. Residues belonging to TM2 and TM3 are embedded into the decane phase. The yellow arrow indicates the location of L^{261}, the cross-linking site to Lys^{27} in PTH-(1-34) (Piserchio *et al.,* 2000a). (See also color plate.)

The emerging structure of ECL1 is very helpful in understanding the bimolecular ligand–receptor interaction revealed by cross-linking studies. It suggests an antiparallel organization of the two amphiphilic helices: the C-terminal helix in PTH, which includes the photophore carrier, Lys^{27}, and the [256-264] helical portion in ECL1, containing the contact site L^{261} (Pellegrini *et al.,* 1998b). The two helices are oriented with their hydrophobic faces interfacing the membrane and their polar faces exposed to the solvent and are capable of forming numerous intermolecular interactions. Integrating these additional findings into the PTH–PTH1-Rc model results in the enhancement and refinement of the overall bimolecular topology. It defines more unambiguously the position of the C-terminal helix of PTH. This helix is now placed between the ECL1 and the C-terminal juxtamembrane helix of the N-ECD of hPTH1-Rc (Fig. 10). The topological organization of the receptor is consistent now not only with the individual bimolecular contact sites between position 1, 13, and 27 in PTH and the respective sites in PTH1-Rc (namely M^{425}, a site in the proximity of R^{186}, and L^{261}), but also accommodates the contact site between position 23 in PTHrP and Y^{23}-L^{40} in PTH1-Rc.

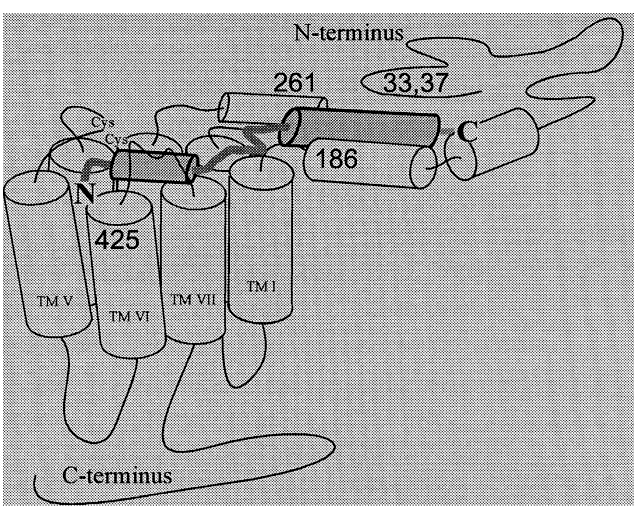

Figure 10 Topological organization of the PTH–PTH1-Rc complex. Schematics are the results of conformational analysis of ligand and receptor domains, contact sites as revealed by photoaffinity, cross-linking studies, and molecular modeling. The location of contact sites in PTH1-Rc derived from PAS studies is indicated (Ser^{1}–M425; Lys^{13}–R186; Trp^{23}–T33/Q37; Lys^{27}–L261). Helical domains in the receptor and ligand are presented as cylinders (Piserchio *et al.,* 2000a).

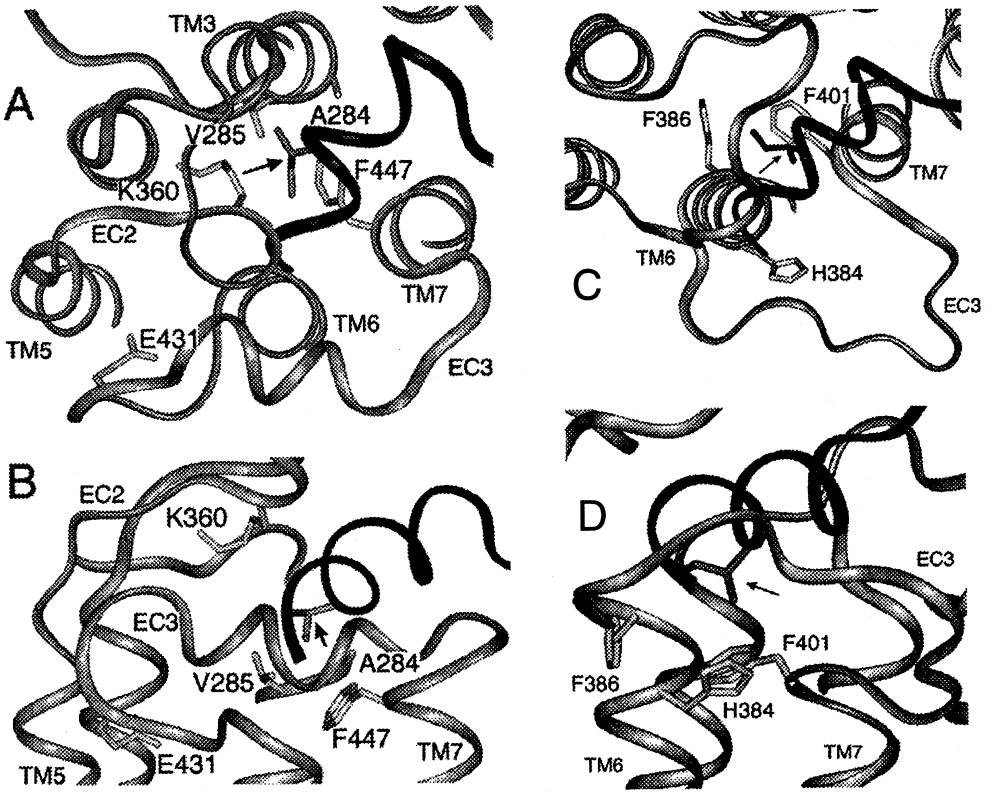

Figure 11 Illustration of the binding pocket for Ile^5 of PTH in PTH1- and PTH2-Rc (Rolz *et al.,* 1999). In PTH1-Rc Ile^5, the side chain (indicated by black arrow) is accommodated in a hydrophobic pocket made up of the ectopic portions of TM3 (A^{284} and V^{285}) and TM7 (F^{447}). Top (A) and side (B) views of this pocket in PTH1-Rc. The receptor and the ligand are depicted as ribbons in gray and black, respectively. In PTH2-Rc, the binding pocket for residue 5 in the ligand is more limited in size compared to the same pocket in PTH1-Rc due to the presence of F^{386} and F^{401} in the ectopic portions of TM6 and TM7, respectively. Top (C) and side (D) views of this pocket in PTH2-Rc. In addition, in PTH1-Rc the presence of E^{432} at the ectopic portion of TM6, in the entrance to the binding pocket of His^5, can attract His^5 by favorable Coulombic interaction. However, in PTH2-Rc the presence of H^{384}, at the bottom of the binding pocket for residue 5, will destabilize the interaction with an incoming side chain of His^5-containing ligand.

Rölz and co-workers studied in detail the emerging experimentally derived model complexes (Adams *et al.,* 1998; Bisello *et al.,* 1998; Zhou *et al.,* 1997) between PTH/PTHrP ligands and PTH1- and PTH2-Rc to identify interresidue contacts within the heptahelical TMs (Rolz *et al.,* 1999). They are able to offer insights that can explain ligand specificity (Behar *et al.,* 1996a; Gardella *et al.,* 1996a), the consequences of some site-directed mutations (Bergwitz *et al.,* 1997; Clark *et al.,* 1998; Gardella *et al.,* 1996b; Lee *et al.,* 1995a; Turner *et al.,* 1998), the constitutive activity of JCM-mutated receptors (Schipani *et al.,* 1995, 1997), the consequences of cross-linking studies (Bisello *et al.,* 1998), some structure–activity relations in the ligand (Cohen *et al.,* 1991; Rosenblatt *et al.,* 1976), and some aspects of signal transduction. For example, there is a loss of affinity for PTH-(1-34) following mutations W437A/L/E or Q440A/L in PTH1-Rc, an effect much reduced for PTH-(3-34) (Lee *et al.,* 1995a). The model positions both Q^{440} and W^{437} on the same face of ECL3, both projecting toward the center of the TM bundle (Rolz *et al.,* 1999). The side chains of these residues participate in forming the hydrophobic pocket that accommodates Val^2 in the ligand, providing stabilizing interactions by shielding it from the extracellular aqueous environment. Mutating Q^{440} and/or W^{437} to any smaller or a more polar residue will compromise the binding pocket for Val^2 by exposing it to water. The model also attempts to explain position 5 in PTH and PTHrP as a receptor-subtype specificity switch (Behar *et al.,* 1996a; Gardella *et al.,* 1996a). It suggests that in PTH1-Rc, the Ile^5 side chain is accommodated by a hydrophobic pocket. The bottom of this pocket is composed of hydrophobic residues at the ectopic end of TM3 (A^{284} and V^{285}) and TM7 (F^{447}), and it is large enough to accommodate either Ile^5 or His^5 (Fig. 11). In PTH2-Rc, due to the presence of F^{386} and F^{401} located at the ectopic ends of TMs 6 and 7, respectively, the binding pocket for residue 5 is reduced in size compared to the same pocket in PTH1-Rc. Therefore, the smaller pocket in PTH2-Rc cannot accommodate His^5-containing PTHrP or hybrid ligands and discriminates against them (Fig. 11) (Rolz *et al.,* 1999). These authors also encourage the use of their model as a tool for predicting the pharmacological consequences of

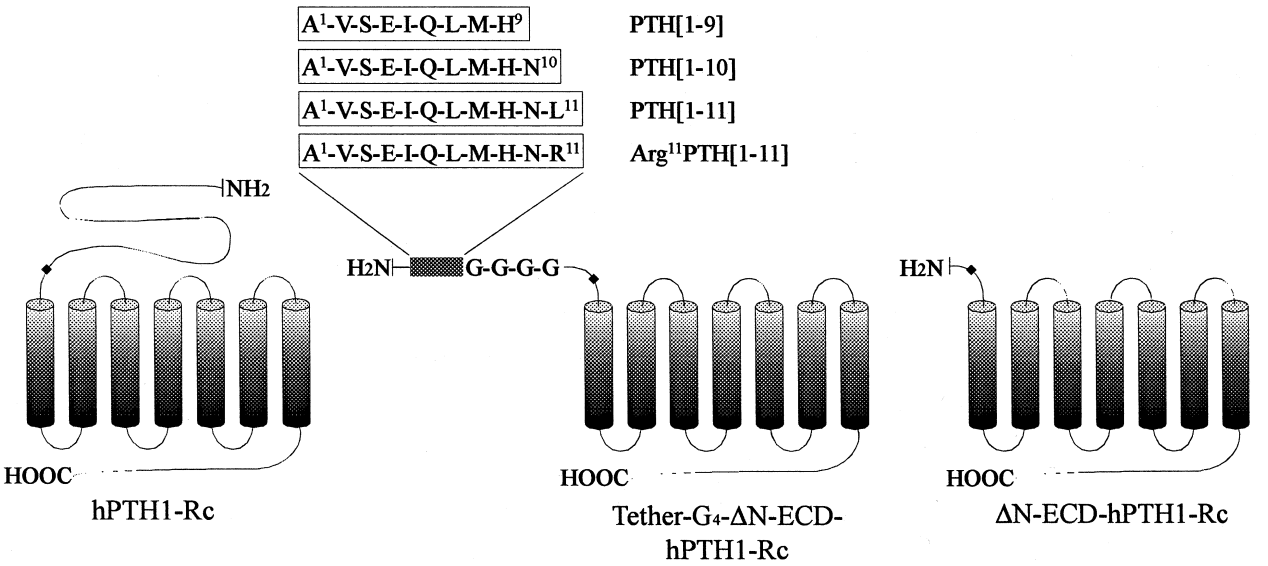

Figure 12 Design of ligand-tethered hPTH1-Rc. Schematics include the wild-type hPTH1-Rc on the left; N-ECD-truncated hPTH1-Rc (ΔN-ECD-hPTH1-Rc) on the right, and the tethered G_4-ΔN-ECD-hPTH1-Rc in the middle. Also listed are the different sequences derived from the N-terminal of PTH that are tethered to E^{182} (solid diamond) via a tetraglycine (G_4) spacer. All the recombinant receptors retain the 23 amino acid residues that form the signal sequence in the native receptor. Therefore, the putative N-terminal residue in all the receptors is Y^{23} generated upon cleavage by signal peptidase. The figure was modified from Shimizu and co-workers (2000a).

specific mutations such as receptor-subtype specificity-reversing mutations.

Ligand-Tethered hPTH1-Rc

Shimizu and coworkers (2000a) reported, what seems to be the absolute integration of ligand and receptor entities. Borrowing from the protease-activated thrombine receptor system (Kawabata and Kuroda, 2000), they generated constitutively active, ligand-tethered hPTH1-Rc (Shimizu *et al.,* 2000a). The elements they use in the construction of the ligand-tethered hPTH1-Rc are the following (Fig. 12): 1) a peptide as small as PTH-(1-14) that can stimulate weak cAMP formation with both wild-type and N-ECD-truncated rPTH1-Rc, rΔNt (Luck *et al.,* 1999); (2) residues 1-9 in PTH-(1-14), critical for interacting with the rΔNt (Luck *et al.,* 1999); (3) position 13 in PTH, which photocross-links to PTH1-Rc in the proximity of R186 (Adams *et al.,* 1995; Zhou *et al.,* 1997); and (4) the hydrophobic residues F^{184} and L^{187} in PTH1-Rc, which are functionally important for the interaction with the 3-14 portion of PTH-(1-34) (Carter *et al.,* 1999b). In this ligand-tethered hPTH1-Rc, N-ECD was truncated from E^{182}, which is juxtaposed to the TM1 (designated as ΔN-ECD-hPTH1-Rc). This truncated receptor was extended by a Gly_4 spacer (G_4-ΔN-ECD-hPTH1-Rc) and linked to N-terminal fragments of PTH. These fragments very in size from 9 to 11 residues (Shimizu *et al.,* 2000a).

Transient expression of the ligand-tethered receptor PTH-(1-9)-G_4-ΔN-ECD-hPTH1-Rc in COS-7 cells resulted in 10-fold higher basal cAMP levels compared to the wild-type hPTH1-Rc control. Tethering the extended and more potent [Arg^{11}]PTH-(1-11) resulted in 50-fold higher basal c-AMP levels than those seen with the wild-type hPTH1-Rc. Interestingly, like in PTH-(1-14) (Luck *et al.,* 1999), where Val^2, Ile^5, and Met^8 are the most critical residues for activation, these residues were also the most critical ones for the constitutive activity of the [Arg^{11}]PTH-(1-11)-G_4-ΔN-ECD-hPTH1-Rc (Shimizu *et al.,* 2000a).

The elegance of this study lies in devising a unique way to specifically "immobilize" the principal activation domain of the ligand in the proximity of the contact sites critical for receptor activation. Correspondence between the efficacy-enhancing substitutions in PTH-(1-11) and the tethered peptide supports the notion that both exercise the same interactions with the receptor that lead to receptor activation. The high effective molarity of the tethered ligand minimizes the role of binding affinity in bimolecular interactions compared to free ligand, thus allowing the identification of residues within the tethered ligand essential for induction of activity. However, the accessibility to the ligand tethered–receptor system requires the employment of molecular biology and therefore it is most applicable to tethered ligands composed of coded amino acids. In addition, stringent requirements for the efficient expression of tethered ligand–receptors in a relevant cellular background may turn out to be major obstacles in practicing and extending this approach in the future. It remains to be demonstrated whether the tethered ligand–receptor system is a source for identifying structural constraints that can contribute to the refinement of the experimentally based ligand–receptor model and to rational drug design. The elimination of most of the entropic component from the ligand–receptor interaction may generate contact interactions

and produce activation mechanisms that differ from those involved in the interaction with a diffusible ligand.

The quality of any model, namely its capacity to realistically represent ligand–receptor interactions and predict the nature of the interface, is based primarily on data and procedures used in its construction. A model can become highly speculative and thus only remotely relevant to biology if overloaded with data derived from indirect and circumstantial observations. It is important to avoid over interpretation of any model and remember the assumptions and approximations used in its construction. Finally, any extrapolation derived from any model must be tested in order to validate its predictive potential. In summary, the evaluation of any model of the ligand–receptor complex in the PTH/PTHrP system should follow the principles mentioned earlier.

Ligand–Receptor "Two-Site" Dynamic Model An Emerging Paradigm

The study of PTH/PTHrP–PTH1-Rc interactions has arrived to a very exciting stage in which several lines of evidence converged to allow understand ligand–receptor interaction at a much more detailed level. Moreover, the integrated and multidisciplinary approach to ligand–receptor studies in the PTH field turned to be synergistic in nature. A study by Hoare and co-workers (2001) brought together several key observations to suggest that ligand–PTH1-Rc interactions can be described by a "two-site" dynamic model (Fig. 13).

The foundation for this model was put down by numerous observations. Like several other class II GPCRs (Beyermann *et al.,* 2000; Holtmann *et al.,* 1995; Juarranz *et al.,* 1999; Stroop *et al.,* 1995), PTH1-RC can be devided into two functional domains: the large N-ECD (N domain) has been proposed to provide most of the principal binding interactions with the ligand (Bergwitz *et al.,* 1996; Juppner *et al.,* 1994) and the rest of the receptor, which includes the ECLs, TMs, and the ICLs designated as the juxtamembrane domain (J domain). Interactions of the ligand with this domain lead to activation and signal transduction (Bergwitz *et al.,* 1996; Gardella *et al.,* 1994; Juppner *et al.,* 1994; Turner *et al.,* 1996). A similar two functional domain architecture is also found in the ligands, PTH and PTHrP; the 15-34 sequence includes the principal binding domain (Caulfield *et al.,* 1990; Rosenblatt *et al.,* 1980), and the 1-14 sequence includes the activation domain for intracellular signaling through AC (Bergwitz *et al.,* 1996; Gardella *et al.,* 1991; Luck *et al.,* 1999; Shimizu *et al.,* 2000a,b; Takasu *et al.,* 1999a) and PKC (Takasu *et al.,* 1999a). Mutational analyses of the PTH1-Rc and analyses of PTH/PTHrP–PTH1-Rc photoconjugates revealed potential contact sites and spatial proximity between specific amino acid residues of the ligand and the receptor. Structural analyses of ligand and receptor domains, together with computer modeling, generated for the first time experimentally based models of the PTH–PTH1-Rc complex with atomic details.

In the "two-site" model of PTH/PTHrP–PTH1-Rc the C-terminal portion of PTH or PTHrP interacts with the N domain of the receptor and the N-terminal sequence of the ligand binds to the J-domain of the receptor (Bisello *et al.,* 1998; Juppner *et al.,* 1994; Luck *et al.,* 1999; Mannstadt *et al.,* 1999). Nevertheless, this model does not account for the dynamic nature of receptor conformation moving between G protein-coupled (GR) and -uncoupled (R) conformational states and its effect on the mechanism of ligand binding.

Hoare and co-workers (2001) reported that [$Ala^{3,10,12}$, Arg^{11}] rPTH-(1-14)NH_2 [PTH-(1-14)] and PTH-(3-34) bind

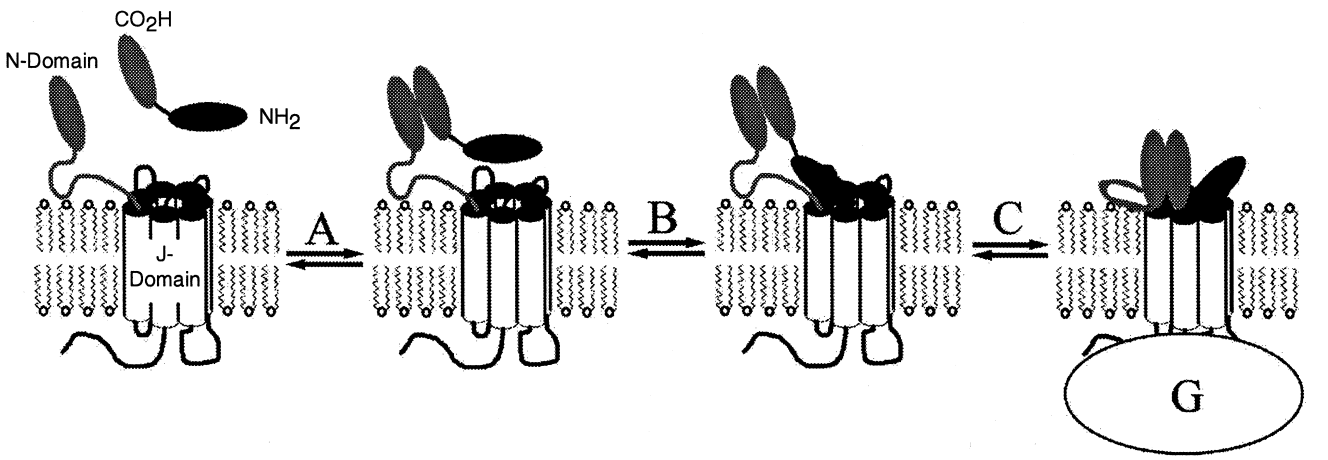

Figure 13 Model for modulation of PTH-(1-34) binding to the PTH1-Rc by the G protein. (A) The C-terminal portion of the ligand interacts with the N domain of the receptor. Subsequently, the N-terminal portion of the ligand binds to the J domain of the receptor (B). (C) Interaction of the receptor with the G protein forms RG, increasing the affinity to the J domain, possibly by producing a closure of receptor conformation. Reciprocally, interaction of the ligand with the J domain increases the affinity of receptor for the G protein, leading to its activation. Binding of the G protein to the other states of the receptor (the unoccupied and the one interacting only with the N-terminal portion of the ligand) has been omitted for clarity (Hoare *et al.,* 2001).

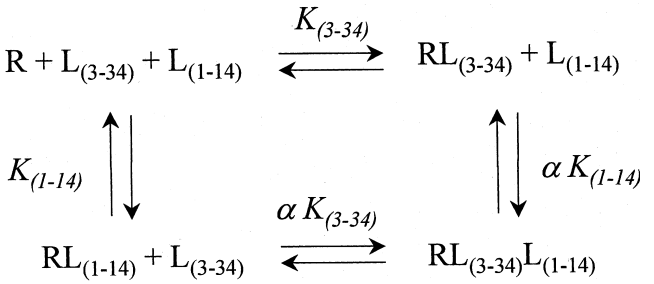

Figure 14 Model for simultaneous binding of ^{125}I-PTH-(3-34) and PTH-(1-14) to PTH1-Rc, where R is the receptor; $L_{(3\text{-}34)}$ is ^{125}I-PTH-(3-34); $L_{(1\text{-}14)}$ is PTH-(1-14); $K_{(3\text{-}34)}$ is the equilibrium association constant for ^{125}I-PTH-(3-34); $K_{(1\text{-}14)}$ is the equilibrium association constant for PTH-(1-14); and α is the cooperativity factor defining the effect of $L_{(1\text{-}14)}$ occupancy on the receptor-binding affinity of $L_{(3\text{-}34)}$ and reciprocally the effect of $L_{(3\text{-}34)}$ occupancy on the receptor-binding affinity of $L_{(1\text{-}14)}$ (Hoare *et al.,* 2001).

to two spatially distinct sites in PTH1-Rc (Fig. 14): the former binds selectively to RG, predominantly through the J domain, and only partially inhibits ^{125}I-PTH-(3-34) binding, and the latter binds predominantly to the N domain, is $GTP_{\gamma}S$ insensitive, and only partially inhibits PTH-(1-14)-stimulated AC activity. The higher binding affinity of agonist ligands to RG vs the R state of the receptor implies different conformations of the receptor in both states. At the uncoupled state, PTH-(1-14) and the PTH-(3-34) bind almost independently of each other. However, the negative cooperativity between the binding of ^{125}I-PTH-(3-34) and PTH-(1-14) is significantly greater in the RG state than in the uncoupled one. Moreover, agonist binding to the RG state is pseudo-irreversible. PTH-(3-34) inhibits PTH-(1-14)-stimulated cAMP accumulation, increases EC_{50} by 18-fold, and reduces E_{max} in a noncompetitive manner.

Taken together, these observations suggest that the receptor is in a "open" conformation in the uncoupled state, permitting simultaneous binding of both PTH-(3-34), the N domain interacting ligand, and PTH-(1-14), the J domain interacting ligand. At the coupled state, for which agonist has higher affinity than for the uncoupled state, the receptor is in a more "closed" conformation, preventing simultaneous access of both ligands to their preferred binding sites and trapping the ligand within the coupled receptor.

This study offers new and interesting insights on the mechanism of PTH–PTH1-Rc interaction. Although it does not offer structural details for the dynamic process, it does provide some new concepts that will stimulate additional studies to validate and refine the emerging model.

Future Directions

Our current understanding of bimolecular PTH/PTHrP–PTH1-Rc interactions at the atomic level and the events that follow receptor occupancy and receptor activation is still incomplete. Discovery of new PTH receptor subtypes and new endogenous ligands has provided new opportunities for understanding structure–function relations. When sufficiently advanced, the experimentally based models of the bimolecular ligand–receptor interface will allow us not only to understand the pharmacological profiles of PTH- and PTHrP-derived ligands better, but also serve as a molecular template for rational drug design to develop more selective and more efficacious hormone-derived and hormone mimetic drugs. This model will also provide the means for understanding aberrant mechanisms underlying pathological mutations of PTH1-Rc that lead to clinical disorders such as JMC and BLC.

The lack of a truly bone anabolic drug to complement the currently available arsenal of anti resorptive drugs for osteoporosis is highly noticeable. One area of research that has grown steadily in interest over the last decade is the potential utility of PTH- or PTHrP-derived agonists for the treatment of osteoporosis (Goltzman, 1999). It is very well established that low-dose, intermittent administration of several forms of PTH stimulates bone formation, leading to an overall anabolic effect on bone (Howard *et al.,* 1981; Tam *et al.,* 1982). Further observations have been made in animals and in human studies (Hock *et al.,* 1988; Hodsman and Fraher, 1990; Reeve *et al.,* 1990; Slovik *et al.,* 1986; Tada *et al.,* 1990; Tsai *et al.,* 1989; Wronski *et al.,* 1993). This beneficial effect on bone occurs despite the well-documented action of PTH in stimulating bone resorption via increased osteoclast number and activity. Nevertheless, instigating osteoblastic bone formation without concomitant activation of osteoclasts and resultant bone resorption remains an ultimate goal for the treatment of osteoporosis. To this end, future focus on the development of signaling-selective PTH or PTHrP analogs is one of the more promising directions for analog design.

The ongoing quest to identify the common molecular target for all bone anabolic agents and treatments may turn out to be either a very ambitious objective or a completely elusive one. However, based on current knowledge, dissection of PTH-induced signaling pathways to identify the anabolic one seems to be a more plausible and attainable goal. Nevertheless, discordance between binding affinity and signaling efficacy *in vitro* on the one hand and the predictive potential of these *in vitro* parameters for anabolic activity *in vivo* (Frolik *et al.,* 1999) on the other are puzzling. We anticipate that better understanding of the mechanism of PTH ligand–receptor interactions will provide the answers and guide the development of novel, potent, safe, and compliance-friendly bone anabolic drugs. Important subjects for future studies include characterizing the conformational changes in the PTH1-Rc induced by interaction with ligands of different pharmacological traits, elucidating the mechanisms involved in receptor coupling to the various G proteins, identifying and understanding the role of interactions of different adapter molecules participating in the signaling cascades, identifying and assigning function to the different PTH-induced signaling pathways and downstream effects that regulate gene expression and protein synthesis, and understanding the mechanism of receptor desensitization/

internalization and recycling, and their roles in PTH-induced activities *in vitro* and *in vivo.* Given the probability of substantial progress in many of the frontiers just listed, PTH or PTHrP agonists are likely to find clinical utility in the treatment of disorders of calcium and bone metabolism.

Parathyroid hormone is essential for the maintenance of calcium homeostasis through direct actions on its principal target organs, bone and kidney, and through indirect actions on the gastrointestinal tract. Parathyroid hormone acts directly on the skeleton to promote calcium release from bone and on the kidney to enhance calcium reabsorption. The indirect effects of parathyroid hormone on the gastrointestinal tract lead to greater calcium absorption through its actions to facilitate the conversion of 25-hydroxyvitamin D to 1,25-dihydroxyvitamin D. Actions of parathyroid hormone at these three sites, the kidney, the skeleton, and the gastrointestinal tract, result in restoration of the extracellular calcium concentration. When the hypocalcemic signal for parathyroid hormone release returns to normal, calcium ion continues to regulate the release of parathyroid hormone. In the setting of a hypercalcemic signal, not due to abnormal secretion of parathyroid hormone (i.e., primary hyperparathyroidism), parathyroid hormone secretion is inhibited. The resulting physiological events associated with reduced concentrations of parathyroid hormone lead to reduced calcium mobilization from bone, a reduction in renal tubular reabsorption of calcium, and, by virtue of reducing the conversion of 25-hydroxyvitamin D to 1,25-dihydroxyvitamin D, to reduced absorption of dietary calcium. Hence in hypercalcemic states, control of parathyroid hormone secretion by calcium reduces serum calcium levels.

Parathyroid hormone helps to regulate phosphorus metabolism. An increase in phosphorus leads to a reduction in the circulating calcium concentration. The resultant increase in parathyroid hormone leads to phosphaturia, a classical physiological effect of the hormone and restoration of the serum phosphorus concentration (see Chapter 20).

Cellular responsiveness to parathyroid hormone occurs via receptor-mediated activation of intracellular events and several major biochemical pathways. Details of the initial steps by which a change in extracellular calcium is sensed by the parathyroid cell and the mechanisms by which parathyroid hormone binds to its receptor, as well as the induction of several different messenger systems, are covered in Chapters 23, 26, and 28, respectively. This chapter focuses on the physiological and cellular effects of parathyroid hormone on the skeleton but also considers the kidney and the cardiovascular system, the latter being a recently recognized target of parathyroid hormone action.

Biologically Active Parathyroid Hormone and Its Peripheral Metabolism

The principal form of biologically active parathyroid hormone is the intact molecule, PTH(1-84). The half-life of PTH(1-84) in the circulation is less than 3 min. Clearance of parathyroid hormone occurs rapidly in the liver (60–70%), kidney (20–30%), and, to a much lesser extent, in other organs (Bringhurst *et al.,* 1988). Peripheral metabolism of parathyroid hormone is not altered by dietary calcium, hypercalcemia, or parathyroid disease (Bringhurst *et al.,* 1989; Fox *et al.,* 1983). Hepatic clearance is complex, involving high capacity, nonsaturable uptake by Kupffer cells

that cleave intact parathyroid hormone into discrete fragments and by hepatocytes that take up small amounts of hormone. Carboxy-terminal (C-terminal) fragments, resulting from cleavage between residues 33 and 34 and 36 and 37 of intact parathyroid hormone, are released by Kupffer cells into the circulation. The half-life of C-terminal fragments is 5–10 times longer than intact hormone. C-terminal fragments of parathyroid hormone are also metabolized and cleared by the kidney and hence do not reenter the circulation easily. The rapid metabolism of biologically active parathyroid hormone ensures that available parathyroid hormone for receptor binding is directed by the secretory rate of parathyroid hormone from the parathyroid glands in response to minute-to-minute fluctuations in the serum calcium concentration.

In normal settings, 70–95% of circulating parathyroid hormone is present as inactive C-terminal fragments; intact PTH(1-84) constitutes only 5–30% of the circulating forms of the molecule. The amino-terminal (N) fragment, PTH-(1-34), has biological activity comparable to PTH(1-84), and it may be generated during hepatic proteolysis of the intact molecule. Despite these points and the fact that many studies of PTH action have employed the N-terminal fragment, there is little evidence that it is present in appreciable quantities in the circulation. The liver-generated N-terminal product is degraded rapidly *in situ* (Bringhurst *et al.,* 1988). If the N-terminal fragment of parathyroid hormone serves biological functions *in vivo,* it would appear to be necessary to invoke local production at target sites themselves for which there is currently little convincing evidence.

Similar to C-terminal fragments, midregion fragments of parathyroid hormone are present in the circulation and are cleared through renal mechanisms. Under certain circumstances, studies have supported a biological role for these mid- and C- terminal fragments of parathyroid hormone. Murray and colleagues (1994), for example, have demonstrated that the C-terminal fragment, PTH(53-84), can stimulate alkaline phosphatase activity in osteoblast cells under conditions when the intact molecule is inhibitory. This and other C-terminal fragments have been considered as possible activators of osteoclast formation (Kaji *et al.,* 1994). The notion that cleavage products of polypeptide hormones may contain their own informational content gained further credence by studies with the sister molecule, parathyroid hormone-related protein (PTHRP). Both PTH and PTHRP contain dibasic sequences of amino acids that theoretically render them susceptible to intracellular processing enzymes. With PTHRP, several such cleavage products like PTHRP(67-86) and PTHRP(107-111) have been shown in special circumstances to stimulate placental calcium transport and to inhibit osteoclastic bone resorption, respectively (Care *et al.,* 1991; Fenton *et al.,* 1991, 1993). These observations suggest that PTH and PTHRP are polyhormones (or polyparacrine factors) that lead to the generation of a series of cell-specific, biologically active products. This concept is developed further in Chapters 28, 29, and 30. Studies suggesting the presence of unique receptor proteins for these nonclassical PTH products add strength to this hypothesis (Inomata *et al.,* 1995; Orloff and Stewart, 1995; Orloff *et al.,* 1995). The idea also becomes more interesting in view of the fact that these so-called breakdown products increase markedly in the presence of renal impairment.

Circulating heterogeneity of parathyroid hormone is due not only to peripheral metabolism but also to secretion of various fragments by the parathyroid glands themselves. Proteolytic degradation of parathyroid hormone within the parathyroid cell provides a calcium-sensitive mechanism to regulate intracellular parathyroid hormone content and the species of parathyroid hormone to be secreted. The absolute rate of hormone degradation is decreased under conditions of hypocalcemia, thus leading to increased secretion of intact parathyroid hormone. Intracellular hormone degradation is increased during states of hypercalcemia, leading to a reduction in secretion of intact parathyroid hormone (MacGregor *et al.,* 1979; Mayer *et al.,* 1979). *In vivo,* although secretion of intact parathyroid hormone persists at low levels when hypercalcemia is present, the ratio of mid- and C-terminal fragments to intact hormone is higher (D'Amour *et al.,* 1986; Kubler *et al.,* 1987). Thus, C-terminal fragments of parathyroid hormone are even more predominant in the circulation during hypercalcemic states, not due to hyperparathyroidism. Conversely, during hypocalcemia, intact parathyroid hormone becomes more evident in the circulation.

Most recently, a larger and heretofore not well-recognized molecule, PTH(7-84), has been found to circulate in appreciable quantities. Similar to other peptide fragments that do not contain the amino-terminal portion of the full-length molecule, this fragment is thought to be generated by peripheral metabolism or from the parathyroid gland when hypercalcemia is present. In renal failure, this fragment is likely to accumulate because its primary clearance route is the kidney. The recent development of an immunoradiometric assay that measures only the PTH(1-84) whole molecule may be of use in clinical situations where it is essential to measure only biologically intact hormone (see Chapter 75). It is also of interest that this large "inactive" fragment has been shown to harbor antagonist properties not only with respect to the calcemic actions of active parathyroid hormone, but also in nonparathyroid examples of hypercalcemia. The idea that PTH(7-84) may have its own actions, perhaps through a specific receptor system alluded to earlier, adds to the complexity of servomechanisms at which both parathyroid hormone-dependent and parathyroid hormone-independent hypercalcemia could be regulated, at least in part, by the parathyroid glands.

The proportion of N-terminal, C-terminal, large fragment, or intact PTH in the circulation has become a topic of great interest as our understanding of receptor–ligand interactions unfolds further (see Chapters 24 and 26). Cross-linking and mutagenesis studies suggest that interactions between the carboxyl-terminal portion of PTH(1-34) and the amino-terminal extracellular domain of the PTH receptor activate second messenger signaling (Erdman

et al., 1998; Luck *et al.,* 1999; Greenberg *et al.,* 2000; Grauschopf *et al.,* 2000). The carboxyl terminus of PTH induces receptor activation though conformational changes and/or G protein coupling and results in efficient receptor–ligand endocytosis (Huang *et al.,* 1999). In contrast, the N terminus of hPTH contains a critical activation domain for phospholipase C coupling (Takasu *et al.,* 1999). Investigations of crystalline hPTH(1-34) reveals an extended helical confirmation with a receptor-binding pocket in the N terminus and a hydrophobic interface at the C terminus (Jin *et al.,* 2000).

Cellular Actions of Parathyroid Hormone on Bone

There is a wealth of knowledge regarding the actions of PTH on bone cells *in vitro.* However, placing this information into the context of *in vivo* pharmacologic and physiologic actions of PTH is challenging. The cellular actions of PTH and the regulation of modeling and remodeling processes in bone were reviewed extensively by Parfitt in 1976 (Parfitt, 1976a,b,c,d). These concepts are revisited in this chapter but with references to new insights obtained from more recent pharmacologic studies.

PTH Regulation of Osteoblasts and Their Osteoprogenitors

Anabolic actions of parathyroid extract were first described in young rats, guinea pigs, kittens, and rabbits in the 1930s (Burrows, 1938; Pugsley and Selye, 1933; Jaffe, 1933; Parsons and Potts, 1972). At the time, the responses were thought to reproduce some of the pathologic processes of hyperparathyroidism in which an early destructive phase was followed by a reparative phase of bone formation (Heath, 1996). When hPTH(1-34) was first synthesized in the 1970s (Potts *et al.,* 1995), the anabolic effect of PTH on bone was revisited. Small clinical trials in the 1970s and early 1980s suggested that PTH could be used to restore bone in patients with osteoporosis (Cosman and Lindsay, 1998; Dempster *et al.,* 1993). The anabolic response of PTH has long been viewed with skepticism, as the literature was dominated by the dogmas that PTH was a hormone controlling calcium homeostasis, with its major effect manifest by stimulating bone resorption. Research of the past decade has shown reproducibly the osteoblast and its progenitor to be the primary *in vivo* target of PTH. The mechanisms of action are still not well understood, although we know that PTH regulates gene expression in the osteoblast, supporting synthesis of matrix proteins required for new bone formation (Parfitt, 1976a), proteins regulating osteoclast differentiation (Parfitt, 1976b), and proteins associated with matrix degradation and turnover (Parfitt, 1976c).

At the cellular level, several mechanisms of inhibition of proliferation by PTH occur and include inhibition of osteoprogenitor proliferation in young rats. Topoisomerase IIα, a marker of proliferation (Feister *et al.,* 2000), decreased expression of H4 (Onyia *et al.,* 1995) and caused a lack of stimulation of thymidine incorporation (Onyia *et al.,* 1995; Young, 1962, 1964; Onyia *et al.,* 1997). In young rats, in which proliferating cells are abundantly available adjacent to the growth plates and in cortical endosteum of the metaphyses and the periosteal diaphyseal surfaces (Kimmel and Jee, 1980; Kember, 1960), PTH targets cells in the G_1/S phase of the cell cycle (Onyia *et al.,* 1995; Young, 1962, 1964; Roberts, 1975; Hock *et al.,* 1994). The effects of PTH in young rats suggest possible roles in skeletal development, accretion of peak bone mass, and increased bone formation. In adult rats, there is no evidence that proliferating osteoprogenitor cells are targeted. Following exposure to [^{3}H-]thymidine in PTH-treated rats, there were no radiolabeled osteoblasts, and only unlabeled, nonproliferative bone surface cells are activated (Dobnig and Turner, 1995). An electron microscopy study supports the concept that PTH rapidly stimulates differentiation of nonproliferating osteoprogenitors lining quiescent bone surfaces (Roberts, 1975). *In vitro* studies have shown inconsistent effects of PTH on bone cell proliferation (Onishi *et al.,* 1997; Onishi and Hruska, 1997; Verheijen and Defize, 1995; Chaudhary and Avioli, 1998; Pfeilschifter *et al.,* 1993; Patridge *et al.,* 1985). In UMR-106 cells, PTH blocked entry of cells into S phase of the cell cycle, thereby increasing the number of cells in G_1, and cell proliferation was inhibited as a consequence of an increase in p27Kap1 (Onishi and Hruska, 1997). Histomorphometric studies have consistently shown early increases in bone-forming surfaces, consistent with the stimulation of differentiation of osteoprogenitors, rather than proliferation of osteoblasts (Cosma and Lindsay, 1998; Dempster *et al.,* 1993; Onyia *et al.,* 1997; Leaffer *et al.,* 1995; Hodsman and Steer, 1993; Meng, *et al.,* 1996).

When PTH binds to the G protein-coupled, seven-transmembrane receptor *in vitro,* cyclic AMP has been implicated as the key signaling pathway activated. The relative importance of cAMP *in vivo* is not well understood. Activation of calcium and protein kinase C (PKC) signal transduction pathways require higher doses of PTH *in vitro* than those required to activate the cAMP–protein kinase A (PKA) pathways. Thus, it has been proposed that cAMP is the key pathway by which the anabolic responses of PTH are effected (Potts *et al.,* 1995; Whitfield and Morley, 1998; Civitelli *et al.,* 1990). In fibroblasts, cAMP signaling activates PKA-controlled cell growth by abrogating signaling required for detachment of cells, inhibiting both progression through the cell cycle and apoptosis (Frisch, 2000; Howe and Juliano, 2000). If valid for osteoprogenitors, this could provide mechanisms by which PTH promotes differentiation but not proliferation of bone cells. In an additional control step, PTH has the capability to reverse the increase in cAMP through regulation of the inducible cAMP early repressor genes in cultured bone cell lines (Tetradis *et al.,* 1998; Bogdanovic *et al.,* 2000).

For a few years, it was thought that the use of certain analogs, such as hPTH(1-31), which induced anabolic

actions of PTH and activated only cAMP, validated the *in vitro* findings (Whitfield and Morley 1998). Subsequently, this analog was shown to activate cAMP *in vitro* under conditions in which there were high numbers of PTH1 receptors (Takasu and Bringhurst, 1998). In addition, an experiment in mice revealed that hPTH(1-31) was equivalent to hPTH(1-38) in stimulating cortical periosteal and trabeculear endosteal surfaces, but PTH(1-31) had a more attenuated effect on the cortical endosteum (Mohan *et al.,* 2000; Hock, 2000).

Stimulation of bone formation in endocortical surfaces is the hallmark of the anabolic effect of PTH irrespective of the species or experimental model (Cosman and Lindsay, 1998; Dempster *et al.,* 1993; Whitfield and Morley, 1998; Oxlund *et al.,* 1993). Thus, different mechanisms of action may be invoked in osteoblasts on differing bone surfaces within the same bone, a phenomenon that has not been considered in *in vitro* models. The magnitude of these differences is not enough to modify the outcome, as the increment of gain in bone mass and bone strength in PTH-treated mice remains equivalent between the two agonist ligands (Mohan *et al.,* 2000). The magnitude of changes in cyclic AMP and the PKA pathway cannot explain the paradoxal actions of PTH to inhibit and stimulate bone formation and to spare or stimulate osteoclast-mediated resorption. Application of new concepts on how waves of differing amplitude and frequency of cAMP and Ca^{+2} signaling traverse a cell and may be amplified in neighboring cells by activation of intracellular calcium-sensing receptors should be examined for the relevance to signal transection in bone cells in response to PTH (Bretschneider *et al.,* 1997; Dormann *et al.,* 1998; Hofer *et al.,* 2000; Thomas, 2000).

As one of the cAMP-dependent mechanisms, the upregulation of c-fos and the role of the immediate early gene comprising the AP-1 fos and jun family members have been widely studied. *In vivo,* PTH [as either hPTH(1-84) or hPTH(1-34)] increased c-fos, fra-2, junB, and c-jun significantly above baseline levels in the metaphyses of young mice at doses as low as 1 μg/kg (Stanislaus *et al.,* 2000; Liang *et al.,* 1999). Although other AP-1 members, δfosB (Sabatakos *et al.,* 2000) and fra-1 (Jochum, 2000), regulate bone formation, PTH did not regulate their expression in young rats (Stanislaus *et al.,* 2000). The regulation of c-fos in bone has the greatest magnitude of change of the PTH-regulated AP-1 family members and is time and cell dependent (Stanislaus *et al.,* 2000). *In situ* hybridization of young rat bone showed that bone-lining cells expressed an increased amount of c-fos within 15 to 60 min of exposure to hPTH(1-84) (0.2 mg/kg), followed by stromal cell and osteoclast expression after 1 to 2 hr (Lee *et al.,* 1994). Cells in which c-fos expression was delayed expressed few PTH1 receptors, consistent with an indirect effect of PTH on these cells (Lee *et al.,* 1994). *In vitro,* constant exposure to PTH(1-34) and PTHrP(1-34) induced c-fos gene expression rapidly in bone cell lines (Kano *et al.,* 1994; McCauley *et al.,* 1997; Clohisy *et al.,* 1992). Antisense olionucleotides complimentary to c-fos mRNA inhibited mRNA translation and antagonized the PTH- or PTHrP-induced inhibition of proliferation in UMR106 osteoblast-like cells, as well as induction of osteoclast differentiation in the presence of these cells (Kano *et al.,* 1994). The early inducible gene c-fos has also been implicated in the process of programmed cell death in other cells, and the PTH-induced increases in c-fos may be relevant to the inhibition of apoptosis in bone cells. Irrespective of whether anabolic or catabolic effects of PTH are induced, the increase in c-fos and interpretation of its significance is complex. It is not known if the increase in c-fos is due to activation of equivalent or different pathways in equivalent or different target cells.

The ability of PTH to promote commitment to osteoblast differentiation was demonstrated using a fibroblast osteoprogenitor colony-forming assay (CFU-f) with bone marrow stromal cells of neonatal or young rats (Ishizuya *et al.,* 1997; Nishida *et al.,* 1994). *In vitro,* PTH inhibits the expression and synthesis of matrix proteins, including collagen I, osteocalcin, and alkaline phosphatase, regardless of whether exposure is for a few hours or several days in differentiated osteoblasts (Tetradis *et al.,* 1998; Bogdanovic *et al.,* 2000; Clohisy *et al.,* 1992; Howard *et al.,* 1980, 1981; Dietrich *et al.,* 1976; Kream *et al.,* 1993; Raisz and Kream 1983a,b; Tetradis *et al.,* 1996,1997). *In vivo,* following an injection of PTH, collagen I mRNA was upregulated within 6 hr and bone matrix synthesis was increased within 24 hr in young growing rats (Onyia *et al.,* 1995, 2000; Hock *et al.,* 1994).

In vitro data may predict *in vivo* data associated with continuous exposure to PTH. Following continuous infusion of PTH in adult rats, osteoblasts are associated with fibrosis rather than new bone matrix (Dobnig and Turner, 1997; Kitazawa *et al.,* 1991), and the ratio of IGF I to IGF-BP3, detected in bone-lining cells by immunohistochemistry, is altered (Watson *et al.,* 1999). Prolonged exposure to PTH in cultured bone cells altered several nuclear matrix proteins (Bidwell *et al.,* 1998). Some of these appear to be architectural transcription factors and some, such as NMP4 (a nuclear matrix protein), and NP (a soluble nuclear protein), bind directly to the regulatory region of the rat type I collagen α(I) promoter in the presence of PTH (Bidwell *et al.,* 1998; Alvarez *et al.,* 1998). These experiments suggest that regulation of the nuclear matrix by PTH may modify the profile of transcribed genes under different exposures.

One of the most interesting recent developments in studies of the anabolic effects of PTH has been the consistent finding that PTH upregulates expression of both matrix-degrading proteins, such as matrix metalloproteinases and ADAMTS-1, and cytokines associated with regulating matrix degradation and turnover, such as interleukin (IL)-6 and IL-11 (Onyia *et al.,* 1995, 1997; Clohisy *et al.,* 1992; Greenfield *et al.,* 1993, 1995, 1996; Huang *et al.,* 1998; McClelland *et al.,* 1998; Winchester *et al.,* 1999; Elias, *et al.,* 1995). The role of the osteoblast in generating matrix metalloproteases was suggested by studies showing collagenase 3 to be a target of cbfa-1, a key transcription factor

linked to osteoblast differentiation (Jiminez *et al.,* 1999; Selvamurugan *et al.,* 2000a,b). Parathyroid hormone may induce retraction of osteoblasts from the bone surface through a calpain-dependent, proteolytic modification of the osteoblast cytoskeleton (Murray *et al.,* 1997). The consequence of cell retraction and detachment due to matrix degradation is apoptosis of cells that are unable to reattach. A transient increase in apoptosis in proliferating cells and osteocytes of young rat metaphyses was recorded during the initial response to PTH (Stanislaus *et al.,* 2000). A subset of osteoblasts may be highly susceptible to apoptosis. The existence of a susceptible osteoblast subset was suggested by data showing that cultured HEK293 cells transfected with high numbers of PTH1 receptor exhibited apoptosis when exposed to PTH (Turner *et al.,* 2000). Also, studies have suggested that local increases in phosphate concentrations may induce apoptosis in mineralizing cells (Meleti *et al.,* 2000; Boyan *et al.,* 2000). *In vitro,* PTH stimulated transport of inorganic phosphorus by a Na-dependent carrier in the rat osteosarcoma cell line UMR-106 in a dose-dependent manner, and P_i uptake was attenuated by PKC inhibitors or by downregulation of PKC by phorbol ester treatment (Arao *et al.,* 1994). Thus, the probability of apoptosis in susceptible cells may be enhanced by the ability of PTH to regulate phosphate homeostasis.

The transient increase in apoptosis of osteoblasts (Stanislaus *et al.,* 2000) and upregulation of matrix metalloproteinases (McClelland *et al.,* 1998; Zhao *et al.,* 1999) are consistent with mechanisms activating bone turnover. One consequence of matrix activation degrading enzymes may be that reconditioned bone surface can serve as an attractant for newly differentiating osteoblasts to increase bone-forming surfaces (anabolic action) or as an attractant for differentiating osteoclasts to continue resorption of old surfaces (catabolic action). Reattachment of detached osteoblasts may delay or inhibit their apoptosis. In mice and rats, continued intermittent PTH has been associated with inhibition of apoptosis (Stanislaus *et al.,* 2000; Jilka *et al.,* 1999). Differences in the profile of responses to intermittent exposure to PTH required to promote osteoblast differentiation and function and the profile of responses to continue with infusion of PTH that activate osteoclast differentiation and function have yet to be identified.

PTH Regulation of Osteoclasts and Their Osteoprogenitors

Barnicott (1948) first recognized the resorptive properties of PTH. In this study, remnants of parathyroid glands were laid on the inverted underside of calvaria and reimplanted under the skulls of mice. Significant bone resorption in the calvaria resulted. This work laid the foundation for *in vitro* assays utilizing rat and mouse bones in which resorption was induced routinely by PTH (Raisz, 1963, 1965). PTH indirectly enhances bone resorption and release of calcium from bone surfaces by activation of osteoclasts. This is despite evidence for direct binding of ^{125}I-bovine PTH(1-84) to avian osteoclats (Teti *et al.,* 1991) and for activation of resorption via a direct effect on the osteoclast (Mears, 1971; Miller and Kenney, 1985; Murrills *et al.,* 1990). The effect of PTH on osteoclasts is most likely indirect given recent data. *In vivo,* PTH induces a transient increase in apoptosis of osteoblasts (Stanislaus *et al.,* 2000) and upregulation of osteoblast matrix metaloproteinases (McClelland *et al.,* 1998; Zhao *et al.,* 1999). This is consistent with PTH-mediated mechanisms activating bone turnover in which protein synthesized by osteoblasts activates osteoclasts. In genetically modified mice in which collagenase is unable to cleave collagen I, daily PTH injections over the skull did not induce osteoclast-mediated resorption but did occur in control animals (Zhao *et al.,* 1999). *In vitro,* osteoclast-like cells in culture failed to respond to PTH unless cocultured with stromal or osteoblast-like cells (Kanzawa *et al.,* 2000; Suda *et al.,* 1999; Horwood *et al.,* 1998; McSheehy and Chambers, 1986; Fuller *et al.,* 1998a,b).

It is currently thought that stromal cells and osteoblast lineage cells regulate osteoclast differentiation through cell–cell contact by controlling the synthesis of osteoprotegerin (OPG/OCIS) and the ligand for the receptor activator of NF-κB (RANKL/ODF/TRANCE/OPGL) (Kanzawa *et al.,* 2000; Suda *et al.,* 1999; Horwood *et al.,* 1998). These two secreted proteins compete for binding to the osteoclast progenitor receptor activator NF-κB(RANK), a TNF receptor family member (Suda *et al.,* 1999). If RANKL binding to RANK predominates, as seen following PTH treatment of cultured osteoblast-like osteosarcoma cells transfected with the PTH1 receptor (Itoh *et al.,* 2000), osteoclast progenitors differentiate into osteoclasts in the presence of M-CSF (Suda *et al.,* 1999; Fuller *et al.,* 1998b). In addition, PTH downregulates OPG expression via a cAMP/PKA pathway in a variety of bone cell lines (Kanzawa, *et al.,* 2000). Reciprocal regulation of OPG and RANKL expression by PTH preceded its effects on osteoclast formation by 18–23 hr. These effects were more pronounced in primary bone marrow cells than in calvaria bone organ cultures or MC3T3.E1 cells (Lee and Lorenzo, 1999). *In vivo* studies of young rats treated once daily with hPTH(1-34) for 3 days showed an altered ratio of mRNA for osteoprotegerin and RANKL (Onyia *et al.,* 2000), but it is not known if the magnitude of these changes translates into relevant function.

Changes in resorption associated with once daily treatment of PTH are rarely detected in rat models *in vivo.* In humans and animals with osteonal bone skeletons, increased resorption in response to PTH in cortical bone occurs, but only after the increase in surface bone formation, which occurs during the first remodeling period (sigma) (Cosman and Lindsay, 1998; Hodsman and Steer, 1993; Mashiba *et al.,* 2000; Hirano *et al.,* 1999, 2000; Burr *et al.,* 2000). This increase in new bone-forming surfaces appears to offset the increase in resorption that precedes new osteonal formation in intracortical bone. As suggested by *in vitro* data (Kanzawa *et al.,* 2000; Suda *et al.,* 1999; Horwood *et al.,* 1998),

increased resorption plays a key role in the mechanisms activated when PTH is given by continuous infusion and is activated within the first 3 days of infusion in young rats (J. M. Hock, unpublished data). In humans and dogs, continuous infusion of PTH was associated with histomorphometric and biochemical data consistent with the early induction of resorption and increased bone turnover (Malluche *et al.,* 1982; Cosman *et al.,* 1991, 1998). In rats, resorption results in loss of bone mass despite a small increase in bone-forming surfaces (Watson *et al.,* 1999; Hock and Gera, 1992; Tam *et al.,* 1982).

It is not known if osteoclast activation following the continuous infusion of PTH is a direct effect due to shifts in the ratio of OPG and RANKL expression in osteoblasts and stromal cells or if the shift in matrix protein synthesis by osteoblasts to a more fibroblast-like profile (Dobnig and Turner, 1997) results in an extracellular matrix (ECM) feedback signal to activate increased bone turnover. One difficulty in developing experimental models of gene expression is to match the *in vivo* infusion dose of PTH with that of PTH given by once daily injections. PTH infusion induces hypercalcemia at doses above 80 μg/kg/day in rats, and infusion at 160 μg/kg/day was associated with increased mortality (Hock and Gera, 1992). When hPTH(1-34) was infused at 40 μg/kg/day in young rats and compared to a PTH injection of 40 μg/kg/day, there was upregulation of c-fos and IL-6 mRNA expression following injection and equivalent upregulation of c-fos but no alteration of IL-6 mRNA levels following infusion (Liang *et al.,* 1999). These responses were detected in the femur metaphysis, which is enriched for osteoblasts, but not in the cortical diaphysis, which contains predominantly hematopoietic and stromal cells. In primary cultures of bone marrow stromal cells from either metaphysis or diaphysis of rat femurs, PTH increased both c-fos and IL-6 expression (Tu *et al.,* 1997), suggesting that, *in vivo,* there are site-specific regulatory factors controlling the profile of genetic responses, in addition to those associated with different treatment regimens. Confounding their interpretation is a study in which serum IL-6 was increased in mice infused with PTH or rats in which PTH was locally injected over calvaria to mimic a resorption model. Blocking IL-6 release was associated with a decrease in resorption markers, with no change in biochemical markers of formation (Grey *et al.,* 1999; Pollock *et al.,* 1996). There were no measures of bone mass to ascertain if this altered profile was associated with a catabolic or anabolic effect, and no comparison was made to intermittent, once daily administration of PTH.

One frustrating limitation of these gene-profiling studies has been our lack of knowledge of how the balance of increased activation frequency may favor formation (anabolic effect of intermittent PTH) or resorption (catabolic effect of continuous PTH). A mathematical model that assumes a longer delay in osteoclast activation (due to a requirement for signals from the osteoblast to osteoclast progenitors) than the delay required for osteoblast differentiation argues that osteoblast function will predominate with intermittent PTH, whereas resorption will be greater with continuous PTH (Kroll, 2000). The importance of interval duration of PTH administration emphasized in this theoretical model has some support from preliminary data. In rats treated with PTH, six injections in 1 hr once daily or infusion for 1 hr once daily, induced an equivalent bone gain to that of one injection/day, whereas six injections over 8 hr or continuous infusion for longer than 1 hr/day resulted in bone loss (Dobnig and Turner, 1997; Frolik *et al.,* 1997; Turner *et al.,* 1998). While our knowledge of genetic regulation and signal transduction in bone cells has expanded, there is still limited understanding of the genes that differentially regulate modeling, growth processes, and remodeling *in vivo* to change the shape of bones or to regulate the spatial distribution of bone within a bone organ or within the skeleton as a whole.

The role of C-terminal fragments of parathyroid hormone in the process of bone resorption is controversial. It has been suggested that PTH(35-84), PTH(53-84), or PTH(69-84) may have a role in stimulating osteoclast-like formation (Takasu and Bringhurst, 1998; Kaji *et al.,* 1994). Mouse bone cell cultures, which contain both osteoclasts and progenitor cells, responded to the addition of these C-terminal fragments with an increase in bone resorption. No effect was noted, however, in the bone-resorbing activity of isolated rabbit osteoclasts, suggesting methodological or species differences. *In vivo,* no differences at the bone or molecular level have been shown between the responses to full-length hormone, hPTH(1-84), and hPTH(1-34) (Cosman and Lindsay, 1998; Stanislaus *et al.,* 2000; Ejersted *et al.,* 1993; Mosekilde *et al.,* 1991). An intact N terminus was required for PTH to increase bone mineral density in mature ovariectomized rats (Armento-Villareal *et al.,* 1997).

Candidate Cytokines and Hormones as Mediators of PTH Actions

Several candidate agents have been implicated as mediators in regulation of the osteoblast axis by PTH. Growth hormone (GH) has been evaluated either as a direct regulator of bone cell biology or as a stimulator of IGF-1, which was known to stimulate osteoblast proliferation and differentiation *in vitro* (Canalis *et al.,* 1994; Schmidt *et al.,* 1994). A study of young male hypophysectomized rats showed that GH was required for PTH to increase bone mass equivalent to the increment seen in treated, intact controls (Hock and Fonseca, 1990). As the effects of GH on bone may be mediated by IGF-1, it was inferred that IGF-1 might be required for the anabolic effect of PTH. It is possible that this IGF-1 mechanism may only be activated during skeletal development when growth plates are still active. The addition of PTH to older, mature hypophysectomized female rats resulted in increased osteoblast number and trabecular bone volume, even in the absence of GH (Schmidt *et al.,* 1995). Other studies of PTH in combination with either GH alone or combined with IGF-1 in intact

old female rats showed no minor additional effect of either GH or IGF-1 (Gunness and Hock, 1995; Mosekilde *et al.,* 2000). It has been suggested that GH in older animals may enhance the effect of PTH by stimulating periosteal formation to change the geometry of the bones, making them more resistant to fracture in biomechanical tests (Mosekilde *et al.,* 2000); data to prove this additive effect of GH are limited. Collectively, these data suggest that GH is required for the anabolic effect of PTH during the "adolescent" phase of skeletal growth in rats, but is not necessary after skeletal maturation in rats.

The role of IGF-1 and its binding proteins, especially IGF-BP5, which is anabolic in cultured bone cells (Gabbitas and Canalis, 1998; Canalis, 1997), remains ambiguous. One elegant study showed that a neutralizing IGF-1 antibody blocked the effects of PTH on collagen synthesis in cultured fetal rat calvaria and implicated IGF-1 as a key mediator of PTH effects on osteoblasts (Canalis *et al.,* 1989). In calvarial bone cells isolated from 2-day rats and treated with hPTH(1-34) for 6 hr, osteoblast commitment to differentiation was blocked by the IGF-1 antibody (McCauley *et al.,* 1997). These data suggest that IGF-1 may be one of the mediators of PTH effects on skeletal growth and maturation. Bone organ culture or cells isolated from fetal or neonatal animals may not respond to hormonal stimulation under the same constraints as those from postnatal and mature rats or mice (Canalis *et al.,* 1994). Alternatively, as IGF-1 inhibits collagenase (Canalis *et al.,* 1995), IGF-1 may mediate a different aspect of the anabolic mechanism, namely regulating the process by which osteoblasts condition the bone surface as a prerequisite to attract osteoclast progenitors to bone. As skeletal cells secrete the six known IGF-binding proteins (IGFBPs) and two of the four known IGFBP-related proteins (IGFBP-rP), there may be additional levels of regulation if IGF-1 mediates the action of PTH *in vivo* (Schmid *et al.,* 1989; LaTour *et al.,* 1990; McCarthy *et al.,* 1991; Moriwake *et al.,* 1992; Shimasaki *et al.,* 1991). IGFBPs may prolong the half-life of IGF-1 and compete with its receptors for binding. IGF-BP4 may inhibit osteoblast function *in vitro,* whereas IGF-BP5 enhances the stimulatory effects of IGF-1 (Pereira and Canalis, 1999; Qin *et al.,* 1998). PTH induces IGFBP-rP-1 and IGFBP-rP-2 in osteoblasts by transcriptional control (Pereira and Canalis, 1999; Pereira *et al.,* 2000).

In cultured mouse cells and bone organ culture, hPTH-(1-34) increased expression of FGF-2 and FGF receptors 1 and 2 within 30 min (Hurley *et al.,* 1999). In cultured rat osteoblasts, TGFβ may downregulate the PTH1 receptor to decrease receptor binding and signal transduction by cAMP (Jongen *et al.,* 1995). This may be a reciprocal action to the ability of PTH to increase TGFβ1 by the PKC pathway and TGFβ2 via the PKA pathway in cultured human and rat osteoblasts (Wu and Kumar, 2000). However, *in vivo* studies have not shown gene expression of growth factors to be significantly regulated by PTH until after 4 weeks of treatment (Watson *et al.,* 1995; Pfeilshifter *et al.,* 1995); the effects are dose dependent and occur at higher doses than those needed to induce an increase in bone mass (Stanislaus *et al.,* 2000; Pfeilshifter *et al.,* 1995; Sato *et al.,* 1997). This delay in upregulation suggests that an increase in growth factors may be more an indication of the highly significant increase in osteoblast numbers and function rather than a primary mediator of the anabolic actions of PTH. Withdrawal of PTH treatment in rats results in downregulation of the osteoblast response in 24–48 hr (Gunness-Hey and Hock, 1989), but the molecular and cellular consequences have not studied to determine the effects on the multiple cytokines regulating local bone cell balance.

Cellular Actions of Parathyroid Hormone on Kidney Phosphate Transport

The classic action of parathyroid hormone on the kidney is to cause phosphaturia. Approximately 85% of the phosphorus reabsorption occurs in the proximal tubule. A low phosphorus intake stimulates the tubular phosphorus absorption and a high phosphorus intake inhibits phosphorus reabsorption. The alterations occur independent of changes in PTH, serum calcium levels, or extracellular fluid volume. Phosphorus transport in the proximal tubule occurs against an electrochemical radiant. Reabsorption is transcellular, absorptive, and dependent on the low concentration of intracellular calcium maintained on the basolateral side by Na,K-ATPase. In the proximal tubule, phosphorus is transported into the cell through the actions of a membrane-bound, sodium–phosphate cotransporter, Npt2(NaPi2).

The actions of parathyroid hormone place a further constraint on the already limited capacity of the kidney to reclaim filtered phosphate. Whether this active transport process is expressed simply as a maximal rate ($TmPO_4$) or in relationship to the glomerular filtration rate ($TmPO_4$/GFR), the parathyroid hormone is inhibitory when present and permissive when absent. Inhibition of phosphate transport occurs primarily in the proximal convoluted tubule and the pars recta (Agus *et al.,* 1981). Phosphate reabsorption may also be inhibited by PTH in the distal tubule. This effect is accompanied by the inhibition of sodium and fluid reabsorption. Renal tubular reabsorption of phosphate is an active process and, when corrected for GFR, is an accurate measure of renal responsiveness to parathyroid hormone, one of the earliest physiological observations to be made for parathyroid hormone (Ellsworth and Howard, 1934).

The cellular basis for phosphate transport in the kidney has been explored extensively. Lederer and McLeish (1995) demonstrated that activation of purinergic P2 receptors attenuated the inhibitory effect of parathyroid hormone on Na^+-dependent phosphate transport by a G-protein-dependent mechanism. In LLC-PK1 kidney cells that were stably transfected with the PTH/PTHRP receptor, PLC activation and parathyroid hormone-stimulated phosphate transport were dependent on receptor density. This finding is in contrast to the intracellular cyclic AMP response to parathyroid

hormone. Thus, receptor-dependent parathyroid hormone effects on phosphate uptake are linked more closely to PKC activity than to cyclic AMP (Guo *et al.,* 1995). Other investigators have shown the importance of PTH1 receptor density in intracellular calcium and cAMP pathways (Jobest *et al.,* 1997).

In cultured opposum kidney cells, parathyroid hormone-induced phosphaturia is modulated by luminal cAMP, which, in turn, is metabolized to adenosine by brush-border membrane ectoenzymes such as ecto-nucleotidase (5′-NU). Parathyroid hormone stimulates 5′-NU in a time-, concentration-, and protein synthesis-dependent manner (Siegfied *et al.,* 1995). In this system, downregulation or inhibition of protein kinase C attenuated the effect of parathyroid hormone, supporting a role for PKC activation in parathyroid hormone-induced renal phosphate loss.

The coupling of PTH to its receptors has been best characterized in the proximal tubules of the kidney. These ligand–receptor interactions mediate the regulation of TmP/GFR in the proximal tubule, whereas those in the distal nephron regulate calcium reabsorption. Both of these mechanisms are coupled with different intracellular signal transduction systems. Utilizing prolonged exposure of parathyroid hormone and a protein PKC activator (mezerein) in an opossum kidney cell line (OK/E), assessments were made on cAMP production, PKC activity, and Na-dependent phosphate transport. Short-term exposure (5 min) to PTH stimulated cAMP production, whereas a longer incubation (6 hr) reduced cAMP production. Na-dependent phosphate transport was maximally inhibited under desensitizing conditions and was not affected by reintroduction of PTH. Addition of a PKC activator, mezerein, for 6 hr enhanced PTH-, cholera toxin-, and forskolin-stimulated cAMP production, suggesting enhancement of $G_s\alpha$ receptor coupling, and increased adenylate cyclase activity. However, PKA- and PKC-dependent regulation of the sodium–phosphate transporter was blocked in mezerein-treated cells. Thus, PTH-induced decreases in cAMP production were associated with a reduction in membrane-associated PKA activity, whereas the PKC activator, mezerein, increased cAMP production and decreased membrane and cytosolic PKA activity. This differential modulation of cAMP production in the regulation of sodium-dependent phosphate transport suggests that agonist specific activation and downregulation of PKC isoenzymes may be involved in the changes in cAMP production and sodium-dependent phosphate transport (Cole, 1997).

To determine differences between PKA and PKC intracellular signaling pathways, the effect of PTH on renal proximal tubule sodium-dependent phosphate transport was tested in opossum kidney cells. PKC-dependent phosphorylation of phospholipase A_2 stimulates arachadonic acid release, a potent inhibitor of P_i transport. Arachadonic acid is metabolized to 20-hydroxyeicosatetraenoic acid (20-HETE) in the proximal tubule. The addition of 20-HETE specifically inhibited sodium-dependent phosphate transport in OK cells and is thought to be one of the mediators of PTH action (Silverstein *et al.,* 1998). Further studies attempted to determine the effects of protein kinase A and protein kinase C activation on membrane expression of NaPi-4, the type II sodium–phosphate cotransporter in opossum kidney (OK cells). Treatment of OK cells with PTH decreased the expression of NaPi-4 as early as 2 hr, and the effect was sustained for over 24 hr. A nonhydrolyzable cAMP analog, 8-bromo-cAMP, inhibited NaPi-4 expression by over 90% over a 24-hr period. Phorbol ester inhibited NaPi-4 expression less than 10%. PTH(3-34), a fragment that stimulates PKC only, inhibited phosphate transport but had no effect on NaPi-4 expression. These studies suggest that PKA inhibits sodium–phosphate uptake in OK cells by downregulation of NaPi-4 expression and does not provide a role for PKC (Lederer *et al.,* 1998). These results were confirmed and extended with the use of unique PTH analogs that signal specifically through the PKA or PKC pathway. In isolated murine proximal tubules, PTH(1-34), an activator of PKC, and PKA was effective when added to either the apical or the basolateral perfusate. PTH(3-34), which signals PKC, acted only via the luminal perfusate. Activation of PKA with 8-bromo-cAMP or PKC with a phorbol ester mimicked the effects. *In vivo,* the specific analogs downregulated the sodium–phosphate cotransporter (designated NaPi-IIa in this study) in the brush border membrane. These studies indicate that functional PTH receptors are located on both membrane domains and that apical PTH receptors may preferentially initiate stimulation of phosphate reuptake through a PKC-dependent mechanism (Traebert *et al.,* 2000).

The proteolytic pathway in the regulation of Na-Pi cotransporter II by PTH is also an important regulatory pathway. In opossum kidney cells, inhibition of lysosomal degradation prevented the PTH-mediated degradation of the transporter. Inhibition of the proteosomal pathway, however, did not have the same effect. Lysosomal inhibitors prevented the PTH-mediated degradation of the sodium–phosphate transporter, but they did not inhibit the PTH-mediated inhibition of the Na-Pi cotransporter. The Na-Pi cotransporter was constitutively transported to and degraded within endosomes/lysosomes, and degradation was enhanced in the presence of PTH (Pfister *et al.,* 1998).

In vivo studies have confirmed many of the effects on the Na-Pi cotransporter. Both dietary phosphorus and PTH are important physiological regulators of phosphate reabsorption in the renal proximal tubule. In thyroparathyroidectomized (TPTX) rats, Na-Pi-II protein and mRNA were increased in the kidney transport compared to sham-operated animals. Administration of PTH to TPTX rats caused a decrease in the amount of Na-Pi-II protein but did not change the levels of Na-Pi-II mRNA. Dietary phosphorus deprivation in TPTX rats did not alter the amount of Na-Pi-II mRNA or protein. Switching TPTX animals from a low phosphorus diet to a high phosphorus diet decreased Na-Pi-II immunoreactivity from superficial nephrons but not from juxtamedullary nephrons. These studies suggest that dietary phosphorus can regulate the amount of Na-Pi-II protein in superficial nephrons in a PTH-independent

manner (Takahashi *et al.,* 1998). The type II Na-Pi cotransporter gene (designated Npt-2) is in the renal brush border membrane and undergoes endocytosis in the presence of PTH. In mice homozygous for the disrupted Npt-2 gene, decreased renal phosphorus reabsorption occurs in response to PTH. PTH has no effect on serum phosphorus concentration, on fractional excretion of P_i, or Na-dependent P_i transport in renal brush border in the transgenic mice. In contrast, PTH elicits a fall in serum phosphorus concentration, an increase in urinary phosphorus concentration, and a decrease in brush border membrane Na-Pi cotransport with a corresponding reduction in Npt-2 protein in wild-type mice. Both Npt-2 −/− and Npt-2 +/+ mice exhibit a significant rise in the urinary cAMP/creatinine ratio in response to PTH, proving that there is not a generalized resistance to PTH in Npt-2 −/− mice. Phosphorus deficiency per se also does not account for the PTH resistance in Npt-2 −/− mice, as phosphate-depleted normal mice respond to PTH. These transgenic animals have shown that Npt-2 gene expression is critical for PTH effects on renal phosphorus handling (Zhao and Tenenhouse, 2000). In distal tubules, PTH inhibits phosphate reabsorption, but the transporters that are involved in this process have not yet been characterized.

Cation/Anion Transport

Parathyroid hormone inhibits proximal tubule reabsorption of sodium, bicarbonate, calcium, and phosphate (Agus *et al.,* 1981; Pollock *et al.,* 1986). Extracellular calcium homeostasis is highly dependent on the multiple roles that the kidneys play in the regulation of calcium reabsorption. The mechanisms of calcium reabsorption occur throughout the entire length of the nephron but vary significantly among segments. There is extensive recovery of calcium by the proximal tubules that is under regulation by a paracellular pathway and not known to be regulated by hormones. In the thick ascending limbs, calcium absorption occurs through cellular and paracellular routes. Parathyroid hormone and calcitonin regulate the cellular components while the paracellular component is modulated by sodium reabsorption. The least understood area of calcium reabsorption is in the distal tubule. It is thought here that calcium absorption is transcellular, although a definitive transport system has not been well characterized. PTH, 1,25-dihydroxyvitamin D, and calcitonin all play regulatory roles in the distal nephron.

The amount of calcium filtered per day by a 70-kg man is greater than 10 g and four times more than the calcium content of the entire extracellular fluid compartment. To maintain neutral calcium balance, approximately 98% of filtered calcium is reabsorbed along the renal tubule. Of this filtrate, 70% of filtered calcium is reabsorbed in the proximal tubule. Twenty percent of filtered calcium is reabsorbed in the loop of Henle, and the distal convoluted tubule is responsible for approximately 8% of calcium reabsorption and is the major site of urine calcium excretion. The basolateral membrane of the thick ascending limb of the loop of Henle now has receptors identified that are stimulated by increased levels of serum calcium, resulting in a decrease activity of the Na-K-Cl_2 pump (Brown *et al.,* 1998). Cellular calcium absorption across the polarized epithelial cells involves entry across an apical (mucosal, luminal) membrane, followed by extrusion across the basolateral membrane into the interstitial fluid. Apical calcium entry is mediated by calcium channels, and basolateral efflux involves energy-dependent extrusion accompanied by plasma membrane Ca^{2+}-ATPase and Na^+/Ca^{2+} exchanger.

Oral or intravenous phosphate administration will cause an increase in distal calcium reabsorption in kidney and reduced calcium excretion. Extrarenal mechanisms may contribute to the hypocalciuria associated with phosphate administration. Calcium and phosphate may form a complex in the intestine, decreasing the amount of calcium available for absorption. In addition, phosphate can complex with calcium and bone in soft tissues, which will further reduce the filtered load of calcium. In a phosphate-replete state, hypercalciuria occurs. Excess phosphate will stimulate PTH secretion, resulting in reduced ionized calcium, which further enhances PTH release, which, in turn, enhances calcium reabsorption. It has been proposed that a defect in proximal tubular calcium absorption may be present, as well as a direct effect of phosphate to decrease calcium reabsorption in the distal nephron.

PTH is the principal regulator of renal tubule calcium reabsorption. Increased levels of PTH increase renal tubule calcium reabsorption and reduce glomerular filtration. At the same time, PTH reduces glomerular filtration and thus the filtered load of calcium by reducing the glomerular ultrafiltration coefficient. Patients with hyperparathyroidism, however, are hypercalciuric. The PTH-induced increase in tubule calcium reabsorption produces hypercalcemia and an increased filtered load of calcium. Overall, this produces an increase urinary calcium excretion. PTH increases calcium reabsorption in the distal convoluted tubule through the facilitation of opening of calcium channels. Genetic disorders of calcium excretion have been described and are often due to inactivating mutations of renal ion channels and transporters (Scheinman, 1999). In addition, PTH stimulates the conversion of 25-hydroxyvitamin D to 1,25-dihydroxyvitamin D in the renal proximal tubule, which will further enhance intestinal calcium absorption and bone resorption, leading to an increase in the filtered load of calcium. Chronic hypercalcemia will decrease renal reabsorption of phosphorus, whereas chronic hypocalcemia has the opposite effect.

In human studies, the increase in urinary calcium excretion in response to a calcium load occurs with inverse changes in PTH levels. It is often thought that the effect of changes in serum calcium on its own excretion is poorly understood in human subjects. Using a PTH clamp protocol, calcium-regulated renal calcium and magnesium handling were explored in eight male normal volunteers. Graded calcium infusions were given, and PTH was maintained in the

normal range while the subjects were placed on a high and then a low sodium diet. The curve describing urinary sodium as a function of serum calcium was sigmoidal on both high and low sodium diets. This study, as well as previous studies, shows that there is a PTH-independent calcium-dependent change in renal calcium, magnesium, and sodium handling, which is mediated, in part, by the calcium-sensing receptor in the loop of Henle (Brown and Hebert, 1997) .

The role of PTH in the pathogenesis of postmenopausal osteoporosis was difficult to decipher. Although all postmenopausal women are estrogen deficient, a subset has higher rates of bone resorption and greater bone loss. One proposed defect to explain these findings was an impairment in renal calcium conservation. At baseline, there were no differences in PTH concentrations or renal-filtered load of calcium in 19 osteoporotic postmenopausal women compared to 19 elderly normal women. Before PTH infusion, osteoporotic women had lower values for tubular reabsorption of calcium and higher urinary calcium excretion when corrected for glomerular filtrate. After infusion of hPTH-(1-34), tubular reabsorption of calcium increased and calcium excretion decreased in both groups. This study suggests that postmenopausal women with osteoporosis had a PTH-independent defect in renal calcium conservation that may have impacted negative calcium balance (Heshmati *et al.,* 1998). Decreased sensitivity to PTH, resulting in lower bone turnover, better renal calcium conservation, and less osteoporosis, has been noted in Black women compared to White women. Even at baseline, Black women have superior renal calcium conservation, and in response to administration of 1,25-dihydroxyvitamin D, Black women have a greater decrement in PTH. These data suggest that Black women conserve calcium more efficiently under both static and dynamic conditions (Cosman *et al.,* 2000).

PTH is the major regulator of renal 1α-hydroxylase. When serum levels of calcium decrease, parathyroid glands release more calcium due to sensing by the calcium-sensing receptor. The increase in PTH restores calcium levels to normal by its direct effects on bone and kidney. In addition, indirect effects include stimulation of renal 1α-hydroxylase, which accelerates the conversion of 25-hydroxyvitamin D to 1,25-dihydroxyvitamin D (calcitriol). Enhancement of intestinal calcium absorption by 1,25-dihydroxyvitamin D aids in the restoration of calcium levels to normal. Vitamin D receptors are present on the parathyroid glands and act as sensors to detect adequate levels of 1,25-dihydroxyvitamin D, thus helping in the regulation of PTH synthesis and release.

Cellular effects of PTH on other cations and ions are less well described. For example, in the distal tubule, little data have been gathered regarding the effects of PTH on sodium excretion. Expansion of the extracellular fluid volume with sodium chloride decreases tubular magnesium reabsorption and increases urinary magnesium excretion. The decrease in proximal magnesium resorption parallels the decline in sodium reabsorption. In a cell culture model of distal tubular epithelium, Rodriquez-Commes and colleagues (1995) used equivalent short circuit current as an estimate of net sodium transport. Parathyroid hormone increased the current in A6 cells in a dose-dependent manner, and the effect appeared to be mediated by both cyclic AMP and intracellular calcium. PTH is responsible for both water and electrolyte transport along the nephron. Using the TPTX rat model, clearance and microperfusion studies were performed to assess the role of PTH. Normal levels of PTH were necessary to maintain concentrating ability in the animal model. In isolated medullary-collecting tubules, the lack of PTH did not alter antidiuretic hormone-induced changes in osmotic permeability, suggesting that PTH-mediated effects occurred at other locations in the nephron (Zaladek Gil *et al.,* 1999).

Numerous chloride channels have been isolated from kidney tubules, and several of them have been implicated in the maintenance of calcium homeostasis. Mutation in the chloride channel designated ClC-5 can result in the formation of kidney stones. In the thyroparathyroidectomized rat model, in the presence of vitamin D deficiency, lower serum and higher urinary calcium concentrations occur compared to control animals. ClC-5 mRNA and protein levels were decreased compared to control and vitamin D-deficient animals. Replacement of PTH reversed these findings, suggesting that PTH modulates the expression of ClC-5 in the kidney cortex, but PTH did not regulate ClC-5 gene expression in the medulla (Silva, 2000).

At the cellular level, parathyroid hormone inhibits activity of the apical membrane Na^+/H^+ exchanger. PTH(1-34) and PTHRP(1-34) stimulate adenylyl cyclase and PKC activities in renal proximal tubule OK cells. PTH(3-34), PTH(28-42), and PTH(28-49) enhance PKC activity only. All fragments inhibited the Na^+/H^+ exchanger, suggesting that signal transduction from the parathyroid hormone receptor to the Na^+/H^+ exchanger could be mediated by PKC or PKA. Inhibition of PCK attenuated the PTH(28-42)-induced inhibition of the Na^+/H^+ exchanger activity (Azarani *et al.,* 1995).

Other Renal Actions of PTH

Alternative roles for parathyroid hormone in the regulation of kidney metabolism were evaluated by Nissim and co-workers (1995). The action of parathyroid hormone on the regulation of renal glutamine and ammonia metabolism was shown to be stimulatory. Using OK kidney cells as a model, parathyroid hormone and acute acidosis stimulated glutamine metabolism by both phosphate-dependent glutaminase and glutamate dehydrogenase pathways. It was proposed that this mechanism may be mediated by decreased activity of the Na^+/H^+ exchanger. The relationship between parathyroid hormone and acidosis is of particular interest because of the well-known effect of parathyroid hormone to inhibit bicarbonate transport in the parts recta (Tam *et al.,* 1982).

Other effects of parathyroid hormone on the kidney have been tested in animal models. In a model of renal insufficiency in rats, osteopontin mRNA increased and alkaline

phosphatase decreased in renal tissue exposed to parathyroid hormone (Liang and Barnes, 1995).

Megalin is a multifunctional receptor expressed at the apical surface of proximal tubules and belonging to the low-density lipoprotein receptor gene family. This receptor is important for the endocytosis of macromolecules filtered at the glomerulus (Farquahr, 1995). It is known that proximal tubules are important in the clearance of PTH, and it has been shown that megalin mediates the endocytosis of PTH (Hilpert, 1999). Megalin-mediated PTH endocytosis was specific and purified megalin specifically recognized full-length PTH(1-84) and synthetic amino-terminal peptide fragments. In megalin-deficient mice, excretion of amino-terminal, but not of carboxyl-terminal, PTH fragments increased substantially (Willnow *et al.,* 1999).

Renal Expression and Action of PTH/PTHRP Receptors

The type I receptor (PTH1r) for PTH and PTH-related peptide is a G-protein-coupled receptor with seven transmembrane domains highly expressed in bone and kidney. The PTH1r has been implicated in specific genetic diseases affecting calcium homeostasis. Thus, intense investigations of its receptor and peptide ligands have been of great interest. The discovery of a PTH2 receptor subtype that responds to PTH but not PTHrP has further complicated our understanding of PTH action. The use of site-directed mutagenesis and photoaffinity cross-linking methods has provided specialized and specific exploration of receptor–ligand interactions (Mannstadt *et al.,* 1999).

The gene encoding the PTH/PTHRP (PTH1r) receptor has been cloned and several promoter regions have been identified. The first promoter was cloned from human kidney (Adams *et al.,* 1995; Juppner, 1994; Orloff *et al.,* 1994). A second promoter region located >3 kb upstream of this original promoter was amplified from mouse kidney RNA and corresponds to two previously unidentified exons composed of an untranslated sequence (McCuaig *et al.,* 1995; McCuaig *et al.,* 1994). These cDNAs are highly homologous to the 5′ end of a cDNA isolated from human kidney. This promoter, which is not (G+C)-rich and lacks a consensus TATA element, is highly tissue specific. It is strongly active in the kidney.

A third human promoter, P3, has also been identified and is widely expressed more so in the kidney than in other tissues. A third human promoter, P3, is widely expressed and accounts for approximately 80% of renal PTHr transcripts in the adult. In contrast, P1 activity in the kidney is weak. P2 is active at midgestation in many human tissues, including bone. P2-specific transcripts are spliced differentially in a number of human cell lines in adult tissues (Bettoun *et al.,* 1998).

Function of all three promoters is inhibited by CpG methylation *in vitro.* The first promoter (P1) is selectively hypomethylated in the adult kidney *in vivo,* suggesting that demethylation is required for renal P1 function. This occurs early and is established by 11.75 weeks of fetal age, several weeks prior and to and consistent with the onset of P1 activity. P3 is unmethylated at midgestation and is inactive. This promoter exhibits characteristics of both tissue-specific and ubiquitously active promoters. The adult methylation patterns of P1 and P3 indicate that their function requires factors expressed late in development (Bettoun *et al.* 2000).

Additional studies have revealed that the PTH/PTHRP receptor in the kidney is controlled by physiological perturbations. A model of secondary hyperparathyroidism caused by a vitamin D-deficient diet in rats is associated with a twofold reduction in PTH/PTHRP receptor mRNA. When the secondary hyperparathyroid state was corrected by vitamin D, the complement of PTH/PTHRP mRNA was restored (Turner *et al.,* 1995). In another model of secondary hyperparathyroidism, namely chronic renal failure, it could also be shown that PTH/PTHRP receptor mRNA was downregulated. Control of the secondary hyperparathyroidism with parathyroidectomy restored PTH/PTHRP mRNA levels. Of interest, verapamil was also able to restore PTH/PTHRP mRNA levels in this model (Tian *et al.,* 1994). Finally, dexamethasone had a potentiating effect on the PTH/PTHRP receptor system in OK cells by altering binding to and immunoreactivity of the PTH/PTHRP receptor (Abou-Samra *et al.,* 1994).

Actions of Parathyroid Hormone on the Vasculature and Cardiovascular System

Although not originally conceived as a vasoactive substance, it is now generally appreciated that both thyroid hormone and PTHRP have important effects to regulate vascular tone. Parathyroid hormone-induced relaxation of vascular smooth muscle (Mok *et al.,* 1989) is a mechanism for a classical hypotensive property that was first demonstrated by Collip and Clark (1925). The actions of parathyroid hormone and PTHRP as vascular smooth muscle relaxants raise questions about the physiological significance of both in this regard. PTHRP has been studied intensely because of the attractiveness of a mechanism that would depend on local production of this paracrine factor. Studies by Hongo *et al.* (1991) and Rian *et al.* (1994) have demonstrated that PTHRP is produced locally by vascular smooth muscle and endothelial cells. Sensitivity to forces of stretch, as shown in smooth muscle of the bladder (Yamamoto *et al.,* 1992) and in the oviduct (Thiede *et al.,* 1991), argues for very sensitive and regional signaling mechanisms. To help discern the intracellular signaling mechanisms that may be associated with changes in blood pressure, specific parathyroid hormone fragments were injected via the femoral vein into anesthetized rats. Human PTH(1-30)NH_2 and hPTH(1-31)NH_2 had potent hypotensive effects when injected intravenously and specifically stimulated adenyl cyclase activation. Infusion of hPTH(7-84), which stimulates phospholipase C, did not cause hypotension in this model. These data suggest that

the hypotensive effects of PTH are mediated through an intracellular cAMP mechanism (Whitfield *et al.,* 1997).

Several studies have addressed the clinical relevance of the association between parathyroid hormone levels and blood pressure measurements. The prevalence of hypertension has been noted to be higher in patients with primary hyperparathyroidism than in the general population. In a population health survey, serum parathyroid hormone levels were measured in a large number of subjects aged 39–79. In a follow-up study in 1998, 72 subjects had elevated levels of PTH and 100 subjects had normal serum PTH levels. After excluding patients with hyperparathyroidism, measurements of serum calcium, serum vitamin D, bone mineral density, and systolic and diastolic blood pressures were obtained. Subjects with elevated PTH levels had significantly lower serum calcium levels and intakes of dietary calcium than those with normal PTH levels. Differences in vitamin D intake or serum levels did not differ between the two groups. Subjects with elevated levels of parathyroid hormone had significantly lower bone mineral density in the lumbar spine than those with normal PTH levels. Females with elevated serum PTH levels had significantly higher systolic and diastolic blood pressures, but this was not true for male subjects (Jorde *et al.,* 2000). A second study looked at the association between serum parathyroid hormone levels in normotensive elderly subjects undergoing 24-hr ambulatory blood pressure monitoring. In this group of 123 subjects aged 63–88 years, serum PTH levels correlated to nocturnal systolic blood pressure, nocturnal diastolic blood pressure, daytime systolic blood pressure, and mean 24-hr systolic blood pressure on univariate and multivariate analysis. Nocturnal, daytime, and mean 24-hr blood pressures were not correlated to serum calcium, 25-hydroxyvitamin D, age, body mass index, or alcohol consumption. In this study, gender differences were also determined. However, men had higher levels of diastolic blood pressure than women. The authors concluded that serum PTH levels were strongly related to blood pressure, particularly nocturnal blood pressure in elderly subjects (Morfis *et al.,* 1997).

To further explore the relationship between blood pressure and levels of parathyroid hormone, interventional studies have been performed in human subjects. The acute administration of parathyroid hormone was utilized to mimic the role of secondary hyperparathyroidism in the pathogenesis of hypertension in patients with renal failure. Because uremia is characterized by insulin resistance and hyperinsulinemia, administration of physiologic doses of hPTH(1-34) was performed under conditions of a euglycemic clamp technique in 10 healthy male subjects. The study design was a double-blind, crossover using a sham infusion or 200 units of hPTH(1-34). The infusion of hPTH(1-34) resulted in a significant increase in mean arterial pressure compared to sham infusions. Intra-individual changes in intracellular calcium concentration determined in platelets were significantly correlated with changes in mean arterial pressure, but insulin sensitivity was not affected by PTH infusion. Thus, subacute administration of physiologic doses of parathyroid hormone under hyperinsulinemic conditions alters intracellular calcium and blood pressure in healthy subjects (Fliser *et al.,* 1997).

The effects of parathyroid hormone on the vasculature extends to potential actions on vascular reactivity as well as the blood pressure per se. Nilsson *et al.* (1999) have shown that in primary hyperparathyroidism, there is an abnormal vasodilatory response to the local infusion of metacholine and nitroprusside. Parathyroid hormone has also been shown to modulate the secretion of endothelin-1, whereas endothelin, in turn, may influence parathyroid hormone secretion. Endothelin levels have been shown to be elevated in the plasma of patients with primary and secondary hyperparathyroidism (Lakatos *et al.,* 1996). More recently, Smith *et al.* (2000) have shown that in mild primary hyperparathyroidism, certain indices of vascular stiffness were higher in primary hyperparathyroidism than in control subjects. Commentary by Silverberg (2000) places this observation in a clinical context.

The most clinically relevant question is whether improvement of blood pressure will occur in patients with elevated levels of parathyroid hormone. Several studies have evaluated blood pressure measurements before and after parathyroidectomy (Schleiffer, 1992). In most cases, hypertension occurs after extirpation of the abnormal parathyroid gland(s) and restoration of parathyroid hormone to normal levels (Sancho *et al.,* 1992). In one study of hypertensive patients on maintenance dialysis, 19 patients were evaluated 1 month before total parathyriodectomy, the first month after surgery, and also after 16 months. There was neither a clinical nor a statistically significant change in either systolic or diastolic blood pressure over time (Ifudu *et al.,* 1998).

In addition to vascular dilatory properties, parathyroid hormone and PTHRP have major effects in influencing cardiac function (Dipette *et al.,* 1992, Schluter and Piper, 1998). These actions include increases in heart rate, coronary blood flow, and contractility. PTH and PTHRP are active in the absence of changes in autonomic reflexes (Bogin *et al.,* 1981; Chui *et al.,* 1991, Dipette *et al.,* 1992; Roca-Cusachs *et al.,* 1991; Tenner *et al.,* 1983). In isolated perfused hearts, parathyroid hormone and PTHRP are positive inotropic agents (Nickols *et al.,* 1989). These studies were not able to determine whether parathyroid hormone and PTHRP are directly inotropic agents because both agents have concomitant effects on heart rate and coronary blood flow, each perturbation having the potential to influence inotropy.

To determine whether parathyroid hormone and PTHRP can directly stimulate cardiac contractility, the isolated, perfused rat heart was studied under conditions where the individual contributions of heart rate, coronary blood flow, and contractility could be assessed independently (Ogino *et al.,* 1995,). In this model, both parathyroid hormone and PTHRP stimulated heart rate, coronary blood flow, and contractility in a dose-dependent manner. When heart rate was fixed by pacing, the effect on coronary blood flow and contractility was still appreciated. However, when heart rate and coronary blood flow were rendered constant by pacing and by maximal dilatation (nitroprusside), respectively, neither parathy-

roid hormone nor PTHRP could directly increase inotropy. These studies provide evidence that the cardiac actions of parathyroid hormone and PTHRP are mediated by effects on heart rate and coronary blood flow as compared with direct actions on contractility per se. More recent studies have called attention to the actions of parathyroid hormone and PTHRP on heart rate as due to increases in the pacemaker current, I_f, of the sinoatrial node (Hara *et al.,* 1995, Hara *et al.,* 1998). These observations provide an electrophysiological basis (Shimoyama *et al.* 1998a) and, more recently, a biochemical basis (Shimoyama *et al.,* 1998b) for the actions of parathyroid hormone and PTHRP to directly alter automaticity of the heart. The demonstration that PTHRP is expressed in the heart (Moniz *et al.,* 1990, Moseley *et al.,* 1991), coupled with the known sensitivity of PTHRP to mechanical stretch forces (Pirola *et al.,* 1994; Thiede *et al.,* 1990; Yamamoto *et al.,* 1992), provides an attractive hypothesis by which PTHRP could be induced to improve cardiac function when the heart is challenged by increases in end diastolic volume.

CHAPTER 28

Renal and Skeletal Actions of Parathyroid Hormone (PTH) and PTH-Related Protein

F. Richard Bringhurst

The kidney is the focal point for the physiological regulation of mineral ion homeostasis by circulating parathyroid hormone (PTH). By directly controlling renal tubular reabsorption of calcium and phosphate and the synthesis of $1,25(OH)_2D$, PTH exerts control over both intestinal absorption and urinary excretion of these key mineral ions. Renal tubular responses to PTH deficiency, PTH or PTHRP excess, or defects in function of the type-1 PTH/PTHrP receptor (PTHR) lead to alterations in blood calcium, phosphate, or $1,25(OH)_2D$ that are the hallmarks of numerous clinical disorders, described later in this volume. This chapter reviews current understanding of the mechanisms whereby PTH (and PTHrP) control renal tubular epithelial function. The discussion will focus principally on the known actions of PTH, as relatively little is known of the possible physiologic actions of PTHrP in the kidney. Because the PTHR recognizes the active amino termini of both ligands equivalently, however, it is likely that the effects described for PTH would pertain to PTHrP as well. Expression and action of PTHrP in the kidney are discussed in the last section of the chapter. Whereas species of PTH or PTHrP receptors distinct from the PTHR have been discovered recently (see Chapter 24), the role(s) of these, if any, in normal renal physiology currently is unknown. While not unequivocally proven in each case, it is likely that the effects of PTH and PTHrP described here are mediated by the PTHR.

PTHR Expression, Signaling, and Regulation in the Kidney

The PTHR is widely expressed within the kidney among cells with dramatically different physiologic roles. The response to PTHR activation observed in individual renal cells is a complex function of the number and location of expressed PTHRs on the cell surface; the cell-specific expression of effectors capable of coupling to the PTHR; the cell-specific repertoire of PTHR-regulated genes; enzymes, channels, and transporters; the local concentrations of PTH or PTHrP ligand; exposure to other agents that regulate PTHR function heterologously; and the pattern of recent exposure to PTHR ligand(s).

PTHR Expression within the Kidney

The PTHR is widely but not universally expressed by the various cell types that collectively comprise the mammalian nephron. Early work, based on measurements of regional cAMP responses (Ardaillou *et al.,* 1983; Chabardes *et al.,* 1980; Dousa *et al.,* 1977; Morel, 1981; Sraer *et al.,* 1978) and PTH radioligand binding *in vivo* (Rouleau *et al.,* 1986), indicated that PTHRs are expressed in glomeruli, proximal convoluted (PCT), and straight tubules (PST), the cortical

thick ascending loop of Henle (cTAL), and portions of the distal nephron, including the distal convoluted tubules (DCT), connecting tubules (CNT), and early portions of the cortical collecting ducts (CCD). More recently, these functional observations have been confirmed by *in situ* hybridization of tissue sections or by reverse-transcriptase polymerase chain reaction (RT-PCR) of microdissected nephron segments, using probes derived from cloned PTHR cDNA (Lee *et al.,* 1996; Riccardi *et al.,* 1996; Yang *et al.,* 1997). Minor disparities regarding PTHR expression in Henle's loop and CCD arising from use of these sensitive molecular techniques likely reflect methodologic issues (Lee *et al.,* 1996; Riccardi *et al.,* 1996; Yang *et al.,* 1997).

Given that circulating PTH peptides may be filtered at the glomerulus and appear in the tubular urine, it is of interest that PTHRs are expressed on the apical (luminal) as well as the basolateral membranes of proximal tubular cells (Amizuka *et al.,* 1997; Kaufmann *et al.,* 1994; Shlatz *et al.,* 1975). However, these apical-membrane receptors appear not to be coupled tightly, if at all, to adenylyl cyclase (Kaufmann *et al.,* 1994; Shlatz *et al.,* 1975). Moroever, a high-capacity apical peptide-uptake mechanism, mediated by the multifunctional endocytic clearance receptor megalin (Hilpert *et al.,* 1999), likely would limit the access of filtered bioactive PTH peptides to these receptors. PTHRs are also expressed within the vasculature of the kidney, including peritubular (but not glomerular) endothelial cells and vascular smooth muscle cells (Amizuka *et al.,* 1997). As discussed further later, such receptors may mediate local or systemic vascular effects of PTHRP and PTH, respectively.

As described in more detail in Chapter 24, the PTHR gene incorporates multiple promoters and 5′-untranslated exons and therefore can generate multiple transcripts via alternative promoter usage and different patterns of RNA splicing (Amizuka *et al.,* 1997; Bettoun *et al.,* 1998; Jobert *et al.,* 1996; Joun *et al.,* 1997; McCuaig *et al.,* 1995). It is of interest that certain promoters (i.e., P1 in mouse and P3 in human) seem to be used exclusively in kidney cells, whereas a different promoter (P2) is employed to generate those PTHR mRNAs that are widely expressed in other tissues and organs (Amizuka *et al.,* 1997; Bettoun *et al.,* 1998; Joun *et al.,* 1997). Whether these differences simply reflect opportunities for tissue-specific gene regulation or lead to expression of structurally different forms of the PTHR (Jobert *et al.,* 1996; Joun *et al.,* 1997) remains to be established.

PTHR Signal Transduction in Renal Cells

The PTHR is known to couple to multiple intracellular signal transducers and effectors, including but perhaps not limited to G_s and the G_q/G_{11} family of heterotrimeric G proteins (Abou-Samra *et al.,* 1992) (see also Chapters 24 and 26). Administration of PTH *in vivo* leads to the rapid generation of nephrogenous cAMP (McElduff *et al.,* 1987; Tomlinson *et al.,* 1976) and to activation of protein kinase C (PKC) in basolateral renal cortical membranes (Bellorin-Font *et al.,* 1995). This signaling plurality via the PTHR has been abundantly confirmed and further characterized in extensive studies *in vitro,* which have involved isolated renal tubules or slices, primary renal cortical cell cultures, a widely employed established opossum kidney cell line with characteristics of PCTs (OK cells), immortalized immunoselected distal tubular cells, and various established epithelial cell lines of renal origin (i.e., COS-7, HEK293, LLC-PK1), devoid of endogenously expressed PTHRs, which have been transfected with cDNA encoding the cloned PTHR (Abou-Samra *et al.,* 1992; Azarani *et al.,* 1995, 1996; Bringhurst *et al.,* 1993; Coleman and Bilezikian, 1990; Friedman *et al.,* 1996, 1999; Goligorsky *et al.,* 1986a; Guo *et al.,* 1995; Henry *et al.,* 1983; Hruska *et al.,* 1986, 1987; Janulis *et al.,* 1992; Jobert *et al.,* 1997; Martin *et al.,* 1994; Meltzer *et al.,* 1982; Nemani *et al.,* 1991; Offermanns *et al.,* 1996; Pines *et al.,* 1996; Quamme *et al.,* 1989a; Schneider *et al.,* 1994; Siegfried *et al.,* 1995; Smith *et al.,* 1996; Tamura *et al.,* 1989; Teitelbaum and Strewler, 1984). Collectively, these studies indicate that PTH can activate adenylyl cyclase, protein kinase A (PKA), phospholipase C (PLC), PKC, and cytosolic-free calcium (Ca_i^{2+}) transients, as well as phospholipase A_2 (PLA_2) (Derrickson and Mandel, 1997; Ribeiro *et al.,* 1994; Ribeiro and Mandel, 1992) and phospholipase D (PLD) (Friedman *et al.,* 1996, 1999). Other signaling mechanisms may be recruited by PTHRs in renal cells as well. For example, PTH-induced activation of mitogen-activated protein kinases in renal epithelial cells may proceed via activation of nonreceptor tyrosine kinases, phosphorylation of EGF receptors, and subsequent assembly of active Ras/Raf-1/MEK complexes (Cole, 1999; Lederer *et al.,* 2000).

The repertoire of PTHR signaling appears to differ depending on the region of the nephron in which it is expressed. For example, cells of proximal tubular origin manifest an acute spiking Ca_i^{2+} response that likely is triggered by inositol trisphosphate released via PLC activation. Cells of distal tubular origin, in contrast, exhibit a very delayed and sustained Ca_i^{2+} response (probably due to apical Ca^{2+} entry; see later) and show PKC activation in the absence of PLC stimulation (Friedman *et al.,* 1996). The PKC response to PTH in these DCT cells may be mediated by PLD (Friedman *et al.,* 1999). The coupling of specific PTHR-generated signals to the various physiologic responses to PTH or PTHRP that occur in different renal epithelial cells has not yet been fully clarified and will be discussed further later.

Regulation of PTHR Signaling in Renal Cells

As in other PTH/PTHRP target cells, the responsiveness of renal epithelial cells to PTH or PTHRP may be regulated, both by previous or chronic exposure to the homologous ligand and by other agonists that do not interact directly with the PTHR. Desensitization of renal cellular responsiveness during continuous exposure to high concentrations of PTH or

PTHRP has been well documented and studied extensively. Chronic hyperparathyroidism, either primary or secondary to calcium or vitamin D deficiency, as well as acute infusion of PTH, leads to PTH resistance in humans or animals, manifested by impaired cAMP and phosphaturic responses (Bellorin-Font *et al.,* 1995; Carnes *et al.,* 1980; Forte *et al.,* 1976; Tomlinson *et al.,* 1976; Tucci *et al.,* 1979). In humans, the cAMP response may be desensitized more readily than the phosphaturic response at low doses of hormone (Law and Heath, 1983). Similar desensitization is observed in cultured renal epithelial cells (Fujimori *et al.,* 1993; Guo *et al.,* 1997; Henry *et al.,* 1983; Pernalete *et al.,* 1990; Urena *et al.,* 1994a).

Several factors may contribute to this renal resistance to PTHR activation, including a reduced number of cell surface PTHRs, persistent occupancy of PTHRs by ligand, and defective coupling between available PTHRs and the G proteins that mediate activation of effectors such as adenylyl cyclase or PLC (i.e., a "postreceptor" defect). The relative roles of these factors in causing PTHR desensitization appear to vary according to the specific situation and experimental system (Carnes *et al.,* 1978; Forte *et al.,* 1976; Mahoney and Nissenson, 1983; Mitchell *et al.,* 1988; Tamayo *et al.,* 1982; Turner *et al.,* 1995). As reviewed in more detail in Chapters 24 and 26, it is clear that PTHRs are internalized rapidly following ligand occupancy and activation, a response that lowers cell surface receptor expression and that is due to PTHR phosphorylation by both PTHR-dependent activation of "signal kinases" (PKA, PKC) and the action(s) of generic G protein-coupled receptor kinases (Blind *et al.,* 1996; Dicker *et al.,* 1999; Qian *et al.,* 1998). The particular PTHR-generated signals that mediate PTHR desensitization in renal epithelial cells may be cell type specific. For example, in OK proximal tubular cells, homologous desensitization of the PTHR cAMP response is PKC dependent (Pernalete *et al.,* 1990), whereas in PTHR-transfected LLC-PK1 cells, desensitization is pathway specific, i.e., adenylyl cyclase is fully desensitized by cAMP-dependent signaling only, whereas desensitization of the PLC response is linked to prior PLC activation (Guo *et al.,* 1997). Control of receptor expression may be an important mechanism for modulating the relative, as well as the absolute, intensities of signaling along the various transduction pathways coupled to the PTHR. Thus, as shown in a series of PTHR-transfected LLC-PK1 renal epithelial cell subclones that comprised a broad range of receptor expression, the magnitude of the PLC response was influenced much more strongly by changes in cell surface PTHR density than the adenylyl cyclase response (Guo *et al.,* 1995). This was interpreted as evidence that the coupling between G_s and the PTHR in these cells is more efficient than that between the PTHR and the G_q that presumably mediates PLC activation. In any event, it is clear that changes in PTHR expression may allow differential modulation of PTHR signaling responses in a given renal cell.

Expression of PTHRs on the surface of kidney cells is also controlled by the rate of PTHR gene transcription, although current understanding of this process is incomplete. Hypoparathyroidism, induced by either parathyroidectomy or dietary phosphate depletion, strongly upregulates PTHR mRNA levels in rat renal cortex (Kilav *et al.,* 1995). Curiously, the opposite effect, i.e., suppression of PTHR mRNA by exposure to high concentrations of PTH, has not been observed either *in vivo* or *in vitro* (Kilav *et al.,* 1995; Urena *et al.,* 1994a). Renal PTHR mRNA expression is reduced in rats with renal failure, but this apparently is due to some aspect of uremia or renal disease other than secondary hyperparathyroidism *per se*, as it is not prevented by parathyroidectomy (Largo *et al.,* 1999; Urena *et al.,* 1994b, 1995). In rats with secondary hyperparathyroidism due to vitamin D deficiency, renal cortical PTHR mRNA levels actually were found to be twice as high as normal, a change that could not be corrected by normalizing serum calcium (Turner *et al.,* 1995). This experiment has been interpreted as evidence of a suppressive action of vitamin D on PTHR gene transcription in the proximal tubule, although this may not be true of all renal epithelial cells. For example, PTHR expression is upregulated severalfold by $1,25(OH)_2D_3$ in immortalized DCT cells (Sneddon *et al.,* 1998). In cultured OK cells, TGFβ1 was shown to diminish PTHR mRNA expression, but the possible physiologic significance of this effect *in vivo* has not been clarified (Law *et al.,* 1994). PTHR mRNA expression was not affected by the mild secondary hypoparathyroidism induced by ovariectomy in rats nor by subsequent estrogen treatment (Cros *et al.,* 1998).

Calcium and Magnesium Excretion

The action of PTH to maintain blood calcium was among the first to be described, and early observations in animals or patients with hypoparathyroidism or hyperparathyroidism clearly implicated abnormalities in renal calcium handling (see Chapters 56 and 62). Alterations in serum magnesium concentrations frequently are encountered also in patients with parathyroid disorders, which led to the understanding that PTH participates in magnesium homeostasis as well (see Chapter 21). The mechanisms whereby Ca^{2+} and Mg^{2+} are reabsorbed are similar and interrelated in some regions of the nephron but different in others.

Sites and Mechanisms of Calcium and Magnesium Reabsorption

Calcium and Mg^{2+} are reabsorbed at many sites along the nephron (de Roufignac and Quamme, 1994; Friedman, 1998). Approximately 60% of filtered Ca^{2+}, but only 20% of filtered Mg^{2+}, is reabsorbed by the proximal tubule. Reabsorption here is almost entirely passive, driven by both the ambient lumen-positive voltage and the progressive concentration of these ions within the tubular urine as Na^+ and water are reabsorbed along the proximal segments (de Roufignac and

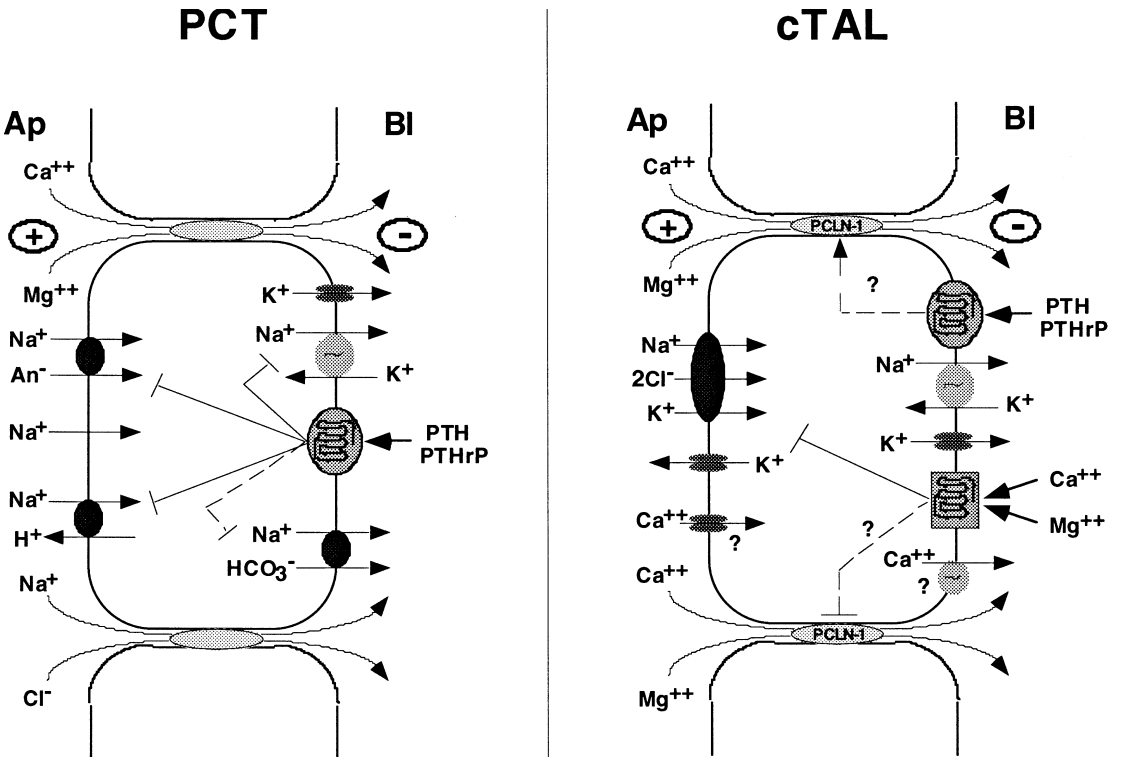

Figure 1 Calcium and magnesium reabsorption in PCT and cTAL. In the PCT (left), Ca^{2+} and Mg^{2+} are reabsorbed passively via paracellular routes at rates driven by the lumen-positive transepithelial voltage and limited by the conductance of the intercellular junctions for these cations. Transpeithelial voltage, depicted as positive at the apical ("Ap") relative to the basolateral ("Bl") side of the epithelium, is generated by paracellular diffusion of Cl^- ions, which, like Ca^{2+} and Mg^{2+} ions, are concentrated progressively along the lumen by active transcellular Na^+ reabsorption. Major mechanisms of Na^+ reabsorption shown include Na^+/H^+ exchange, Na^+-dependent cotransport of anions (phosphate, amino acids, sulfate, etc.), and a small apical Na^+ conductance, all driven by the low intracellular Na^+ concentration established by the Na^+-K^+-ATPase, which pumps 3 Na^+ ions out for each 2 K^+ ions that enter the cell. The stoichiometry of the basolateral electrogenic Na^+/HCO_3^- cotransporter (1 Na^+ per 3 HCO_3^- ions) allows for active basolateral extrusion of some Na^+ because of the negative intracellular potential (not shown) and the favorable HCO_3^- concentration gradient that drive HCO_3^- exit. PTHRs expressed in PCT inhibit Na^+ transport by multiple mechanisms and thereby moderately impair Ca^{2+} and Mg^{2+} reabsorption (dashed lines indicate responses about which some uncertainty exists). In cTAL (right), Ca^{2+} and Mg^{2+} reabsorption again occurs mainly via voltage-dependent paracellular transport, although transcellular Ca^{2+} transport, presumably mediated by apical Ca^{2+} channels and basolateral Ca^{2+}-ATPases, has also been described ("?"). Apical NKCC2 cotransporters and ROMK K^+ channels maintain the lumen-positive transepithelial voltage necessary for cation transport, which is inhibited by the Ca^{2+}/Mg^{2+}-dependent activation of the CaSR and by the loop diuretic furosemide. Chloride exits across the basolateral membrane via one or more Cl^- channels, including ClC-Kb (not shown). The channel protein parcellin-1 appears to be critical for paracellular cation transport in the cTAL and could be a target for CaSRs and PTHRs, which, respectively, reduce and augment cation transport in this nephron segment.

Quamme, 1994; Frick *et al.,* 1965; Friedman, 1998) (Fig. 1). In the proximal tubule, the route of reabsorption for both Ca^{2+} and Mg^{2+} is almost entirely paracellular, and differences in permeability of the intercellular tight junctions for the two cations presumably account for the preferential reabsorption of Ca^{2+} here.

Both Ca^{2+} and Mg^{2+} are also passively reabsorbed in the cTAL of Henle's loop, although here the permeability for Mg^{2+} may be greater than that for Ca^{2+}, as 60% of Mg^{2+} but only 20% of Ca^{2+} is reabsorbed in this segment. The lumen-positive transepithelial voltage gradient that drives Ca^{2+} and Mg^{2+} transport in the cTAL is maintained by, and proportional to, the rate of Na^+-K^+-$Cl^-{}_2$ transport, which is dependent, in turn, on the activities of the NKCC2, ClC-Kb, and ROMK transporters (Hebert *et al.,* 1984). The calcium-sensing receptor (CaSR) is also especially strongly expressed in Henle's loop, and activation of this receptor by high peritubular Ca^{2+} or Mg^{2+} concentrations inhibits Ca^{2+} and Mg^{2+} reabsorption in the cTAL, presumably by reducing the transepithelial voltage gradient (Brown *et al.,* 1998) (see Chapter 23). It is also possible that the CaSR may mediate inhibition by Ca^{2+} and Mg^{2+} of the cAMP response to PTH (Bapty *et al.,* 1998; Slatopolsky *et al.,* 1976; Takaichi and Kurokawa, 1986). Paracellin-1, a novel member of the claudin family of tight-junction proteins that is expressed only in Henle's loop and the DCT, has been identified as the cause of an autosomal recessive renal magnesium and Ca^{2+}-wasting disorder (Simon *et al.,* 1999). While not yet demonstrated directly, it seems likely that the expression of paracellin-1 may control the passive permeability of the cTAL for both Ca^{2+} and Mg^{2+}. There is also some evidence for active, transcellular transport of Ca^{2+} by

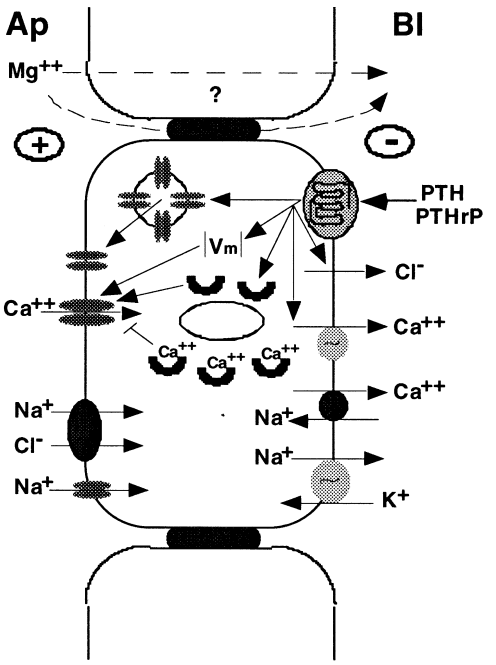

Figure 2 PTH regulation of distal tubular calcium reabsorption. In DCT, Ca^{2+} reabsorption involves apical Ca^{2+} entry via voltage-sensitive Ca^{2+} channels and subsequent basolateral extrusion by Ca^{2+}-ATPases and, uniquely, Na^+/Ca^{2+} exchangers driven by the Na^+-K^+-ATPase. Multiple Ca^{2+} channels may be expressed here, including CaT2 and the ECaC channel that is activated by hyperpolarizing voltages (increased $|V_m|$). Inhibition of the thiazide-sensitive NaCl transporter, with continued basolateral Cl^- exit, hyperpolarizes the cell toward the K^+ equilibrium potential, which then increases Ca^{2+} entry by CaT2/ECaC and possibly other channels activated by hyperpolarizing potentials. Calbindin D28K binds and shuttles Ca^{2+} from the apical membrane to the basolateral sites of active Ca^{2+} extrusion, thereby buffering the cytoplasm from high concentrations of transported Ca^{2+}. Calbindin D28K is induced by $1,25(OH)_2D_3$ and may directly activate apical Ca^{2+} channels, which otherwise are inhibited by intracellular Ca^{2+} ions. PTHR activation leads to insertion of additional apical Ca^{2+} channels, hyperpolarization of the cell (? via enhancing basolateral Cl^- exit), and thus activation of Ca^{2+} channels, increased calbindin D28K expression, and stimulation of the basolateral Ca^{2+}-ATPase. The routes and mechanisms of Mg^{2+} reabsorption in DCT are unknown.

the cTAL (Friedman and Gesek, 1995). Calcium-sensitive cation channels have been found in cTAL apical membranes (Chraibi *et al.,* 1994), as have Ca^{2+}-ATPases that would be necessary for extrusion across the steep basolateral electrochemical gradient (Caride *et al.,* 1998).

Finally, small but critical fractions of filtered Ca^{2+} and Mg^{2+} — approximately 5–10% each — are reabsorbed in the distal nephron (i.e., the DCT, CNT, and early CCD). The mechanism of Mg^{2+} reabsorption by the distal nephron is obscure, but it seems to be closely related to that of NaCl, in that both pharmacologic (thiazide diuretics) and genetic (Gitelman's syndrome) inhibition of the thiazide-sensitive NaCl cotransporter (TSC) impairs Mg^{2+} reabsorption. In contrast, Ca^{2+} reabsorption in the distal nephron, which involves transcellular active transport against an unfavorable electrochemical gradient (Costanzo and Windhager, 1978; Lau and Bourdeau, 1995; Shareghi and Stoner, 1978), is promoted by TSC inhibition, which hyperpolarizes the apical cell membrane. Cells of the distal nephron express several proteins that are required for effective transcellular active Ca^{2+} transport (Friedman, 1998) (see Fig. 2). Calcium enters the apical membrane via multiple Ca^{2+} channels (Barry *et al.,* 1998; Matsunaga *et al.,* 1994), one of which, ECaC, has been cloned from rabbit and shown to be expressed in the distal tubule, to be activated by hyperpolarizing voltages, and to be inactivated by intracellular Ca^{2+} (Hoenderop *et al.,* 1999a,b;). Another Ca^{2+} transporter, CaT2, with properties similar but not identical to those of ECaC, has been cloned from rat and also shown to be expressed in distal tubular cells (Peng *et al.,* 2000). These cells also express the vitamin D-dependent calbindin-D28K calcium-binding protein, which can transport Ca^{2+} across the cytoplasm while buffering the submicromolar cytosolic-free Ca^{2+} concentration against the high mass flux of transported Ca^{2+} (Bronner and Stein, 1988; Liu *et al.,* 1996; Van Baal *et al.,* 1996). Calbindin-D28K may also directly activate apical membrane Ca^{2+} channels (Bouhtiauy *et al.,* 1994). Extrusion of transported Ca^{2+} across the basolateral membrane can occur via both a direct Ca^{2+}-ATPase and a high-capacity Na^+/Ca^{2+} exchanger driven by the transmembrane Na^+ gradient.

PTH Regulation of Renal Calcium and Magnesium Excretion

Administration of PTH *in vivo* increases the net renal reabsorption of both Ca^{2+} and Mg^{2+} (Bailly *et al.,* 1984; Burnatowska *et al.,* 1977; de Roufignac and Quamme, 1994; Everhart-Caye *et al.,* 1996; Massry and Coburn, 1973; Peacock *et al.,* 1969). PTH augments Mg^{2+} reabsorption in the cTAL (De Rouffignac *et al.,* 1991; Di Stefano *et al.,* 1990; Shareghi and Agus, 1982) and possibly in the distal nephron as well (Bailly *et al.,* 1985), but the mechanism(s) involved is obscure. PTH may increase the transepithelial voltage that drives paracellular Mg^{2+} (and Ca^{2+}) transport in the cTAL, but this is controversial (Di Stefano *et al.,* 1990; Shareghi and Agus, 1982) and, in any event, is unlikely to explain the magnitude of the PTH effect (de Roufignac and Quamme, 1994). Other experiments indicate that the PTH response probably is mediated by an increase in paracellular Mg^{2+} permeability (Wittner *et al.,* 1993). In this regard, it will be of interest to learn if PTH upregulates paracellin-1 expression or permeability.

Although PTH increases net renal Ca^{2+} reabsorption overall, it inhibits Ca^{2+} reabsorption somewhat in the PCT (Agus *et al.,* 1971, 1973; Amiel *et al.,* 1970). As will be discussed further later, this results from the action of PTH to reduce Na^+ reabsorption (via inhibition of both NaP_i cotransport and Na^+/H^+ exchange) and Na^+-K^+-ATPase activity, processes that otherwise support net solute and water reabsorption and thereby establish the elevated intraluminal concentrations of Ca^{2+} and Cl^- required for the effective paracellular movement of Ca^{2+} in the PCT. In contrast, PTH augments Ca^{2+} reabsorption in the cTAL and in the distal nephron, especially

in the CNT (Agus *et al.,* 1973; Bourdeau and Burg, 1980; Imai, 1981; Shareghi and Stoner, 1978; Shimizu *et al.,* 1990a), and it is these actions that account for the overall positive effect of PTH on renal Ca^{2+} reabsorption. The mechanism of the PTH effect in the cTAL has not been studied intensively but likely proceeds via an increase in transepithelial voltage and enhanced paracellular Ca^{2+} transport (Di Stefano *et al.,* 1990), although some evidence suggests a component of transcellular transport as well (Friedman, 1988).

The distal nephron clearly is the major site at which PTH regulates Ca^{2+} transport. PTH exerts several specific actions in these cells that independently contribute to increased Ca^{2+} reabsorption. PTH increases Ca^{2+} uptake across apical membranes of distal tubular cells, an effect that can be observed in apical membrane vesicles isolated following PTH administration *in vivo* or to isolated tubules *in vitro* (Bourdeau and Lau, 1989; Lajeunesse *et al.,* 1994). In cultured cells obtained from mouse cTAL and DCT, PTH induced a delayed (10 min) and sustained increase in cytosolic Ca^{2+} that was of extracellular origin, was blocked by dihydropyridine Ca^{2+} channel antagonists, and appeared to result from the exocytosis of membranes harboring preformed but functionally latent intracellular Ca^{2+} channels (Bacskai and Friedman, 1990). These channels were of low conductance and were activated by hyperpolarizing voltages (Matsunaga *et al.,* 1994), features also reported for the subsequently cloned ECaC channel (Hoenderop *et al.,* 1999b). It is not yet clear, however, if either ECaC or CaT2 serves as a major route of regulated Ca^{2+} entry in distal tubular cells, nor is it established that these channels are regulated by PTH. Importantly, PTH acutely hyperpolarizes distal tubular cells, at least in part by increasing basolateral Cl^- conductance (Gesek and Friedman, 1992). This action could activate ECaC or CaT2 channels (Hoenderop *et al.,* 1999b; Peng *et al.,* 2000) and also increase both the driving force for apical membrane Ca^{2+} entry and the rate of Na^+/Ca^{2+} exchange at the basolateral membrane (White *et al.,* 1996). Increased Na^+/Ca^{2+} exchange has been demonstrated following PTH administration *in vivo* and *in vitro* (Hanai *et al.,* 1986; Scoble *et al.,* 1985). Moreover, activation of Na^+/Ca^{2+} exchange is critical for the action of PTH to increase Ca^{2+} reabsorption, as this can be blocked completely in rabbit CNTs and DCT cells either by disrupting the Na^+ gradient that drives the Na^+/Ca^{2+} exchanger with ouabain or monensin or by removing extracellular Na^+ from the basolateral compartment (Shimizu *et al.,* 1990b; White *et al.,* 1996). The fact that this exchanger is expressed only in the distal, and not the proximal, nephron may explain, at least in part, why distal and not proximal tubular cells can conduct transcellular Ca^{2+} transport (Bouhtiauy *et al.,* 1991; Lajeunesse *et al.,* 1994; White *et al.,* 1996, 1997). PTH may also increase Ca^{2+} extrusion by activating basolateral Ca^{2+}-ATPase (Levy *et al.,* 1986), although this is not observed in all systems (Bouhtiauy *et al.,* 1991). Finally, expression of the calbindin-D28K protein in renal cortex has been shown to decrease following parathyroidectomy and to increase following PTH infusion into intact rats (Hemmingsen *et al.,* 1996). The powerful inductive effect of $1,25(OH)_2D_3$ on calbindin-D28K expression in the distal nephron (Christakos *et al.,* 1981; Rhoten *et al.,* 1985) may be involved in mediating this action of PTH, given that PTH augments $1,25(OH)_2D_3$ synthesis (see later) and that $1,25(OH)_2D_3$ directly accelerates the distal tubular calcium reabsorptive response to PTH *in vitro* (Friedman and Gesek, 1993). Other evidence indicates that PTH can increase calbindin-D28K independently of $1,25(OH)_2D_3$ or serum calcium, however (Hemmingsen *et al.,* 1996).

PTHR Signal Transduction in Regulation of Calcium and Magnesium Excretion

The particular PTHR-generated signals responsible for these various effects of PTH on components of the distal tubular Ca^{2+}-reabsorptive response are not fully clarified. The initial entry of Ca^{2+} across the apical membrane seems to require activation of both PKA and PKC in immortalized murine DCT cells (Friedman *et al.,* 1996, 1999). In many experimental systems, the PTH effect on distal Ca^{2+} transport can be mimicked by cAMP analogs or phosphodiesterase inhibitors (Bourdeau and Lau, 1989; Lau and Bourdeau, 1989; Shimizu *et al.,* 1990b), although in isolated rabbit CNT/CCD tubules, in which this cAMP mimicry also pertains, the effect of PTH was prevented by chelerythrine, a PKC inhibitor, but not by dideoxyadenosine, an adenylyl cyclase inhibitor that did block PTH-dependent cAMP accumulation (Hoenderop *et al.,* 1999a). Further evidence implicated a Ca^{2+}-independent ("atypical") PKC as a mediator of this PTH effect (Hoenderop *et al.,* 1999a). In murine DCT cells, PTH activates the mitogen-activated protein kinase ERK2 via a PKC-dependent mechanism, and inhibition of the ERK2 kinase (MEK) blocks PTH-induced increases in cytosolic Ca^{2+} (Sneddon *et al.,* 2000). Similarly, the ability of dibutyryl cAMP to promote Ca^{2+} transport in rabbit distal tubules was potentiated greatly by phorbol esters, which exerted no effect alone, and PKC inhibitors did block the effect of the combination of phorbol and cAMP analog as well as that of the cAMP analog alone (Hilal *et al.,* 1997). PTH stimulation of Na^+/Ca^{2+} exchange, transepithelial hyperpolarization, and, in canine cells, Ca^{2+}-ATPase is also reproduced by cAMP analogs (Bouhtiauy *et al.,* 1991; Hanai *et al.,* 1986; Levy *et al.,* 1986; Scoble *et al.,* 1985; Shimizu *et al.,* 1990a), although, as just noted, such evidence clearly does not exclude a role for other PTHR messengers in these processes as well. Considering that PTH may have to orchestrate a series of independent "elemental responses" to achieve effective distal tubular Ca^{2+} reabsorption, including membrane hyperpolarization, increased exocytosis of latent Ca^{2+} channels, increased calbindin-D28K expression, increased Na^+/Ca^{2+} exchange [this possibly secondary entirely to the hyperpolarization and increased cytosolic-free Ca^{2+} (Friedman, 1998)] and increased Ca^{2+}-ATPase activity, and that these responses may not all occur in the same cells, it is perhaps not surprising that some ambiguity persists regarding the roles of PKA vs PKC (or other PTHR-activated effectors)

in controlling overall distal tubular Ca^{2+} transport. Apparent requirements for multiple effectors may reflect a convergence of several signals on a single mechanism, independent actions of different effectors on one or more of the elemental cellular responses that contribute to the overall Ca^{2+}-reabsorptive response, or both.

Phosphate Excretion

Phosphaturia was one of the earliest recognized actions of PTH (Albright *et al.,* 1929; Collip, 1925; Ellsworth and Howard, 1934; Hiatt and Thompson, 1956). With the advent of micropuncture analysis, it became clear that the effect of PTH to inhibit phosphate reabsorption occurs almost entirely in the proximal tubules, especially in the late portion of the PCT (Agus *et al.,* 1971, 1973; Amiel *et al.,* 1970; Brunette *et al.,* 1973; LeGrimellec *et al.,* 1974; Strickler *et al.,* 1964; Wen, 1974). Some evidence points to a small component of PTH-inhibitable phosphate reabsorption in the distal nephron as well (Amiel *et al.,* 1970; Bengele *et al.,* 1979; Pastoriza-Munoz *et al.,* 1978; Pastoriza-Munoz *et al.,* 1983; Wen, 1974).

Mechanisms of Proximal Tubular Phosphate Reabsorption

Extensive experimentation with isolated perfused tubules, renal membranes, and membrane vesicles since the mid-1970s, reviewed exhaustively by Murer and colleagues (Gmaj and Murer, 1986; Murer *et al.,* 1991; Murer, 1992), has provided a clear picture of the mechanisms of proximal tubular phosphate reabsorption. Phosphate (P_i) must be moved across the apical membrane of the cell against a steep electrochemical gradient imposed by the strongly negative intracellular potential. This is accomplished by Na^+/P_i cotransporters energized by the high transmembrane Na^+ gradient. Early biochemical analyses had indicated that multiple such Na^+/P_i cotransporters, with distinct kinetic, allosteric, and physical properties, are located within the renal cortex (Levi, 1990; Walker *et al.,* 1987). Some of these may be so-called "housekeeping" cotransporters, presumed to reside on the basolateral membranes, that are expressed ubiquitously by all cells and involved in maintaining intracellular P_i concentrations, whereas others are epithelial specific and devoted to the specialized function of transepithelial phosphate transport (Murer, 1992) (Fig. 3).

Three major classes (types I, II, and III) of Na^+/P_i ("NaP_i") cotransporters, products of different genes, have been cloned and shown to be expressed in PCT cells (Custer *et al.,* 1993, 1994; Murer and Biber, 1997; Tenenhouse, 1997). Type I and type IIa NaP_i cotransporters are localized to the apical brush border membrane of PCT cells (Murer *et al.,* 1996). [Type IIb transporters, closely related to type IIa, are expressed in intestine but not in kidney (Hilfiker *et al.,* 1998),] Type III NaP_i cotransporters, originally identified as cell surface virus

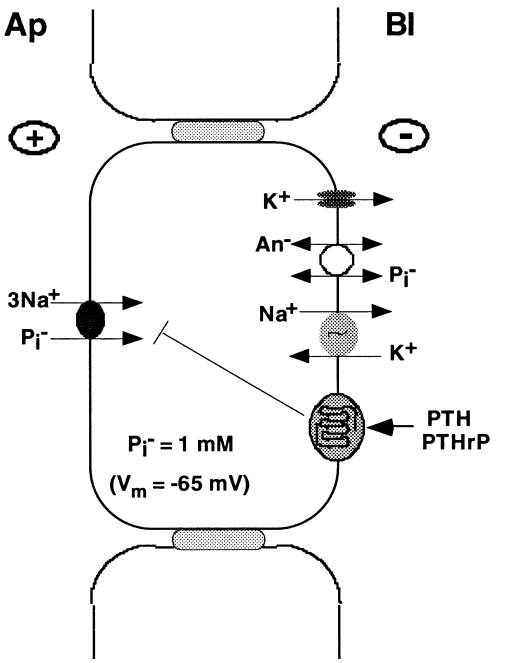

Figure 3 Phosphate reabsorption in the proximal tubule. Phosphate (P_i) must be transported actively across the apical membrane of the PCT cell because of the strongly interior-negative potential and the fact that the cytosolic P_i concentration (1 m*M*) is roughly 100-fold above equilibrium. This transport is accomplished by an electrogenic type IIa NaP_i cotransporter [stoichiometry = 3 Na^+ ions per Pi (mono- or dibasic) ion] that is energized by the steep transmembrane Na^+ gradient established by the basolateral Na^+-K^+-ATPase. Activity of this cotransporter is reduced by PTHR activation. Mechanisms of basolateral P_i exit are not well understood, but an anion exchanger could allow P_i to leave the cell passively.

receptors (Glvr-1 and Ram-1), are widely expressed, both within and outside the kidney (Kavanaugh and Kabat, 1996). Type III cotransporters, which are regulated by extracellular P_i deprivation and, via a PKC-dependent mechanism, by PTHRs, are also expressed by DCT cells and thus might be involved in phosphate reabsorption in both proximal and distal nephrons (Fernandes *et al.,* 2001; Tenenhouse *et al.,* 1998). As shown by targeted gene disruption in mice, type IIa cotransporters account for 70% of renal P_i reabsorption (Beck *et al.,* 1998). They are 80- to 90-kDa glycoproteins that are predicted to span the membrane eight times, with both their amino and carboxyl termini oriented into the cytosol (Murer and Biber, 1997). Type IIa cotransporters are electrogenic and transport Na^+ and $H_2PO_4^-$ in a molar ratio of 3:1 (Murer and Biber, 1997). Expression and activity of type IIa NaP_i cotransporters ("NaP_i-2", in rat; "NaP_i-3" or "NPT2" in human) are strongly regulated by both parathyroid status and dietary phosphate (Keusch *et al.,* 1998; Lotscher *et al.,* 1999; Murer *et al.,* 1996; Pfister *et al.,* 1997; Ritthaler *et al.,* 1999; Takahashi *et al.,* 1998), and PTH regulation of serum P_i and tubular NaP_i reabsorption is lost in mice lacking type IIa cotransporters (Zhao and Tenenhouse, 2000). Thus, regulation of NaP_i-2 activity is the principal mechanism whereby PTH controls phosphate reabsorption in the PCT.

PTH Regulation of Proximal Tubular Phosphate Reabsorption

Early work had demonstrated that PTH rapidly lowers the maximal rate of NaP_i cotransport in brush border membrane vesicles and that recovery from this effect requires new protein synthesis, suggesting that PTH causes degradation of NaP_i cotransporters (Dousa *et al.,* 1976; Gmaj and Murer, 1986; Hammerman, 1986; Malmstrom and Murer, 1987). Functional and immunohistochemical analyses of NaP_i-2 protein expression in rat kidney and in cultured OK cells have confirmed that PTH induces a rapid (15 min) movement of NaP_i-2 protein away from the apical membrane, into the subapical endocytic apparatus, followed by a microtubule-dependent delivery to lysosomes and proteolytic degradation (Kempson *et al.,* 1995; Keusch *et al.,* 1998; Lotscher *et al.,* 1999; Pfister *et al.,* 1997; Zhang *et al.,* 1999) (see Fig. 4). This PTH-induced retrieval of NaP_i-2 from apical membranes requires the presence of a specific dibasic amino acid motif in the most carboxyl-terminal of the putative cytosolic loops of NaP_i-2 and apparently is not mediated by the direct action of kinases upon the NaP_i-2 protein (Karim-Jimenez *et al.,* 2000). PTH does not acutely reduce NaP_i-2 mRNA expression, although parathyroidectomy does lead to increases of severalfold in levels of both apical NaP_i-2 protein and mRNA (Kilav *et al.,* 1995; Pfister *et al.,* 1998; Saxena *et al.,* 1995; Takahashi *et al.,* 1998).

PTHR Signal Transduction in the Regulation of Phosphate Excretion

Early experiments *in vivo* or with isolated renal membranes indicated a role for cAMP-dependent actions of PTH in regulating phosphate excretion, based mainly on mimicry of the PTH effect by cAMP analogs or cAMP phosphodiesterase inhibitors (Agus *et al.,* 1973; Gmaj and Murer, 1986; Hammerman, 1986). Many of these studies were conducted before the cAMP-independent signaling features of the PTHR were recognized, however (Dunlay and Hruska, 1990).

The involvement of specific PTHR-generated signals in NaP_i regulation has been pursued extensively *in vitro* using the OK opossum kidney cell line, which expresses both type IIa NaP_i cotransporters and PTHRs (Juppner *et al.,* 1991), exhibits other features of PCT cells, and manifests PTH-dependent inhibition of NaP_i cotransport (Caverzasio *et al.,* 1986; Cole *et al.,* 1988; Lederer *et al.,* 1998; Martin *et al.,* 1994; Murer, 1992; Pfister *et al.,* 1999; Segal and Pollock, 1990). There is general agreement that direct pharmacologic activation of either PKA or PKC can inhibit NaP_i activity in OK cells. The importance of the cAMP response of PTHR was highlighted by experiments in which expression of a dominant-negative inhibitor of PKA (mutant PKA regulatory subunit gene) in OK cells completely blocked NaP_i downregulation by PTH (Segal and Pollock, 1990) and by the demonstration that NaP_i regulation by PTH was unaffected when PLC/PKC activation was completely

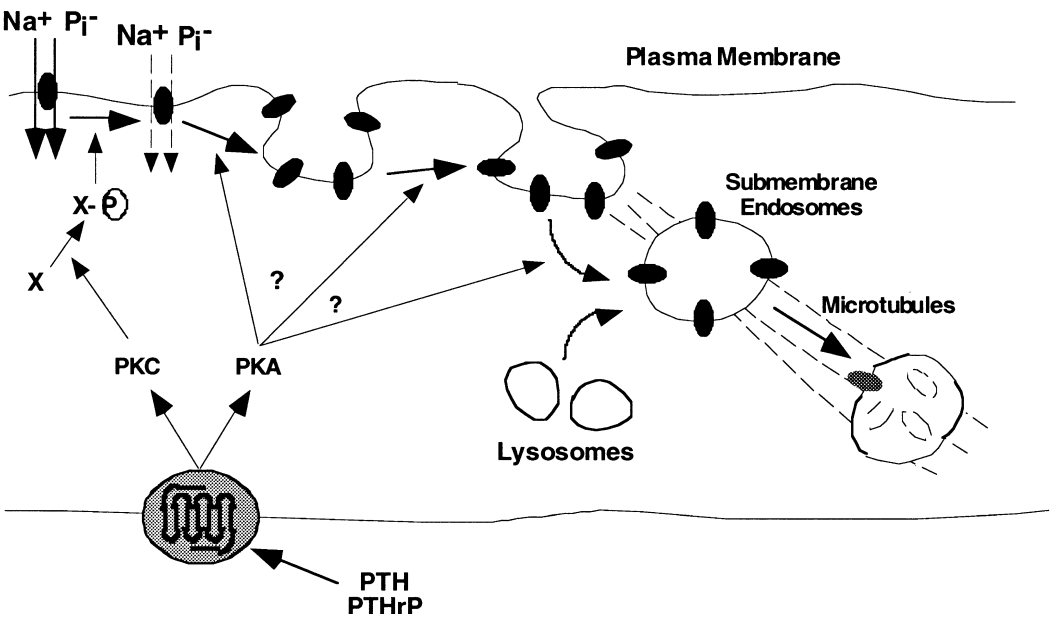

Figure 4 Regulation of NaP_i cotransport by PTH. Activation of PTHRs on the basolateral membrane of PCT cells stimulates PKA and PKC. PKC induces a rapid decrease in the activity of NaP_i-2 transporters expressed on the apical surface, an effect that is mimicked by PTH(3-34). This may involve phosphorylation of one or more intermediary proteins ("X"), as consensus PKC phosphorylation sites within the NaP_i-2 protein can be eliminated without affecting this regulatory effect of PKC. Activation of PKA also impairs NaP_i cotransport, but this effect is more delayed and involves retrieval of surface NaP_i-2 cotransporters by a microtubule-dependent process of endocytosis, lysosomal fusion, and degradation. The responsible PKA substrates and details of their actions currently are unknown ("?").

inhibited by the drug U73122 (Martin *et al.,* 1994). However, a role for PKC was suggested by findings that NaP_i activity could be at least partially regulated by PTH analogs, such as PTH(3-34), at concentrations that do not activate adenylyl cyclase or PKA but which do stimulate PKC (Cole *et al.,* 1988, 1989; Pfister *et al.,* 1999; Reshkin *et al.,* 1991). Moreover, NaP_i regulation in OK cells by PTH(1-34) can be blocked by pharmacologic inhibition of PKC and may be observed at concentrations that activate PKC but are too low to measurably stimulate PKA (Cole *et al.,* 1988; Malmstrom *et al.,* 1988; Quamme *et al.,* 1989a,b). The NaP_i-2 protein can be phosphorylated and contains several consensus sites for PKC, but mutation of these sites does not interrupt PKC- or PTH-dependent downregulation of NaP_i-2 activity (Hayes *et al.,* 1995; Karim-Jimenez *et al.,* 2000; Murer *et al.,* 1996). Thus, PKC-dependent phosphorylation of other proteins, which then act to regulate NaPi-2, may mediate this effect (Hayes *et al.,* 1995; Murer *et al.,* 1996).

Studies involving selective application of PTH(1-34) or PTH(3-34) to the apical vs basolateral surfaces of perfused murine proximal tubules indicate that PTHRs present in both membrane domains can induce rapid retrieval of apical NaP_i proteins but that this occurs via an exclusively PKC-dependent mechanism via activation of apical PTHRs, whereas basolateral PTHRs apparently accomplish this through a pathway more dependent on PKA (Traebert *et al.,* 2000). *In vivo,* apical PTHRs presumably may be activated by PTH peptides that are filtered through the glomerulus and then appear in the luminal fluid. Other experiments suggest that PKA and PKC activation may lead to temporally and qualitatively distinct changes in NaP_i-2 protein expression and activity (Lederer *et al.,* 1998; Pfister *et al.,* 1999) (Fig. 4). For example, PTH(3-34) initially inhibited NaP_i activity comparably to PTH(1-34), but did so with no, or much less, induced clearance of the protein from the cell surface, which suggested that the main effect of PKC was to reduce the activity of the cotransporter, whereas that of PKA may relate more directly to the physical removal of the protein from the apical membrane via endocytosis (Lederer *et al.,* 1998; Pfister *et al.,* 1999). Thus, while a coherent view has yet to fully emerge, it seems reasonable to conclude at present that activation of PKA and PKC via the PTHR each can separately downregulate NaP_i activity, that stimulation of both kinases may be necessary for a full response to the hormone, and that PTHRs located on different surfaces of PCT cells may be coupled to different distal effectors of NaP_i regulation.

Sodium and Hydrogen Excretion

Studies *in vivo* and with isolated renal tubules *in vitro* have established that PTH produces an acute natriuresis and diuresis and rapidly inhibits proximal tubular acid secretion (HCO_3^- reabsorption) (Agus *et al.,* 1971; Bank and Aynedian, 1976; McKinney and Myers, 1980; Puschett *et al.,* 1976; Schneider, 1975). As illustrated in Fig. 1, Na^+ reabsorption in the PCT proceeds via both the active, transcellular route and the passive, paracellular pathway. These mechanisms account for roughly 60 and 40%, respectively, of Na^+ reabsorption (Rector, 1983). Much of the transcellular Na^+ reabsorption in PCTs involves Na^+-dependent cotransport of anions such as phosphate, sulfate, and amino acids or the operation of apical Na^+/H^+ exchangers.

PTH Regulation of Proximal Tubular Sodium and Hydrogen Excretion

Effective reabsorption of Na^+ and HCO_3^- in the proximal tubule requires the concerted activities of apical Na^+/H^+ exchangers (type 3 NHEs or NHE3s), basolateral Na^+-K^+-ATPases (to maintain the transmembrane Na^+ gradient), and electrogenic basolateral Na^+-$3HCO_3^-$ cotransporters, among others (Alpern, 1990). PTH exerts at least three or four independent actions that conspire to powerfully inhibit Na^+ and HCO_3^- reabsorption. These include inhibition of apical Na^+/H^+ exchange, apical Na^+/P_i^- cotransport, basolateral Na^+-K^+-ATPase activity, and, possibly, basolateral Na^+-HCO_3^- cotransport (see Fig. 1).

PTH strikingly inhibits the activity of the amiloride-sensitive NHE3 in proximal tubular apical brush border membranes and in OK cells (Helmle-Kolb *et al.,* 1990; Hensley *et al.,* 1989; Kahn *et al.,* 1985; Pollock *et al.,* 1986), directly impairing both Na^+ reabsorption and H^+ excretion. Conversely, parathyroidectomy increases NHE3 exchanger activity (Cohn *et al.,* 1983). In rats, NHE3 protein and mRNA expression are increased and decreased, respectively, during sustained hyper-and hypoparathyroidism (Girardi *et al.,* 2000). The possibility that PTH may inhibit basolateral base exit via regulation of Na^+-$3HCO_3^-$ cotransporters is unsettled, as this has been observed in proximal tubules of rat (Pastoriza-Munoz *et al.,* 1992) but not of rabbit (Sasaki and Marumo, 1991). However, *in vivo* or *in vitro* administration of PTH greatly reduces the activity of the basolateral Na^+-K^+-ATPase in rat proximal tubules (Derrickson and Mandel, 1997; Ominato *et al.,* 1996; Ribeiro *et al.,* 1994; Ribeiro and Mandel, 1992).

PTHR Signal Transduction in the Regulation of Sodium and Hydrogen Excretion

The mechanisms whereby PTHRs regulate these various effectors of proximal tubular Na^+ and H^+ excretion are both different and complex. Within 30–60 min of PTH exposure *in vivo,* NHE3 is phosphorylated and inactivated, after which it is sequestered (but not destroyed) via a more delayed internalization to a high-density intracellular membrane fraction (Fan *et al.,* 1999; Hensley *et al.,* 1989; Zhang *et al.,* 1999). Experiments in OK cells also indicate that PTH reduces the sensitivity of the exchanger to the intracellular H^+ concentration (Miller and Pollock, 1987). Functional analysis of expressed recombinant NHE3 exchangers (Zhao *et al.,* 1999a) supports previous evidence (Agus *et al.,* 1973; Kahn *et al.,* 1985; Sasaki and Marumo, 1991; Weinman *et al.,* 1988) that NHE3 is a direct substrate for PKA. Involvement

of the cAMP/PKA signaling cascade in PTH regulation of NHE3 was suggested by the demonstration that PTH(1-34), but not a PTH(3-34) analog devoid of PKA activity, induced NHE3 internalization in rat proximal tubules (Zhang *et al.,* 1999). Also, PTHrP(1-34) inhibited NHE3 activity in an OK cell subclone in which this peptide could increase cAMP but not cytosolic Ca_i^{2+}, PLC, or PKC (Maeda *et al.,* 1998). Careful temporal analysis of events in cultured OK cells indicates that PTH induces a rapid, cAMP/PKA-dependent phosphorylation of multiple serine residues within the cytoplasmic "tail" of NHE3 that is maximal within 5 min and is associated with a reduction in exchanger activity but no change in NHE3 surface expression (Collazo *et al.,* 2000). This initial inactivation of surface exchangers, due either to phosphorylation *per se* or association with regulatory proteins, is followed by a more delayed, dynamin-dependent endocytosis of NHE3 proteins that becomes evident by 30 min.

However, NHE3 activity can be regulated by PKC via processes independent of NHE3 phosphorylation, and evidence developed using both kinase inhibitors and signal-selective PTH analogs in OK cells strongly supports the involvement of PKC- and PKA-dependent pathways in NHE3 regulation by PTHRs (Azarani *et al.,* 1995, 1996; Helmle-Kolb *et al.,* 1990; Kahn *et al.,* 1985). By analogy with mechanisms of PTH-regulated PCT phosphate and DCT calcium excretion, then, it is likely that these two PTHR signal kinases exert cooperative but distinct effects in controlling NHE3 expression and activity.

In the case of basolateral Na^+-K^+-ATPase, analysis of PTH regulation has disclosed a novel pathway of PTHR signaling. Administration of PTH(1-34) *in vivo* causes a rapid inactivation of proximal tubular basolateral Na^+-K^+-ATPase activity without inducing destruction or sequestration of the pump proteins (Zhang *et al.,* 1999). In this case, PTH(3-34) does mimic the action of PTH(1-34) by activating PKC (not PKA) (Ominato *et al.,* 1996; Ribeiro *et al.,* 1994). This occurs via PTHR coupling to a Gq/G11 family member and leads to a series of further responses, which include activation of PLA_2, generation of arachidonic acid, and metabolism of arachidonate via the P450 monooxygenase pathway to produce active eicosanoids, notably 20-hydroxyeicosatetraenoic acid ("20-HETE") (Derrickson and Mandel, 1997; Ominato *et al.,* 1996; Ribeiro *et al.,* 1994; Ribeiro and Mandel, 1992). In a manner as yet unknown, 20-HETE then leads to inhibition of Na^+-K^+-ATPase activity (Derrickson and Mandel, 1997; Ominato *et al.,* 1996). This monooxygenase-dependent pathway accounts for most of the PTH regulation of Na^+-K^+-ATPase activity, although a portion of the response is attributable to cAMP/PKA activation (Ribeiro and Mandel, 1992).

PTH Regulation of Sodium and Hydrogen Excretion beyond the Proximal Tubule

While it is true that PTH strongly inhibits proximal tubular HCO_3^- reabsorption, this is compensated to some extent by its effect to increase HCO_3^- reabsorption in Henle's loop and H^+ secretion in the CD (Bank and Aynediian, 1976; Bichara *et al.,* 1986; Paillard and Bichara, 1989). Moreover, phosphaturia induced by PTH also contributes to net acid secretion (Mercier *et al.,* 1986), and PTH actually can increase net renal acid secretion during metabolic acidosis (Bichara *et al.,* 1990). Similarly, in perfused mouse CTAL, PTH may exert an antinatriuretic effect, manifested as augmented paracellular transport driven by an increased transepithelial voltage (Wittner and Di Stefano, 1990). Thus, the overall effect of PTH on renal acid and sodium excretion may vary markedly depending on the particular physiologic state of the organism.

Vitamin D Metabolism

Synthesis of $1,25(OH)_2D_3$ is increased by PTH and reduced by parathyroidectomy (Fraser and Kodicek, 1973). This results from regulated expression, in proximal tubular cells, of the $25(OH)D_3$ 1α-hydroxylase gene, the promoter for which is induced rapidly by PTH *in vitro* (Garabedian *et al.,* 1972; Kong *et al.,* 1999a; Murayama *et al.,* 1999). This effect of PTH can be overridden *in vivo* by the direct suppressive action of hypercalcemia on 1α-hydroxylase expression (Weisinger *et al.,* 1989). It is variably impaired in older animals or humans, even though indices of PTHR signaling *per se* remain normal (Friedlander *et al.,* 1994; Halloran *et al.,* 1996). PTH induction of 1α-hydroxylase mRNA is transcriptional, additive to that of calcitonin, occurs in the genetic absence of the vitamin D receptor, and is antagonized by coadministration of $1,25(OH)_2D_3$, which directly inhibits expression when given alone (Murayama *et al.,* 1999).

The signaling pathways employed by the PTHR to increase $1,25(OH)_2D_3$ synthesis have been examined extensively *in vivo* and *in vitro*. Involvement of cAMP is suggested by the fact that the PTH effect can be mimicked by cAMP analogs, forskolin, or phosphodiesterase inhibitors (Armbrecht *et al.,* 1984; Henry, 1985; Horiuchi *et al.,* 1977; Korkor *et al.,* 1987; Larkins *et al.,* 1974; Rost *et al.,* 1981; Shigematsu *et al.,* 1986). Moreover, in a transformed murine proximal tubular cell line, transciptional induction of the 1α-hydroxylase occurred with either PTH or forskolin, and the effects of both were blocked by the PKA-selective inhibitor H89 (Murayama *et al.,* 1999). However, careful studies of the effects of added PTH in isolated perfused rat proximal tubules have correlated rapid (30–60 min) increases in $1,25(OH)_2D_3$ synthesis with PKC activation on the basis of (a) concentration dependence [PKC and $1,25(OH)_2D_3$ synthesis were increased at PTH concentrations 100- to 1000-fold lower than required for PKA activation], (b) selective inhibition by PKC inhibitors, and (c) activation by truncated PTH analogs [i.e., PTH(3-34), PTH(13-34)] that can trigger PKC but not PKA in this system (Janulis *et al.,* 1992, 1993). More information clearly is needed, but available data seem most consistent with both a predominant effect of cAMP/PKA on transcriptional regulation of 1α-hydroxylase gene expression and a more rapid, posttransciptional effect of PKC on 1α-hydroxylase enzyme activity.

The 25(OH)D 24-hydroxylase also is regulated by PTH. In kidney homogenates, cultured proximal tubular cells, and certain proximal tubular cell lines, PTH inhibits 24-hydroxylase activity by mechanisms that may involve cAMP (Henry, 1985; Matsumoto *et al.,* 1985; Shigematsu *et al.,* 1986; Shinki *et al.,* 1992; Tanaka and DeLuca, 1984). It also antagonizes the inductive effect of $1,25(OH)_2D_3$ on both 24-hydroxylase and vitamin D receptor expression (Reinhardt and Horst, 1990). Interestingly, PTH leads to opposite effects on 24-hydroxylase and vitamin D receptor expression in proximal and distal tubules. Thus, PTH augments $1,25(OH)_2D_3$-dependent induction of 24-hydroxylase in DCT cells, possibly by increasing expression of the vitamin D receptor (Yang *et al.,* 1999), whereas it inhibits expression of both the 24-hydroxylase and the receptor in proximal tubules, as described earlier.

Other Renal Effects of PTH

A variety of other effects of PTH on renal metabolism, secretion, and membrane function have been described, the physiologic roles of which currently are less clear than those described elsewhere in this chapter. Examples include rapid microvillar shortening in cultured proximal tubular cells (Goligorsky *et al.,* 1986b); increased renin release from perfused rat kidneys (Saussine *et al.,* 1993); increased proximal tubular gluconeogenesis, ammoniagenesis, and phosphoenolpyruvate carboxykinase (PEPCK) mRNA expression (Chobanian and Hammerman, 1988; Wang and Kurokawa, 1984; Watford and Mapes, 1990); activation of an apical Cl^- channel in rabbit proximal tubular cells (Suzuki *et al.,* 1991); and stimulation of ecto-5′-nucleotidase activity in apical membranes of OK cells, an effect that is mimicked by PTH(3-34) but not by forskolin and is blocked by PKC inhibitors (Siegfried *et al.,* 1995).

Renal Expression and Actions of PTHrP

PTHrP is expressed in the glomeruli, distal tubules, and collecting ducts of fetal kidneys and in PCT, DCT, and glomeruli of the adult kidney (Aya *et al.,* 1999; Philbrick *et al.,* 1996). In one study in rats, PTHrP mRNA was found in glomeruli, PCT, and macula densa but not in cTAL, mTAL, DCT, or CD (Yang *et al.,* 1997). It is unlikely that PTHrP is critical for normal renal development, as the kidneys of mice missing functional PTHrP genes appear histologically normal.

When tested, active amino-terminal fragments of PTHrP generally exhibit renal actions identical to those of PTH, including stimulation of cAMP production and regulation of P_i transport, Ca^{2+} excretion, and $1,25(OH)_2D_3$ synthesis (Everhart-Caye *et al.,* 1996; Pizurki *et al.,* 1988; Yates *et al.,* 1988). However, longer PTHrP fragments may possess unique properties. For example, in an assay of HCO_3^- excretion by the perfused rat kidney, hPTHrP(1-34) was equipotent with hPTH(1-34), whereas hPTHrP(1-84), hPTHrP(1-108), and hPTHrP(1-141) were each less active than hPTH(1-34) (Ellis *et al.,* 1990). As discussed in Chapter 25, the PTHrP gene can generate multiple transcripts and protein products, some of which may undergo unique nuclear localization. It is quite possible, therefore, that locally expressed PTHrP may exert actions in the kidney that are not shared with PTH, although this has not yet been addressed adequately.

A possible role for locally produced PTHrP in the renal response to ischemia has been suggested by findings that PTHrP expression is induced by ischemia or following recovery from ATP depletion (Garcia-Ocana *et al.,* 1999; Largo *et al.,* 1999; Soifer *et al.,* 1993). PTHrP is expressed in the intimal and medial layers of human renal microvessels and in the macula densa (Massfelder *et al.,* 1996). PTHrP (like PTH) increases renin release from the juxtaglomerular apparatus and also stimulates cAMP in renal afferent and efferent arterioles, leading to vasodilation and enhanced renal blood flow (Endlich *et al.,* 1995; Helwig *et al.,* 1991; Musso *et al.,* 1989; Nickols *et al.,* 1986; Saussine *et al.,* 1993; Schor *et al.,* 1981; Simeoni *et al.,* 1994). Evidence for involvement of both cAMP and nitric oxide in PTHrP-induced vasorelaxation *in vitro* has been derived from use of specific inhibitors (Massfelder *et al.,* 1996). Thus, enhanced local PTHrP production induced by inadequate renal perfusion or ischemia may be involved in both local and systemic autoregulatory mechanisms, whereby direct local vasodilatory actions are supplemented by the systemic activation of angiotensinogen that increase-arterial pressure and further sustain renal blood flow.

PTHrP and Receptors for PTH and PTHrP in Bone

Expression of PTHrP in Bone

PTHrP is expressed and secreted by osteoblast-like osteosarcoma cells (Rodan *et al.,* 1989; Suda *et al.,* 1996a) and is secreted by rat long bone explants *in vitro* (Bergmann *et al.,* 1990). Messenger RNA for PTHrP is detected in periosteal cells of fetal rat bones (Karmali *et al.,* 1992). *In situ* hybridization and immunohistochemistry have localized PTHrP mRNA and protein to mature osteoblasts on the bone surface of fetal and adult bones from mice and rats (Amizuka *et al.,* 1996; Lee *et al.,* 1995) and to flattened bone-lining cells and some superficial osteocytes (Amizuka *et al.,* 1996) in postnatal mice. In addition, the PTHrP gene is expressed in preosteoblast cells in culture, and in some studies its expression is reduced as preosteoblasts undergo differentiation (Kartsogiannis *et al.,* 1997; Oyajobi *et al.,* 1999; Suda *et al.,* 1996a). PTHrP is also expressed in tissues adjacent to bone, including growth plate cartilage (Amizuka *et al.,* 1996; Lee *et al.,* 1995) and synovium (Funk *et al.,* 1998), sites where the peptide could affect bone during endochondral bone formation or destructive rheumatoid arthritis, respectively.

Receptors and Second Messenger Systems for PTH and PTHrP in Bone

As discussed in detail in Chapter 24, a shared receptor for PTH and PTHrP (PTH/PTHrP receptor or PTH1R) is present on bone cells; this is a G protein-coupled receptor that recognizes PTH and PTHrP equally well. The receptor couples its ligands to two cellular effector systems: the adenylyl cyclase/cAMP/protein kinase A pathway and the phospholipase C/protein kinase C pathway (Chapters 24 and 26). As will become clear as the individual effects of PTH on bone are laid out, PTH and PTHrP utilize cAMP for virtually every action in bone for which a second messenger has been identified, although in some cases the protein kinase C pathway is also used.

The PTH/PTHrP receptor is expressed widely in the osteoblast lineage. In addition to mature osteoblasts on the trabecular, endosteal, and periosteal surfaces (Amizuka *et al.,* 1996; Fermor and Skerry, 1995; Lee *et al.,* 1993, 1995) and osteocytes (Fermor and Skerry, 1995; van der Plas *et al.,* 1994), the receptor mRNA and protein are expressed in marrow stromal cells near the bone surface (Amizuka *et al.,* 1996), a putatively preosteoblast cell population that had been shown previously to bind radiolabeled PTH (Rouleau *et al.,* 1988, 1990). Considering the anabolic effect of PTH on bone formation, it will be important to understand at what point in the osteoblast lineage receptors for PTH are first expressed. Transcripts for the PTH/PTHrP receptor are absent or nonabundant in STRO-1+ positive, alkaline phosphatase negative marrow stromal cells (Gronthos *et al.,* 1999; Stewart *et al.,* 1999), which are thought to represent relatively early osteoblast precursors, and PTH/PTHrP receptor expression can be induced by the differentiation of stromal cells, MC3T3 cells, or C3H10T1/2 cells with dexamethasone or bone morphogenetic proteins (Feuerbach *et al.,* 1997; Hicok *et al.,* 1998; Liang *et al.,* 1999; Stewart *et al.,* 1999; Wang *et al.,* 1999; Yamaguchi *et al.,* 1996). Other data suggest that PTH receptors are limited to a relatively mature population of osteoprogenitor cells that express the osteocalcin gene (Bos *et al.,* 1996). It thus appears that the PTH/PTHrP receptor appears at a point in osteoblast differentiation when the cells are acquiring other markers of the mature osteoblast phenotype.

Whether receptors for PTH or PTHrP are expressed on the osteoclast is controversial. Initial studies using receptor radioautography failed to demonstrate them (Rouleau *et al.,* 1990; Silve *et al.,* 1982), and recent studies have not identified PTH/PTHrP receptor mRNA or protein on mature osteoclasts (Amizuka *et al.,* 1996; Lee *et al.,* 1993, 1995), although PTH/PTHrP receptors are reportedly present on osteoclasts from patients with renal failure (Langub *et al.,* 2001). However, relatively low-affinity binding of radiolabeled PTH peptides to osteoclasts or preosteoclasts has been reported (Teti *et al.,* 1991). The functional importance of such putative receptors is unclear. As discussed in detail later ("Effects of PTH and PTHrP on Osteoclasts"), the presence of osteoblasts or stromal cells seems to be required to elicit effects of PTH on osteoclasts *in vitro* (McSheehy and Chambers, 1986). The effects of PTH treatment are mimicked by expression of a constitutively active PTH/PTHrP receptor on osteoblasts (Calvi *et al.,* 2001), indicating that osteoclast receptors are dispensible. Studies have found a requirement for the RANKL/RANK system of cytokines and receptors for bone resorption by PTH or PTHrP (Fuller *et al.,* 1998; Lee and Lorenzo, 1999; Morony *et al.,* 1999; Yamamoto *et al.,* 1998), consistent with the interpretation that stromal or osteoblastic cells expressing the cytokine RANKL are required for the induction of bone resorption by PTH.

Both PTH and PTHrP have additional receptors besides the PTH/PTHrP receptor. The PTH2R is a G protein-coupled receptor closely related to the PTH1R (Mannstadt *et al.,* 1999; Usdin *et al.,* 1995), which recognizes the amino-terminal domain of PTH but not of PTHrP (Chapter 24). This receptor is expressed predominantly in brain and has yet to be demonstrated in bone. Evidence for actions of carboxyl-terminal PTH peptides on bone has been presented (Murray *et al.,* 1991; Nakamoto *et al.,* 1993; Nguyen-Yamamoto *et al.,* 2001; Sutherland *et al.,* 1994), as discussed elsewhere in this chapter and in Chapter 24, and evidence for a specific receptor for carboxyl-terminal PTH peptides on osteoblasts (Inomata *et al.,* 1995; Nguyen-Yamamoto *et al.,* 2001) and osteocytes (Divieti *et al.,* 2001) has been presented.

As discussed in Chapter 25, the polyhormone PTHrP is cleaved to produce a set of peptides: those that contain the amino terminus activate the shared PTH/PTHrP receptors, and additional peptides representing the midregion and carboxyl terminus of PTHrP appear to have distinct biological actions mediated by their own receptors (Philbrick *et al.,* 1996; Wysolmerski and Stewart, 1998). Receptors that are specific for amino-terminal PTHrP and do not recognize PTH have been identified in brain (Yamamoto *et al.,* 1997) and other tissues (Gaich *et al.,* 1993; Orloff *et al.,* 1992), and midregion peptides of PTHrP have actions on placental calcium transport that imply a distinct receptor (Care *et al.,* 1990; Kovacs *et al.,* 1996), but there is presently no evidence for either receptor in bone. Carboxyl-terminal PTHrP fragments [e.g., PTHrP(107-139)] are reported to inhibit bone resorption (Cornish *et al.,* 1997; Fenton *et al.,* 1991b) and stimulate (Goltzman and Mitchell, 1985) or inhibit (Martinez *et al.,* 1997) the growth of osteoblasts and their function (Esbrit *et al.,* 2000; Gray *et al.,* 1982), and it is thus likely that a specific receptor for this peptide is present on osteoblasts, and conceivably also on osteoclasts.

Effects of PTH and PTHrP on Bone Cells

Effects on Osteoblast Precursor Cells

In view of the anabolic effects of PTH and PTHrP, evidence for a proliferative effect on osteoblast precursors has been sought. Administration of PTH *in vivo* does not increase mRNA for the proliferation marker histone H4 (Onyia *et al.,* 1995). Immediate early gene expression is increased after *in*

vivo administration of PTH in osteoblasts and osteocytes (Lee *et al.,* 1994; Liang *et al.,* 1999), but the immediate early gene response is delayed in stromal cells, suggesting that they may respond secondarily to factors elaborated by osteoblasts (Lee *et al.,* 1994).

Effects on Osteoblasts

TRANSCRIPTION FACTORS

PTH induces the expression of the immediate early gene families c-fos (c-fos, fra-1, fra-2) and c-jun (c-jun, junD) in osteoblastic cell lines and in osteoblasts *in vivo* (Clohisy *et al.,* 1992; Lee *et al.,* 1994; McCauley *et al.,* 1997; McCauley *et al.,* 2001; Stanislaus *et al.,* 2000a). The effect on c-fos is the largest and best studied. PTH induces c-fos mRNA in a fashion that does not require protein synthesis and is mediated by phosphorylation of the transcription factor CREB by protein kinase A (Evans *et al.,* 1996; Pearman *et al.,* 1996; Tyson *et al.,* 1999) to induce binding to a CRE in the c-fos promoter (Evans *et al.,* 1996; Pearman *et al.,* 1996). The protein kinase C signaling pathway does not appear to be involved in this response (Evans *et al.,* 1996; McCauley *et al.,* 1997).

Because many bone cell genes are regulated by PTH, as discussed later, interactions of PTH with osteoblast-specific transcriptional regulation are likely. A splice variant of the runt-domain transcription factor cbfa1 called OSF2 is required for determination of the osteoblast phenotype and confers osteoblast-specific expression on the osteocalcin gene (Ducy *et al.,* 1997; Ducy and Karsenty, 1998). Although it is not known how PTH interacts with cbfa1 at the osteocalcin promoter, a cbfa1 site in the collagenase-3 (MMP-13) promoter is required along with an AP-1 site for the stimulation of collagenase-3 gene transcription by PTH (Porte *et al.,* 1999; Selvamurugan *et al.,* 1998). There were no acute changes in cbfa1 levels in these studies, and it appears that cbfa1 is activated transcriptionally by phosphorylation in its AD3 domain by protein kinase A (Selvamurugan *et al.,* 2000; Winchester *et al.,* 2000). It has also been reported that PTH and other agents that raise cAMP levels in MC3T3 cells reduce the level of cbfa1 and the activity of cbfa1-dependent genes by activating the destruction of the transcription factor by the ubiquitin-proteosome pathway (Tintut *et al.,* 1999).

CYTOKINES

Insulin-like Growth Factors Bone is a rich source of insulin-like growth factors (IGF) secreted by osteoblasts (see Chapter 45), with IGF-I predominating in rodent bone and IGF-II in human bone (Conover, 1996). The secretion of IGF-I by rat (McCarthy *et al.,* 1989) and IGF-I and IGF-II by mouse (Linkhart and Mohan, 1989) osteoblasts *in vitro* and *in vivo* (Watson *et al.,* 1995) is stimulated by PTH. PTH appears to utilize cAMP as the predominant intracellular second messenger to stimulate IGF gene expression because its effects are mimicked by cAMP analogs or agents that increase cAMP, but not by calcium ionophores or phorbol esters (McCarthy *et al.,* 1990).

Two sets of results raise the possibility that effects of PTH on IGF-I secretion may be essential for its overall anabolic effect on bone. Continuous exposure to PTH, which has catabolic effects on bone *in vivo,* inhibited collagen synthesis by isolated rat calvariae, but exposure to PTH for the first 24 hr of a 72-hr experiment increased collagen synthesis markedly (Canalis *et al.,* 1990). The stimulation of collagen synthesis by PTH is blocked by antibodies to IGF-I, but the stimulation of [^{3}H]thymidine incorporation is not (Canalis *et al.,* 1989). Moreover, treatment of intact rats with PTH under conditions where it has an anabolic effect on bone leads to an increase in mRNA for IGF-I (Watson *et al.,* 1995) and the bone matrix content of both IGF-I and TGF-β. Finally, skeletal unloading leads to resistance to the anabolic effect of PTH, and also resistance *in vitro* to IGF-I, a result that was interpreted as suggesting that resistance to IGF-I may account for the resistance of the unloaded skeleton to PTH (Kostenuik *et al.,* 1999).

PTH and PTHrP also affect the secretion of binding proteins for IGF's (Chapter 45). There are six IGF-binding proteins (IGFBP) and all are present in bone (Conover, 1996). IGFBP-4 inhibits IGF action, but IGFBP-5 seems to function predominately to anchor IGFs to the extracellular matrix and may, in some circumstances, have stimulatory effects on IGF action. Exposure of bone cells to PTH or PTHrP increases the secretion of IGFBP-4 (Latour *et al.,* 1990) and IGFBP-5 (Conover *et al.,* 1993) by cAMP-dependent mechanisms and also increases the level of a related protein, IGFBP-RP-1 (Pereira and Canalis, 1999). Both IGFBPs are subject to proteolysis, and there is limited evidence to suggest that IGFBP protease activity may be regulated by PTH (Hakeda *et al.,* 1996; Kudo *et al.,* 1996). It is not clear whether the effects of PTH on IGFBP levels are biologically significant.

Transforming Growth Factor-β PTH and PTHrP increase both the secretion of TGF-β by osteoblast-like bone cells and the release of TGF-β from calvarial explants (see Chapter 49); the latter may represent in part the release of preformed TGF-β during bone resorption (Finkelman *et al.,* 1992; Merry and Gowen, 1992; Oursler *et al.,* 1991; Pfeilschifter and Mundy, 1987). Intermittent PTH treatment of rats increases the bone matrix content of TGF-β1 as well as IGF-I (Watson *et al.,* 1995), raising the possibility that the anabolic effects of PTH observed with intermittent administration could be mediated, at least in part, by increased secretion of this potent osteoblast growth and differentiation factor. The effect of PTH on TGF-β1 may be protein kinase C mediated, whereas its effect on TGF-β2 is protein kinase A mediated (Wu and Kumar, 2000).

Interleukin-6 Family Cytokines The cytokines IL-6, IL-11, leukemia inhibitory factor (LIF), ciliary neurotrophic factor (CNTF), oncostatin M(OSM), and cardiotropin 1 (CT-1) bind to related receptors and share a signal transduction pathway (Horowitz and Lorenzo, 1996; Manolagas *et al.,* 1996) (see Chapter 53). The pathway involves the common receptor subunit gp 130, binding of JAK family protein

kinases, and phosphorylation and nuclear translocation of the STAT family of transcription factors. Of this cytokine family, three members are prominently stimulated by PTH and PTHrP in bone cells: IL-6 (Feyen *et al.,* 1989; Greenfield *et al.,* 1993; Li *et al.,* 1991; Lowik *et al.,* 1989), IL-11 (Ducy *et al.,* 1997; Elias *et al.,* 1995), and LIF (Greenfield *et al.,* 1993). Both PTHrP(1-34) and PTHrP(107-139) are reported to induce the expression of IL-6 (de Miguel *et al.,* 1999). The production of IL-6 is also increased by PTH in mouse calvaria (Huang *et al.,* 1998) and *in vivo* (Onyia *et al.,* 1995; Pollock *et al.,* 1996). PTH activates transcription of the IL-6 gene (Huang *et al.,* 1998; Onyia *et al.,* 1997a) using cAMP as its principal signaling pathway (Greenfield *et al.,* 1995; Huang *et al.,* 1998; Onyia *et al.,* 1997a), although protein kinase C may also play a role (Sanders and Stern, 2000).

It has been suggested from neutralization experiments that the induction by PTH of osteoblast secretion of IL-6 (Greenfield *et al.,* 1995; Grey *et al.,* 1999) or IL-11 (Girasole *et al.,* 1994), both of which are bone-resorbing cytokines, may be one mechanism by which the osteoblast transmits the bone-resorbing signal of PTH to the osteoclast. However, studies have shown that blockade of the intracellular signaling pathway, using dominant-negative STAT factors (O'Brien *et al.,* 1999) or an IL-6 receptor antagonist, (Devlin *et al.,* 1998), fails to inhibit bone resorption by PTH, even though bone resorption by IL-6 is blocked. Compelling evidence is now available to indicate that the principal mediators of the bone-resorbing effect of PTH are another set of cytokines, RANKL and osteoprotegerin, or OPG. This issue is discussed further later, under "RANK Ligand and Osteoprotegerin."

Other Cytokines and Prostaglandins PTH induces osteoblasts to secrete granulocyte–macrophage colony-stimulating factor (GM-CSF) (Horowitz *et al.,* 1989; Weir *et al.,* 1989) (see Chapter 52). As discussed in Chapter 54, PTH also stimulates production of the prostaglandin PGE_2 by mouse calvarial osteoblasts (Klein-Nulend *et al.,* 1990, 1991; Pilbeam *et al.,* 1989). The direct target of PTH is the enzyme prostaglandin G/H synthase (PGHS-2) (Kawaguchi *et al.,* 1994) whose protein levels are increased by PTH. Another isoform, PGHS-1, is expressed constitutively but is not affected by PTH. The effect of PTH is mediated by cAMP as the dominant second messenger (Klein-Nulend *et al.,* 1990). PGE_2, in turn, has diverse effects on bone, which have been summarized (Pilbeam *et al.,* 2000). Knockout of the prostaglandin G/H synthase or the EP2 receptor for PGE_2 markedly inhibits the bone resorption response to PTH *in vitro* (Li *et al.,* 2000; Okada *et al.,* 2000) and the hypercalcemic response to PTH in mice is abrogated in the absence of prostaglandin G/H synthase (Okada *et al.,* 2000).

RANK Ligand and Osteoprotegerin One of the most important new insights into the regulation of bone metabolism in recent years has been the delineation of a new system for osteoblast–osteoclast cross-talk (Chapter 53). It has three major elements. The first is a new member of the TNF family of cytokines that is expressed on the osteoblast and stromal cell surface; this cytokine is variously known as RANK ligand (RANKL), osteoprotegerin ligand (OPGL), osteoclast differentiation factor (ODF), and TNF-related activation-induced cytokine (TRANCE) (Hofbauer *et al.,* 2000). By binding to a receptor on osteoclast precursors, RANKL provides an essential feeder function for osteoclastogenesis, accounting for earlier observations that coculture of bone marrow cells and stromal cells is required for osteoclastogenesis (Suda *et al.,* 1996b); RANKL also activates bone resorption by mature osteoclasts and inhibits osteoclast apoptosis (Burgess *et al.,* 1999; Fuller *et al.,* 1998; Hofbauer, 1999; Lacey *et al.,* 1998; Yasuda *et al.,* 1998b). RANKL is both necessary and, with M-CSF, sufficient for osteoclastogenesis; disruption of the RANKL gene leads to severe osteopetrosis (Kong *et al.,* 1999b).

The second element of this system is the receptor for RANKL on the surface of osteoclast precursors and mature osteoclasts. This receptor is called RANK (receptor activator of NF-κB) or ODAR (osteoclast differentiation and activation receptor). Disruption of the receptor gene also produces severe osteopetrosis (Hsu *et al.,* 1999). The third element is a decoy receptor, osteoprotegerin (OPG) or osteoclastogenesis inhibitory factor (OCIF) (Simonet *et al.,* 1997; Yasuda *et al.,* 1998a,b). Targeted deletion of OPG produces severe osteoporosis (Mizuno *et al.,* 1998; Simonet *et al.,* 1997), whereas overexpression leads to osteopetrosis (Simonet *et al.,* 1997).

Both genetic and cell biological approaches to this system have yielded decisive results: following an early commitment step under the control of M-CSF, binding of RANKL to RANK is both necessary and sufficient for osteoclastogenesis. The system has a second function to regulate the activity of the mature osteoclast, and exposure of osteoclasts to RANKL inhibits their apoptosis. The decoy receptor OPG must also be important to modulate the tone of the system, as elimination of OPG produces a severe form of osteoporosis. It is conceivable that a parallel system exists, as M-CSF-dependent osteoclast formation from cultured mouse bone marrow cells is induced by TNF-α and is blocked by antibodies to its receptor, but not by OPG or antibodies to RANK (Kobayashi *et al.,* 2000).

The bone-resorbing effects of PTH, long known to require the intermediation of osteoblasts (McSheehy and Chambers, 1986), appear to occur principally through activation of the RANKL/RANK system. Exposure to PTH increases the expression of RANKL in murine bone marrow cultures, cultured osteoblasts, and mouse calvariae (Hofbauer *et al.,* 1999; Lee and Lorenzo, 1999; Yasuda *et al.,* 1998b), and simultaneously decreases the expression of OPG (Lee and Lorenzo, 1999), probably via protein kinase A, with the kinetics *in vivo* of an immediate early gene (Onyia *et al.,* 2000). Stimulation of osteoclastogenesis by PTH is blocked by antibodies to RANKL (Tsukii *et al.,* 1998) or by OPG (Lacey *et al.,* 1998; Yasuda *et al.,* 1998b). Infusion of OPG into animals blocks the hypercalcemic response to PTH or PTHrP (Morony *et al.,* 1999; Oyajobi *et al.,* 2001; Yamamoto *et al.,* 1998). Bone resorption by mature osteoclasts in response to PTH has

long been recognized as requiring coculture with osteoblasts or marrow stromal cells (McSheehy and Chambers, 1986), but when purified cultures of isolated osteoclasts that were unresponsive to PTH were exposed to RANKL, the cytokine was sufficient to induce bone resorption (Fuller *et al.,* 1998). It thus appears that both the stimulation of new osteoclast formation and the activation of the mature osteoclast by PTH and PTHrP take place by binding of the ligand to receptors on osteoblasts, followed by simultaneous induction of the presentation of RANKL on the osteoblast surface and inhibition of secretion of OPG. It is conceivable that the effect of PTH on RANKL and OPG is indirect, involving other cytokines as intermediate steps. It is also possible that a parallel pathway exists in which other cytokines such as IL-6 or IL-11 could mediate part of the effect of PTH on bone resorption, but if so it is likely to be of secondary importance. In the resorption of alveolar bone during eruption of teeth, PTHrP is secreted by stellate reticulum cells and appears to act by binding to receptors on dental follicle cells, which express RANKL and in turn secrete an osteoclast-activating factor likely to be RANKL, as its effects can be neutralized by OPG (Nakchbandi *et al.,* 2000).

CELL PROLIFERATION AND APOPTOSIS

Continuous exposure to PTH(1-34) or PTHrP(1-34) exerts an antiproliferative action on osteoblast-like UMR-106 osteosarcoma cells (Civitelli *et al.,* 1990; Kano *et al.,* 1991; Onishi and Hruska, 1997). This effect is cAMP mediated and results, at least in part, from increased levels of p27Kip1, a regulator of G1 phase cyclin-dependent kinases (Onishi and Hruska, 1997). However, in some cell lines (Finkelman *et al.,* 1992; Onishi *et al.,* 1997; Somjen *et al.,* 1990) and primary cultures (van der Plas *et al.,* 1985), PTH appears to increase osteoblast or preosteoblast proliferation. In the preosteoblast cell line TE-85, the mitogenic response to PTH requires an increase in levels of the the cyclin-dependent kinase cdc2, probably brought about by increased levels of E2F (Onishi *et al.,* 1997).

Treatment of rats with intermittent injections of PTH is reported in some studies to increase the number of osteoprogenitor cells (Kostenuik *et al.,* 1999; Nishida *et al.,* 1994), but not the proliferation of osteoprogenitors (Onyia *et al.,* 1995, 1997b). These data are compatible with the conclusion that PTH increases entry of cells into an osteoprogenitor compartment, e.g., commitment, without an effect on their proliferation. In an important study, continuous labeling of bone with [^{3}H]thymidine during a period of intermittent treatment with PTH(1-34) resulted in no increase in labeled osteoblasts, despite a marked increase in osteoblast number (Dobnig and Turner, 1995). This indicates that the anabolic effect of PTH does not require the proliferation of osteoblast precursors or of mature osteoblasts on the bone surface. The large increase in osteoblast number produced in this study by intermittent treatment with PTH was attributed to the activation of preexisting bone-lining cells to osteoblasts (Dobnig and Turner, 1995), but is also possible that PTH induces the commitment of late osteoprogenitors to the osteoblast lineage without a requirement for mitosis. Another alternative explanation for the increase in osteoblast number with intermittent PTH treatment is provided by recent work that indicates that treatment of mice with intermittent PTH inhibits osteoblast apoptosis (Jilka *et al.,* 1999) (see Chapter 10). Prolongation of the osteoblast life span by PTH could account for the observed increase in osteoblast number, although it is not clear how large a quantitative effect on osteoblast survival would result from the observed inhibition of apoptosis. The integrated effects of PTH on bone formation are discussed further later and in Chapter 75.

EFFECTS ON ION CHANNELS

In several bone cell types, PTH induces multiphasic changes in membrane potential, most often depolarization followed by sustained hyperpolarization (Edelman *et al.,* 1986; Ferrier *et al.,* 1987, 1988; Fritsch *et al.,* 1988). Depolarization has been attributed to cAMP-dependent inactivation of quinine-sensitive K channels (Ferrier *et al.,* 1988). Depolarization of bone cells induces calcium entry through L-type voltage-sensitive Ca channels (Barry *et al.,* 1995; Ferrier *et al.,* 1987; Fritsch and Chesnoy-Marchais, 1994; Yamaguchi *et al.,* 1987). Sustained hyperpolarization may result in return from opening of Ca-sensitive K channels (Moreau *et al.,* 1996), which may be identical to mechanosensitive cation-selective channels also activated by PTH (Duncan *et al.,* 1992). PTH enhances the $[Ca^{2+}]_i$ response of osteoblast-like MC3T3-E1 cells to mechanical stimulation, as well as the COX-2 response to stimulation (Ryder and Duncan, 2000, 2001).

EFFECTS ON CELL SHAPE

PTH treatment of cultured osteoblasts induces a marked retraction of the cell (Miller *et al.,* 2000), and similar changes have been observed with treatment *in vivo* (Matthews and Talmage, 1981). The change in cell shape is cAMP mediated (Babich *et al.,* 1997) and is associated with the disassembly of actin stress fibers (Egan *et al.,* 1991). It can be blocked by inhibitors of the protease calpain (Murray *et al.,* 1995). The significance of changes in cell shape is unknown, but it has been suggested that osteoblast retraction could have a role in bone remodeling by baring portions of the bone surface in response to PTH.

EFFECTS ON GAP JUNCTIONS

PTH increases intercellular communication of bone cells by increasing connexin-43 gene expression (Schiller *et al.,* 1997) and opening gap junctions (Donahue *et al.,* 1995; Schiller *et al.,* 1992). The significance of intercellular communication to the overall effects of PTH on osteoblasts is not clear, although it is reported that the reduction of connexin-43 levels by transfection of antisense cDNA markedly inhibited the cAMP response to PTH (Vander Molen *et al.,* 1996) and blocked the effect of PTH on mineralization by osteoblast-like cells (Schiller *et al.,* 2001).

Effects on Bone Matrix Proteins and Alkaline Phosphatase

The most abundant protein of bone matrix is type I collagen. Given acutely, PTH consistently inhibits collagen synthesis in cultured rat calvaria and in cultured bone cells (Kream *et al.,* 1986; Partridge *et al.,* 1989) by decreasing transcription of the pro-α1(I) gene (Kream *et al.,* 1980) (see Chapter 12). PTH treatment of calvaria inhibits transcription of a 2.3-kb fragment of the pro-α1(I) promoter, indicating that at least one major *cis*-acting element required for the inhibition of gene transcription resides in this portion of the promoter (Kream *et al.,* 1993). PTHrP and agents that increase cAMP have effects similar to PTH (Kano *et al.,* 1992; Pines *et al.,* 1990). Acute infusion of PTH into humans also inhibits collagen synthesis (Simon *et al.,* 1988). In contrast, treatment of calvaria with PTH intermittently can stimulate collagen gene expression (Canalis *et al.,* 1990). The stimulatory effect of PTH on collagen synthesis in calvaria is attributed to the stimulation of IGF-1 production because it is blocked by IGF-1 antibodies (Canalis *et al.,* 1989). Moreover, when given intermittently in an anabolic regimen, treatment with PTH *in vivo* increases bone collagen gene expression (Opas *et al.,* 2000). The reversal of direction of the PTH effect *in vivo* can probably be attributed, at least in part, to increased bone remodeling and increases in osteoblast number induced by the chronic regimen.

Treatment of osteosarcoma cells with PTH has a stimulatory effect on several other bone matrix proteins, including osteocalcin (BGP) (Noda *et al.,* 1988; Theofan and Price, 1989; Towler and Rodan, 1995; Yu and Chandrasekhar, 1997); administration of PTH or PTHrP acutely inhibits osteocalcin release from isolated rat hindlimb, but chronic administration of PTH is stimulatory (Gundberg *et al.,* 1995). The primary signaling pathway is protein kinase A, but protein kinase C may mediate part of the effect of PTH on osteocalcin gene transcription (Boguslawski *et al.,* 2000). Exposure to PTH stimulates bone sialoprotein gene expression in embryonic chick bone cells (Yang and Gerstenfeld, 1997). In ROS 17/2.8 cells, PTH appears to stimulate BSP gene transcription by blocking an inhibitory pit-1 site in the promoter through the agency of protein kinase A (Ogata *et al.,* 2000). However, PTH inhibits deposition of bone sialoprotein in mineralizing osteoblast cultures (Wang *et al.,* 2000). PTH treatment inhibits expression of the osteopontin gene in rat osteosarcoma cells (Noda and Rodan, 1989).

Amino-terminal peptides derived from PTH can either stimulate or inhibit secretion of alkaline phosphatase from bone cells, depending on the cell line (Jongen *et al.,* 1993; Kano *et al.,* 1994; Majeska and Rodan, 1982; McPartlin *et al.,* 1978; Thomas and Ramp, 1978; Yee, 1985). It is reported that carboxyl-terminal PTH fragments can stimulate alkaline phosphatase (Murray *et al.,* 1991; Sutherland *et al.,* 1994), and PTHrP(107-139) is reported to inhibit alkaline phosphatase (Valin *et al.,* 1999). Treatment of women with anabolic regimens of intermittent PTH(1-34) injections increases alkaline phosphatase (Finkelstein *et al.,* 1998), presumably at least in part due to an increase in osteoblast number.

Effects on Proteases of Bone

PTH stimulates the secretion of a number of proteases from osteoblasts (Partridge *et al.,* 1996; Partridge and Winchester, 1996) (see Chapter 16). These include stromelysin (Meikle *et al.,* 1992), gelatinase B (Meikle *et al.,* 1992), the disintegrin and metalloprotease ADAMTS-1 (Miles *et al.,* 2000), and collagenase-3 (MMP-13) (Partridge *et al.,* 1987; Quinn *et al.,* 1990; Scott *et al.,* 1992; Walker *et al.,* 1964; Winchester *et al.,* 1999). Stimulation of the collagenase-3 promoter by PTH requires interactions of an AP-1 site and a binding site for runt-domain transcription factors such as Osf-2; PTH phosphorylates CREB through protein kinase A to activate AP-1 (Porte *et al.,* 1999; Selvamurugan *et al.,* 1998) and phosphorylates cbfa1/osf2, also through protein kinase A (Selvamurugan *et al.,* 2000); cooperation of these transcription factors is required for expression of bone sialoprotein (Winchester *et al.,* 2000). Bone resorption by PTH is markedly abrogated in mice with a mutation in the Collal gene that renders the helical domain of type I collagen resistant to cleavage by collagenase (Zhao *et al.,* 1999b). It has been suggested that collagenase action on a hypomineralized layer of collagen on bone surfaces may be necessary for osteoblast attachment, although multiple other explanations for the observation are also possible. PTH treatment also increases secretion of the inhibitor TIMP (Meikle *et al.,* 1992). Finally, activity of the serine protease plasminogen activator is increased by PTH in bone cell cultures (Hamilton *et al.,* 1985; Leloup *et al.,* 1991). Whether the plasminogen activator is urokinase or tissue-type plasminogen activator and whether the effect of PTH is to increase the level of the protease or decrease the level of its inhibitor PAI-1 are controversial (Catherwood *et al.,* 1994; Fukumoto *et al.,* 1992; Partridge and Winchester, 1996).

Effects on Osteocytes

As noted earlier, PTHrP and the PTH/PTHrP receptor appear to be expressed on osteocytes (Amizuka *et al.,* 1996; Fermor and Skerry, 1995; van der Plas *et al.,* 1994). A receptor specific for the carboxyl-terminal domain of PTH is also expressed on osteocytic cells (Divieti *et al.,* 2001). Exposure to PTH induces ultrastructural changes in osteocytes (Krempien *et al.,* 1978). Although it was long thought that osteocytes, together with bone-lining cells, participate in the acute release of calcium from bone in response to PTH (Talmage *et al.,* 1976), this remains conjectural and seems unlikely in view of evidence that the RANK/RANKL system in osteoclasts is involved (Morony *et al.,* 1999). The current view of osteocytes has for them a predominant role in mechanotransduction. Mechanical loading of rat caudal vertebrae induces an increase in c-fos expression in osteocytes that requires the presence of PTH (Chow *et al.,* 1998). In rat osteocytes, PTH enhances calcium influx through mechanosensitive calcium channels in response to stretch (Miyauchi *et al.,* 2000).

However, it is not known in detail how PTH interacts with the mechanotransduction system (Burger and Klein-Nulend, 1999) (see also Chapter 6).

Integrated Effects of PTH and PTHrP on Bone

PTH, PTHrP, and Bone Resorption

CELLULAR BASIS OF PTH ACTION

PTH and PTHrP increase bone resorption by stimulating both the appearance of new osteoclasts and the activity of existing osteoclasts. The mechanistic details of osteoclastogenesis (Suda *et al.,* 1996b) and osteoclast activation (Duong and Rodan, 1999) are beyond the scope of this chapter, but have been summarized elsewhere; in neither case does PTH have a distinctive effect, rather the distal cellular responses of osteoclast precursors and mature cells to all bone resorbing agents seem to represent a final common pathway.

Both the stimulation of osteoclastogenesis and the activation of the mature osteoclast appear to require the participation of stromal cells or osteoblasts (Akatsu *et al.,* 1989; McSheehy and Chambers, 1986; Suda *et al.,* 1996b). To recapitulate what has been summarized in previous sections of this chapter, osteoclasts have not been shown to possess high-affinity PTH/PTHrP receptors (Amizuka *et al.,* 1996; Lee *et al.,* 1993, 1995; Rouleau *et al.,* 1990; Silve *et al.,* 1982), although several groups have identified low-affinity receptors (Teti *et al.,* 1991). It appears that the effects of PTH are mediated predominately by increased expression of the cytokine RANKL (OPGL, ODF, TRANCE) on the cell surface of stromal cells (Hofbauer *et al.,* 1999; Lacey *et al.,* 1998; Lee and Lorenzo, 1999; Tsukii *et al.,* 1998; Yasuda *et al.,* 1998b), perhaps together with a decrease in expression of the decoy receptor OPG (Yasuda *et al.,* 1998b). The precise target cell in the osteoclast lineage responsible for mediating the bone-resorbing effects of PTH and PTHrP has not been identified, but various marrow stromal cell lines will suffice *in vitro* (Suda *et al.,* 1996b) and bone resorption is still active when mature osteoblasts have been ablated (Corral *et al.,* 1998).

By binding to its cognate receptor (RANK) on osteoclast precursors and mature osteoclasts, RANKL stimulates both osteoclastogenesis and the activity of mature osteoclasts. Osteoclast activation by RANKL is apparently responsible for both bone resorption at the cellular level and for hypercalcemia, as both are blocked by the decoy receptor OPG (Morony *et al.,* 1999; Yamamoto *et al.,* 1998). Although it was suggested previously that the early phase of the increase in the plasma concentration of ionized calcium, e.g., within 1-2 hr, might have an osteoclast-independent mechanism, involving release of calcium by bone-lining cells (Talmage *et al.,* 1976), even early responses to PTH in animal models are blocked by inhibiting the RANK/RANKL system (Morony *et al.,* 1999).

COMPARATIVE EFFECTS OF PTH AND PTHRP

The bone-resorbing effects of amino-terminal PTH and PTHrP are essentially indistinguishable when studied using isolated osteoclasts (Evely *et al.,* 1991; Murrills *et al.,* 1990), bone explant systems (Raisz *et al.,* 1990; Yates *et al.,* 1988), or infusion into the intact animal (Kitazawa *et al.,* 1991; Thompson *et al.,* 1988). PTHrP may be somewhat less potent than equimolar infusions of PTH to induce hypercalcemia in humans, probably due to differences in plasma half-life (Fraher *et al.,* 1992).

As discussed in Chapter 3, PTHrP is a polyhormone, the precursor of multiple biologically active peptides. Carboxyl-terminal peptides that are predicted to arise from cleavage of PTHrP in the polybasic region PTHrP(102-106) have been synthesized and shown to inhibit bone resorption in several explant systems (Fenton *et al.,* 1991a,b, 1993), although not all (Sone *et al.,* 1992), and also *in vivo* (Cornish *et al.,* 1997). On this basis, the minimal peptide that inhibits bone resorption, PTHrP(107-111), has been called osteostatin.

Effects of PTH and PTHrP on Bone Formation

The anabolic effects of PTH and PTHrP are discussed in Chapter 75, and their involvement in the pathogenesis of bone changes in primary hyperparathyroidism is presented.

This section synthesizes a view of the effects of PTH and PTHrP on bone formation from the perspective of the individual cellular actions of the hormones that have been summarized in the preceding sections of this chapter.

Continuous exposure to PTH leads to a coupled increase in bone formation and bone resorption, with a net loss of bone mass in most circumstances, whereas intermittent treatment with injections of PTH once daily, or less frequently, produces a net anabolic effect (Tam *et al.,* 1982) (see Chapter 75 for a review). In contrast, the initial interpretation of bone histomorphometry in malignancy-associated hypercalcemia was that, unlike primary hyperparathyroidism, bone resorption was uncoupled from bone formation (Stewart *et al.,* 1982), raising the possibility that the effects of PTHrP on bone formation differed radically from the effects of PTH. However, in animal models of humoral hypercalcemia, increases in bone resorption were appropriately coupled to increases in bone formation (Strewler *et al.,* 1986). It has been shown that intermittent administration of PTHrP(1-36) into humans for 2 weeks leads to increases in biochemical markers of bone formation and a decrease in markers of bone resorption (Plotkin *et al.,* 1998). PTHrP(1-36) is somewhat less effective than PTH(1-34) as an anabolic agent in the ovariectomized rat (Stewart *et al.,* 2000). Moreover, a carboxyl-substituted analog of PTHrP(1-34) also mimicks the anabolic action of PTH in the rat (Frolik *et al.,* 1999; Vickery *et al.,* 1996). Thus, the anabolic effects of PTH and PTHrP, administered intermittently, appear similar.

Any attempt to understand the cellular basis for the anabolic actions of PTH and PTHrP must take into account

their histomorphological effects. The increase in bone formation is best correlated with marked increases in bone formation surfaces and activation frequency (Boyce *et al.,* 1996; Dempster *et al.,* 1999; Lane *et al.,* 1996; Manolagas, 2000; Shen *et al.,* 1993). Thus, a major effect of PTH is to increase the number of active, bone-forming osteoblasts. Increases in the mineral apposition rate are also seen but tend to be smaller (Boyce *et al.,* 1996; Dempster *et al.,* 1999; Lane *et al.,* 1996; Shen *et al.,* 1993). Duration of the active bone formation phase is not prolonged in dogs treated with PTH (Boyce *et al.,* 1996) but is increased in primary hyperparathyroidism (Dempster *et al.,* 1999).

An increase in the number of active osteoblasts could occur in several ways, and PTH may not have the same effect in all circumstances—its predominant effect on growing bone in a young rodent may differ from its predominant effect in aged bone. First, PTH could increase the birth rate or proliferation of osteoblast precursors in bone marrow. In the rat, an anabolic regimen of PTH does not increase the proliferation of osteoblast precursors based on the absence of an increase in labeled nuclei on the bone surface after continuous labeling with [^{3}H]thymidine (Dobnig and Turner, 1995). This is compelling evidence against the view that a proproliferative effect of PTH is decisive in increasing osteoblast number. However, intermittent exposure to PTH could increase homing to the bone surface of late, postmitotic osteoblast precursors in the bone marrow, which are recognized as having PTH receptors (Amizuka *et al.,* 1996; Rouleau *et al.,* 1990).

Second, PTH treatment could activate bone-lining cells to again become active osteoblasts. There is no direct evidence for or against this hypothesis. However, bone-lining cells cover a relatively large bone surface per cell because of their flattened, spread shape, and it is not clear that the numbers of bone-lining cells are adequate to account for the increase in osteoblast number that is observed with PTH treatment.

Third, an anabolic PTH regimen could increase the life span of the active osteoblast. In the mouse, intermittent treatment with a high dose of PTH reduces the rate of osteoblast apoptosis (Jilka *et al.,* 1999), although PTH treatment actually increased the number of apoptotic osteoblasts in metaphyseal bone of young rats (Stanislaus *et al.,* 2000b). However, it is not clear whether the reduction in cell death is quantitatively sufficient to account for the anabolic activity of PTH. If the life span of an active osteoblast is several months, as surmised (Manolagas, 2000), then the turnover rate of osteoblasts would be considerably too slow for a reduction in the rate of apoptosis to account for a rapid expansion of the osteoblast pool—one that occurs within a week of the onset of PTH administration in rodent models—e.g., if the osteoblast life span is 100 days, their turnover rate is 1% per day, and the maximal increase in osteoblast pool size to be expected from complete abolition of apoptosis would also be 1% per day. If a reduction in apoptosis rate were the primary effect of PTH, increases not only in mean wall thickness but also in the duration of the active formation period would be expected. It is reasonably clear that mean wall thickness is increased by anabolic PTH regimens or in primary hyperparathyroidism, but whether the duration of the active formation period is also increased has not been fully resolved (Boyce *et al.,* 1996; Dempster *et al.,* 1999). In order to determine the mechanism by which PTH or PTHrP increases osteoblast number, and thereby has its anabolic effect, it will ultimately be necessary to learn the origin and fate of osteoblasts that participate in the anabolic effects by determining their precise cellular kinetics.

Perspectives on PTH and PTHrP in Bone

As evident from the previous section on anabolic effects of PTH and PTHrP, there is much to be learned about how the individual effects of the hormones on bone cells are integrated to produce the final effects of the hormones on the physiology of the skeleton. Moreover, there is large lacune in our understanding of the skeletal role of PTHrP. Although bone cells both secrete and respond to PTHrP, PTHrP is a major regulator of cartilage (the precursor of endochondral bones), and it is tantalizing to speculate that PTH evolved as a systemic hormone to overdrive the local regulation of bone metabolism by its sister peptide, the physiology of PTHrP in the skeleton has been refractory to study. Genetic models, so powerful in unraveling the role of PTHrP in the cartilaginous phase of endochondral bone formation (Chapter XX), have yielded little information about bone per se because any changes observed in bone when the PTHrP/receptor system are perturbed are potentially explained by perturbations in endochondral bone formation. To apply genetic methods to the study of PTHrP in bone, what is now necessary is tissue-specific targeting of PTHrP and its receptor in bone, and such studies are underway. By ablating PTHrP or the PTH/PTHrP receptor in bone only and ultimately restoring sequence-specific portions of the polyhormone PTHrP to such animals, it will eventually be possible to determine what is the local role of PTHrP in bone and how PTH and PTHrP interact as regulators of skeletal physiology.

Introduction

Documentation of the skeletal abnormalities in mice that either overexpressed parathyroid-related protein (PTHrP) in their skeletons or had the genes for PTHrP and the PTH receptor ablated by the techniques of homologous recombination provided an exciting impetus for the rapid accumulation of knowledge regarding the mechanisms by which PTHrP regulates bone and cartlilage development and physiology. These findings are reviewed in Chapters 13 and 15. Since the mid-1990s, increasing evidence has accumulated that PTHrP and the PTH/PTHrP receptor family also contribute to the development and functioning of several nonskeletal organs. Data regarding the action of PTHrP in the vascular system and the central nervous system are reviewed in Chapter 16. In this, the last of the series of chapters on the physiologic actions of PTHrP, we review data regarding the function(s) of PTHrP in several other nonskeletal sites. We first consider the functions of PTHrP in skin. Next, we review its functions in the mammary gland, placenta, and other reproductive tissues. Finally, we examine its role in the endocrine pancreas.

Skin

PTHrP and PTHrP Receptor Expression

Normal human keratinocytes were the first nonmalignant cells shown to produce PTHrP (Merendino *et al.,* 1986), and multiple studies have confirmed that rodent and human keratinocytes in tissue culture express the PTHrP

gene and secrete bioactive PTHrP (reviewed in Philbrick *et al.,* 1996). PTHrP expression has also been examined in skin *in vivo* using both immunohistochemistry and *in situ* hybridization. During fetal development in rats and mice, PTHrP is expressed principally within the epithelial cells of developing hair follicles (Karmali *et al.,* 1992; Lee *et al.,* 1995). In mature skin, PTHrP has been found at low levels throughout the epidermis from the basal layer to the granular layer. Some studies have suggested that PTHrP is more highly expressed in the superbasal keratinocytes (Danks *et al.,* 1989; Hayman *et al.,* 1989), although not all studies have reported this pattern (Atillasoy *et al.,* 1991; Grone *et al.,* 1994). A variety of factors have been reported to regulate PTHrP production by cultured keratinocytes (see Philbrick *et al.,* 1996, for review). For example, glucocorticoids and 1,25 $(OH)_2D$ have been shown to downregulate PTHrP production, whereas fetal bovine serum, matrigel, and an as yet unidentified factor(s) secreted from cultured fibroblasts have been shown to upregulate PTHrP production. The upregulation of PTHrP production by fibroblast-conditioned media is particularly interesting, as PTHrP, in turn, acts back on dermal fibroblasts, suggesting that it may function in a short regulatory loop between keratinocytes and dermal fibroblasts (Shin *et al.,* 1997; Blomme *et al.,* 1999a). Finally, *in vivo,* PTHrP expression has been shown to be upregulated at the margins of healing wounds in guinea pigs (Blomme *et al.,* 1999b). Interestingly, in this study, PTHrP was also detected in myofibroblasts and macrophages, suggesting that keratinocytes may not be the only source of PTHrP in skin.

It is now clear that keratinocytes do not express the type I PTH/PTHrP receptor (PTHR1), but dermal fibroblasts do (Hanafin *et al.,* 1995; Orloff *et al.,* 1995). PTHrP has been shown to bind to skin fibroblasts and to elicit biochemical and biological responses in these cells (Shin *et al.,* 1997; Blomme *et al.,* 1999a; Wu *et al.,* 1987). In addition, studies utilizing *in situ* hybridization have demonstrated that PTHR1 mRNA in fetal skin, is absent from the epidermis, yet abundant in the dermis, especially in those cells adjacent to the keratinocytes (Karmali *et al.,* 1992; Lee *et al.,* 1995; Dunbar *et al.,* 1999a). There are fewer data concerning the expression patterns of the PTHR1 in more mature skin, but, in mice, it appears that the relative amount of PTHR1 mRNA in dermal fibroblasts is reduced in adult as compared to fetal skin (J. P. Zhang and J. J. Wysolmerski, unpublished data). Although keratinocytes do not express the classical PTH/PTHrP receptor, studies have shown that these cells bind and respond to PTHrP by inducing calcium transients, suggesting that there may be other receptors for PTHrP expressed on these cells (Orloff *et al.,* 1992, 1995). However, to date, no such receptors have been isolated, so their existence remains uncertain.

Biochemistry of PTHrP

As described in Chapters 3 and 4, during transcription, the PTHrP gene undergoes alternative splicing to generate multiple mRNAs, which in human cells give rise to three main protein isoforms. In addition, each of these isoforms is subject to posttranslational processing to generate a variety of peptides of varying length. Human keratinocytes have been shown to contain mRNA encoding for each of the three main isoforms, although, as in other systems, no clearly defined or unique role has yet emerged for any of the three individual isoforms (Philbrick *et al.,* 1996). Keratinocytes have also been shown to process full-length PTHrP into a variety of smaller peptides, including PTHrP(1-36) and a midregion fragment beginning at amino acid 38 (Soifer *et al.,* 1992). These cells have also been shown to secrete a large (~10 kDa) amino-terminal form that is glycosylated (Wu *et al.,* 1991). There is currently no specific information regarding the secretion of COOH-terminal peptides of PTHrP in skin, but keratinocytes are also likely to produce these peptides.

Function of PTHrP

Several studies suggest that PTHrP is involved in the regulation of hair growth. As noted earlier, the PTHrP gene in embryonic skin is expressed most prominently in developing hair follicles, and overexpression of PTHrP in the basal keratinocytes of skin in transgenic mice leads to a severe inhibition of hair follicle morphogenesis during fetal development (Wysolmerski *et al.,* 1994). The effects of PTHrP overexpression appear to act early during hair follicle induction, implicating PTHrP in the regulation of epidermal patterning during embryogenesis. However, any such function of PTHrP during hair follicle morphogenesis is not critical because disruption of the PTHrP or PTHR1 genes does not seem to affect hair follicle formation or patterning in mice (Karaplis *et al.,* 1994; Lansk *et al.,* 1996; Foley *et al.,* 1998).

In addition to effects on hair follicle morphogenesis, it has also been suggested that PTHrP may participate in regulation of the hair cycle. It has been reported that the systemic administration of PTHR1 antagonists to young mice perturbs the hair cycle by prematurely terminating telogen, prolonging anagen growth, and inhibiting catagen (Schilli *et al.,* 1997). These findings imply that PTHrP acts to inhibit hair follicle growth by pushing growing hair follicles into the growth-arrested or catagen/telogen phase of the hair cycle. If this hypothesis were correct, one would expect PTHrP knockout mice to exhibit findings similar to PTHR1 antagonist-treated mice. However, this does not appear to be the case. In mice that lack PTHrP in their skin, the hair cycle appears to be normal (Foley *et al.,* 1998). In fact, rather than a promotion of hair growth, these mice demonstrate a thinning of their coat over time. These conflicting results are difficult to rationalize at this point, but they raise the intriguing possibility that the PTHR1 antagonist might be inhibiting the function of another member of the PTH receptor family and that there may be ligands for such a receptor in skin other than PTHrP.

PTHrP has also been implicated in the regulation of keratinocyte proliferation and/or differentiation. Although

studies in cultured cells have alternately suggested that PTHrP either enhances or inhibits keratinocyte proliferation, data from studies *in vitro* have consistently suggested that PTHrP promotes the differentiation of keratinocytes (reviewed in Philbrick *et al.,* 1996). In contrast, studies *in vivo* have suggested that PTHrP inhibits keratinocyte differentiation (Foley *et al.,* 1998). A careful comparison of the histology of PTHrP-null and PTHrP-overexpressing skin demonstrated reciprocal changes. In the absence of PTHrP, it appeared that keratinocyte differentiation was accelerated, whereas in skin exposed to PTHrP overexpression, keratinocyte differentiation appeared to be retarded (Foley *et al.,* 1998). Therefore, in a physiologic context, PTHrP appears to slow the rate of keratinocyte differentiation and to preserve the proliferative, basal compartment. Remarkably, these changes in the rate of keratinocyte differentiation are exactly analogous to those noted for chondrocyte differentiation in the growth plates of mice overexpressing PTHrP as compared to PTHrP- and PTHR1–null mice (Philbrick *et al.,* 1996) (see Chapter 15). Again, at present, it is difficult to rationalize conflicting data regarding the effects of PTHrP on keratinocyte differentiation, but studies in genetically altered mice clearly indicate that PTHrP participates in the complex regulation of these processes *in vivo*. Further research will be needed to understand its exact role.

An important but still unresolved question is whether the effects of PTHrP on keratinocyte proliferation, differentiation, and hair follicle growth are the result of its effects on keratinocytes directly or via its effects on dermal fibroblasts. At present there are more data to support the paracrine possibility. PTHR1 is expressed on dermal fibroblasts *in vivo* and in culture (Lee *et al.,* 1995; Hanafin *et al.,* 1995). Dermal fibroblasts have been demonstrated to show biochemical and biological responses to PTHrP (Shin *et al.,* 1997; Blomme *et al.,* 1999a; Wu *et al.,* 1987). Furthermore, PTHrP has been shown to induce changes in growth factor and extracellular matrix production that could, in turn, lead to changes in keratinocyte proliferation and/or differentiation and hair follicle growth (Shin *et al.,* 1997; Blomme *et al.,* 1999a; Insogna *et al.,* 1989). Of course, the autocrine and paracrine signaling pathways are not mutually exclusive, but any direct autocrine effects of PTHrP on keratinocytes, as discussed earlier, would require the presence of PTHrP receptors other than the PTHR1 on these cells. Although preliminary biochemical evidence has suggested that this possibility exists, no such receptors have been identified on keratinocytes (Orloff *et al.,* 1992, 1995). An alternative possibility by which PTHrP might have cell autonomous effects on keratinocytes is via an intracrine pathway involving its translocation to the nucleus (Philbrick *et al.,* 1996). Clearly, much research is needed to define the receptors and signaling pathways by which PTHrP acts in skin. Only when this information is available will we be able to understand the mechanisms leading to the skin phenotypes that have been observed in the various transgenic models discussed earlier.

Pathophysiology of PTHrP

To date, PTHrP has not been implicated in any diseases of the skin. It has been suggested that skin and skin appendage findings in the rescued PTHrP-null mice are reminiscent of a series of disorders collectively known as the ectodermal dysplasias (Foley *et al.,* 1998), but PTHrP has not been formally linked to any of these diseases. The most common tumors causing humoral hypercalcemia of malignancy (HHM) are those of squamous histology, but these tumors rarely arise from skin keratinocytes. In fact, the most common skin tumors, basal cell carcinomas, do not overexpress PTHrP and are not associated with hypercalcemia (Philbrick *et al.,* 1996). Although PTHrP appears to participate in the normal physiology of the skin, it is not clear at this juncture if it will be involved in skin pathophysiology.

Mammary Gland

PTHrP was reported to be expressed in mammary tissue and to be secreted into milk very soon after its discovery (Thiede and Rodan, 1988; Budayr *et al.,* 1989). It is now known that PTHrP is critically important for the proper development and functioning of the mammary gland throughout life. In addition, it has been implicated as an important modulator of the biological behavior of breast cancer. The mammary gland develops in several discrete stages and only reaches its fully differentiated state during pregnancy and lactation. PTHrP appears to serve different functions during these different stages of mammary development; therefore, we will organize our discussion around three principal stages of mammary development: embryonic development, adolescent growth, and pregnancy and lactation. For each stage, we will first outline the pertinent developmental events in rodents, as data regarding the function(s) of PTHrP largely come from studies in mice and rats. Next, we will discuss the localization of PTHrP and PTHrP receptors and the regulation of the expression of PTHrP and its receptors. Finally we will address the function of PTHrP.

Embryonic Mammary Development

In mice, there are two phases of embryonic mammary development. The first involves the formation of five pairs of mammary buds, each of which consists of a light bulb-shaped collection of epithelial cells surrounded by several layers of fibroblasts known as the mammary mesenchyme (Sakakura, 1987). After the formation of these buds, mouse mammary development displays a characteristic pattern of sexual dimorphism. In male embryos, in response to androgens, the mammary mesenchyme destroys the epithelial bud and male mice are left without mammary glands or nipples (Sakakura, 1987). In female embryos, however, the mammary buds remain quiescent until embryonic day 16 (E16) when they undergo a transition into the second step

of embryonic development, formation of the rudimentary ductal tree. This process involves the elongation of the mammary bud, its penetration out of the dermis and into a specialized stromal compartment known as the mammary fat pad, and the initiation of ductal branching morphogenesis. At the time of birth, the gland consists of a simple epithelial ductal tree consisting of 15–20 branched tubes within a fatty stroma (Sakakura, 1987). This initial pattern persists until puberty at which time the mature virgin gland is formed through a second round of branching morphogenesis, regulated by circulating hormones (discussed later).

The PTHrP gene is expressed exclusively within epithelial cells of the mammary bud, soon after it begins to form. PTHrP mRNA continues to be localized to mammary epithelial cells during the initial round of branching morphogenesis, as the bud grows out into the presumptive mammary fat pad and begins to branch (Dunbar *et al.,* 1998, 1999a; Wysolmerski *et al.,* 1998). At some point after birth, PTHrP gene expression is downregulated, and in the adult virgin gland PTHrP mRNA is found only within specific portions of the duct system (discussed later) (Dunbar *et al.,* 1998). In contrast to the PTHrP gene, the PTHR1 gene appears to be expressed within the mesenchyme, but its expression is widespread and is not limited to the developing mammary structures. Transcripts for the PTHR1 gene are found within the mammary mesenchyme but also throughout the developing dermis (Dunbar *et al.,* 1999a; Wysolmerski *et al.,* 1998). It is not clear when the receptor gene is first expressed within the subepidermal mesenchyme. However, it appears already to be present when the mammary bud begins to form and it continues to be expressed within fibroblasts surrounding the mammary ducts as they begin to grow out and branch (Wysolmerski *et al.,* 1998; Dunbar *et al.,* 1998).

Epithelial expression of PTHrP and mesenchymal expression of the PTHR1 are not unique to the developing mammary gland, and this pattern has long led to speculation that PTHrP and its receptor might contribute to the regulation of epithelial–mesenchymal interactions during organogenesis. There is now solid evidence that this is the case during embryonic mammary development, where PTHrP appears to serve as an epithelial signal that influences cell fate decisions within the developing mammary mesenchyme. Data supporting this notion come from studies in several genetically altered mouse models. First, in PTHrP or PTHR1 knockout mice, there is a failure of the normal androgen-mediated destruction of the mammary bud due to the failure of the mammary mesenchyme to differentiate properly and to express androgen receptors (Dunbar *et al.,* 1999a) (see Fig. 1). Second, in PTHrP or PTHR1 knockout mice, the mammary buds fail to grow out into the fat pad and initiate branching morphogenesis, again due to defects in the mammary mesenchyme (Wysolmerski *et al.,* 1998; Dunbar *et al.,* 1998). Finally, in keratin 14 (K14) PTHrP transgenic mice that ectopically overexpress PTHrP within all the basal keratinocytes of the developing embryo, subepidermal mesenchymal cells, which should acquire a dermal fate, instead become mammary mesenchyme (Dunbar *et al.,* 1999a).

As demonstrated by these studies, PTHrP signaling is essential for mammary gland formation in rodents. When the mammary gland begins to form, the PTHR1 is expressed in all the mesenchymal cells underneath the epidermis, but PTHrP is expressed only within the mammary epithelial buds and not within the epidermis itself (Karmali *et al.,* 1992; Thiede and Rodan, 1988; Wysolmerski *et al.,* 1998). As the mammary bud grows down into the mesenchyme, PTHrP produced by mammary epithelial cells interacts over short distances with the PTHR1 on the immature mesenchymal cells closest to the epithelial bud and triggers these cells to differentiate into mammary mesenchyme. In this way, PTHrP acts as a patterning molecule contributing to the formation of small patches of mammary-specific stroma around the mammary buds and within the surrounding sea of presumptive dermis. The process of differentiation set in motion by PTHrP signaling is critical to the ability of the mammary-specific stroma to direct further morphogenesis of the epithelium. In the absence of this signaling, the mesenchyme can neither destroy the epithelial bud in response to androgens nor trigger the outgrowth of the bud and the initiation of branching morphogenesis (Dunbar *et al.,* 1998, 1999a; Wysolmerski *et al.,* 1998).

Although the above model just described was developed from studies in mice, it appears that PTHrP is also critical to the formation of breast tissues in human fetuses. It has been demonstrated that a fatal form of dwarfism known as Blomstrand's chondrodyplasia is a result of null mutations of the PTHR1 gene (Jobert *et al.,* 1998) (see Chapter 44). Affected fetuses have skeletal abnormalities similar to those caused by deletion of the PTHrP and PTHR1 genes in mice (see Chapter 15) and, in addition, lack breast tissue or nipples (Wysolmerski *et al.,* 1999). In normal human fetuses, the PTHrP gene is expressed within the mammary epithelial bud, and the PTHR1 gene is expressed in surrounding mesenchyme (Wysolmerski *et al.,* 1999). Therefore, in humans, as in mice, epithelial-to-mesenchymal PTHrP–PTHR1 signaling is essential to the formation of the embryonic mammary gland.

Adolescent Mammary Development

Following birth, the murine mammary gland undergoes little development until the onset of puberty. At that point, in response to hormonal changes, the distal ends of the mammary ducts form specialized structures called terminal end buds. These structures serve as the sites of cellular proliferation and differentiation for a period of active growth that gives rise to the typical branched duct system of the mature virgin gland (Daniel and Silberstein, 1987). Once formed, the ductal tree remains relatively unchanged until another round of hormonal stimulation during pregnancy induces the formation of the lobuloalveolar units that produce milk.

Similar to findings in the embryonic mammary gland during puberty, PTHrP appears to be a product of mammary

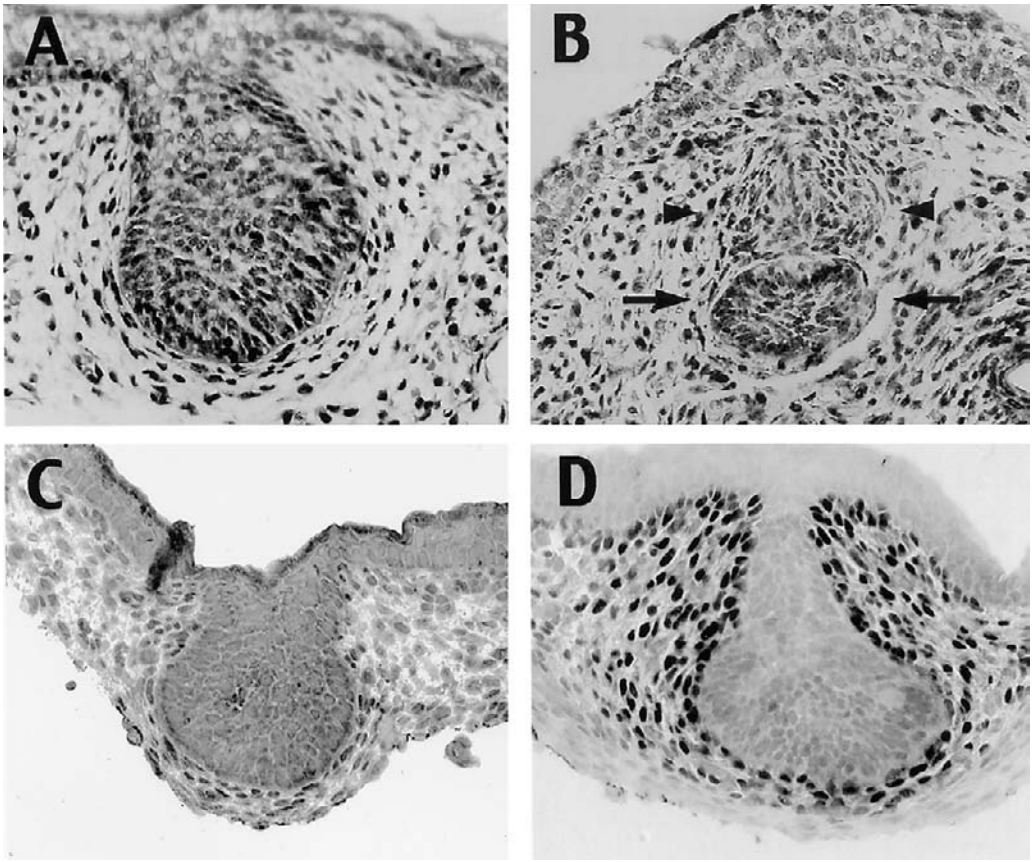

Figure 1 Failure of sexual dimorphism during embryonic mammary development. Mammary buds from PTHrP knockout (A and B) and wild-type (B and D) embryos at E15. Note the destruction of the mammary bud in normal male embryos (B) as evidenced by the mesenchymal condensation that has obliterated the bud stalk (arrowheads) and the degenerating epithelial remnant (arrows). In PTHrP knockout males (A), this process is completely absent. The destruction of the mammary bud is an androgen-dependent phenomenon, and mesenchymal cells are the targets for androgen action, as evidenced by positive staining for androgen receptors seen in the mammary mesenchyme surrounding a normal female mammary bud in D. In PTHrP knockout mammary buds, this process fails due to the failure of androgen receptor expression in the mammary mesenchyme as shown in C. Modified from Dunbar *et al.* (1999a), with permission.

epithelial cells and the PTHR1 appears to be expressed in stromal cells (Dunbar *et al.,* 1998). However, the structure of the pubertal gland is more complex than that of the embryonic gland and, here, there are conflicting data regarding the localization of PTHrP and the PTH receptor. Although there is general agreement that PTHrP is expressed in epithelial cells in the postnatal gland, there is some disagreement regarding the specific epithelial compartments in which PTHrP is found. Studies employing *in situ* hybridization in mice have suggested that, after birth, the overall levels of PTHrP gene expression in mammary ducts are reduced except for in the terminal end buds during puberty (Dunbar *et al.,* 1998). In these structures, appreciable amounts of PTHrP mRNA were detected in the peripherally located cap cells. In other parts of the gland there was little, if any, specific hybridization for PTHrP. In contrast, studies looking at mature human and canine mammary glands using immunohistochemical techniques have suggested that PTHrP can be found in both luminal epithelial and myoepithelial cells throughout the ducts (Grone *et al.,* 1994; Liapis *et al.,* 1993). Furthermore, studies using cultured cells have suggested that PTHrP is produced by luminal and myoepithelial cells isolated from normal glands (Ferrari *et al.,* 1992; Seitz *et al.,* 1993; Wojcik *et al.,* 1999). There have been fewer reports looking at the localization of PTHR1 expression in the postnatal mammary gland, but as in embryological development, it is expressed in the mammary stroma (Dunbar *et al.,* 1998). *In situ* hybridization studies have found the highest concentration of PTHR1 mRNA in the stroma immediately surrounding terminal end buds during puberty (Dunbar *et al.,* 1998). This same study found lower levels of PTHR1 mRNA distributed generally within the fat pad stroma, but very little expression in the dense stroma surrounding the more mature ducts. In addition, these investigators found no evidence of PTHR1 mRNA in freshly isolated epithelial cells (Dunbar *et al.,* 1998). However, in contrast to these findings, other studies have suggested that PTHR1 is expressed in cultured luminal epithelial and myoepithelial cells (Seitz *et al.,* 1993; Wojcik *et al.,* 1999), as well as in cultured breast cancer cell lines (Birch *et al.,* 1995). In summary, during puberty,

PTHrP and its receptor are found predominantly within the terminal end buds, with PTHrP localized to the epithelium and PTHR1 localized in the stroma. It remains an open and interesting question whether, at some time during mammary ductal development, epithelial cells express low levels of PTHR1.

Studies in transgenic mice have suggested that PTHrP is an important regulator of mammary morphogenesis during puberty. Overexpression of PTHrP in mammary epithelial cells using the K14 promoter results in an impairment of ductal branching morphogenesis (Wysolmerski *et al.,* 1995). There are two aspects to the defect. First, the terminal end buds advance through the mammary fat pad at a significantly slower rate than normal. Second, there is a severe reduction in the branching complexity of the ductal tree. As seen in Fig. 2, this results in a spare and stunted epithelial duct system. Experiments altering the timing and duration of PTHrP overexpression in the mammary gland using a tetracycline-regulated K14-PTHrP transgene have demonstrated that the two aspects of this pubertal phenotype appear to represent separate functions of PTHrP. The branching (or patterning) defect results from embryonic overexpression of PTHrP, whereas the ductal elongation defect is a function of overexpression of PTHrP during puberty (Dunbar *et al.,* 1999b). These effects on ductal patterning provide further evidence of the importance of PTHrP as a regulator of embryonic mammary development. In addition, the localization patterns for PTHrP and PTHR1 during puberty, combined with the effects of pubertal overexpression of PTHrP on ductal growth, suggest that PTHrP also functions later in mammary development. During puberty it appears to modulate epithelial–mesenchymal interactions that govern ductal elongation.

Pregnancy and Lactation

Mammary epithelial cells only reach their fully differentiated state during lactation. Under hormonal stimulation during pregnancy, there is a massive wave of epithelial proliferation and morphogenesis that gives rise to terminal ductules and lobuloalveolar units. During the later stages of pregnancy the epithelial cells fully differentiate and then begin to secrete milk during lactation. By the time lactation commences, the fatty stroma of the mammary gland is completely replaced by actively secreting lobuloalveoli. Upon the completion of lactation, there is widespread

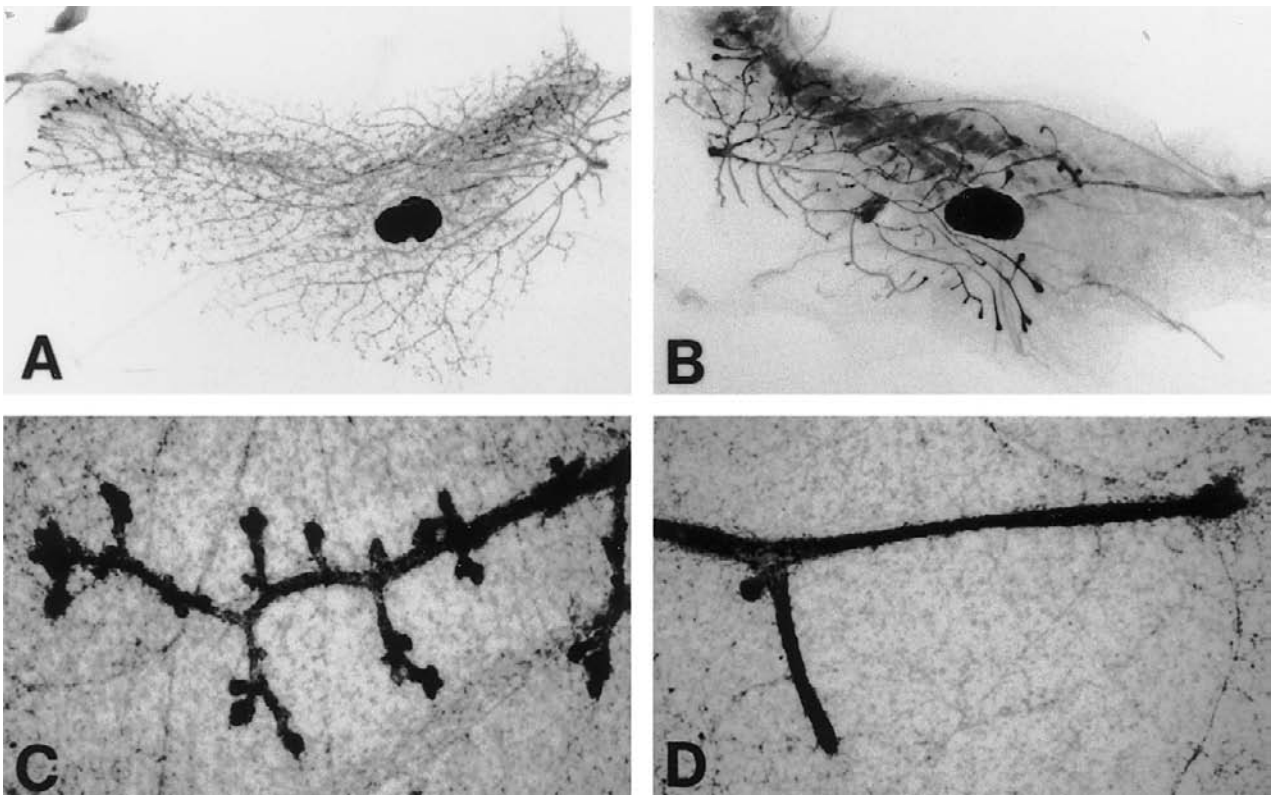

Figure 2 Overexpression of PTHrP in the mammary gland of K14–PTHrP transgenic mice antagonizes ductal elongation and branching morphogenesis during puberty. Typical whole mount analyses of fourth inguinal mammary glands from wild-type (A) and K14–PTHrP transgenic mice (B) at 6 weeks of age. The dark oval in the center of each gland is a lymph node. Growth of the ducts during puberty is directional and each gland is arranged so that the primary duct (the origin of the duct system) is toward the center of the figure. Note that overexpression of PTHrP results in an impairment of the elongation of the ducts through the fat pad, as well as dramatic reduction of the branching complexity of the ductal tree. (C and D) Higher magnifications of a portion of the ducts from wild-type (C) and transgenic (D) glands demonstrating the reduction in side branching caused by the overexpression of PTHrP. Modified from Wysolmerski *et al.* (1995), with permission.

apoptosis of the differentiated epithelial cells and the gland remodels itself into a duct system similar to that of the virgin animal (Daniel and Silberstein, 1987).

Localization studies in humans, rodents, and cows have all noted epithelial cells to be the source of PTHrP in the mammary gland during pregnancy and lactation (Liapis *et al.,* 1993; Wojcik *et al.,* 1998, 1999; Rakopoulos *et al.,* 1990). Based on the assessment of whole gland RNA, PTHrP expression appears to be upregulated at the start of lactation under the control of both local and systemic factors (Philbrick *et al.,* 1996; Thiede and Rodan, 1988; Thiede, 1989; Thompson *et al.,* 1994; Buch *et al.,* 1992). Thiede and Rodan (1988; Thiede, 1989) originally reported that PTHrP expression in rats is dependent on suckling and on serum prolactin concentrations. However, prolactin must serve only as a permissive factor, for additional studies have shown that the suckling response is a local one and that PTHrP only rises in the milked gland (Thompson *et al.,* 1994). Furthermore, PTHrP expression increases gradually over the course of lactation, and in later stages, its expression becomes independent of serum prolactin levels (Bucht *et al.,* 1992). It is clear that much of the PTHrP made during lactation ends up in milk, in which levels of PTHrP are up to 10,000-fold higher than in the circulation of normal individuals and 1000-fold higher than in patients suffering from humoral hypercalcemia of malignancy (Philbrick *et al.,* 1996). PTHrP concentrations in milk have generally been found to mirror RNA levels in the gland, increasing over the duration of lactation and rising acutely with suckling (Thompson *et al.,* 1994; Yamamoto *et al.,* 1992a; Law *et al.,* 1991; Goff *et al.,* 1991). In addition, evidence shows that PTHrP levels correlate with the calcium content of milk in humans and cows, but not in rodents (Yamamoto *et al.,* 1992a; Law *et al.,* 1991; Goff *et al.,* 1991; Vemura *et al.,* 1997; Kovacs and Kronenberg 1997). Finally, in mice, PTHrP mRNA levels are promptly downregulated during the early stages of involution and then increase to prelactation levels about a week into the remodeling process (M. Dunbar and J. J. Wysolmerski, unpublished data).

In contrast to PTHrP, there has been little study of the expression or regulation of PTHrP receptors during pregnancy and lactation. In early pregnancy, the PTH/PTHrP receptor is expressed at low levels in the stroma surrounding the developing lobuloalveloar units (Dunbar *et al.,* 1998). Studies using whole gland RNA demonstrate a reciprocal relationship between PTHR1 and PTHrP mRNA levels. That is, as PTHrP expression rises during lactation, PTHR1 mRNA levels decrease, and as PTHrP mRNA levels fall during early involution, PTHR1 expression increases to its former level (M. Dunbar and J. J. Wysolmerski, unpublished data). This may represent active downregulation of the receptor by PTHrP or may simply reflect the changing amount of stroma within the gland at these different stages. However, in a study of cells isolated from lactating rats, it was suggested that epithelial cells, as well as stromal cells, express this receptor (Wojcik *et al.,* 1999) so the regulation of receptor expression during pregnancy and lactation may be complex.

Initial reports of the presence of PTHrP in the mammary gland and in milk prompted a great deal of speculation regarding its functions in breast tissue during lactation. These proposals have revolved around four general hypotheses: (1) PTHrP may be involved in maternal calcium homeostasis and the mobilization of calcium from the maternal skeleton; (2) PTHrP may be involved in regulating vascular and/or myoepithelial tone in the lactating mammary gland; (3) PTHrP may be involved in transepithelial calcium transport into milk; and/or (4) PTHrP may be involved in neonatal calcium homeostasis or neonatal gut physiology. Although the true function(s) of PTHrP during lactation remains obscure, some experimental evidence addresses the first two of these possibilities. These data are discussed in the following paragraphs. However, at this point, the latter two ideas remain simple speculation and are not discussed further.

The control of maternal mineral metabolism and the mobilization of skeletal calcium for milk production remain enigmatic. Although a significant proportion of the calcium transported into milk is derived from the maternal skeleton, neither of the established calcium-regulating hormones, PTH nor $1,25(OH)_2D$, seems to be necessary or sufficient to account for this phenomenon (Kovacs and Kronenberg, 1997). Therefore, the finding that PTHrP was produced in the lactating breast aroused interest in this protein as the missing factor acting to mobilize calcium during lactation. Although not every study has concurred in support of such a role, the weight of evidence across species now suggests that PTHrP levels in the systemic circulation are elevated during lactation (Kovacs and Kronenberg, 1997). In addition, circulating PTHrP levels have been shown to correlate with bone density changes in lactating humans (Sowers *et al.,* 1996), and it appears that suckling leads to transient increases in circulating PTHrP levels (Dobnig *et al.,* 1995). Suckling has also been shown to lead to increases in urinary phosphate and cAMP excretion in rodents and in cows (Yamamoto *et al.,* 1991; Barlet *et al.,* 1993), changes that might be expected if PTHrP released from the mammary gland was acting in a systemic fashion. Of course, none of these data actually prove that the source of PTHrP in the circulation of lactating humans or animals is the mammary gland itself. More significantly, passive immunization of lactating mice with anti-PTHrP antibodies has not been found to influence maternal calcium homeostasis or the calcium content of milk (Melton *et al.,* 1960). Therefore, although PTHrP remains an appealing candidate regulator of maternal calcium homeostasis during lactation, such an action remains unproven.

The second potential function of PTHrP during lactation concerns the regulation of vascular and/or myoepithelial cell tone. As discussed in Chapter 16, PTHrP has been shown to modulate smooth muscle cell tone in a variety of organs, including the vascular tree, where it acts as a vasodilator. Consistent with these effects, two studies have shown that PTHrP increases mammary blood flow during lactation (Davicco *et al.,* 1993; Thiede *et al.,* 1992). The

injection of amino-terminal fragments of PTHrP into the mammary artery of dried ewes was shown to increase mammary blood flow and to override the vasoconstrictive effects of endothelin (Davicco *et al.,* 1993). Thiede and colleagues (1992) have demonstrated that the nutrient arteries of the inguinal mammary glands of rats make PTHrP and that its production is responsive to suckling and prolactin. Myoepithelial cells in the breast are similar, in some ways, to vascular smooth muscle cells and are thought to participate in the control of milk ejection by contracting in response to oxytocin (Daniel and Silberstein, 1987). Therefore, it is interesting that myoepithelial cells in culture have been shown to express PTHR1 and to respond to PTHrP by elevating intracellular cAMP (Seitz *et al.,* 1993; Wojcik *et al.,* 1999). Furthermore, mirroring the effects of PTHrP on the endothelin-induced contraction of vascular smooth muscle, PTHrP has been shown to block the rise in intracellular calcium normally induced in response to oxytocin in myoepithelial cells (Seitz *et al.,* 1993). Although much more study is needed, current data support speculation that PTHrP might have effects on mammary blood flow and/or milk ejection.

Pathophysiology of PTHrP in the Mammary Gland

Although PTHrP has not been directly implicated in the pathogenesis of any specific disease of the mammary gland, there are now several instances in which it appears to contribute to pathophysiology in the human breast. First, as noted previously, fetuses afflicted with Blomstrand's chondrodystrophy lack nipples and breast tissue (Wysolmerski *et al.,* 1999). Second, there have been two case reports in which lactational hypercalcemia was noted to be related to elevations in circulating levels of PTHrP (Khosla *et al.,* 1990; Reid *et al.,* 1992). One of these cases was caused by massive breast hyperplasia, and the patient required reduction mammoplasty in order to ameliorate her hypercalcemia (Khosla *et al.,* 1990). Finally, the area with the most potential impact on human health is the relationship of PTHrP production to breast cancer. This is evolving into a complicated topic and will be addressed only briefly here. However, it will be reviewed in more depth in Chapter 43.

It is well documented that PTHrP is produced by a number of primary breast carcinomas and that this sometimes leads to classical humoral hypercalcemia of malignancy (Isales *et al.,* 1987). A potentially more widespread role may be the involvement of PTHrP in the osteotrophism of breast cancer (Guise *et al.,* 1996; Yin *et al.,* 1999). Animal models have suggested that PTHrP production by breast tumor cells is important to their ability to form skeletal metastases (Guise *et al.,* 1996; Yin *et al.,* 1999). However, there is conflicting evidence as to whether PTHrP production by a primary breast tumor is predictive of bone metastases in patients (Bundred *et al.,* 1996; Henderson *et al.,* 2001). The largest and most carefully controlled study to date suggested that PTHrP production by the primary tumor is actually a negative predictor, not a positive predictor, of skeletal metastases (Henderson *et al.,* 2001). It may be that PTHrP production does not enable a tumor cell to get into the skeleton, but once there, the ability of tumor cells to upregulate PTHrP production within the bone microenvironment becomes important to their ability to grow in the skeleton (Yin *et al.,* 1999). These are important issues, and ongoing studies should provide us with more information in the near future.

Reproductive Tissues

PTHrP and Placental Calcium Transport

Nearly all of the calcium, and a large proportion of the inorganic phosphate (85%) and magnesium (70%), transferred from the mother to the fetus is associated with development and mineralization of the fetal skeleton (Grace *et al.,* 1986). The concentrations of both total and ionized Ca in all mammalian fetuses studied during late gestation have been observed to be higher than maternal levels. As a result of studies in which the sheep was used extensively for the study of fetal calcium control, one of the first suggested physiological roles of PTHrP was that of regulating the transport of calcium from mother to fetus in the mammal, thereby making calcium available to the growing fetal skeleton (Rodda *et al.,* 1988).

Immunoreactive PTH levels were found to be low in fetal lambs, whereas PTH-like biological activity in serum was high (Care *et al.,* 1985), suggesting the presence of another PTH-like substance. Parathyroidectomy in the fetal lamb resulted in loss of the calcium gradient that exists between mother and fetus, as well as impairment of bone mineralization, implicating parathyroids as the source of the regulatory agent. Crude, partially purified or recombinant PTHrP, but neither PTH nor maternal parathyroid extract that contained no immunoreactive PTHrP, restored the gradient (Rodda *et al.,* 1988). Thus, PTHrP appeared to be the active component of the fetal parathyroid glands responsible for maintaining fetal calcium levels and suppressing fetal PTH levels. In support of this hypothesis, immunoreactive PTHrP was found to be readily detectable in sheep fetal parathyroids from the time they form (MacIsaac *et al.,* 1991) and was also found in early placenta, suggesting that the latter tissue may be a source of PTHrP for calcium transport early in gestation.

The portion of PTHrP that appears to be responsible for regulating placental calcium transport lies between residues 67 and 86 (Care *et al.,* 1990), but the responsible receptor has not yet been identified. While syncytiotrophoblasts are believed to be central in the transport of calcium to the fetus, cytotrophoblasts (which differentiate to form the syncytium) are believed to be the calcium-sensing cells, and raising the extracellular calcium concentration has been shown to inhibit PTHrP release from these cells (Hellman *et al.,* 1992). The calcium-sensing receptor (CaR) has been localized to cytotrophoblasts of human placenta (Bradbury

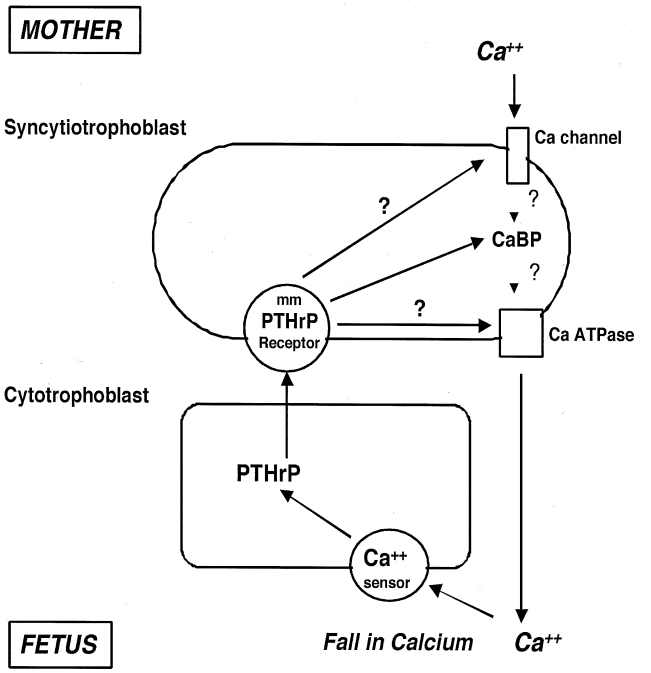

Figure 3 A potential model for the interactions of PTHrP and the CaR in regulating placental calcium transport. A fall in circulating calcium in the fetus activates the calcium-sensing receptor (CaR) on the cytotrophoblast. This leads to PTHrP secretion by the cytotrophoblast, which may then act via the putative midmolecule PTHrP receptor to promote calcium transport from maternal to fetal circulation. The nature and cellular location of the midmolecule PTHrP receptor are unknown, but are likely to be on the syncytiotrophoblast implicated in calcium transport across the placenta. Midmolecule PTHrP signaling could involve several mechanisms as indicated and may include participation of a calcium-binding protein (CaBP). (Modified from Bradbury (1999), with permission).

et al., 1997), and the work of Kovacs *et al.* (1998) has implicated it in placental calcium transport. Furthermore, a calreticulin-like, calcium-binding protein has been isolated from trophoblast cells and its expression is increased by treatment with PTHrP(67-84) but not with N-terminal PTHrP (Hershberger and Tuan, 1998). A working hypothesis for how the CaR, midregion PTHrP, and a midregion PTHrP receptor might interact to regulate transplacental calcium transport is presented in Fig. 3.

Although these observations are strongly suggestive of involvement of PTHrP and the CaR, the mechanisms of placental calcium transport are still not fully understood. Support for the role of PTHrP also comes from the PTHrP gene knockout mouse in which placental calcium transport is severely impaired (Kovacs *et al.,* 1996). In mice homozygous for deletion of the PTHrP gene, fetal plasma calcium and maternal–fetal calcium gradient were significantly reduced. When fetuses were injected *in utero* with fragments of PTHrP or PTH, calcium transport was significantly restored only by treatment with a midmolecular region of PTHrP that does not act via the PTHR1. Furthermore, in mice rendered null for the PTHR1 gene, placental calcium transport was increased, and PTHR1 null fetuses had plasma PTHrP levels more than 10 times higher than controls (Kovacs *et al.,* 2001). The circulating PTHrP in the fetal mice was found to be derived from several tissues, including liver and placenta, but the parathyroids were excluded as a source of PTHrP in this setting (Kovacs *et al.,* 2001).

Thus, conclusions from the murine studies are similar to those in the sheep, namely that PTHrP contributes to fetal skeleton calcium supply by controlling maternal–fetal calcium transport through actions mediated by a midmolecule portion of the PTHrP molecule.

Uterus and Extraembryonic Tissues

The uterus, both pregnant and nonpregnant, is another of the many sites of production and action of PTHrP. The relaxing effect of PTH on uterine smooth muscle had been long recognized (Shew *et al.,* 1984), and it was not surprising that PTHrP had the same effect (Shew *et al.,* 1991). The finding that expression of mRNA for PTHrP in the myometrium during late gestation in the rat was controlled by intrauterine occupancy by the fetoplacental unit raised the possibility of a role for PTHrP in regulating uterine muscle tone (Thiede *et al.,* 1990).

In studies in rats with or without estrogen treatment, protein and mRNA for PTHrP were localized not only in the myometrium, as had been shown in pregnancy (Thiede *et al.,* 1990), but also in the epithelial cells lining the endometrium and endometrial glands. Indeed, the strongest PTHrP production appeared to be in these sites (Paspaliaris *et al.,* 1992), suggesting that the endometrium and endometrial glands might be the major uterine site of PTHrP production and that PTHrP might be a local regulator of endometrial function and myometrial contractility. Estrogen treatment enhanced uterine production of PTHrP, but most significantly, the relaxing effect of PTHrP on uterine contractility *in vitro* was enhanced greatly by the pretreatment of noncycling rats with estrogen. In keeping with this observation, uterine horns from cycling rats in proestrous and estrous phases of the cycle showed a greater responsiveness to PTHrP than those from noncycling rats. These findings are consistent with a role for PTHrP as an autocrine and/or paracrine regulator of uterine motility and function. Furthermore they suggest that PTHrP belongs to a class of other locally acting peptides such as oxytocin, vasoactive intestinal peptide, and relaxin, for which pretreatment of animals with estrogen increases the response of the uterus (Ottesen *et al.,* 1985; Mercado-Simmen *et al.,* 1982; Fuchs *et al.,* 1982).

Further evidence for a specific and regulated role of PTHrP in the uterus during gestation comes from the observation of a temporal pattern in the relaxation response to PTHrP by longitudinal uterine muscle during pregnancy in the rat, with maximal responses at times when estrogen levels would be high. In contrast, the circular muscle did not respond at any stage during gestation (Williams *et al.,* 1994). The inability of PTHrP to relax uterine muscle in the last stages of gestation does not support a direct role in the

onset of parturition. It has been hypothesized that PTHrP may be involved in keeping the uterine muscle relaxed to accommodate the fetus during pregnancy, with the demonstration (Thiede *et al.,* 1990) that expression of mRNA was dependent on the presence of the fetus and that levels increased throughout pregnancy and decreased sharply after delivery. It seems likely, therefore, that the observed fall in PTHrP reflects the recontracted state of the uterine muscle, consistent with the observation in the bladder (Yamamoto *et al.,* 1992b), and that the level of expression is functionally related to contractility. The temporal expression of PTHrP in endometrial glands and blood vessels (Williams *et al.,* 1994) also supports roles in other regulated functions that might include uterine growth during pregnancy and the regulation of uterine and placental blood flow (Mandsager *et al.,* 1994).

Placenta and Fetal Membranes

PTHrP mRNA and protein have been detected in rat and human placenta in various cell types (Hellman *et al.,* 1992; Germain *et al.,* 1992; Bowden *et al.,* 1994). In addition, neoplastic cells of placental origin secrete PTHrP, including hydatidiform moles and choriocarcinomas *in vitro* (Deftos *et al.,* 1994). The presence of PTH/PTHrP receptor mRNA has been demonstrated in rat (Urena *et al.,* 1993) and human (Curtis *et al.,* 1998) placenta and infusion of PTHrP(1-34) into isolated human placental lobules stimulates cyclic AMP production (Williams *et al.,* 1991). Three further sets of observations lend support to the hypothesis that PTHrP is involved in placental/uterine interactions and that its most likely role in the placenta and placental membranes is related to the growth and maintenance of the placenta itself during pregnancy. First, PTHrP production by cultured amniotic cells has been shown to be regulated by prolactin, human placental lactogen, transforming growth factor-β (TGFβ), insulin, insulin-like growth factor, and epidermal growth factor (Dvir *et al.,* 1995). Second, PTHrP has been shown to regulate epidermal growth factor receptor expression in cytotrophoblast cultures (Alsat *et al.,* 1993), an event associated with placental development. Third, studies of vascular reactivity in isolated human placental cotyledons preconstricted with a thromboxane A_2 mimetic showed PTHrP to be a very effective vasodilator (Macgill *et al.,* 1997). The narrow concentration range to which the tissue responded, together with the desensitization in response to repeated PTHrP infusions, was consistent with a paracrine and/or autocrine action of PTHrP in human gestational tissues. Adequacy of the fetoplacental circulation is essential for the nutritional demands of the growing fetus, and both humoral and local factors are likely to be important in its control. It is possible that alterations of the expression, localization, and/or action of PTHrP might contribute to the genesis of conditions such as preeclampsia and intrauterine growth retardation in which placental vascular resistance is increased (Gude *et al.,* 1996). Another related and potentially interacting influence is angiotensin II, known to be a powerful enhancer of PTHrP production in the vasculature and in human placental explants (Li *et al.,* 1998). The ability of angiotensin II to stimulate estradiol production in human placental explants through actions upon its AT_1 receptor (Kalenga *et al.,* 1995) provides a further link with PTHrP control.

The most likely source of increased amniotic fluid PTHrP concentrations during pregnancy is the amnion itself, as PTHrP mRNA expression is also highest at term and greater in the amnion than in choriodecidua or placenta (Bowden *et al.,* 1994; Ferguson *et al.,* 1992; Wlodek *et al.,* 1996). In tissue from women with full-term pregnancies and not in labor, the concentration of N-terminal PTHrP has been found to be higher in amnion covering the placenta than in the reflected amnion covering the decidua parietalis (Bowden *et al.,* 1994). Nevertheless, the concentration of N-terminal PTHrP in reflected amnion (the layer apposed to the uterus) was inversely related to the interval between rupture of the membranes and delivery. The observation that PTHrP levels in the amnion decrease after rupture of the fetal membranes has led to the proposal that PTHrP derived from the membranes may inhibit uterine contraction and that labor may occur following loss of this inhibition. Plasma levels of PTHrP increase during pregnancy and at 6 weeks postpartum (Gallacher *et al.,* 1994; Ardawi *et al.,* 1991;) with the likely sources being placenta and breast, respectively. Human fetal membranes have been shown to inhibit contractions of the rat uterus *in vitro* (Collins *et al.,* 1993) so this tissue does appear to produce factors that can modulate uterine activity. Furthermore, primary cultures of human amniotic cells secrete PTHrP into the medium (Germain *et al.,* 1992). Thus, while the physiological function(s) of amnion-derived PTHrP is currently unknown, preliminary evidence suggests that it may play a role in regulation of the onset of labor. It is also possible that it is a source of PTHrP ingested by the fetus, with a growth factor role in lung and/or gut development.

In summary, although many functional studies remain to be completed, potential roles for PTHrP produced by fetal membranes and placenta include transport of calcium across the placenta, accommodation of stretch of membranes, growth and differentiation of fetal and/or maternal tissues, vasoregulation, and the regulation of labor.

Implantation and Early Pregnancy

Some physiological functions other than control of myometrial activity were suggested by findings of Beck *et al.* (1993), who identified PTHrP mRNA as being limited to epithelial cells of implantation sites. This pregnancy-related expression appeared at day 5.5 in the rat fetus in the antimesometrial uterine epithelium of implantation sites, raising the possibility of a further function of PTHrP, playing a part in the localization of implantation or initial decidualization. Decidual cells produced mRNA for PTHrP both in normal gestation and after the induction of deciduomata. Expression of the gene in these cells followed epithelial expression by 48 hr. It was concluded from this work that

the location of PTHrP gene expression in the uterus, together with the time of its expression, suggests that it plays a part in implantation of the blastocyst. Further evidence for a function of PTHrP in the implantation process came from Nowak *et al.* (1999), who showed that PTHrP and TGFβ were potent stimulators of trophoblast outgrowth by mouse blastocysts cultured *in vitro*. The TGFβ effect appeared to be mediated by PTHrP, which itself was acting through a mechanism distinct from the PTHR1.

Thus, both the timing and the localization of PTHrP gene expression suggested that it might play a part in the implantation of the blastocyst (Beck *et al.,* 1993). Upon finding substantial levels of immunoreactive PTHrP in uterine luminal fluid of estrogen-treated immature rats, and because the PTH/PTHrP receptor was known to be expressed in rat uterus (Urena *et al.,* 1993), Williams *et al.* (1998) investigated the role of PTHrP acting through this receptor in influencing early pregnancy in the rat. Infusion of either a PTHrP antagonist peptide or a monoclonal anti-PTHrP antibody into the uterine lumen during pregnancy resulted in excessive decidualization. The latter appeared to be the result of a decrease in the number of apoptotic decidual cells in the antagonist-infused horn. In pseudopregnant rats, infusion of receptor antagonist into the uterine lumen resulted in increases in wet weight of the infused horn compared with the control side, indicating an effect on decidуoma formation.

These observations suggest that activation of the PTH/PTHrP receptor by locally produced PTHrP might be crucial for normal decidualization during pregnancy in rats, probably not by being involved in the initiation of the decidual reaction, but rather in the maintenance of the decidual cell mass.

Summary

The multiple roles of PTHrP in the reproductive tissues and cycle and in the placenta largely reflect its roles as a paracrine/autocrine/intracrine regulator. Of the many functions it exerts in these systems, probably the only endocrine one is that in which PTHrP in the fetal circulation regulates placental calcium transport. There remains much to be learned of the place of PTHrP in reproductive and placental physiology and pathology.

Endocrine Pancreas

PTHrP and Its Receptors

The presence of PTHrP in the pancreatic islet became apparent shortly following the identification of PTHrP in 1987. Asa *et al.* (1990) demonstrated that PTHrP was present in islet cells and demonstrated that it was present in all four cell types of the islet, including the α, β, δ and PP cells. PTHrP mRNA was demonstrated to be present in isolated islet RNA as well (Drucker *et al.,* 1989), demonstrating that the peptide could be produced within the islet. Gaich and collaborators (1993) confirmed these findings, demonstrating that PTHrP was indeed present in islet cells of all four types and that it was also present in pancreatic ductular epithelial cells. The peptide is not present in adult pancreatic exocrine cells. Plawner and colleagues (1995) demonstrated that PTHrP is present in individual β cells in culture and showed that PTHrP colocalized with insulin in the Golgi apparatus, as well as in insulin secretory granules. Interestingly, in a perifusion system employing a β cell line, PTHrP was shown to be cosecreted with insulin from β cells following depolarization of the cell (Plawner *et al.,* 1995). The secreted forms of PTHrP included amino-terminal, midregion, and carboxy-terminal forms of PTHrP (see later).

With regard to receptors for PTHrP on β cells, little direct evidence has been provided for the presence of the PTHR1, although its presence has not been sought rigorously. However, there can be no question as to the presence of some type of PTHrP receptor on the pancreatic β cell, as it is clear that PTHrP(1-36) elicits prompt and vigorous responses in intracellular calcium in cultured β cell lines. For example, Gaich *et al.* (1993) have demonstrated that PTHrP(1-36) in doses as low as 10^{-12} *M* stimulates calcium release from intracellular stores. Interestingly, unlike events observed in bone and renal cell types where PTHrP receptor activation is associated with activation of cAMP/PKA, as well as the PKC/intracellular calcium pathways, only the latter is observed in cultured β cells in response to PTH or PTHrP(1-36) (Gaich *et al.,* 1993). Whether this reflects the presence of a different type of receptor on β cells or differential coupling of the PTHR1 to subsets of specific G proteins or catalytic subunits in β cells as compared to bone and renal cells has not been studied.

Regulation of PTHrP and PTHrP Receptors

There is little information describing how or to what degree PTHrP or the PTH receptor family is regulated in the pancreatic islet. As will become clear from the sections that follow, there are physiologic reasons why such regulation might occur under normal circumstances, but this area remains unexplored.

Biochemistry of PTHrP

PTHrP undergoes extensive posttranslational processing as described in Chapters 3 and 4. Most of what is known or inferred regarding PTHrP processing is derived from studies in the rat insulinoma line, RIN-1038 (Soifer *et al.,* 1992; Yang *et al.,* 1994; Wu *et al.,* 1991). These cells have served as a model of PTHrP processing, as they have been shown to serve as a model for authentic processing of other human neuroendocrine peptides, such as insulin, proopiomelanocortin, glucagon, and calcitonin. Using a combination of untransfected RIN-1038 cells, RIN-1038 cells overexpressing hPTHrP(1-139), hPTHrP(1-141), or hPTHrP(1-173), and

a panel of region-specific radioimmunoassays and immunoradiometric assays, RIN cells have been shown to secrete PTHrP(1-36), PTHrP(38-94), PTHrP(38-95), and PTHrP(38-101) (Soifer *et al.,* 1992; Yang *et al.,* 1994; Wu *et al.,* 1991). In addition, RIN 1038 cells have been shown to secrete a form of PTHrP that is recognized by a PTHrP(109-138) radioimmunoassay (Yang *et al.,* 1994), and another form that is recognized by a PTHrP(139-173) radioimmunoassay (Burtis *et al.,* 1992).

As described earlier, PTHrP(1-36) stimulates intracellular calcium increments in cultured β cells (Gaich *et al.,* 1993). PTHrP (38-94) has also been shown to stimulate intracellular calcium release in these cells (Wu *et al.,* 1991). PTHrP (38-94) does not activate adenylyl cyclase in cultured β cells, and other PTHrP species have not been explored in β cells in functional terms.

Function of PTHrP

Pancreas development in rodents begins at approximately day E9-10, and by day E18-19, clusters of β cells have begun to coalesce and form immature islets (Edlund, 1998). These islet cell clusters continue to increase in number, in size, and in density of β cells in the week following delivery and then decline abruptly in number through a wave of β-cell apoptosis (Finegood *et al.,* 1995).

The role of PTHrP in β-cell development and function is poorly understood at present. The pancreas of PTHrP-null mice (Karaplis *et al.,* 1994) develops normally in anatomic terms (R. C. Vasavada and A. F. Stewart, unpublished observations), but nothing is known about the function of these islets. PTHrP-null mice die immediately after delivery, so nothing is known of islet function or development following birth in the absence of PTHrP. "Rescued" PTHrP mice do exist (Wysolmerski *et al.,* 1998) and they survive to adulthood. These mice have normal appearing pancreata and islets (R. C. Vasavada and A. F. Stewart, unpublished observations), but they have dental abnormalities, are undernourished, and grow poorly. Therefore, it is difficult to characterize their islets in functional terms, as islet mass, proliferation, and function are heavily dependent on fuel availability. Streuker and Drucker (1991) have suggested that PTHrP may play a role in β-cell differentiation, as it is upregulated in β-cell lines in the presence of the islet-differentiating agent, butyrate.

In an effort to understand the role of PTHrP in the pancreatic islet, Vasavada and collaborators have developed transgenic mice that overexpress PTHrP under the control of the rat insulin-II promoter (RIP) (Vasavada *et al.,* 1996; Porter *et al.,* 1998). RIP-PTHrP mice display striking degrees of islet hyperplasia and an increase in islet number, as well as the size of individual islets. This increased islet mass is associated with increased function: RIP-PTHrP mice are hyperinsulinemic and hypoglycemic as compared to their littermates (Vasavada *et al.,* 1996; Porter *et al.,* 1998). They become profoundly and symptomatically hypoglycemic with fasting. Interestingly, RIP-PTHrP mice are also resistant to the diabetogenic effects of β-cell toxin, streptozotocin. Following the administration of streptozotocin, normal mice readily develop diabetes, but RIP-PTHrP mice either fail to become diabetic or develop only mild hyperglycemia (Porter *et al.,* 1998).

The mechanism(s) responsible for the increase in islet mass in the RIP-PTHrP mouse remains undefined. There are two levels at which this question can be addressed: identification of the source of the cells responsible for the increase in islet mass and the signaling mechanisms that are responsible for the increase. With respect to the first, islet mass can, in theory, be increased by three pathways: (a) the recruitment of new islets from the pancreatic duct or its branches distributed throughout the exocrine pancreas, in a process referred to as "islet neogenesis"; (b) induction of proliferation of existing β cells within islets; and/or (c) prolongation of the life span of existing β cells. Of these options, there is clear evidence against the second possibility (Vasavada *et al.,* 1996), suggesting that islet neogenesis [e.g., PTHrP is present in the normal pancreatic duct and is upregulated during ductular differentiation into β cells (Gaich *et al.,* 1993; Mashima *et al.,* 1999)] or inhibition of islet cell death (as occurs in the presence of PTHrP in other cell types) the likely explanation. These processes are under active study.

At the signaling level, little is known regarding the mechanism of action of PTHrP on β cells. While it is known that PTHrP can stimulate intracellular calcium in cultured β-cell lines (Gaich *et al.,* 1993; Wu *et al.,* 1991), it is not known whether this occurs *in vivo* in normal, nontransformed β cells within intact islets. Nor is it known if PTHrP stimulates adenylyl cyclase in normal β cells *in vivo* or if it participates in nuclear or intracrine signaling in β cells as it appears to in chondrocytes, osteoblasts, vascular smooth muscle cells, or other cell types (Aarts *et al.,* 1999; Massfelder *et al.,* 1997; Lam *et al.,* 1999) (see Chapter 6). These processes, too, are under study.

Finally, and importantly, the results of overexpression studies do not demonstrate that PTHrP plays β cell mass-enhancing roles *in vivo* under normal circumstances. In the absence of meaningful data from knockout or rescued knockout mice, it is difficult to be sure if PTHrP is important in normal islet biology. This question, too, will need to await further studies such as the conditional or islet-specific deletion of the PTHrP gene.

Pathophysiology of PTHrP

From the discussion given earlier, it is clear that the normal physiologic role of PTHrP in the pancreatic islet remains undefined. In contrast, PTHrP plays clear pathophysiologic roles in at least some pancreatic islet neoplasms. PTHrP overexpression with resultant development of humoral hypercalcemia of malignancy has been demonstrated on multiple occasions in multiple investigators' hands (Asa *et al.,* 1990; Stewart *et al.,* 1986; Wu *et al.,* 1997; Skrabanek *et al.,* 1980). In the only large series of malignancy-associated

hypercalcemia in which tumors have been fully subdivided based on histology (Skrabanek *et al.,* 1980), islet cell carcinomas, which are not particularly common, produce humoral hypercalcemia of malignancy fully as often as pancreatic adenocarcinomas, a very common neoplasm. Historically, islet tumors were among the first in which PTHrP bioactivity was identified (Stewart *et al.,* 1986; Wu *et al.,* 1997). Furthermore, patients with islet carcinomas regularly demonstrate increases in circulating PTHrP as determined by radioimmunoassay or immunoradiometric assays (Lansk *et al.,* 1996). When assessed by immunohistochemistry, these tumors also demonstrate increased staining for PTHrP (Asa *et al.,* 1990; Drucker *et al.,* 1989).

The significance of these findings for islet tumor oncogenesis is not known. Is this simply a random derepression of the PTHrP gene or is it a specific upregulation of the PTHrP gene? Is there a pathologic role for PTHrP in the development of pancreatic islet tumors, corresponding to the mass enhancing effects of PTHrP in the islets of the RIP-PTHrP mouse? These questions remain interesting but unanswered at present.

Conclusion

Advances in mouse genetics and in transgenic technology have been a boon to the study of physiology. This has certainly been the case for the PTHrP field, where studies in genetically altered mice have provided a starting place for the study of the physiology of a protein that was discovered out of its natural context. This chapter outlined the current state of knowledge regarding the physiological roles of PTHrP in skin, the mammary gland, placenta, uterus, and pancreas. Much of this information (although not all) has come from studies performed in a variety of transgenic mice. These studies have shown that PTHrP is important to both the development and the physiologic functioning of these organs. However, at this point, we have only the rudiments of an understanding of the functions of PTHrP at these sites. Thus, we continue to have more questions than answers. There will be many challenges to be overcome before we truly comprehend all the nuances of the functions of PTHrP at these sites. There will also be new tools with which to investigate these questions (as this chapter is being written, several eagerly anticipated experiments ablating the PTHrP and PTHR1 genes in organ-specific fashion are in the pipeline). The next several years promise to be an exciting time for the investigation of the nonskeletal effects of this remarkable molecule.

Vascular and Cardiovascular Actions

Historical Perspectives

The origins of parathyoid hormone (PTH) as a putative cardiovascular regulatory factor date to the early 1900s when the calcemic properties of the hormone were first identified. In classic studies, Collip and Clark (1925) demonstrated that systemic injection of extracts of parathyroid glands lowered systemic blood pressure into dogs (Fig. 1). The first formal characterization of the cardiovascular activity of PTH was conducted by Charbon (1968a,b, 1969,) in the early 1960s. These investigators quantified the vasodilatory effects of a purified parathyroid extract in the rabbit and cat and also showed that a synthetic N-terminal fragment displayed similar actions in the dog. Relaxant activity was not blocked by pharmacological antagonists of other known vasoactive agents, suggesting a direct action of the hormone. Since then, numerous studies have unequivocally established the hypotensive/vasodilatory and cardiac effects of PTH (Mok *et al.,* 1989) that can be summarized broadly as follows: First, the hypotensive and vasorelaxant actions of PTH occur in the absence of a change in blood calcium and are mediated by PTH activation of the type 1 PTH/PTH-related protein (rP) (PTH1R) receptor expressed in the smooth muscle layer of the vessel wall. Second, although all vascular beds are relaxed by PTH, resistance vessels appear to be more responsive than conduit vessels. Third, PTH can reduce the pressor effects of other vasoactive agents that exert their action through different mechanisms. Finally, PTH exerts both ionotropic and chronotropic effects on the heart (Ogino *et al.,* 1995).

Although the cardiovascular effects of PTH are undisputed, their physiological significance has been frequently debated. This is in part because the concentrations of PTH required to produce vasodilation (10 to 100 n*M*) are substantially above those that normally circulate (low p*M*). Consequently, it has been difficult to conceptualize how physiological levels of this systemic hormone, which is synthesized only in the parathyroid gland, could function in the local control of vascular tone. Also enigmatic is the fact that patients with primary hyperparathyroidism and elevated circulating PTH levels often have high (not low) blood pressure that sometimes returns to normal after parathyroidectomy. A plausible explanation for the seemingly enigmatic regulatory effects of PTH on the cardiovascular system emerged with the discovery of PTHrP in 1987.

As discussed in Chapter 29 of this volume, PTHrP was identified as the factor responsible for the paraneoplastic syndrome termed humoral hypercalcemia of malignancy. Almost immediately after its cloning, expression of PTHrP was detected in many normal fetal and adult tissues but was

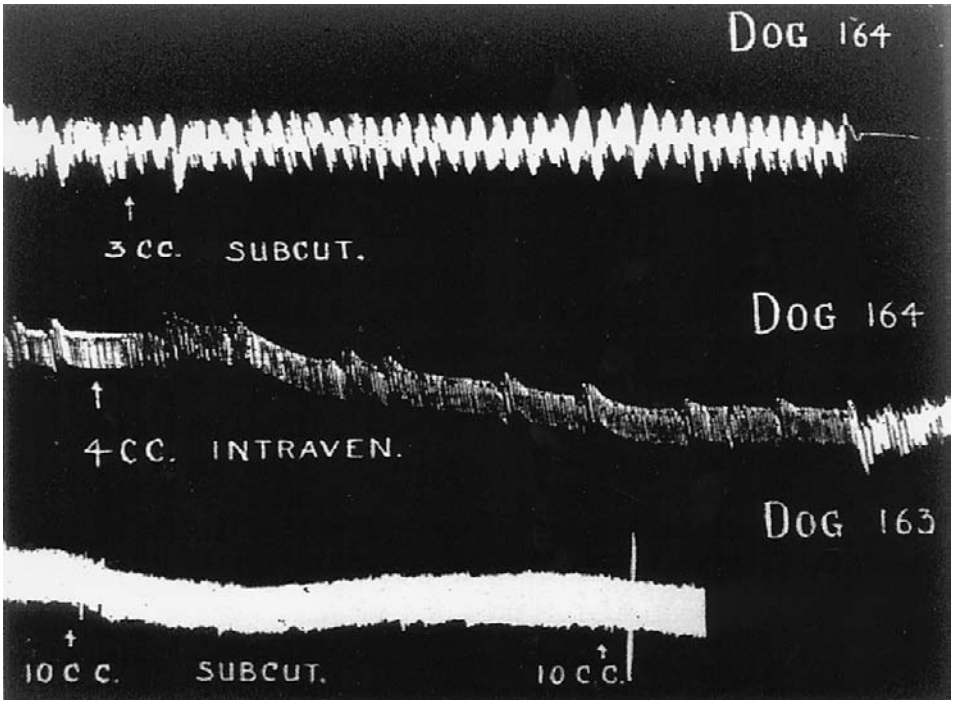

Figure 1 Effects of extracts of parathyroid glands on blood pressure in thyroparathyroidectomized dogs. From Collip and Clark (1925), with permission.

undetectable in the circulation, suggesting that the protein functioned in an autocrine/paracrine mode. Although many functions have been ascribed for PTHrP, three main physiological themes have emerged. Observations in gene knockout mice have demonstrated that PTHrP is required for the development of cartilage, morphogenesis of the mammary gland, and tooth eruption (reviewed in Philbrick *et al.,* 1996, and elsewhere in this volume). PTHrP also appears to participate in maternofetal calcium transfer across the placenta. The third physiological role for PTHrP is in smooth muscle in which the protein functions to regulate contractility and proliferation. Although this chapter focuses on the physiology of PTHrP in *vascular* smooth muscle, it is relevant to begin with a brief review of its physiological effects in other smooth muscle-containing tissues.

In all smooth muscle cell beds studied to date, induction of PTHrP expression occurs in close association with normal physiological stimuli. In the smooth muscle layer of the chicken oviduct, induction of PTHrP expression coincides temporally with egg movement and its arrival in the shell gland (Thiede *et al.,* 1991). In the rat uterus, PTHrP expression is localized to the myometrium and is markedly upregulated by fetal occupancy (Thiede *et al.,* 1990) or by mechanical distention of the uterine horn using a balloon catheter (Daifotis *et al.,* 1992). PTHrP expression is increased in prelabor human amnion and abruptly falls with the onset of labor and rupture of the amniotic sac (Ferguson *et al.,* 1992). In the urinary bladder, induction of PTHrP mRNA occurs during filling in proportion to bladder distension (Yamamoto *et al.,* 1992). Finally, as discussed in detail later, PTHrP is also expressed in vascular smooth muscle, in which it is induced by vasoconstrictor agents and mechanical stimuli. In each of these smooth muscle beds, application of PTHrP to precontracted smooth muscle preparations induces relaxant activity, precisely mimicking the actions described previously for PTH. It would therefore appear that PTHrP rather than PTH represents the physiologically important regulator of smooth muscle tone. Consequently, the remainder of this chapter focuses primarily on the physiology of PTHrP in the cardiovascular system.

PTHrP in the Vasculature

Vascular Anatomy and Contractile Mechanisms

Blood vessels are composed of three principal cell types: the intima, which consists of a single epithelial cell layer; the muscularis layer, made up of vascular smooth muscle cells embedded in a connective tissue matrix; and an outer adventitial layer, which receives input from the cholinergic and adrenergic nervous system. The relative composition and contribution of each of these cell types to vascular growth and tone varies during development and among different vascular beds. For example, during development, blood vessels form initially as simple tubular structures consisting entirely of endothelial cells into which smooth muscle cells migrate to form the vascular wall. In the mature mammal, the large conduit vessels (e.g., aorta) are highly elastic to accommodate high capacity blood flow, whereas resistance vascular beds (e.g., mesentery) typically contain more smooth muscle cells and are densely innervated. Changes in the cellular and connective tissue constituents within the vasculature occur with normal aging

and in particular during pathological conditions such as atherosclerosis. The regulation of vascular growth, remodeling, and smooth muscle cell tone is achieved through a coordinated network of both systemic and local factors, as well as input from adrenergic, cholinergic, peptidegic, and sensory neurons.

Mechanisms regulating vascular smooth muscle cell contractility have been studied in detail (reviewed in Somlyo *et al.,* 1999). The intracellular-free calcium concentration is the major determinant of vascular tone. Depolarization of vascular smooth muscle cells opens L-type voltage-sensitive calcium channels (L-VSCCs), enabling calcium to enter the cell. These events trigger the release of much larger quantities of calcium from the sarcoplasmic reticulum. Alternatively, pharmacologic or ligand activation of G protein receptors (e.g., angiotensin II) activate phospholipase (PLC), which catalyzes phosphoinositol hydrolysis and causes calcium release from intracellular stores. The increases in cytoplasmic calcium achieved by either of these mechanisms activate myosin light chain kinase through the calcium–calmodulin complex and phosphorylation of the 20-kDa regulatory light chain of myosin, with subsequent cross-bridge cycling and force development. The mechanisms of vascular smooth muscle cell relaxation are less well understood. In the most simple scheme, a reduction of cytoplasmic calcium with a fall in myosin light chain kinase activity would suffice to account for dephosphorylation of the regulatory light chain and relaxation. However, other mechanisms have been implicated in cyclic nucleotide-dependent relaxation in vascular and other smooth muscle tissues (McDaniel *et al.,* 1994).

The demonstration of a calcium-sensing receptor in vascular smooth muscle with pharmacological properties similar to those of the parathyroid calcium-sensing receptor (discussed in Chapter 23) has prompted speculation that it might also participate in the regulation of contractile events (Bukoski *et al.,* 1995). Alterations of extracellular calcium over the physiological concentration range depress contractility of precontracted vascular smooth muscle. This effect of extracellular calcium has been shown to be mediated by activation of a calcium-dependent potassium channel and is associated with alterations in myofilament calcium sensitivity. These activities were mimicked by gadolinium, neomycin, and lanthanum, all factors that activate the calcium-sensing receptor. However, the structure of this putative calcium-sensing receptor is unknown and it remains unclear whether it bears homology to the renal or parathyroid or kidney calcium-sensing receptor.

Expression and Regulation of PTHrP

PTHrP is expressed in blood vessels in essentially all vascular beds from a broad range of species, including rodent and human fetal blood vessels (Moniz *et al.,* 1990), adult rat aorta (Burton *et al.,* 1994; Pirola *et al.,* 1994), vena cava (Burton *et al.,* 1994), kidney afferent arterioles, artery and microvasculature (Nickols *et al.,* 1990), the arterial and venous supply of the mammary gland (Thiede, 1994), the serosal arterioles in avian egg shell gland (Thiede *et al.,* 1991), and blood vessels of the rat penis (Lang *et al.,* 1999). The protein appears to be expressed predominantly in the smooth muscle layer of the vessel, although its expression has also been reported in cultured endothelial cells (Rian *et al.,* 1994; Ishikawa *et al.,* 1994a). The regulation of PTHrP mRNA expression has been studied in detail using cultured vascular smooth muscle cells. In primary rat aortic vascular smooth muscle cells, expression of PTHrP is induced rapidly (2–4 hr) but transiently by exposure of quiescent cells to serum (Hongo *et al.,* 1991) (Fig. 2). This mode of tight regulation is reminiscent of the behavior of cytokine mRNAs and would appear to constitute a mechanism that would restrict the activity of PTHrP to a narrow window of time. Among the most potent inducers of PTHrP are vasoconstrictors, including angiotensin II, seritonin, endothelin, norepinephrine, bradykinin, and thrombin, each of which induces PTHrP mRNA and protein levels over the same time course as that observed for serum (Pirola *et al.,* 1993). The induction of PTHrP mRNA by angiotensisn II is dependent on protein kinase C activation and is mediated by both transcriptional and posttranscriptional mechanisms (Pirola *et al.,* 1993). Prior addition of saralaysin and captopril, which inhibit angiotensin II action or generation, respectively, inhibit the serum-induced increase in PTHrP in vascular smooth muscle cells. This finding suggests that the angiotensin II present in serum represents a significant component of the serum induction of PTHrP.

PTHrP is also induced in vascular smooth muscle in response to mechanical stimuli. PTHrP mRNA is increased transiently in rat aorta following distension with a balloon catheter (Pirola *et al.,* 1994). Flow motion-induced

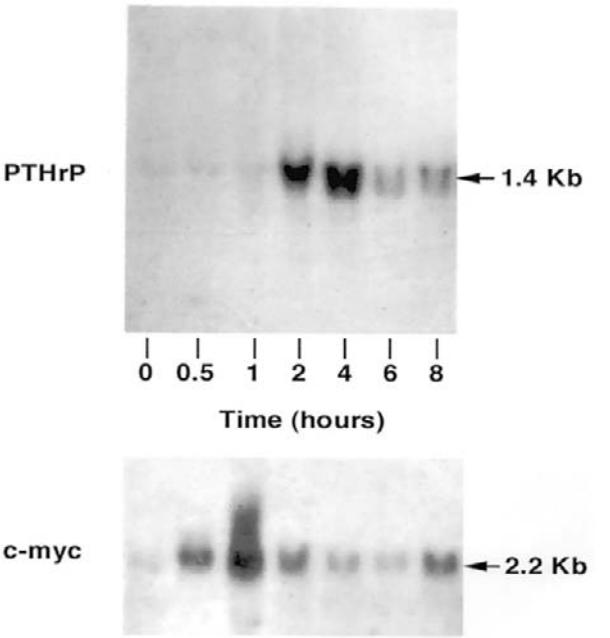

Figure 2 Time course of serum induction of PTHrP mRNA in aortic vascular smooth muscle cells. From Hongo *et al.,* (1991), with permission.

mechanical events induced by rocking or rotation of monolayer cultures of rat aortic vascular smooth muscle cells result in increased PTHrP mRNA expression (Pírola *et al.,* 1994; Noda *et al.,* 1994). The inductive effects of mechanical stretch and angiotensin II on PTHrP mRNA appear to be synergistic, suggesting that they occur through distinct mechanisms (Noda *et al.,* 1994). PTHrP mRNA is also produced in capillaries of slow-twitch soleus and fast-twitch skeletal muscle, and its expression is increased in response to low-frequency stimulation (Schnoider *et al.,* 1999). This maneuver was associated with enhanced capillarization of the muscle, indicating that PTHrP might function to promote to new capillary growth in response to increased contractile activity.

VASCULAR ACTIONS OF PTHRP

Shortly after the identification of PTHrP, a number of studies demonstrated that synthetic N-terminal fragments of the peptide replicated many of the vascular actions of PTH, including its vasrelaxant actions in aorta (Crass and Scarpace, 1993), portal vein (Shan *et al.,* 1994), coronary artery (Nickols *et al.,* 1989), renal artery (Wingulst *et al.,* 1987; Musso *et al.,* 1989), placenta (Macgill *et al.,* 1997; Mandsager *et al.,* 1994), and mammary gland (Prosser *et al.,* 1994). In general, the vasodilatory potency of PTHrP is comparable to that of PTH when examined in organ bath systems. In contrast, in mouse portal vein preparations, PTHrP(1-34) was shown to be a more potent vasorelaxant than PTH(1-34) (Shan *et al.,* 1994). In perfused rabbit kidney (Musso *et al.,* 1989) and in rat aorta (Nickols *et al.,* 1989) the vasorelaxant effects of PTHrP do not appear to require the presence of an intact endothelium. However, in mouse aortic rings, endothelium denudatation attenuates the relaxant activity of PTHrP markedly (Sutliff *et al.,* 1999), possibly reflecting a species difference.

In addition to its effects on vascular tone, PTHrP also modulates vascular smooth muscle cell proliferation. The peptide decreases serum and platelet-derived growth factor (PDGF)-activated DNA synthesis in primary arterial vascular smooth muscle cells (Hongo *et al.,* 1991; Jiang *et al.,* 1995) and in A10 vascular smooth muscle cells stably expressing the PTH1R receptor (Maeda *et al.,* 1996). In both of these cell types, antimitogenic effects require the PTH-like N-terminal portion of the molecule and are mimicked by dibutyryl cAMP or forskolin. The mechanism for the antiproliferative effect of PTHrP involves the induction of the cyclin-dependent kinase inhibitor, $p27^{kip1}$, and impairment of phosphorylation of the retinoblastoma gene product (Rb), which results in cell cycle arrest in mid-G_1 phase (Maeda *et al.,* 1997). However, Massfelder *et al.,* (1997) reported that overexpression of PTHrP in A10 cell vascular smooth muscle cells was associated with an increase in DNA synthesis coincident with an increased nuclear localization of the protein. However, in these studies, exogenous application of PTHrP inhibited A10 cell growth in agreement with the studies cited earlier. A putative nuclear targeting motif was found to be required for the nuclear import of PTHrP in vascular smooth muscle cells in accordance with previous studies in chondrocytes (Henderson *et al.,* 1995). Therefore, the ability of PTHrP to influence the proliferation of vascular smooth muscle cells either positively or negatively appears to depend on where the protein is trafficked in the cell. Cellular levels of PTHrP fluctuate during the cell cycle and reach their highest levels in G_2/M (Okano *et al.,* 1995). It is possible that the protein is directed to the nucleus in the later stages of the cell cycle to participate in mitotic events.

PTHrP also inhibits PDGF-directed migration of vascular smooth muscle cells *in vitro* (Ishikawa *et al.,* 1998). The antimigratory effects of PTHrP are mediated through a cAMP-dependent mechanism that leads to diminished PDGF signaling through the PI3 kinase cascade.

The effects on vascular smooth muscle cell growth and migration *in vitro* are likely to be physiologically relevant to conditions under which VSMC growth and migratory behavior is altered *in vivo*. For example, Ozeki *et al.* (1996) have reported that PTHrP protein and mRNA expression were upregulated markedly in neointimal smooth muscle in rat carotid arteries following experimental balloon injury. Moreover, immunoreactive PTHrP is increased in human arterial tissue removed from patients undergoing angioplasty. In light of the possibility of opposing effects of PTHrP on vascular smooth muscle cell growth cited earlier, these observations can be viewed in one of two ways: either upregulation of PTHrP is a primary stimulus for growth under these conditions or, alternatively, it represents an antiproliferative signal. Consistent with the latter possibility, the local administration of 3′,5′-cyclic AMP or the phosphodiesterase inhibitors aminophylline or amrinone inhibit neointimal formation following experimental balloon injury in rat carotid arteries *in vivo* (Indolfi *et al.,* 1997). Moreover, other studies using a similar model of arterial injury showed high levels of $p27^{kip1}$ expression in media within 2 weeks after angioplasty (Tanner *et al.,* 1998).

The ability of PTHrP to modulate vascular smooth muscle cell growth suggests that the protein might function during the development of the cardiovascular system. Although the cardiovascular system appears to develop normally in the PTHrP knockout mouse, homologous deletion of the PTH1R receptor results in a higher incidence of early fetal death at approximately embryonic day 9–10, coincident with development of the heart and major blood vessels (Lanske *et al.,* 1996). Furthermore, transgenic mice expressing high levels of PTHrP and its receptor in vascular smooth muscle, created by crossing the ligand and receptor overexpressing mice, die at day E9.5 with severe thinning of the ventricle and disruption of ventricular trabeculae (Qian *et al.,* 1999) (Fig. 3, see also color plate). Additional anecdotal evidence for a role of PTHrP in heart and vascular development is evident from the abnormalities seen in patients with the rare fatal condition known as Blomstrand chondrodysplasia caused by an inactivating mutation of PTH1R receptor (Karaplis *et al.,* 1998). These patients die prenataly with coartation of the aorta and hydrops fetalis, the latter condition typically caused by high output heart failure.

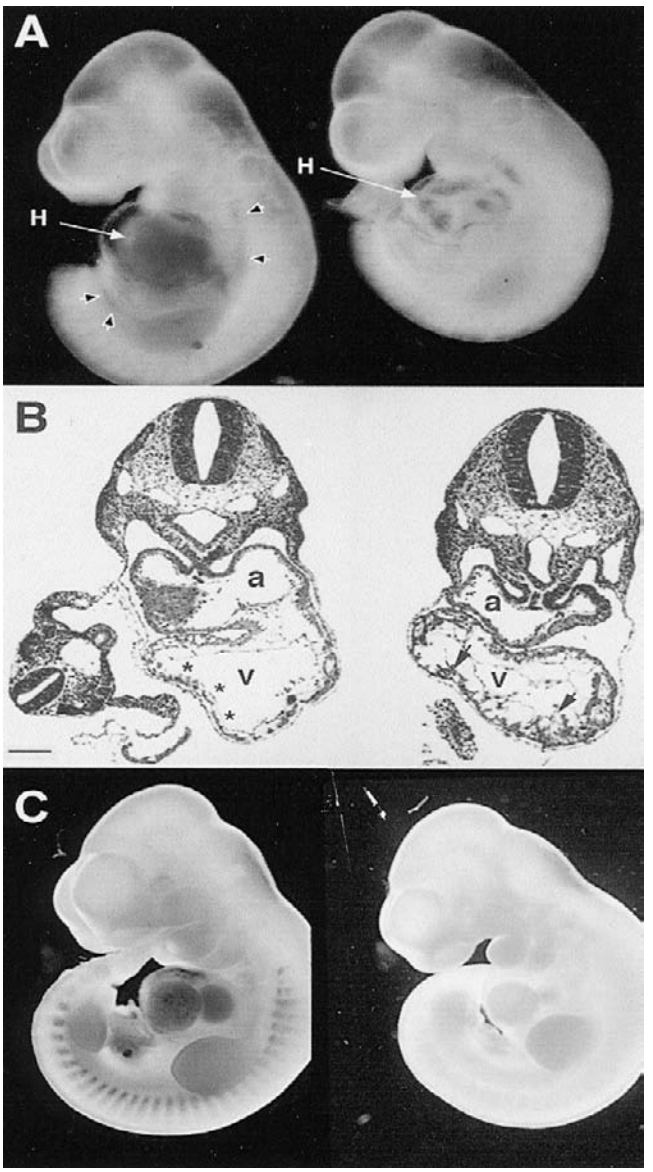

Figure 3 Overexpression of PTHrP and PTH1R disrupts heart development. (A) Whole mounts at E9.5 of double transgenic (left) and wild-type (right) embryos. The double transgenic embryo exhibits a greatly enlarged heart with pericardial effusion and vascular pooling (arrows). (B) Histologic sections of double transgenic (left) and wild-type (right) embryos at E9.5. Trabeculae within the ventricular cavity (v) of the wild-type embryo are prominent (large arrows), whereas in the double transgenic embryo, trabeculae are reduced severely or absent (asterisks). Prominent gaps are also evident between the cardiomyocytes in the double transgenic hearts (small arrowheads). a, atria. Bar: 100 μm, (C, left). (See also color plate).

MODE OF ACTION/RECEPTOR INTERACTIONS

PTHrP exerts its vasodilatory actions by activating the PTH1R. This receptor is expressed in rat vascular smooth muscle beds (Urena *et al.,* 1993), and relaxation of aortic preparations is accompanied by an increased accumulation of cAMP (Ishikawa *et al.,* 1994b). Cultured rat aortic smooth muscle cells also express the PTH1R and respond to N-terminal PTHrP peptide fragments with an increase in cAMP formation (Wu *et al.,* 1993). Moreover, relaxation responses to PTH in aortic strip preparations are potentiated by phosphodiesterase inhibitors and forskolin (Nickols and Cline, 1987). Although the PTH1R receptor appears to be primarily coupled to adenylate cyclase, linkage to calcium–phosphoinositol pathways is suggested by studies by Nyby *et al.* (1995), who demonstrated a transient increase in cytosolic calcium and cAMP in response to PTHrP(1-34) in primary arterial rat vascular smooth muscle cells. However, other studies using similar preparations of primary rat aortic smooth muscle cells showed that PTHrP consistently stimulated cAMP accumulation but had no effect on intracellular calcium (Wu *et al.,* 1993). Furthermore, in A10 embryonic aortic vascular smooth muscle cells stably expressing recombinant PTH1R receptors, PTHrP induced large increases in cAMP accumulation but did not increase cytoplasmic calcium (Maeda *et al.,* 1996) despite the presence of detectable levels of expression of G_q, known to be required for functional coupling of the receptor to the PLC–phosphoinositide calcium pathway. However, when G_q was overexpressed in these cells, PTHrP evoked a calcium transient. It therefore appears that under most conditions the PTH1R receptor couples preferentially to G_s and adenylate cyclase to raise intracellular cAMP, which would be consistent with the established vasodilatory properties of this cyclic nucleotide. This does not, however, preclude the possibility that under certain physiological conditions (or in specific vascular smooth muscle cell beds), PTHrP might also activate PLC, which could mediate other as yet unidentified activities of the protein.

Vasorelaxation induced by cyclic nucleotides in arterial smooth muscle has also been reported to be associated with a reduction in intracellular calcium. In addition, in rat tail artery, PTH relaxes KCl-induced contraction; this effect is inhibited by nifedipine, suggesting an inhibition of the L-VSCC (Wang *et al.,* 1991a). Subsequent patch-clamp experiments (Wang *et al.,* 1991b) confirmed a decrease in L-type voltage-dependent calcium currents in vascular smooth muscle cells in response to PTH. Although not yet formally tested, it is likely that PTHrP also inhibits the L-VSCC activity in vascular smooth muscle, as is the case in cultured neuroblastoma cells.

As discussed in detail elsewhere in this volume (Chapter 29), PTHrP is subject to posttranslational processing to produce both N-terminal peptides, midregion PTHrP fragments, and possibly also C-terminal forms. PTHrP peptides that lack the PTH-like N-terminal region likely activate receptors distinct from the PTH1R and would be expected to exhibit a biological profile different from N-terminal PTHrP peptides. To date, however, there is no evidence that these midregion or C-terminal forms of PTHrP are biologically active either in cultured vascular smooth muscle cells (Wu *et al.,* 1993) or in intact vessel preparations (Sutliff *et al.,* 1999).

Although PTHrP is capable of relaxing vascular preparations devoid of endothelium, studies in mouse aortic

preparations suggest that the endothelial layer may serve to amplify relaxant effects of PTHrP and PTH (Sutliff *et al.,* 1999). The mechanism accounting for the endothelium-dependent relaxant effects of PTH and PTHrP remains unclear, but does not appear to require nitric oxide formation. The recent demonstration of expression of a novel PTH-2 receptor (PTH2R, see later) in endothelial and smooth muscle cells in blood vessels and heart (Usdin *et al.,* 1996) suggests an additional pathway through which PTH-related peptides could alter vascular reactivity.

As with other G-coupled receptors, prolonged exposure of vessel preparations (Nyby *et al.,* 1995) or cultured aortic smooth muscle cells (Okano *et al.,* 1994) to PTHrP is associated with desensitization. Angiotensin II, which induces PTHrP expression in cultured aortic vascular smooth muscle cells, also rapidly desensitizes cells to PTHrP and downregulates the PTH1R receptor mRNA expression (Okano *et al.,* 1994), indicating cross-talk in the signaling circuitry among these vasoactive peptides.

From the studies just summarized, it is possible to construct a simple model for the mode of PTHrP action in vascular smooth muscle (Fig. 4, see also color plate). In response to mitogenic, vasoconstrictor, or mechanical signals, PTHrP is released and acts locally via a short feedback loop to activate the PTH1R receptor and stimulate adenylate cyclase in adjacent cells. Effector pathways downstream of cAMP impact on specific sets of genes, which function to oppose the pressor (contraction coupling) and mitogenic (cell cycle) events. As mentioned earlier, induction of $p27^{kip1}$ with consequent inhibition of Rb phosphorylation would represent one such target for cAMP-induced cell cycle arrest. With regard to relaxant activity, stimulation of cAMP-dependent protein kinase (PKA) is associated with a reduction in cytoplasmic calcium and attenuated myosin light chain kinase activity (McDaniel *et al.,* 1994).

Because PTH and PTHrP activate the same receptor, how does the smooth muscle PTH1R receptor distinguish between these two ligands? A likely possibility is that the sensitivity of a given tissue to PTH or PTHrP is governed by the relative abundance of each ligand and the number of PTH1R receptors. For example, in tissues such as vascular smooth muscle, which express high levels of PTHrP but relatively low numbers of the PTH1R receptor, the fraction of receptor occupancy must be high in order to achieve a response, thus favoring the local (PTHrP) regulator. In contrast, in bone cells, PTHrP expression is low and the receptor expression is high, enabling preferential receptor activation by PTH arriving from the systemic circulation.

PTHrP in the Heart

PTHrP and the PTH1R receptor are expressed in fetal and adult heart from a number of different species (Burton *et al.,* 1994). PTHrP has been immunolocalized to atrial natriuretic peptide-containing granules of rat atria. One interpretation of this finding is that PTHrP, like atrial natriuretic peptide, is released in response to stretch, but this concept has yet to be tested. Both PTH and PTHrP exert pronounced effects on cardiac function (reviewed in Schluter and Piper, 1998).

Infusion of physiological levels of N-terminal fragments of PTH and PTHrP induce hypotension and tachycardia in intact rats (Mok *et al.,* 1989). In isolated perfused hearts, PTHrP induces chronotropic and ionotropic effects that are independent of perfusion pressure (Nickols *et al.,* 1989).

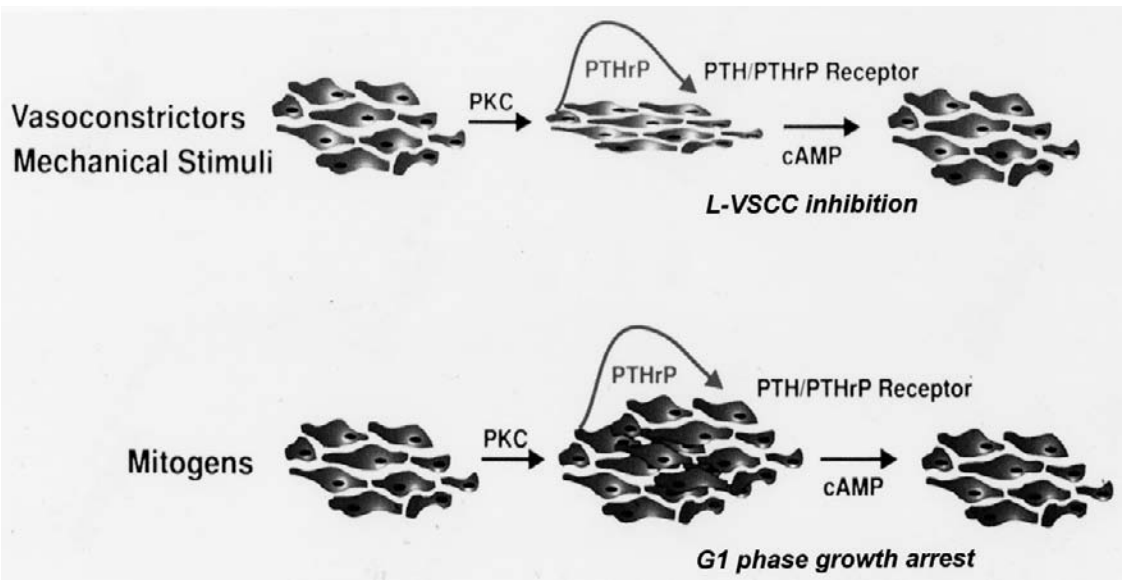

Figure 4 Model for PTHrP production and action in vascular smooth muscle cells (see text for description). (See also color plate.)

More recently it has been established that the inotropic activity of PTHrP occurs indirectly in response to increased coronary blood flow (Ogino *et al.,* 1995). The mechanisms responsible for the chronotropic effects of PTH and PTHrP have been examined in cultured cardiomyocytes (reviewed in Schluter and Piper, 1998). In neonatal cardiomyocytes, PTH increases beating frequency through a cAMP-dependent pathway. These effects are associated with increased L-type calcium currents, precisely the opposite of what is observed in vascular smooth muscle cells. In contrast, in adult rat cardiac myocytes, both PTH(1-34) and PTHrP(1-34) increase the rate of spontaneous contraction, but only PTHrP was found to stimulate cAMP accumulation. The reason for this difference is unclear but may relate to the coupling of the PTH1R receptor to different G proteins. PTH has also been shown to elicit a hypertrophic response in adult rat cardiomyocytes characterized by increased protein synthesis, cell mass, and the reexpression of embryonic cardiac proteins. These effects, together with clinical observations of patients with elevated PTH and increased left ventricular mass, have been interpreted as evidence for a pathogenic role of PTH in ventricular hypertrophy. Finally, as discussed earlier, the timing (E9-10) of embryonic death occurring in PTH/PTHrP receptor-null mice raises the possibility that PTHrP functions during heart development.

Insight into the global actions of PTHrP in the cardiovascular system has come from studies in genetically manipulated mice. Transgenic mice overexpressing either PTHrP or PTH1R in smooth muscle have reduced systemic blood pressure consistent with the prediction that PTHrP acts as a local vasodilator (Qian *et al.,* 1999). In aortic ring preparations from PTHrP-overexpressing mice, the relaxant effects of both PTHrP and acetylcholine seen in nontransgenic mice were attenuated markedly in aortas from PTHrP-overexpressing mice. This finding suggests that local overexpression of PTHrP not only desensitizes the vasculature to PTHrP, but also dampens relaxation to acetylcholine and perhaps other vasorelaxants. Thus it appears that prolonged stimulation of the PTH1R and the consequent increase in cAMP converge on signaling circuitry used by acetylcholine.

PTH-Related Proteins and Hypertensive States

Several lines of circumstantial evidence suggest that PTH and PTHrP alter vascular tone in hypertensive humans and animals. For example, primary hyperparathyroidism is commonly associated with hypertension which may be corrected upon removal of the parathyroid lesion (Young *et al.,* 1988). However, because alterations in circulating PTH also influence other regulators of vascular tone (e.g., ionized calcium), it is probable that the hypertension seen in long-term hyperparathyroidism is a secondary event. Alternatively, prolonged exposure to elevated PTH concentrations in these patients could desensitize vascular tissue to PTH or PTHrP, thereby increasing vascular tone (Nyby *et al.,* 1995). A similar scenario appears to occur in two rat models of hypertension. For example, removal of the parathyroid glands in the spontaneously hypertensive rat (SHR) and the DOCA salt hypertensive rat attenuates the development of hypertension (Schleiffer, 1992). Moreover, the PTH-induced changes in urinary cAMP, magnesium, calcium, and phosphorus responses are blunted in the SH rats, again suggesting a desensitization of the PTH1R receptor. The apparent resistance to PTH and PTHrP in humans and rats with hypertension described earlier prompted Pang and co-workers (1991) to propose the existence of an additional "hypertensive" factor made in the parathyroid gland. However, despite over a decade of work on this putative hypertensive factor, its precise structure is still unknown.

Neurological Actions

Introduction

As noted earlier, interest in potential regulation of excitable cells by PTH/PTHrP began with Collip and Clark's demonstration in 1925 that parathyroid extracts had hypotensive effects in the dog. For the next 60 years, PTH was the focus of work in both vascular and nonvascular smooth muscle and in neurons. In smooth muscle, it now seems quite clear that the physiological regulator is actually PTHrP, acting on the PTH1R. In the central nervous system (CNS), the best functional evidence also involves PTHrP acting on the PTH1R. In addition, evidence shows that PTH may influence pituitary function, and the recently described TIP39 acting on the PTH2R may prove to be an important CNS regulatory system.

There are two aspects of the PTH-smooth/cardiac muscle literature that are relevant to PTHrP function in the CNS. The first is that it is the L-VSCC that seems to be the pivotal target of PTH/PTHrP regulation. The second is that PTH and/or PTHrP appears to be capable of either inhibiting or stimulating L-VSCC-mediated Ca^{2+} influx depending on the cell/tissue in question (Wang *et al.,* 1991a).

PTH/PTHrP Gene Family Expression in the CNS

The CNS was one of the first sites to be examined in detail for PTHrP gene expression, and the gene was found to be widely expressed in neurons of the cerebral cortex, hippocampus, and cerebellum (Weir *et al.,* 1990) (Fig. 5). This work was extended by a second survey, which included the PTH1R as well as PTHrP (Weaver *et al.,* 1995). Both were found to be widely expressed, and they colocalized in a number of sites (Weaver *et al.,* 1995). It was noted at the time that the hot spots for PTHrP gene expression are neuronal populations that have a number of features in common, including high-density L-VSCC expression as well as high-density expression of excitatory amino acid receptors and a known susceptibility to excitotoxicity. The implications of these common features will become clear later in this chapter.

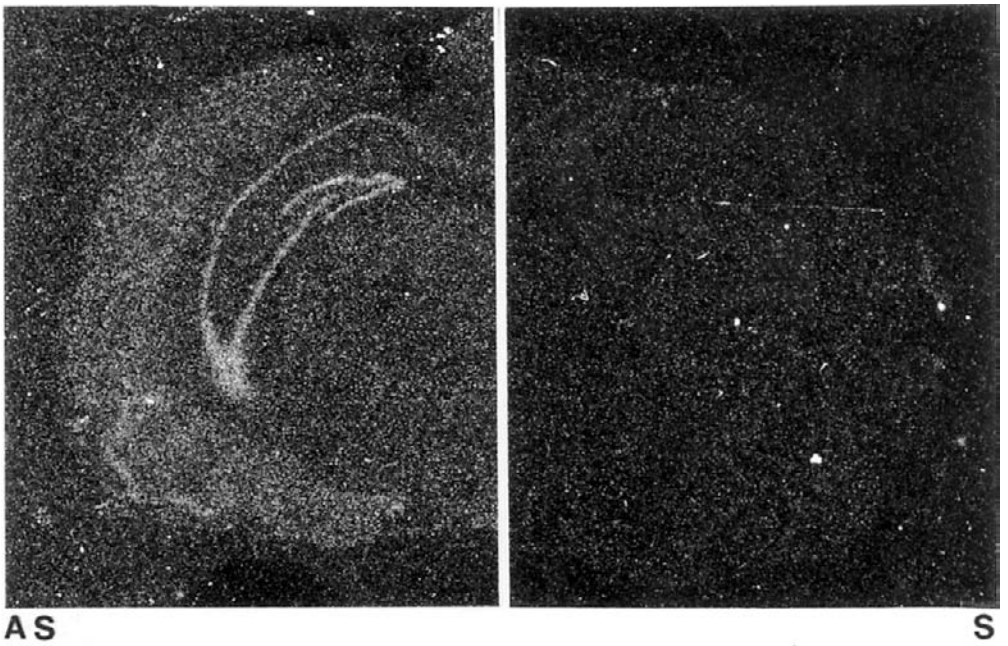

Figure 5 *In situ* hybridization histochemistry of PTHrP mRNA in the CNS of the rat using antisense (AS) and sense (S) oligonucleotides. The dentate gyrus and CA fields of the hippocampus are strongly positive. There are also many PTHrP-positive neurons scattered throughout the cerebral cortex. From Weir *et al.* (1990), with permission.

While early histochemical studies suggested that PTH might be present in a number of neuronal populations, the most careful and reproducible work has localized PTH to nuclei on the hypothalamus with projections into the portal system (Pang *et al.,* 1988; Harvey and Fraser, 1993). The implication is that PTH may regulate pituitary function, specifically including prolactin secretion (Harvey and Fraser, 1993).

Usdin and colleagues identified the PTH2R in a cerebral cortical cDNA library by homology screening in 1995. This receptor is sensitive to PTH(1-34) (EC_{50} about 1 n*M*) but is unresponsive to PTHrP(1-36). The PTH2R is expressed most abundantly in several basal forebrain nuclei and hypothalamic nuclei (Usdin *et al.,* 1996). This group has succeeded in purifying the natural ligand for this receptor using a staggering 50 lbs of bovine hypothalamus as starting material (Usdin *et al.,* 1999). This ligand is a small unmodified peptide of 39 amino acids referred to as tuberoinfundibular peptide 39 (TIP39), and it bears only 9 of 39 amino acids that are identical to those of bovine PTH. Only limited structure–function work has been done, but TIP39 is at least as potent as PTH(1-34) at the PTH2R and may be one or two orders of magnitude more potent than PTH, depending on the species of origin of the PTH2R (Usdin *et al.,* 1999). The sites of PTH2R expression imply potential TIP39 function in regulating the pituitary and in modulating pain sensitivity.

Thus, three ligands and at least two receptors of the PTH/PTHrP gene family are expressed in the CNS. Two of the ligands (PTH and TIP39) are expressed in highly discrete locations, whereas PTHrP is widely expressed in neuronal populations throughout the brain.

Calcium Channels, Neuromodulation, and Signaling Microdomains

CALCIUM CHANNELS

Calcium channels are heteromeric associations of four or five subunits (Walker and De Waard, 1998). The α_1 subunit is the pore-forming structure that is responsible for permeation as well as gating function of the channel. There are a half-dozen classes of calcium channels, each defined by a specific α_1 gene. Given the number of different genes for each subunit and alternate splicing of these gene products, the combinatorial possibilities are enormous (perhaps 1000).

In brief, calcium channels are either L-type or non-L-type (e.g., N, P/Q, T, and R channels) (Walker and De Waard, 1998). L-type channels mediate large and long-lasting Ca^{2+} fluxes (therefore "L") and are composed of three subclasses, defined by their α_1 subunits, as well as by the locations in which they were initially identified. These are S ("skeletal", α_1s), C ("cardiac", α_1c), and D (neuroendocrine, α_1d). L channels are dihydropyridine sensitive, and there are a number of classes of these widely used drugs (e.g., nifedipine, diltiazem).

Virtually every class of calcium channel is expressed in the CNS (Walker and De Waard, 1998). N and P/Q channels are expressed in both pre- and postsynaptic locations and are involved in the regulation of synaptic transmission. L channels are widely expressed in neurons throughout the brain and are found only in postsynaptic locations, specifically on cell bodies and proximal dendrites (Hell *et al.,* 1993). This localization is crucial to L channel function. These channels appear to regulate cytosolic Ca^{2+} levels in the soma and proximal dendrites of neurons as a function of

the integrated excitatory synaptic input into these locations (Hell *et al.,* 1993). Given the location and gating of these channels, it is quite clear that their Ca^{2+} currents are not involved in neurotransmission, but rather with fundamental aspects of neuronal cell biology such as regulation of cellular signaling pathways and regulation of gene expression.

NEUROMODULATION

The clustering of L-VSCCs on neuronal cell bodies is also characteristic of the location of neuropeptide/growth factor receptors. This clustering of receptors is strategically convenient to the nucleus as well as to the regulation of channels of all sorts and the capacity of peptides and growth factors to cross-talk with each other (Hökfelt, 1991). This kind of short-range autocrine/paracrine signaling to the soma and proximal processes of neurons is referred to as "neuromodulation" to emphasize that the regulation and signaling involved are very different from neurotransmission (Hökfelt, 1991).

SIGNALING MICRODOMAINS

Even a generation ago, it was clear that signal transduction corresponded to more than cells simply serving as bags of rising and falling tides of cyclic nucleotides and Ca^{2+}, but the biochemical details that account for the exquisite specificity of signal transduction have become clear only in the past decade. The work of Ghosh and Greenberg (1995) has provided insight into the specificity of neuronal Ca^{2+} signaling. Depending on the specific route of entry into a neuron, Ca^{2+} has highly specific and differential effects on a wide variety of neuronal processes, such as gene expression, learning and memory, modulation of synaptic strength, and Ca^{2+}-mediated cell death (Ghosh and Greenberg, 1995). For example, Ca^{2+} entry via L-VSCCs elicits an entirely different response in terms of gene expression than Ca^{2+} entry mediated via NMDA receptors (Ghosh and Greenberg, 1995). Clearly, every calcium ion entering the cytosol of a neuron is not perceived in the same way. Equally, clearly cAMP generated in a neuron by a voltage-sensitive adenylate cyclase as opposed to a G protein coupled to a hormone receptor is not perceived by the cell in the same way.

A major advance in understanding the specificity of signaling has come from the recognition that microdomains exist at the cell surface that cluster together the receptor/channel in question, the PKA and/or PKC transducers, and the target to be modified. The key recent players that account for this clustering of specific signaling components are the AKAPs (A kinase anchoring proteins) and the RACKs (receptors for activated C kinase) (Mochly-Rosen, 1995). In certain cases, a single AKAP is capable of binding both PKA and PKC, thus serving as a scaffold that brings together all of the early components of a complex regulatory system. The net result of this tethering of signaling receptor, transducer, and target into a microdomain is a tremendous resolution in terms of specificity and speed.

PTHrP Is Neuroprotective

PTHRP GENE EXPRESSION IN NEURONS IS REGULATED BY L-VSCC CA^{2+} INFLUX

It turns out that the regulation of PTHrP gene expression in cerebellar granule cells is a classic example of the kind of specificity of Ca^{2+} signaling described in the previous section. Cerebellar granule cells are a hot spot of PTHrP and PTH1R expression *in vivo* (Weir *et al.,* 1990; Weaver *et al.,* 1995), and cultured cerebellar granule cells are a commonly used neuronal model system *in vitro*. PTHrP gene expression in these cells is a direct function of depolarization, which triggers L-VSCC Ca^{2+} influx that tracks to the PTHrP gene via the calmodulin–CaM kinase cascade (Holt *et al.,* 1996; Ono *et al.,* 1997). Ca^{2+} entry into granule cells by any other granule cells, as in most other cells that express the PTHrP gene, PTHrP is a constitutive secretory product, so

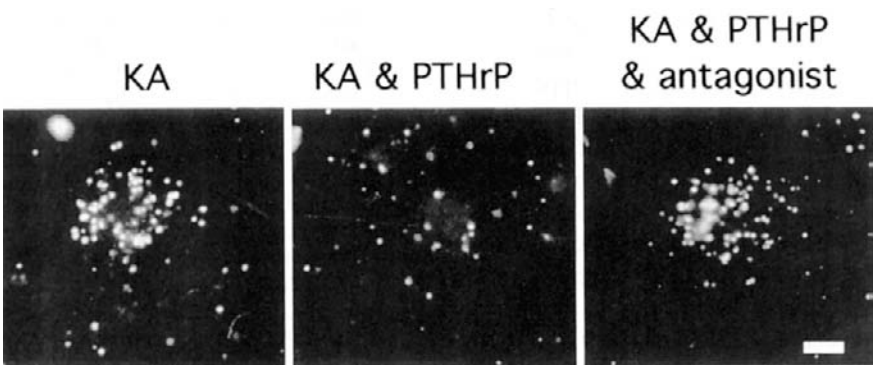

Figure 6 Cell death assessed by propidium iodide staining. Propidium iodide can bind to nuclear DNA only when the cell membrane is not intact; each bright dot therefore represents the nucleus of a dead cell. Kainic acid (KA) alone (left), KA plus PTHrP (center), and KA together with PTHrP and a 10-fold molar excess of a competitive antagonist of PTHrP binding (right). Percentage kill ($\pm$ SEM) under these three conditions was 23 $\pm$ 3% ($n = 10$), 2 $\pm$ 2% ($n = 11$, $P < 0.001$ with respect to KA alone), and 23 $\pm$ 2% ($n = 10$), respectively. Scale bar: 25 μM. From Brines *et al.* (1999), with permission.

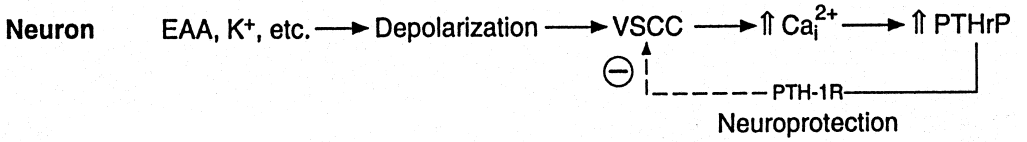

Figure 7 Schema of autofeedback loop in which PTHrP, triggered by L-VCSS Ca^{2+} influx, feeds back via the PTH1R to dampen L-VCSS Ca^{2+} currents.

that the quantity of PTHrP secreted by the cell is a linear function of the level of PTHrP mRNA expression. PTHrP immunolocalizes principally to the granule cell soma (Holt *et al.,* 1996) so that it is presumably secreted by the cell bodies themselves, acting in the autocrine/paracrine fashion typical of a neuromodulatory peptide.

PTHrP Inhibits L-VSCC Ca^{2+} Influx, Defining a Protective Feedback Loop

Overstimulation can lead to neuronal injury or death, a process referred to as excitotoxicity. Excitotoxicity comes in two flavors. High concentrations of the excitory amino acid, glutamate, cause a generalized influx of cations and a collapse in mitochondrial function leading to almost immediate necrosis (Ankarcrona *et al.,* 1995). Lower concentrations of glutamate or exposure to other excitotoxins, such as kainic acid, trigger Ca^{2+} entry via L-VSCCs, which leads to excitotoxicity characterized by a long latency (6–24 hr to cell death) (Ankarcrona *et al.,* 1995; Weiss *et al.,* 1990).

The granule cell system is subject to both immediate and latent forms of excitotoxicity. A low concentration of kainic acid produces about 50% granule cell death at 24 hr, and the calcium channel blocker nitrendipine is capable of fully protecting these cells, thereby defining the central importance of L-VSCC Ca^{2+} influx in long latency excitotoxicity (Brines *et al.,* 1999). It will be recalled that PTH has been shown to inhibit L-VSCCs in smooth muscle and neuroblastoma cells (Wang *et al.,* 1991; Pang *et al.,* 1990). This led to the working hypothesis that PTHrP might be capable of inhibiting L-VSCC Ca^{2+} influx in cerebellar granular cells, which proved to be the case. PTHrP was found to be fully neuroprotective in kainic acid-treated granule cells (Fig. 6) and was as effective as nitrendipine in reducing kainic acid-induced L-VSCC Ca^{2+} influx (Brines *et al.,* 1999). Pang *et al.* (1990) used whole cell patch-clamp techniques to demonstrate that PTH is capable of inhibiting L-VSCC Ca^{2+} influx in mouse neuroblastoma cells and one of us (AEB) has used patch-clamp techniques to demonstrate the same findings with PTHrP in these cells. This effect is mediated by the PTH1R, but nothing is yet known of the mechanism by which the channel is actually regulated.

Taken together, these findings indicate that PTHrP serves as an endogenous L-VSCC regulator that functions in a neuroprotective feedback loop of the sort depicted in Fig. 7. As shown, the L-VSCC itself is the fulcrum of this loop, and the rheostat is L-VSCC Ca^{2+} entry. This loop would provide neuroprotection to individual (autocrine) and neighboring (paracrine) neurons.

As described in Chapter 13, the PTHrP knockout mouse dies at birth as a result of systemic chondrodystrophy. This mouse has been rescued by a genetic strategy, generating a mouse that is PTHrP sufficient in chondrocytes but PTHrP null in all other sites (Wysolmerski *et al.,* 1998). There are no CNS abnormalities per se in the rescued mouse, but it displays a six-fold increase in sensitivity to kainic acid. Thus, as might be predicted from the findings in cultured cerebellar granule cells described above, PTHrP appears to be provided a defense against excitotoxicity that is operative *in vivo* (this work is described briefly because it is as yet unpublished).

Other Potential Calcium Channel Effects

PTHrP increases L-VSCC activity and thereby enhances dopamine secretion in PC-12 cells (Brines and Broadus, 1999). PTH and/or PTHrP has been reported to increase calcium channel-like activity in snail neurons (Kostyuk *et al.,* 1992) and in rat hippocampal neurons (Hirasawa *et al.,* 1998, Fukayama *et al.,* 1995), but these effects are slow and perhaps involve channels other than the classic L-VSCC. UMR-106 osteoblast-like cells contain L-VSCCs that are stimulated by PTH treatment (Barry *et al.,* 1995). L-VSCCs are also widely expressed in a great many other excitable and nonexcitable cells that have thus far not been examined with respect to PTHrP regulation.

Acknowledgments

The authors were asked to write two chapters on PTHrP effects in excitable tissues for separate books texts, the present text and "The Parathyroids" (J. P. Bilezikian, R. Marcus, and M. A. Levine, eds.). Because the chapters were on the same subject and had almost simultaneous due dates, they are virtually identical in context.

CHAPTER 31

$1\alpha,25(OH)_2$Vitamin D_3

Nuclear Receptor Structure and Ligand Specificities for Genomic and Rapid Biological Responses

Anthony W. Norman

Department of Biochemistry and Division of Biomedical Sciences, University of California, Riverside, Riverside, California 92521

Introduction to Vitamin D and $1\alpha,25(OH)_2D_3$

Structure

The term vitamin D designates a group of closely related seco steroids that possess antirachitic activity (see Fig. 1).[1] The two most prominent members of this group are ergocalciferol (vitamin D_2) and cholecalciferol (vitamin D_3) (Norman, 2001). Ergocalciferol is derived from a common plant steroid, ergosterol, and is the form that was employed for vitamin D fortification of foods from the 1940s to 1960s.

Cholecalciferol is the form of vitamin D obtained when radiant energy from the sun strikes the skin and converts the precursor 7-dehydrocholesterol into vitamin D_3. Because the body is capable of producing cholecalciferol, vitamin D technically does not meet the classical definition of a vitamin, i.e., a substance required by the body, but which cannot be made by the body. A more accurate description of vitamin D is that it is a prohormone. It has been shown that vitamin D is metabolized to a biologically active form, $1\alpha,25(OH)_2$vitamin D_3 [$1\alpha,25(OH)_2D_3$], which functions as a steroid hormone (Norman,1996; Reichel *et al.,* 1989). However, because the parent vitamin D was first recognized as an essential nutrient, it continues to be classified among the fat-soluble vitamins. Indeed, even in the last decade of the 20th century there are classic examples of vitamin D deficiency in many countries, as documented by low serum concentrations of $25(OH)D_3$ [e.g., United States (Dawson-Hughes *et al.,* 1997; Jacques *et al.,* 1997), India (Goswami *et al.,* 2000), and South Africa (Feleke *et al.,* 1999)].

Conformational Flexibility

Vitamin D_3 and all its daughter metabolites, including $1\alpha,25(OH)_2D_3$, are unusually conformationally flexible; (see Fig. 2). Three key aspects of the $1\alpha,25(OH)_2D_3$ molecule confer a unique range of conformational mobility on this

[1] The chemical structures of vitamin D and its daughter metabolites are closely related structurally to their provitamin forms as well as to the four ring nucleus of other classical steroids that are derived from the cyclopentanoperhydrophenanthrene ring system, (see Fig. 1). The official nomenclature proposed for vitamin D by the International Union of Pure and Applied Chemistry (IUPAC) relates it to the steroid nucleus, which is numbered as shown in Fig. 1 for the provitamin. The carbons in vitamin D retain the same number as designated in the provitamin. No vitamin D biological activity becomes apparent until ring B of the provitamin is opened. Thus, vitamin D and its metabolites are simply steroids with a broken B ring as a consequence of rupture of the carbon–carbon bond between C-9 and C-10. The presence of the nonintact B ring in the steroid nucleus is officially designated by the use of the term "seco." The formal chemical name of vitamin D_3 is 9,10-secocholesta-5,7,10(19)-trien-3β-ol and $1\alpha,25(OH)_2D_3$ is 9,10-secocholesta-5,7,10(19)-trien-$1\alpha,3\beta$,25-triol.

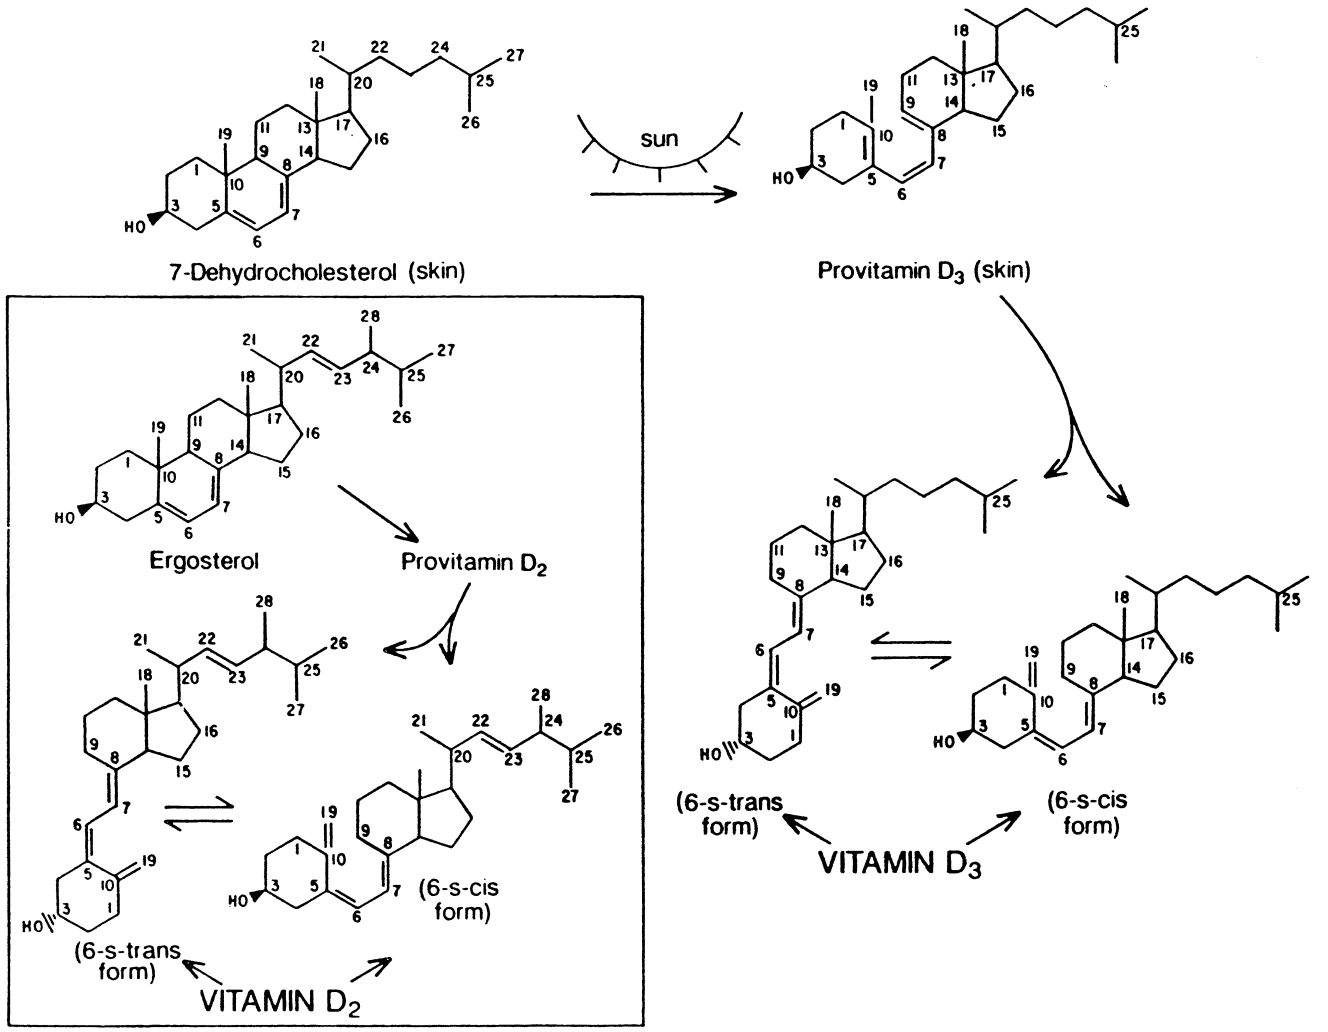

Figure 1 Chemistry and irradiation pathway for production of vitamin D_3 (a natural process) and vitamin D_2 (a commercial process). In each instance the provitamin, which is characterized by the presence of a Δ5, Δ7-conjugated double bond system in the B ring, is converted to the seco B previtamin steroid, where the 9,10 carbon–carbon bond has been broken. Then the previtamin D, in a process independent of ultraviolet light, isomerizes thermally to the vitamin form, which is characterized by a Δ6, Δ8, Δ10, 19-conjugated triple bond system. In solution (and in biological systems), vitamin D is capable of assuming a large number of conformational shapes because of rotation about the 6,7 carbon–carbon single bond of the B ring.

molecule. (a) The intact eight carbon side chain of vitamin D and related seco steroids can easily assume numerous shapes and positions in three-dimensional (3D) space by virtue of rotation about its five carbon–carbon single bonds. A discussion of the consequences of side chain conformational mobility has been presented previously (Midland *et al.,* 1993; Okamura *et al.,* 1992). (b) The cyclohexane-like A ring is free to rapidly interchange (many thousands of times per second) between a pair of chair–chair conformers; this has the consequence of changing the orientation of the key 1α and 3β hydroxyls between either an equatorial or an axial orientation (Wing *et al.,* 1974). (c) Rotational freedom

Figure 2 Structure of 1α,25$(OH)_2D_3$ illustrating the three structural aspects of vitamin D seco steroids that contribute to the conformational flexibility of these molecules. (A) Structure of 1α,25$(OH)_2D_3$ with indication of the three structural features of the molecule, which confer conformational flexibility on this molecule. (B) The dynamic rotation of the cholesterol-like side chain of 1α,25$(OH)_2D_3$ with 360° rotations about the five single carbon–carbon bonds indicated by the curved arrows. Dots indicate the position in three-dimensional space of the 25-hydroxyl group for some 394 readily identifiable side chain conformations. A discussion of the consequences of side chain conformational mobility has been presented (Midland *et al.,* 1993; Okamura *et al.,* 1992, 1994). (C) The rapid (millions of times per second) chair–chair interconversion of the cyclohexane-like A ring of the seco steroid between chair conformer A and chair conformer B; this effectively equilibrates 1α- and 3β-hydroxyls between axial and equatorial orientations. (D) Rapid (millions of times per second) rotational freedom about the 6,7 carbon–carbon bond of the seco B ring generates a population of shapes or conformations ranging from the more steroid-like 6-s-*cis* conformation, to the open and extended 6-s-*trans* form of the hormone (Norman *et al.,* 1993c). (E) Further illustration of the 360° rotation about the 6,7 carbon–carbon bond. Four steps of successive 90° rotation are illustrated. Each intermediate structure has a dramatically *different* shape, particularly with respect to the position of the critical 1α-hydroxyl and the plane of the A ring in relation to the plane of the C/D rings; the preferred shape of the ligand for the VDR_{nuc} is illustrated in Fig. 11.

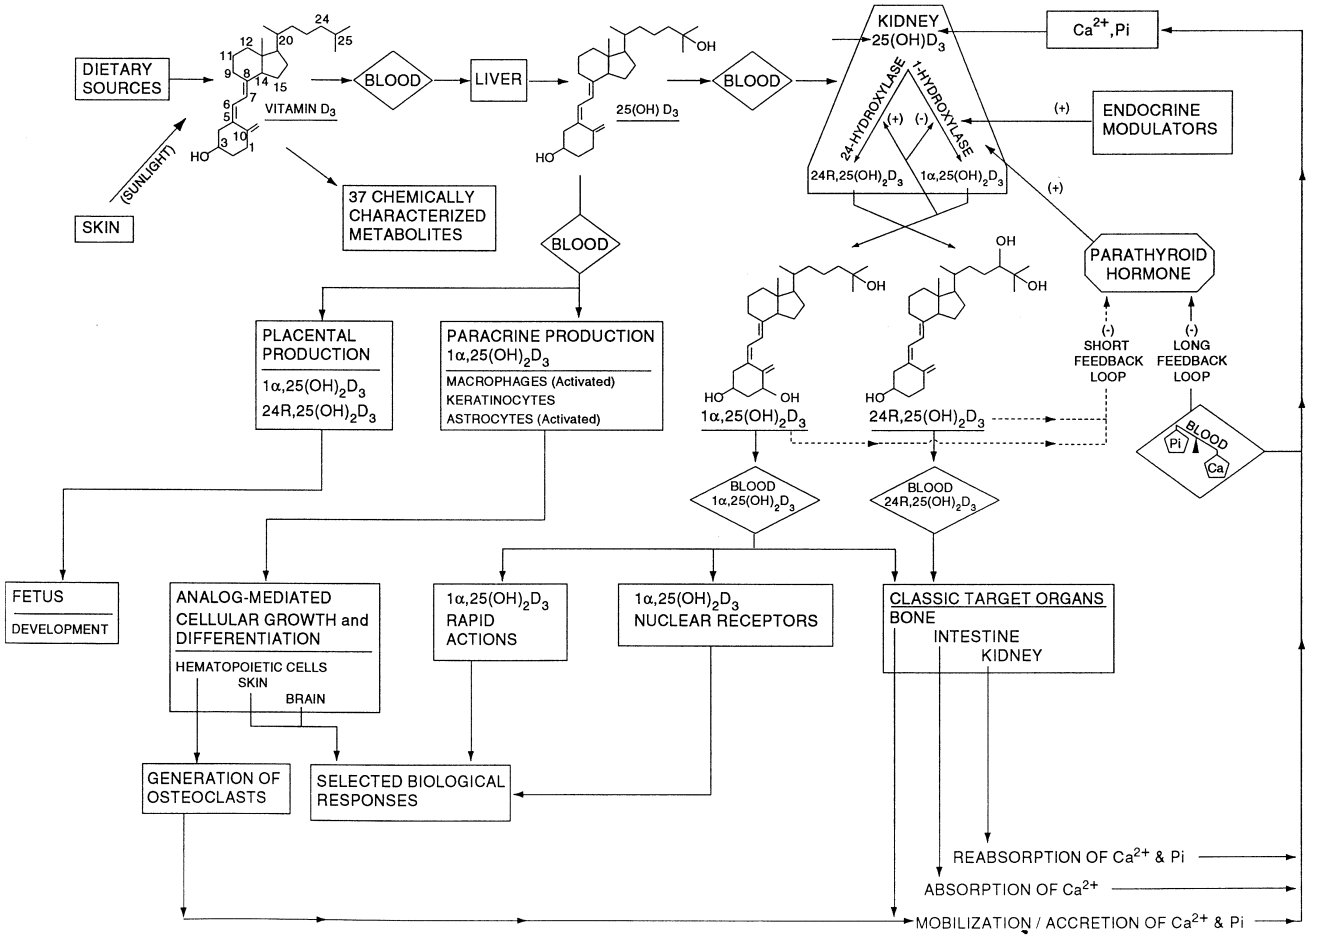

Figure 3 Overview of the vitamin D endocrine system. Target organs and cells for $1\alpha,25(OH)_2D_3$ by definition contain receptors for the VDR_{nuc} that enable them to modulate genomic events. Tissues that possess the VDR_{nuc} are listed in Table I and are discussed in Hannah *et al.,* (1994). In addition, $1\alpha,25(OH)_2D_3$ generates biological effects via rapid response pathways; these sites are listed in Table II and are discussed in Norman (1997). There is emerging evidence that $24R,25(OH)_2D_3$ may also have important biological effects (Seo *et al.,* 1997a).

about the 6–7 carbon–carbon bond of the seco B-ring allows conformations ranging from the more steroid-like 6-s-*cis* conformation to the open and extended 6-s-*trans* form of the hormone (Norman *et al.,* 1993c). It is generally accepted that this conformational mobility of vitamin D seco steroids is displayed by molecules in an organic solvent as well as an aqueous environment similar to that encountered in biological systems. Thus receptors for $1\alpha,25(OH)_2D_3$ have had to accommodate to the reality of binding a highly conformationally flexible ligand.

Vitamin D Endocrine System

The concept of the existence of the vitamin D endocrine system is firmly established (Bouillon *et al.,* 1995; Reichel *et al.,* 1989), (see Fig. 3). The key organ in this endocrine system is the kidney where the renal proximal tubule is responsible for producing the hormonal $1\alpha,25(OH)_2D_3$ in accordance with strict physiological signals (Henry,2000). The parent vitamin D_3 is metabolized to 25(OH)D3 (by the liver) and then to $1\alpha,25(OH)_2D_3$ and $24R,25(OH)_2D_3$ (by the endocrine gland, the kidney), as well as to 34 other metabolites (Bouillon *et al.,* 1995). The seco steroid $1\alpha,25(OH)_2D_3$ has been shown to initiate biological responses via regulation of gene transcription as well as via rapid membrane receptor-initiated pathways. The rapid responses can, for example, involve opening of voltage-gated Ca^{2+} channels (Caffrey *et al.,* 1989) or the rapid stimulation of intestinal Ca^{2+} absorption known as transcaltachia (Nemere *et al.,* 1984) (see Fig. 4).

An additional key participant in the operation of the vitamin D endocrine system is the plasma vitamin D-binding protein (DBP), which carries vitamin D_3 and all its metabolites to their various target organs. The DBP is known to have a specific ligand-binding domain for vitamin D-related ligands, which is different in specificity from the ligand-binding domain of the nuclear vitamin D receptor (Bishop *et al.,* 1994). DBP is similar in function to the corticosteroid-binding globulin (CBG), which carries glucocorticoids, and the steroid hormone-binding globulin (SHBG), which transports estrogens or androgens. DBP is a slightly acidic (p*I* 5.2) monomeric glycoprotein of 53 kDa synthesized and secreted by the liver as a major plasma constituent.

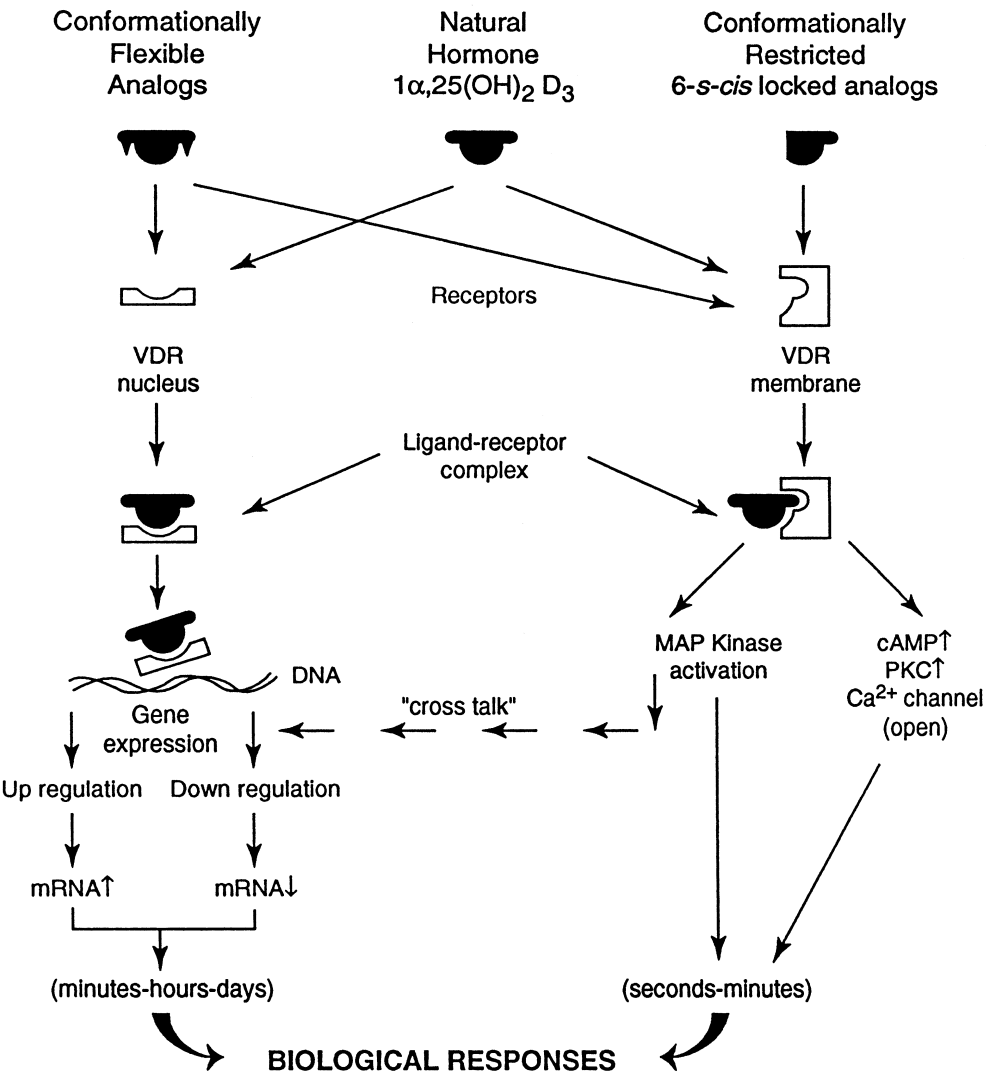

Figure 4 Proposed signal transduction pathways utilized by 1α,25(OH)$_2$D$_3$ ( ) and analogs of 1α,25(OH)$_2$D$_3$ to generate biological responses. Different shapes of 1α,25(OH)$_2$D$_3$ and its conformationally flexible analogs ( ) may interact with either the VDR$_{nuc}$ or the VDR$_{mem}$ to initiate different signal transduction pathways, which result in genomic responses or rapid responses. In contrast, the conformationally restricted 6-s-*cis* analogs ( ) (see Fig.1; JM, JN) can only interact with VDR$_{mem}$. In the genomic pathway (left side), occupancy of the nuclear receptor for 1α,25(OH)$_2$D$_3$ (VDR$_{nuc}$) by a ligand leads to an up- or downregulation of genes subject to hormone regulation. More than 50 proteins are known to be transcriptionally regulated by 1α,25(OH)$_2$D$_3$ [see Table I and Hannah *et al.,* (1994)]. In the membrane-initiated pathway (right side), occupancy of a putative membrane receptor for 1α,25(OH)$_2$D$_3$ by a ligand is believed to lead rapidly to activation of a number of signal transduction pathways, including adenylate cyclase, phospholipase C, protein kinase C (PKC), mitogen-activated protein kinase (MAP kinase), and/or opening of voltage-gated L-type Ca^{2+} channels, which are either individually or collectively coupled to generation of the biological response(s).

From analysis of the cloned cDNA, it has been determined that DBP is structurally homologous to albumin and α-fetoprotein; these three plasma proteins are members of the same multigene family, which likely is derived from the duplication of a common ancestral gene. DBP, originally called group-specific component (Gc), was initially studied electrophoretically as a polymorphic marker in the α-globulin region of human serum (see Cooke *et al.,* 1997; Haddad,1995). Preliminary data describing the X-ray crystal structure of DBP has been presented (Bogaerts *et al.,* 2000).

Signal Transduction Pathways Utilized by 1α,25(OH)$_2$D$_3$ to Generate Biological Responses

Figure 4 presents a schematic model that postulates that the various biologic responses generated by 1α,25(OH)$_2$D$_3$ are dependent on two types of receptors. These are the classic nuclear receptor for 1α,25(OH)$_2$D$_3$ (designated as VDR$_{nuc}$) and a putative membrane receptor (designated as VDR$_{mem}$). It has been postulated that the conformationally flexible steroid hormone 1α,25(OH)$_2$D$_3$ generates biological responses using

Table I Tissue Distribution of Nuclear $1\alpha,25(OH)_2D_3$ Receptor

Adipose	Hair follicle	Parotid
Adrenal	Intestine	Pituitary
Bone	Kidney	Prostate
Bone marrow	Liver (fetal)	Retina
Brain	Lung	Skin
Breast	Muscle, cardiac	Stomach
Cancer cells (many)	Muscle, smooth	Testis
Cartilage	Osteoblast	Thymus
Colon	Ovary, embryonic	Thyroid
Eggshell gland	Pancreas β cell	Uterus
Epididymus	Parathyroid	Yolk sac (bird)

different shapes so as to selectively activate the two general signal transduction pathways (Norman, 1997). (a) One shape of $1\alpha,25(OH)_2D_3$ interacts with the VDR_{nuc} to form a competent receptor–ligand complex that interacts with other nuclear proteins to create a functional gene transcription complex to increase or decrease mRNA coding for selected proteins (Fig. 4, left). (b) A different shape of $1\alpha,25(OH)_2D_3$ interacts with the putative VDR_{mem} that promptly stimulates signal transduction events, which activate the *rapid* appearance of biological responses (Fig. 4, right).

Table I summarizes 33 target organs known to possess the VDR_{nuc} and in which there is an impressive amount of detail concerning the regulation of gene transcription (Hannah *et al.,* 1994).

A wide array of rapid responses stimulated by $1\alpha,25-(OH)_2D_3$ have been reported since the mid-1980s; a summary is given in Table II. Recent additions to the list include demonstration that $1\alpha,25(OH)_2D_3$ can stimulate opening of chloride channels (Zanello *et al.,* 1996) and activation of MAP kinase (Beno *et al.,* 1995; Song *et al.,* 1998). MAP kinase belongs to the family of serine/-threonine protein kinases and can be activated by phosphorylation on a tyrosine residue induced by mitogens or cytodifferentiating agents (Pelech *et al.,* 1992). MAP kinase integrates multiple intracellular signals transmitted by various second messengers and regulates many cellular functions by phosphorylation of a number of cytoplasmic kinases and nuclear transcription factors, including the EGF receptor, c-Myc, and c-Jun (Lange-Carter *et al.,*

[a]The reader should compare the information in this table with the concepts illustrated in Figs. 2 and 3, which summarize the vitamin D endocrine system and signal transduction pathways utilized by $1\alpha,25(OH)_2D_3$ for generation of biological responses.

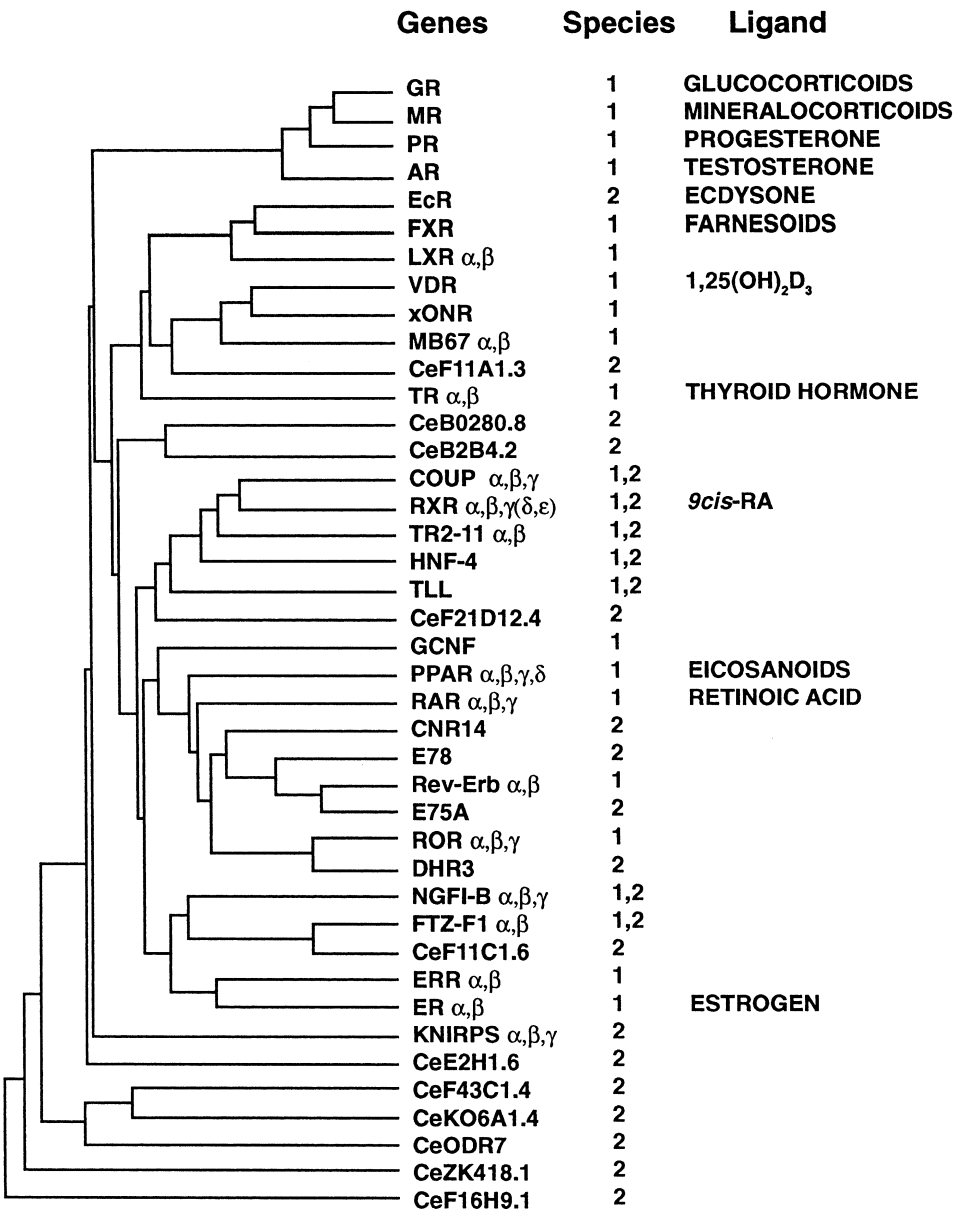

Figure 5 Nuclear receptor superfamily. Hypothesized evolutionary relationships for the extended family of known nuclear receptors and related orphan receptors based on the extent of homology for the nucleotide sequence of the cDNA of the individual protein are summarized. This figure was modified from that presented by Mangelsdorf *et al.* (1995).

1993). These rapid actions of 1α,25(OH)$_2$D$_3$ have been postulated to regulate cell biological function and potentially to interact with other membrane-mediated kinase cascades or to cross-talk with the cell nucleus to control genomic responses associated with cell differentiation and proliferation (Berry *et al.,* 1996).

Nuclear Receptor (VDR$_{nuc}$) for 1α,25(OH)$_2$D$_3$

The VDR$_{nuc}$ belongs to a superfamily of ligand-dependent nuclear receptors, which includes receptors for glucocorticoids (GR), progesterone (PR), estrogen (ER), aldosterone, androgens, thyroid hormone (T$_3$R), hormonal forms of vitamin A (RAR, RXR), vitamin D (VDR), and several orphan receptors (Evans,1988; Lowe *et al.,* 1992; Parker,1991), (see Fig. 5). Figure 5 summarizes the hypothesized evolutionary relationships for the extended family of known nuclear receptors and related orphan receptors in vertebrate and invertebrates (*Caenorhabditis elegans, Drosophila*). For further details, see Carlberg (1996) and Mangelsdorf *et al.* (1995).

Figure 6 illustrates the structural relationship among the gene for the VDR$_{nuc}$, the mRNA, and the protein receptor. At the protein level, comparative studies of the VDR with all the steroid, retinoid, and thyroid receptors reveal that they have a common structural organization consisting of five domains (Krust *et al.,* 1986) with significant amino acid sequence homologies. The different domains act as

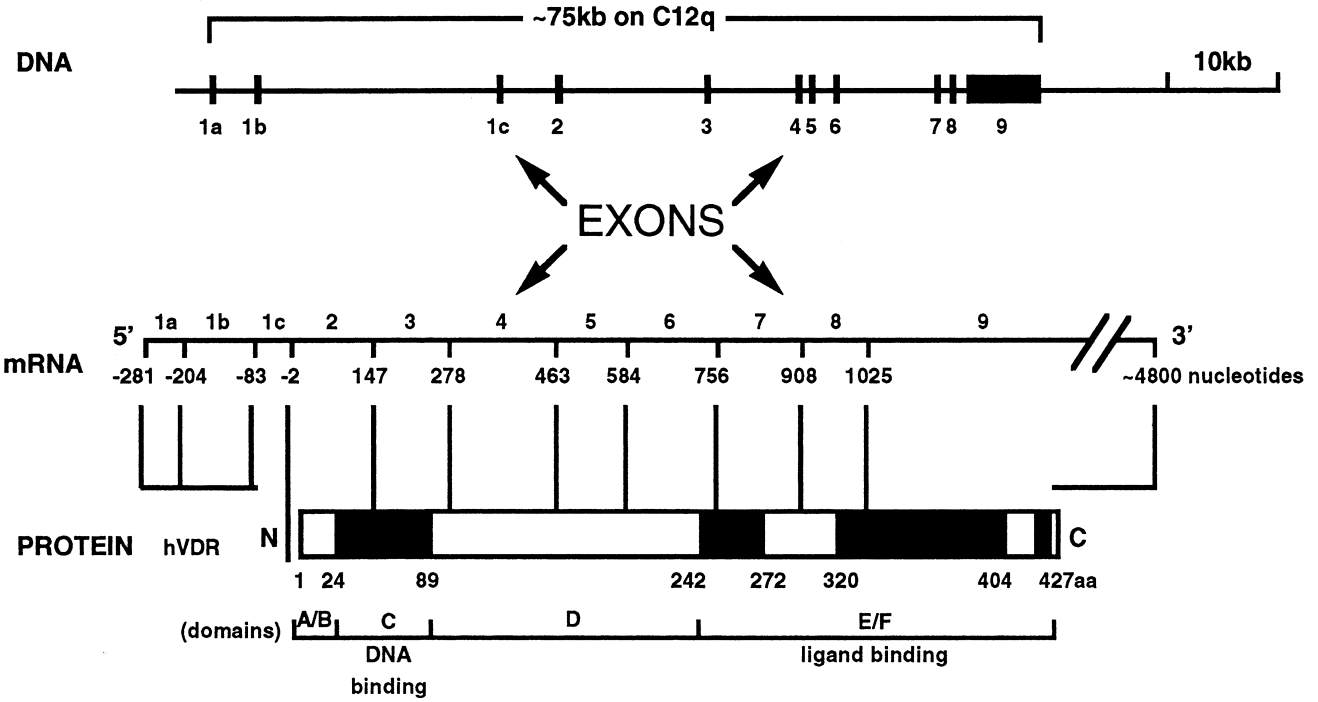

Figure 6 Schematic model of the VDR_{nuc} gene, mRNA, and protein. The gene for the VDR_{nuc} is located on human chromosome 12 and spans approximately 10 kb. The gene has 11 exons, which are processed to yield a full-length mRNA of 4800 nucleotides, the VDR_{nuc} protein is composed of 427 amino acids. Numbers below the hVDR indicate the amino acid residue boundaries for the various domains. Nuclear receptors consist of five domains (A–E) based on regions of conserved amino acid sequence and function. The C domain, the most highly conserved domain, is the DNA-binding domain and defines the superfamily; it contains two zinc finger motifs. The E domain is less conserved and is responsible for ligand binding, dimerization, and transcriptional activation. Subdomains within the domain include ligand 1 (residues 242–272) and ligand 2, or the τ_i or transcriptional inhibition, and dimerization domain (residues 310–404), which contains nine heptad repeats as first described by Forman *et al.* (1990). Domains A/B and D have the least sequence homology. See also information presented in Carlberg *et al.* (1998) and Haussler *et al.* (1998).

distinct modules that can function independently of each other (Beato,1989; Green *et al.,* 1988; Ham *et al.,* 1989). The DNA-binding domain, C, is the most conserved domain throughout the family. About 70 amino acids fold into two zinc finger-like motifs. Conserved cysteines coordinate a zinc ion in a tetrahedral arrangement. The first finger, which contains four cysteines and several hydrophobic amino acids, determines the DNA response element specificity. The second zinc finger, which contains five cysteines and many basic amino acids, is also necessary for DNA binding and is involved in receptor dimerization (Evans, 1988; Forman *et al.,* 1990; Green *et al.,* 1988; Rastinejad *et al.,* 1995).

The next most conserved region is the steroid-binding domain (region E). This region contains a hydrophobic pocket for ligand binding and also contains signals for several other functions, including dimerization (Bourguet *et al.,* 1995; Fawell *et al.,* 1990; Forman *et al.,* 1989; Glass *et al.,* 1989), nuclear translocation, and hormone-dependent transcriptional activation (Beato,1989; Green *et al.,* 1988; Picard *et al.,* 1990a).

The A/B domain is also known as the immuno- or transactivation domain. This region is poorly conserved in amino acids and in size, and its function has not been clearly defined. The VDR has the smallest A/B domain (25 amino acids) of the known receptors, whereas the mineralocorticoid receptor has the largest A/B domain (603 amino acids). An independent transcriptional activation function is located within the A/B region (Evans, 1988; Green *et al.,* 1988; Ham *et al.,* 1989), which is constitutive in receptor constructs lacking the ligand-binding domain (region E). The relative importance of transcriptional activation by this domain depends on the receptor, the context of the target gene promoter, and the target cell type (Tora *et al.,* 1989).

Domain D is the hinge region between the DNA-binding domain and the ligand-binding domain. The hinge domain must be conformationally flexible because it allows the ligand-binding domain and DNA-binding domains some flexibility for their proper interactions. The VDR hinge region contains 65 amino acids and has immunogenic properties (McDonnell *et al.,* 1988).

Receptor Dimerization

The superfamily of nuclear receptors has been classified into subgroups based on their dimerization properties, DNA-binding site preferences, and cellular localization. Group I includes receptors for glucocorticoids, estrogen, mineralocorticoids, progesterone, and androgens. These receptors bind as homodimers to palindromic DNA response elements. Group II includes receptors for VDR_{nuc}, T_3R, RAR, RXR, ecdysone, and several orphan receptors.

These receptors bind as homodimers or heterodimers to direct repeats, palindromic, and inverted palindromic DNA response elements. Group III includes the receptors for reverb A, ROR, SF-1, and NGFI-B. No ligands have yet been identified for these receptors and they bind DNA response elements as monomers or heterodimers.

As a class, group II receptors bind nonsteroid conformationally flexible ligands (where vitamin D is classified as a seco steroid rather than as a steroid). Group II receptors have more flexibility in the types of DNA response elements they can recognize and in the types of dimeric interactions they participate in than group I receptors. All of the group II receptors can form heterodimers with RXR (Kliewer *et al.,* 1992; Yu *et al.,* 1991), and other heterodimeric interactions have also been reported (Carlberg, 1993). The VDR$_{nuc}$ can bind to DNA response elements as homodimers and as heterodimers with RAR, RXR, and T$_3$R (Carlberg,1993; Schräder *et al.,* 1993). The ability to form heterodimers with other receptors allows for enhanced affinity for distinct DNA targets, generating a diverse range of physiological effects, as shown in Fig. 7.

The first zinc finger determines the sequence specificity of the DNA element. The second zinc finger is aligned by the binding of the first finger to the DNA and is involved in the protein–protein contacts responsible for the cooperativity of binding. The spacing of nucleotides between the two half-sites is important for DNA-binding specificity because of the asymmetric dimer interface formed by the DNA-binding domains of a heterodimer pair. Ligand binding may function to modulate receptor dimerization. In fact, VDR$_{nuc}$ has been shown to exist as a monomer in solution either in the presence or in the absence of ligand. When DNA is present, in the absence of ligand, the VDR$_{nuc}$ binds to the DNA both as monomers and homodimers. The addition of ligand stabilizes the bound monomer, which favors the formation of VDR$_{nuc}$-RXR (or other) heterodimers. The presence of the ligand decreases the rate of monomer-to-homodimer conversion and enhances the dissociation of the dimer complex. The presence of the RXR ligand, 9-*cis*-retinoic acid, has the opposite affect on heterodimerization formation; it enhances the binding of RXR homodimers to DR+1 elements (Cheskis *et al.,* 1994). Ligand bound to VDR$_{nuc}$ enhances the binding of RXR-VDR$_{nuc}$ heterodimers to DR+3 elements. Other possible protein–protein interactions can also involve VDR$_{nuc}$, including association with AP-1, EE1A/TFIID; TFIIB. These protein–protein interactions can be determined by the concentration of the protein partner and/or by the concentration of ligand or both, as well as by the nature of the DNA target site itself.

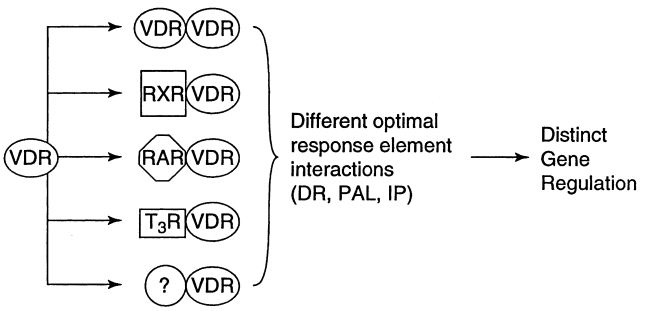

Figure 7 Schematic of possible dimeric interactions of VDR$_{nuc}$ with other receptor members of the superfamily (see Fig. 6). VDR$_{nuc}$ can bind to DNA as a homodimer or as a heterodimer with a variety of other group 2 receptors, i.e., RXR (retinoid X receptor), RAR (retinoid A receptor), T$_3$R (thyroid receptor), and perhaps other receptors or factors not yet identified. Each dimer pair has an enhanced affinity for distinct DNA targets, allowing a small family of receptors to generate a diverse range of physiological effects.

Hormone Response Elements

Each zinc finger appears to be encoded by separate exons as shown by the genomic structure of the ER (Ponglikitmongkol *et al.,* 1988), the PR (Huckaby *et al.,* 1987), and the VDR$_{nuc}$ (Freedman,1992). Most of the knowledge of how zinc fingers interact with DNA response elements has been gained by studies of GR and ER. The palindromic nature of GR and ER response elements suggested that these hormone receptors would bind to DNA as symmetrical dimers. Subsequent studies have confirmed that both GR and ER bind as homodimers to their response elements (Picard *et al.,* 1990b; Schwabe *et al.,* 1990). The principal ER dimerization domain is in its ligand-binding domain (Kumar *et al.,* 1988). Both the ER and the GR contain additional residues in the DNA-binding domain that are also important for dimerization. When the GR and ER DNA-binding domain are translated, they cannot dimerize alone but, in the presence of the correct palindromic response element, they bind to DNA as a dimer in a cooperative manner (Hard *et al.,* 1990). The five amino acid stretch between the first two coordinating cysteines of the second zinc finger is designated the "D" box (Umesono *et al.,* 1988) and mediates spacing requirements critical for cooperative dimer binding to palindromic HREs probably through a dimer interface involving these residues in each monomer (Diamond *et al.,* 1990; Jonat *et al.,* 1990; Schule *et al.,* 1990).

Using the GR and ER as models of receptor–DNA interactions, the binding of VDR$_{nuc}$ to DNA has also been examined. Because VDR$_{nuc}$ can bind to DNA as a heterodimer, often with RXR, VDR$_{nuc}$ and other group II receptors seem to display more variety in how they bind to their response elements (Forman *et al.,* 1989; Freedman,1992; Jones,1990). The primary response element for group II receptors is a direct repeat instead of an inverted palindrome; the protein–protein contacts are nonequivalent. There is an asymmetrical dimerization interface. Amino acid residues, designated the T/A box in the hinge region (domain D) just adjacent to the DNA binding domain, are involved. T/A box residues form an α helix, making backbone and minor groove interactions, which are involved in intramolecular packing against residues in the tip of the first zinc finger and determine the spacing requirements for the heterodimer pair.

Table III summarizes examples of hormone response elements for VDR$_{nuc}$. Natural response elements for group II receptors appear to consist of a direct repeat of the hexamer AGGTCA. The spacing of the direct repeat determines

the receptor preference: VDR_{nuc} prefers a 3-bp space, T_3R prefers 4 bp, and RAR prefers 5 bp (Umesono *et al.,* 1991). RXR, RAR, T_3R, and VDR_{nuc} spacing optimum on a palindrome is no nucleotides between the half-sites. Spacing on inverted palindromes depends on the overhang of the dimeric partners: 11 for VDR_{nuc}-RAR; VDR_{nuc}-RXR is predicted to be 7 to 8, but actually is 9; RXR appears to use a slightly different contact interface when it heterodimerizes with VDR_{nuc} than with other receptors (Schräder *et al.,* 1994). Free rotation around the hinge (domain D) enables the same interaction of the ligand-binding domains of both receptors on each response element. The steric requirements of T/A boxes give the receptor its asymmetry when binding to direct repeats and inverted palindromes and determine optimal spacing, illustrated in Fig. 8.

Ligand Binding

The ligand-binding domain of group II receptors as exemplified by the VDR has been dissected further (see Fig. 6). Subdomains ligand 1 and ligand 2 are nearly identical among receptors of the same binding specificity, but are different among receptors of different binding specificity (Giguere *et al.,* 1987; Harrison,1991; Thompson *et al.,* 1987). Surprisingly, there is greater homology between the ligand binding subdomains of RAR (α, β, γ) and T_3R (α, β) than between RAR and RXR. The τ_i subdomain is highly conserved among all nuclear hormone receptors and is a putative transcriptional inactivating domain. Inactivation of this domain is relieved by ligand binding.

The dimerization domain consists of eight to nine heptad repeats of hydrophobic amino acids. The heptads contain leucine or other hydrophobic residues such as Ile, Val, Met, or Phe at positions one and eight or charged amino acids with hydrophobic side chains such as Arg or Gln in the fifth position. In an ideal coiled–coil α helix, these amino acids would form a hydrophobic surface along one face of the

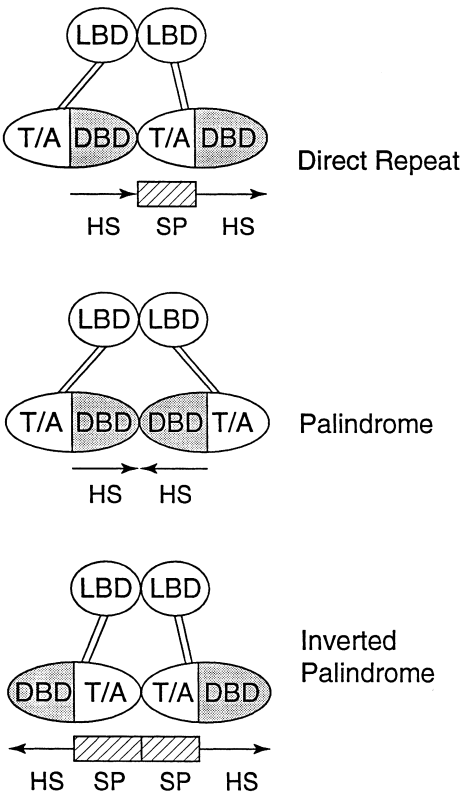

Figure 8 Mechanism of steriod nuclear receptor superfamily dimers binding to DNA response elements. Group II receptors can bind to three types of response elements, which are direct repeats, palindromes, and inverted palindromes. The spacing (SP), number of base pairs between half-sites (HS), is determined by steric constraints of the T/A box. The orintation of the DNA half-sites is shown with arrows. The flexiable hinge domain allows the formation of the same dimerization interface between ligand-binding domains (LBD) regardless of the orientation of the DNA half-sites.

helix that would act as a dimerization interface (Fawell *et al.,* 1990). Deletion/mutation analysis of the VDR$_{nuc}$ ligand-binding domain has shown that Asp-258 and Ile-248 are involved in heterodimerization with RXR. Leu-254 and -262 are critical for heterodimerization. A mutant that is truncated at amino acid 190 becomes constituitively transcriptionally active. Other amino acids identified as being important for heterodimerization are 325–332, 383–390, and 244–263. Residues 403–427 are particularly important for ligand side chain binding [1α,25(OH)$_2$D$_3$] (Nakajima *et al.,* 1994).

VDR Receptor Structure

A dramatic advance in understanding of the 3D structure of the LBD of steroid receptors occurred in the late 1990s with the X-ray crystallographic structure determination of LBD of five hormone receptors. These include LBDs of the thyroid hormone (TR), retinoic acid (RAR), estrogen (ER), progesterone (PR), and PPARγ (see the review by Weatherman *et al.,* 1999). Also, an X-ray structure is available for the LBD of the unoccupied 9-*cis* retinoic acid receptor RXR (Bourguet *et al.,* 1995). Further, ER LBD X-ray structures are known for a ligand (raloxifene), which can act as an *antagonist* of the transcriptional activation function (Brzozowski *et al.,* 1997; Shiau *et al.,* 1998)

The crystal structure of an engineered version of the ligand-binding domain of the nuclear receptor for vitamin D, bound to its natural ligand, has been determined at a 1.8-A resolution (Rochel *et al.,* 2000). The structure of the LBD of the human VDR$_{nuc}$ spans amino acid residues 143–427 (COOH terminus) and is very similar to that of a proposed model of the VDR LBD (Norman *et al.,* 1999), as well as to the LBD of the other five receptor structures (Weatherman *et al.,* 1999). The VDR$_{nuc}$ LBD structure, as does the other five nuclear receptors, consists of 12 α helices that are arranged to create a three-layer sandwich that completely encompasses the ligand 1α,25(OH)$_2$D$_3$ in a hydrophobic core. Impressively, all six X-ray structures are so similar that their ribbon diagrams are virtually superimposable, indicating a remarkable spatial conservation of the secondary and tertiary structures (Weatherman *et al.,* 1999) (see Fig. 9 (see also color plate). In addition, the AF-2 domain of the C-terminal helix 12 contributes to the hormone-binding pocket, suggesting that the ligand could play a role in receptor activation.

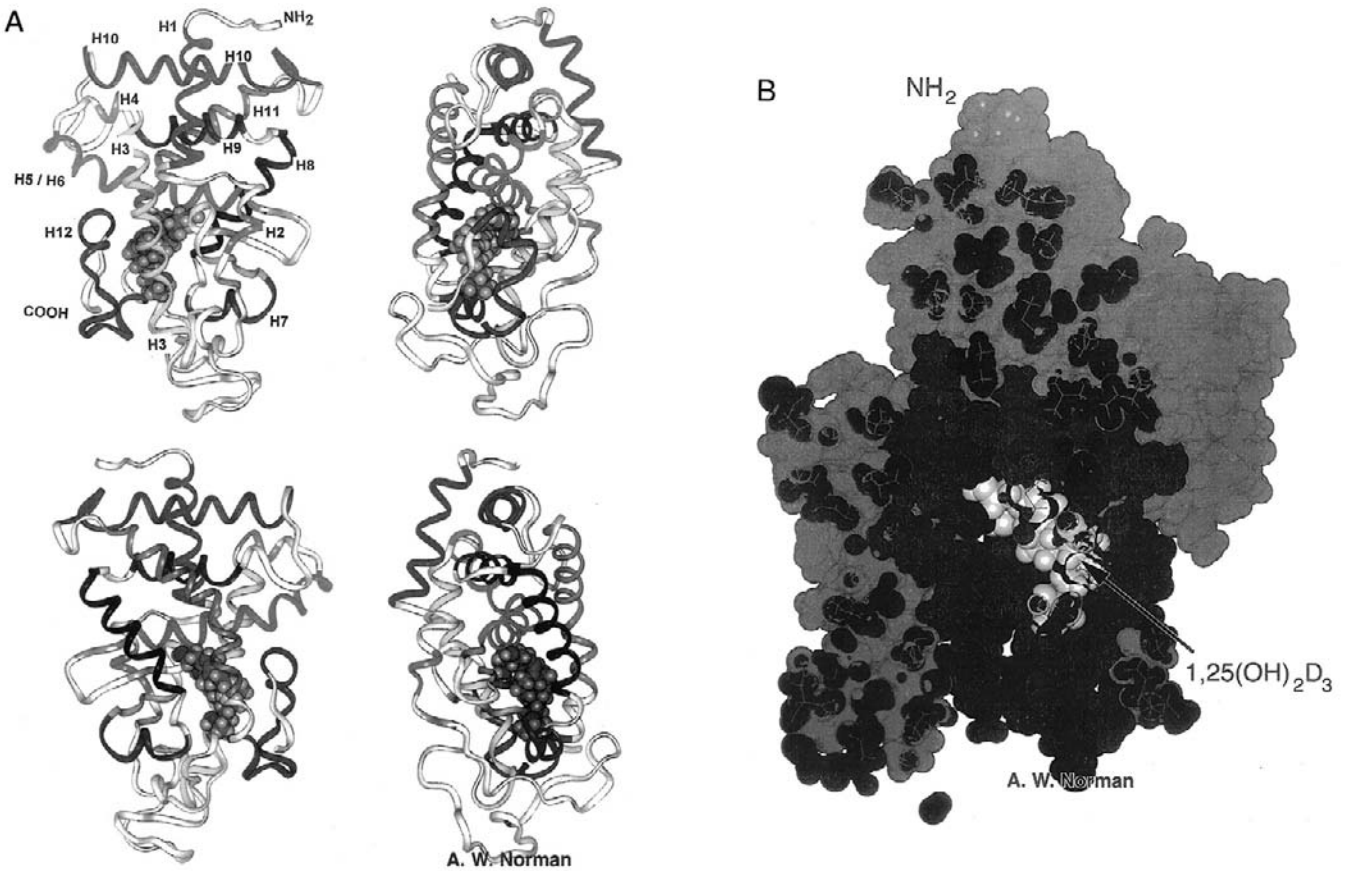

Figure 9 Structural representations of the ligand-binding domain of the nuclear receptor for 1α,25(OH)$_2$D$_3$ derived from X-ray crystallographic analysis (Rochel *et al.,* 2000). The model of the LBD of the human VDR$_{nuc}$ spans amino acid residues 143–427 (COOH terminus) (Baker *et al.,* 1988) and is very similar to that of the LBD of the other five nuclear (TR, ER, P, RaR, and PPAR) receptor structures (Weatherman *et al.,* 1999). Different representations of the same 3D model of hVDR$_{nuc}$ are illustrated. The ligand in each panel is 6-s-*trans* 1α,25(OH)$_2$D$_3$. (A) Ribbon views illustrate four successive 90° rotations of the 12 α helices and β strands that collectively define the VDR$_{nuc}$ model. Helices are numbered in the same order as TR, RAR, and ER structures. (B) An in-plane "slice" exposing the interior so that 1α,25(OH)$_2$D$_3$ is visible. (See also color plate.)

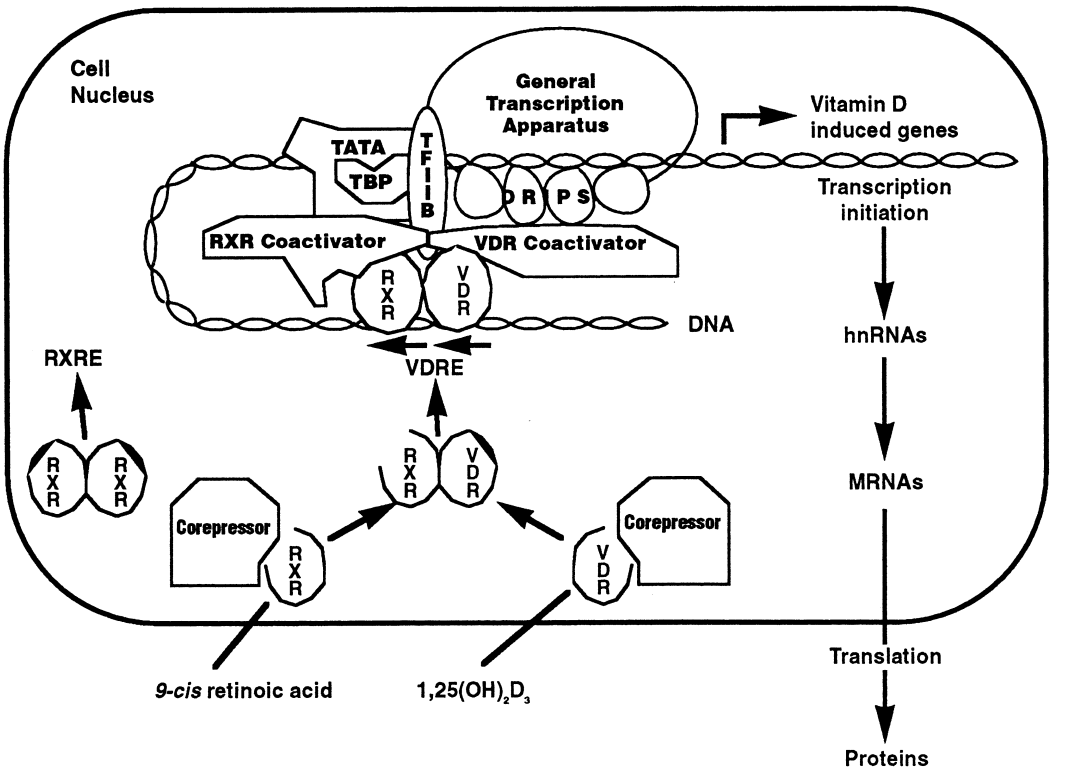

Figure 10 Model of 1α,25(OH) and VDR_{nuc} activation of transcription. The VDR after binding its cognate ligand $1\alpha,25(OH)_2D_3$ forms a heterodimer with RXR. This heterodimer complex then interacts with the appropriate VDRE on the promoter of genes (in specific target cells), which are destined to be up- or downregulated. The heterodimer–DNA complex then recruits necessary coactivator proteins, TATA, TBP, TFIIB, and other proteins to generate a competent transcriptional complex capable of modulating mRNA production.

Figure 10 presents a schematic model of the VDR_{nuc} interaction with its heterodimer partner and their subsequent interaction with the promoter of genes selected for modulation, as well as with other proteins (coactivators, TATA binding protein, etc.) so as to generate a competent transcriptional complex. Over the past decade there has been a continuing evolution of understanding and complexity concerning the details of what constitutes a "competent transcriptional complex." Additional viewpoints and information can be found elsewhere (Barrett *et al.,* 1999; Glass *et al.,* 2000; Leo *et al.,* 2000; Weatherman *et al.,* 1999).

Genetics and the Vitamin D Endocrine System

MUTATIONS IN VDR_{NUC}

Table IV summarizes the 6 natural and 26 experimental mutations in the LBD of the VDR_{nuc} that have identified amino acids critical for normal LBD function. There are also at least 14 other natural mutations in the zinc finger DNA-binding domain C of the VDR_{nuc} [data not presented but reviewed in Haussler *et al.,* (1997b)].

Hereditary vitamin D-resistant rickets (HVDRR), also known as vitamin D-dependent rickets, type II (VDDRII), is a rare genetic disease. Genetic analysis has shown that it is autosomal recessive. Less than 30 kindreds have been reported. The combination of symptoms, i.e., defective bone mineralization, decreased intestinal calcium absorption, hypocalcemia, and increased serum levels of $1\alpha,25(OH)_2D_3$, suggests end-organ resistance to the action of $1\alpha,25(OH)_2D_3$. Patients do not respond to doses of vitamin D, $25(OH)D_3$, or $1\alpha,25(OH)_2D_3$.

The unresponsiveness to $1\alpha,25(OH)_2D_3$ associated with HVDRR has been demonstrated to arise from defects in the gene coding for the VDR_{nuc}. Two types of abnormalities have been defined by binding studies: receptor-negative and receptor-positive phenotypes (see Table IV). Mutations identified in the receptor-negative phenotype involve a mutation that introduces a premature stop codon in the message. The resulting truncated protein is not able to bind ligand. The receptor-positive phenotype arises from one of several missense mutations localized within the zinc finger domains of the DNA-binding domain. Several of these mutant receptors have been demonstrated to be defective in their ability to bind to DNA-cellulose and to be unable to mediate $1\alpha,25(OH)_2D_3$-stimulated gene transcription *in vitro* (Kristjansson *et al.,* 1993; Ritchie *et al.,* 1989; Rut *et al.,* 1994; Sone *et al.,* 1989).

KNOCKOUT OF THE VDR_{NUC}

An animal model of HVDRR was engineered by targeted disruption of DNA encoding the first and the second zinc finger of the DNA-binding domain of the VDR, respectively, by two different groups independently (Li *et al.,* 1997; Yoshizawa *et al.,* 1997). The resultant animals were phenotypically normal at birth. No defects in development and

growth were observed before weaning, irrespective of reduced expression of vitamin D target genes. After weaning (3 weeks after birth), however, VDR-null mutant mice showed marked growth retardation. No overt abnormalities, however, were found in the heterozygotes even at 6 months. Unexpectedly, all of the VDR-null mutant mice developed alopecia and had few whiskers by 7 weeks. Further, the serum levels of calcium and phosphate were reduced at 4 weeks, with markedly elevated serum alkaline phosphatase activity present in the null-mutant mice, whereas in older VDR-deficient mice, these abnormalities became more prominent. These observations in the VDR-null mutant mice are similar to those in a human vitamin D-dependent rickets type II disease, in which mutations in the VDR gene have been identified in several families, although this disease is not lethal.

In the VDR-null mutant mice at 3 weeks, the serum levels of 1α,25(OH)$_2$D$_3$, 24R,25(OH)$_2$D$_3$, and 25(OH)D$_3$ were the same as those in the heterozygous and wild-type mice. However, a marked 10-fold increase in serum 1α,25(OH)$_2$D$_3$ and a clear reduction (to almost undetectable levels) in serum 24R,25(OH)$_2$D$_3$ developed in the VDR-null mutant mice at 4 weeks and persisted at 7 weeks. Immunoreactive PTH levels were also raised sharply after weaning, and the size of the parathyroid glands in the 70-day-old VDR-ablated mice was increased more than 10-fold. These observations establish that VDR is essential for regulation of the 1α- and 24R-hydroxylases by 1α,25(OH)$_2$D$_3$ after weaning, again supporting the idea that VDR plays a critical role only after weaning. The authors suggest that a functional substitute for VDR is present in milk.

Severe bone malformation was induced by the inactivation of the VDR after weaning. Radiographic analysis of VDR-null mutant mice at 7 weeks revealed growth retardation with loss of bone density. A 40% reduction in bone mineral density was observed in the homozygote mutant mice. In gross appearance and on X-ray analysis of tibia and fibula, typical features of advanced rickets were observed, including widening of epiphyseal growth plates, thinning of the cortex, fraying, cupping, and widening of the metaphysis. In marked contrast, in the VDR-ablated mice in whom normal mineral ion homeostasis had been preserved by feeding of a high-calcium, high-lactose diet,

none of these bone parameters were significantly different from those in wild-type littermates raised under identical conditions. Particularly, the morphology and width of the growth plate were indistinguishable from those in wild-type controls, demonstrating that a calcium/phosphorus/lactose-enriched diet started at 16 days of age in the VDR-null mice permits the development of both normal morphology in the growth cartilage and adjacent metaphysis and normal biomechanical competence of cortical bone. Thus, the remarkable conclusion is that there is no clear contribution of the VDR to normal bone development, skeletal growth, maturation, and remodeling. The major contribution of VDR_{nuc} is its role in intestinal calcium absorption.

The male and female VDR-null mutant mice were infertile. Uterine hypoplasia and impaired folliculogenesis were observed in the female, and decreased sperm count and motility with histological abnormality of the testis were observed in the male. Aromatase activities in these mice were low in the ovary, testis, and epididymis. These results indicated that vitamin D is essential for full gonadal function in both sexes (Kinuta *et al.,* 2000).

KNOCKOUT OF THE 25(OH)D_3–24-Hydroxylase

24R,25$(OH)_2D_3$ is the second major dihydroxylated metabolite of vitamin D_3, which is found in significant concentrations in the serum of humans (Castro-Errecaborde *et al.,* 1991; Jongen *et al.,* 1989; Nguyen *et al.,* 1979), rats (Jarnagin *et al.,* 1985), and chicks (Goff *et al.,* 1995). Although the production of 24R,25$(OH)_2D_3$ by the kidney is tightly regulated (Henry *et al.,* 1984), the biological importance of this compound is still the subject of uncertainty and question (Norman *et al.,* 1982a,b). While several possible biological roles and sites of action have been suggested for 24R,25$(OH)_2D_3$, including the regulation of parathyroid hormone release from the parathyroid gland (Canterbury *et al.,* 1978; Norman *et al.,* 1982a), most studies concerning this vitamin D metabolite have focused on its possible actions on bone biology (Nakamura *et al.,* 1992; Norman *et al.,* 1993b; Seo *et al.,* 1997a). The possible existence of a nuclear or cytosolic-binding protein for 24R,25$(OH)_2D_3$ was reported in the chick parathyroid gland (Merke *et al.,* 1981), the long bone of rat epiphysis (Corvol *et al.,* 1980), and the chick tibial fracture-healing callus (Seo *et al.,* 1996a). However, there has been no general confirmation of these early findings. Also, several more recent reports have described specific actions or accumulation of 24R,25$(OH)_2D_3$ in cartilage (Corvol *et al.,* 1980; Seo *et al.,* 1996b) and bone fracture-healing callus tissue (Lidor *et al.,* 1987; Seo *et al.,* 1997a,b).

A strain of mice deficient for the 25(OH)D-24-hydroxylase enzyme has been generated (St.Arnaud *et al.,* 1997) through homologous recombination in embryonic stem cells in order to address the physiological functions of 24R,25$(OH)_2D_3$. The targeted mutation effectively deleted the heme-binding domain of the cytochrome P450 enzyme, ensuring that the mutated allele could not produce a functional protein. Analysis of the phenotype of the knockout animals revealed fascinating and previously unrecognized roles for 24R,25$(OH)_2D_3$. About half of the mutant homozygote mice born from heterozygote females died before weaning. Bone development of those survivors was abnormal in homozygous mutants born of homozygous females. Histological analyses of the bones from these mice revealed an accumulation of unmineralized matrix at sites of intramembranous ossification, particularly the calvaria and exocortical surface of long bones. However, the growth plates from these mutant animals appeared normal, suggesting that 24R,25$(OH)_2D_3$ is not a major regulator of chondrocyte maturation *in vivo.*

Evidence for a Membrane Receptor (VDR_{mem}) for 1α,25$(OH)_2D_3$

It was originally proposed that some rapid actions of 1α,25$(OH)_2D_3$ may be mediated at the cell membrane, i.e., by a membrane receptor (Nemere *et al.,* 1984). For transcaltachia (the rapid hormonal stimulation of intestinal calcium transport), a candidate membrane receptor [VDR_{mem}] has been identified and partially purified (Nemere *et al.,* 1994). A seven-step purification of the putative VDR_{mem} has been presented where the average enrichment in binding (purification) of [^{3}H]-1,25$(OH)_2D_3$ was ≈ 4500-fold (Nemere *et al.,* 1994). The detergent-solubilized purified basal–lateral VDR_{mem} exhibited a specific and saturable binding for 1α,25$(OH)_2D_3$; the K_D was 0.72×10^{-9} *M* and the B_{max} was 0.24×10^{-12} mol/mg protein. The purified protein migrated on a Superose column with a molecular mass of ≈ 60-kDa. At the present time the VDR_{mem} must be designated as "putative" because it has not yet been cloned so as to reveal its biochemical structure.

Other laboratories have also presented evidence for the existence of a VDR_{mem}. These include presence of the VDR_{mem} in human leukemic NB4 cells (Berry *et al.,* 1999; Bhatia *et al.,* 1995), intestinal enterocytes (Lieberherr *et al.,* 1989), ROS 24/1 cells (Baran *et al.,* 1994), and chondrocyte matrix vesicles (Pedrozo *et al.,* 1999; Schwartz *et al.,* 1988); in some instances, a partial purification has been effected (Baran *et al.,* 1998). Several reviews of rapid responses to 1α,25$(OH)_2D_3$ have appeared (Nemere *et al.,* 1999; Norman, 1997).

Some have questioned what is the true physiological relevance of 1α,25$(OH)_2D_3$-mediated rapid response because no phenotype or disease has yet been described. One hypothesis advanced by Gniadecki (1998b) is that 1α,25$(OH)_2D_3$-initiated rapid responses generate signal transduction pathways, which have the end result of altering gene transcription. Certainly the ability of the VDR_{nuc} operating in the nucleus to activate/suppress gene transcription of appropriate genes is well established. However, the process of genomic signaling lacks two important characteristics. (a) Rapidity: it can take several hours to achieve the transition to a new transcriptional steady state, which requires the integrated change at the transcription level of a gene followed by translational generation of the product protein in adequate amounts and, if necessary, post-translational modifications of the protein. When the production of multiple proteins is required for the desired biological response, the time may be increased even further. (b) Modula-

tion: The fine-tuning and expansion of the initiating signal to change gene transcription. Although the primary stimulus for a biological response is principally dependent on the number of activated liganded VDR$_{nuc}$ heterodimer + coactivator complex bound to the promoter, it may be possible for other signal transduction pathways (MAP kinase activation) to modulate the final outcome. One report clearly demonstrated, via gene array analysis, how activation of MAP kinase altered the expression of 383 genes (Roberts *et al.,* 2000).

In addition, the appearance of visible phenotypes is not necessarily the *sine qua non* for physiological importance. Although it is known that VDR$_{nuc}$ exists in 33 target organs/cell types (Bouillon *et al.,* 1995), it was surprising that a VDR$_{nuc}$KO mouse could be born and, after rescue with a high Ca^{2+} diet, be essentially normal, except for the slow development of alopecia (Amling *et al.,* 1999; Yoshizawa *et al.,* 1997) and, in one strain, uterine hypoplasia (Yoshizawa *et al.,* 1997).

At least three classes of candidate VDR$_{mem}$ can be envisioned. These include receptors with intrinsic tyrosine kinase activity, receptors without tyrosine kinase activity, and receptors coupled to G proteins. An activated G protein-coupled receptor could be linked to several second messenger pathways that could lead to the ultimate activation of Raf, MEK1/MEK2, and the MAP kinases, ERK1/ERK2. It will be essential to identify those upstream second messengers that become activated when the putative VDR$_{mem}$ is occupied by the 6-s-*cis* shape of 1α,25(OH)$_2$D$_3$ and result in the activation of MAP kinase. The prime second messenger candidates that have been shown by a number of laboratories to be modulated by 1α,25(OH)$_2$D$_3$ include Shc (Gniadecki, 1996), Grb2 (Gniadecki, 1996), Src (Gniadecki, 1998a; Khare *et al.,* 1997), Ras.GTP, PLCβ (Le Mellay *et al.,* 1997), PLCγ (Khare *et al.,* 1997), PKCα (Berry *et al.,* 1996; Bissonette *et al.,* 1994), and PKCδ (Berry *et al.,* 1996; Bissonette *et al.,* 1994). This will undoubtedly be an area of intensive investigation in the future.

Preferred Ligand Shape for VDR$_{nuc}$, VDR$_{mem}$, and DBP

Table V summarizes and contrasts the ligand structural preferences of the nuclear receptor, the VDR$_{nuc}$, the putative

Table V Ligand Structural Preferences of the Nuclear Receptor and Putative Membrane Receptor for 1α, 25(OH)$_2$D$_3$ and the Vitamin D-Binding Protein[a]

Property	DBP	VDR$_{nuc}$	VDR$_{mem}$
K_D for 1α,25(OH)$_2$D$_3$	5×10^{-7} *M*	$1-4 \times 10^{-10}$ *M*	$2-7 \times 10^{-10}$ *M*
Number of amino acids (human form)	458	427	Not known
Molecular mass protein	58 kDa	51 kDa	≈ 60 kDa
Agonist B-ring orientation	Neither planar 6-s-*cis* (JN) nor planar 6-s-*trans* (JB) shapes bind well	Bowl-shaped 11 6-s-*trans* shape with A ring 30° above the plane of the C/D rings (from X-ray crystallography; see Fig. 11)	Planar 6-s-*cis* conformer (JN) active Planar-s-*trans* (JB) not functional (see Fig. 4)
A ring hydroxy C-1 C-3	Binding to DBP	Calbindin-D$_{28k}$ induction (genomic response)	Transcaltachia (rapid response)
α β	1α,25(OH)$_2$D$_3$ = 100%	1α,25(OH)$_2$D$_3$ = 100%	1α,25(OH)$_2$D$_3$ = 100%
α α	800% (HJ)	10%	75%
β α	6570% (HH)	1%	25%
β β	450% (HL)	1%	0%; but is an antagonist
Side chain properties	Rigid; binding enhanced with aromatic ring (DF)	Semirigid	Not yet studied
Side chain orientation at C-20	Not known	20S more active (analog IE) than 20R (analog C)	Both 20S and 20R ≅ active
Antagonist analog	Not relevant	Analog MK	Analog HL
Antagonist functional shape	Not relevant	Side chain present as a cyclic lactone, which causes a conformational change in the VDR$_{nuc.}$	Probably planar 6-s-*cis*
General reference citations	Bogaerts *et al.* (2000); Swamy *et al.* (2000)	Norman *et al.* (1999); Van Baelen *et al.* (1980)	Norman *et al.* (1997, 2000a)

[a]In all studies described in this table, the conformationally flexible 1α,25(OH)$_2$D$_3$ was the reference compound where its value in each assay is by definition 100%. The rapid responses studied to define the preferred B-ring orientation for the VDR$_{mem}$ included transcaltachia in the perfused chick intestine and $^{45}Ca^{2+}$ influx in ROS 17/2.8 cells (Norman *et al.,* 1997). The genomic responses used to define the preferred B-ring orientation included transcriptional activation of osteocalcin in MG-63 cells grown in culture (Norman *et al.,* 1997). Additional information on the analogs specified by the two-letter codes (*e.g.,* HL) are provided in Table VI and the structures are presented in Fig. 12.

membrane receptor, the VDR_{mem}, as well as for the plasma transport vitamin D-binding protein, DBP. It is apparent that each of these proteins has a unique ligand-binding domain, which specify that their preferred ligand conformations for the conformationally flexible $1\alpha,25(OH)_2D_3$ are all strikingly different from one another.

It has been generally assumed for receptor–ligand interactions that the ligand is frozen in a single conformation dictated by both the structural constraints of the ligand and the three-dimensional architecture of the peptide chains that create the ligand binding domain of the receptor(s). Ligands for the TR and RAR, as for the VDR_{nuc}, are all conformationally flexible, and the X-ray crystallographic structure for each receptor has revealed that *only one definitive conformer* was present in their ligand-binding domain (Renaud *et al.,* 1995; Wagner *et al.,* 1995). This clearly demonstrates that steroid receptors can capture one ligand conformation from a large population of flexible conformers.

Figure 11 illustrates the preferred conformation of the agonist ligands for the VDR_{nuc} and the VDR_{mem}. It is now known from the X-ray structure of the VDR_{nuc} LBD with $1\alpha,25(OH)_2D_3$ present as a ligand that the preferred agonist

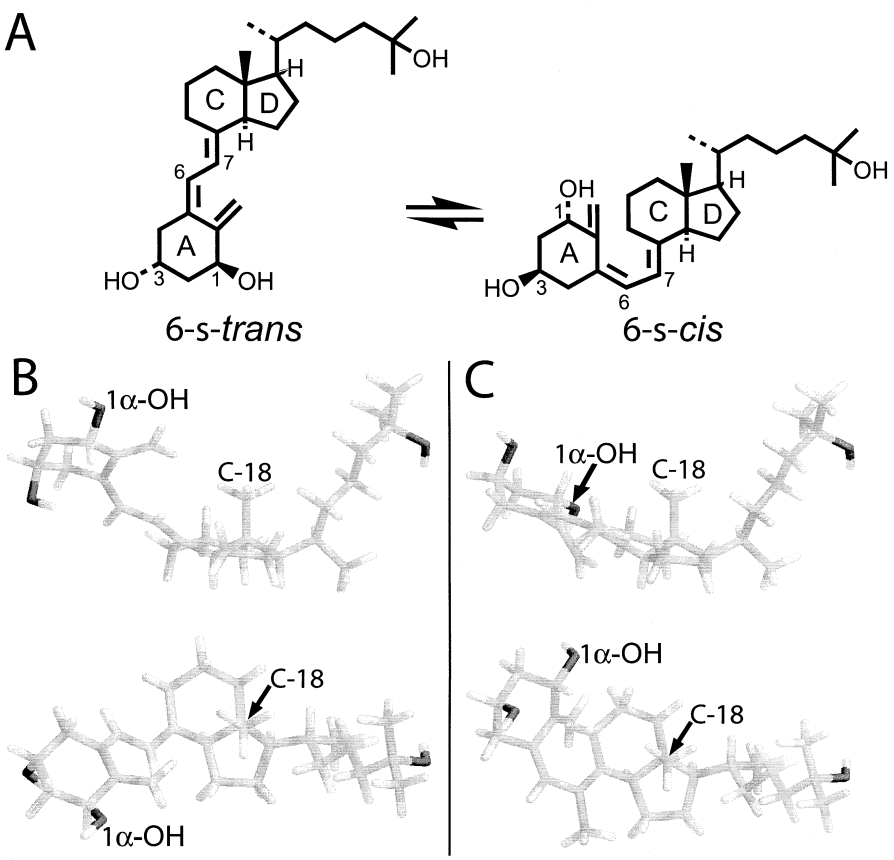

Figure 11 Preferred optimal conformation of agonist ligands for VDR_{nuc} genomic responses (left) and VDR_{mem} rapid responses (right). The three hydroxyl groups in each molecule are shown as black sticks, whereas the remainder of the molecule is shown in gray stick form. For B and C, upper representations show the side view or "edge" representation of the C/D rings + side chain, whereas the lower representations have been rotated 90° toward the viewer. (A) Standard representation of $1\alpha,25(OH)_2D_3$ illustrating the consequences of rotation around the 6,7 carbon bond to generate a population of shapes, including the extremes of 6-s-*trans* and 6-s-*cis* conformers. (B) The stick representation of the shape of $1\alpha,25(OH)_2D_3$ that is present as a ligand in the VDR_{nuc} as revealed by X-ray crystallography (Rochel *et al.,* 2000). The characteristic feature of the ligand in the LBD in the "edge" representation is the bowl-shaped twisted 6-s-*trans* shape with the A ring 30° above the plane of the C/D rings. In addition, the A ring is present as the chair conformer-B, where the 1α-OH is equatorial and the 3β-OH is axial (see Fig. 2C). (C) Shape of the 6-s-*cis* conformer of $1\alpha,25(OH)_2D_3$ is that proposed to be the optimal ligand for the VDR_{mem} as revealed by analog studies (Norman *et al.,* 1993c, 1997). The A ring is present as a chair conformer-B (see Fig. 2C) where the 1α-OH is equatorial and the 3β-OH is axial (see Fig. 2C). The 6-s-*cis*-locked $1\alpha,25(OH)_2$–7-dehydrocholesterol (analog JN; see Fig. 12) is a full agonist of all rapid responses studied thus far (see Tables II and VI). Here the A ring is virtually in the same plane as the C/D rings. The difference in ligand shape for the VDR_{nuc} and VDR_{mem} is particularly evident in the two lower stick representations of B and C. Here the C/D rings + side chain are in the same precise orientation for both representations (they could be superimposed), but the A ring of the VDR_{mem} is planar above the C/D rings, whereas that of the VDR_{nuc} is below the C/D rings.

ligand shape is that represented by a twisted 6-s-*trans* bowl (Rochel *et al.,* 2000). In contrast, an extensive series of studies support the conclusion that the preferred ligand shape for the VDR$_{mem}$ is that represented by a 6-s-*cis*-locked analog such as represented by analogs JM or JN (Norman *et al.,* 1993c, 1997; Zanello *et al.,* 1997). Table VI summarizes the properties of two 6-s-*cis* conformationally restricted analogs, JM and JN, which have achieved prominence in defining the preferred shape for the VDR$_{mem}$.

The preferred ligand for DBP is 25(OH)D$_3$, whereas the preferred ligand of the VDR$_{nuc}$ is 1α,25(OH)$_2$D$_3$. Thus, 25(OH)D$_3$ binds 668-fold more tightly to DBP than 1α,25(OH)$_2$D$_3$. In contrast, 1α,25(OH)$_2$D$_3$ binds 668-fold more tightly to the VDR$_{nuc}$ than 25(OH)D$_3$ (Bishop *et al.,* 1994). As noted in Tables V and VI, some, but not all, of the DBP ligand preferences are somewhat similar to those of the VDR$_{nuc.}$ DBP, like the VDR$_{nuc,}$ prefers neither the precise 6-s-*cis* nor 6-s-*trans* shapes of the B ring, as represented by analogs JN and JB, respectively, but an intermediate shape comparable to analog JW [see Table VI (Norman *et al.,* 1997)]. In JW the plane of the A ring is below the plane of the C/D rings, as dictated by the R orientation of carbon 6; when this is inverted to 6S (as analog JV) so that the A ring is above the plane of the C/D ring, the DBP RCI is reduced ≈20-fold.

Furthermore, some analogs with side chain rigidity have an enhanced binding to both VDR$_{nuc}$ and DBP; the side chain analog LA [(22R)-1α,25(OH)$_2$-16,22,23-triene-D$_3$] with a rigid allene functionality binds 1.54-fold better than 1α,25(OH)$_2$D$_3$ to the VDR$_{nuc}$ (Bouillon *et al.,* 1995), whereas analog DF [22-*p*(-hydroxyphenyl)-23,24,25,26,27-pentanor-1α-(OH)-D$_3$], with an aromatic ring, binds 19.9-fold better than 1α,25(OH)$_2$D$_3$ to DBP (Bishop *et al.,* 1991, 1994). Impressively, analog JX [22-*p*(-hydroxyphenyl)-23,24,25,26,27-pentanor-D$_3$], an analog without a 1α-hydroxyl but with a side chain aromatic ring, binds 2110-fold better than 1α,25(OH)$_2$D$_3$ and 3.15-fold better than 25(OH)D$_3$ to DBP. As summarized in Table V, there are also important differences in ligand affinity between DBP and VDR$_{nuc}$ that are based on the orientation of the carbon 1- and 3-hydroxyls of the A ring. Thus, analog HJ, which has 1α-OH, 3α-OH hydroxyls, binds 8-fold better to DBP than 1α,25(OH)$_2$D$_3$ with 1α-OH, 3β-OH hydroxyls. Similarly, analog HH with a 1β-OH, 3β-OH, binds 65-fold better to DBP than 1α,25(OH)$_2$D$_3$. Thus it is clear that the three-dimensional structure of the DBP LBD imposes unique constraints on the conformation of its preferred ligand, which are different from that of the VDR$_{nuc}$ LBD.

Analogs of 1α, 25(OH)$_2$D$_3$

Extensive efforts in many laboratories and pharmaceutical companies had already generated hundreds of analogs of 1α,25(OH)$_2$D$_3$, which have collectively provided insight into the ligand specificities of the VDR$_{nuc}$ LBD for treatment. Table VI summarizes the properties of several conformationally flexible analogs, which have achieved prominence; all of these conformationally flexible analogs in principal can assume the twisted 6-s-*trans* bowl conformation. The family of 20-epi analogs, represented by ID and IE, has been intriguing; inversion of orientation of the side chain at C-20 results in analogs that are 500- to 200-fold more potent than 1α,25(OH)$_2$D$_3$ with respect to activation of gene expression (Liu *et al.,* 1997; Peleg *et al.,* 1995). Analog KH, which has two eight-carbon side chains, surprisingly is an effective ligand for the VDR$_{nuc}$ (Norman *et al.,* 2000b) (Fig. 12).

An important pair of discoveries was of two analogs of 1α,25(OH)$_2$D$_3$ selectively functioning antagonists either of the VDR$_{mem}$ or the VDR$_{nuc}$. Analog HL is a specific antagonist of rapid responses; these include inhibition of transcaltachia (Norman *et al.,* 1993a), $^{45}Ca^{2+}$ uptake into ROS 17/2.8 cells (Norman *et al.,* 1997), activation of chloride currents in ROS 17/2.8 cells (Zanello *et al.,* 1997), and MAP kinase activation in NB4 cells (Song *et al.,* 1998). In contrast, analog MK is a specific antagonist of the VDR$_{nuc}$ and, when bound to the receptor, blocks the necessary conformation change of the receptor protein LBD helix 12 (see Fig. 9) essential for transactivation. Thus MK blocks gene expression both in whole cells (Miura *et al.,* 1999b) and *in vivo* in the rat (Ishizuka *et al.,* 2000).

Table VI also summarizes the interesting properties of 10 analogs of 1α,25(OH)$_2$D$_3$ that are either approved drugs or are under evaluation for drug development for a variety of vitamin D-related diseases, including osteoporosis, renal osteodystrophy, psoriasis, immunosuppression, and the bone diseases of osteoporosis and renal osteodystrophy (Bouillon *et al.,* 1995). Without exception, these analogs have been identified based on their affinity for the VDR$_{nuc}$ and usually because of a separation of *in vivo* calcemic effects from cell differentiation effects. 1α,25(OH)$_2$D$_3$ is approved for drug use in the diseases of renal osteodystrophy (in 1977), neonatal hypocalcemia, and osteoporosis (in 17 countries of the world, but not in the United States).

Two 1α,25(OH)$_2$D$_3$ analogs are available commercially for the topical treatment of psoriasis. Leo Pharmaceutical's Dovonex (BT) has been approved for clinical use in both Europe (1992) and the United States (1995), whereas Teijin's Bonalfa (CT) was approved for clinical use in Europe (1994). It is anticipated that Chugai's Maxacalcitol (EU) may in the future be approved in Japan for the treatment of psoriasis. All three analogs have structural modifications in their side chain, which tend to improve their antiproliferative and anti-inflammatory effects while diminishing their calcemic effects. Abbott Laboratory's Zemplar (MA) received approval in the United States (1998) for systemic use in the treatment of the secondary hyperparathyroidism associated with chronic renal failure. MA has the side chain of vitamin D$_2$ as well as loss of carbon 19.

Many 1α,25(OH)$_2$D$_3$ analogs are currently under evaluation with regard to their proposed use for treatment of cancers, including acute myeloid leukemia (V, LH), breast (EU, IC, ZHA) or prostate, and colon (LH). These analogs

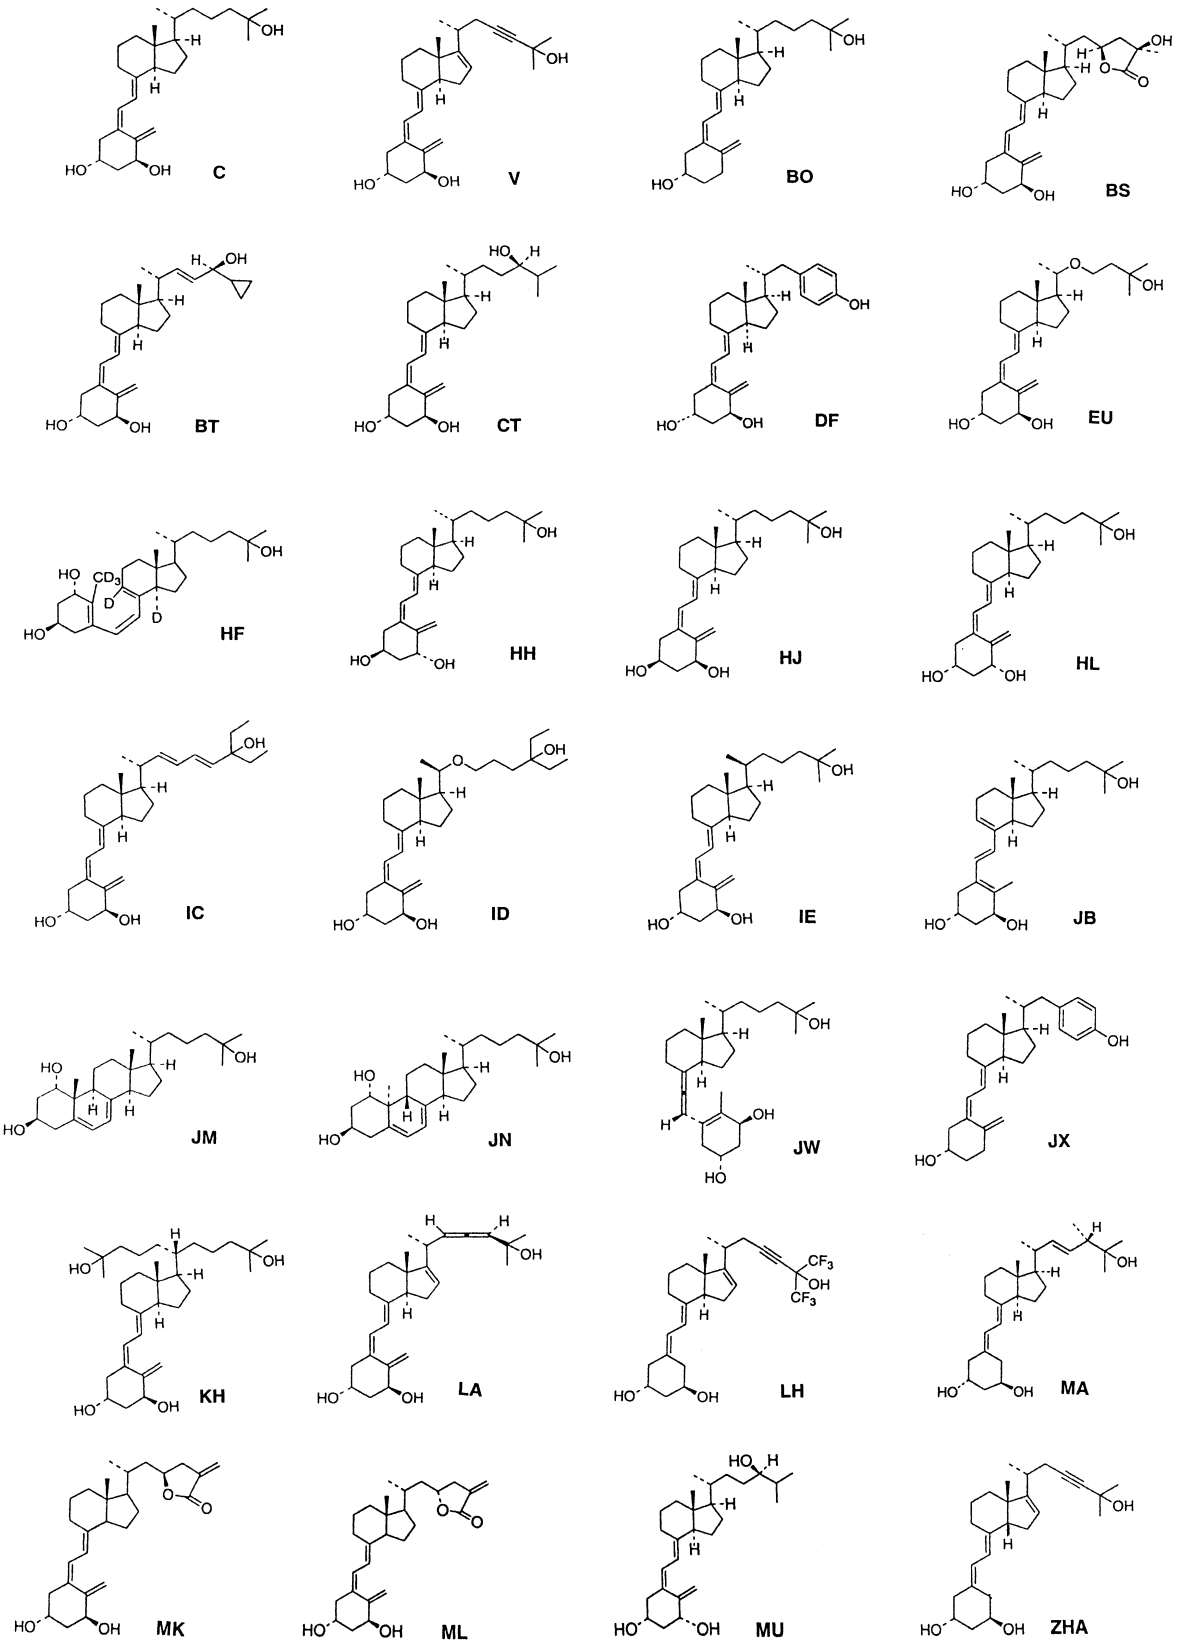

Figure 12 Important $1\alpha,25(OH)_2D_3$ metabolites, agonist analogs, including existing drugs or potential drug candidates, and antagonist analogs. Table VI presents the chemical name and summarizes the important properties of all the vitamin D-related steroids presented here and in the text.

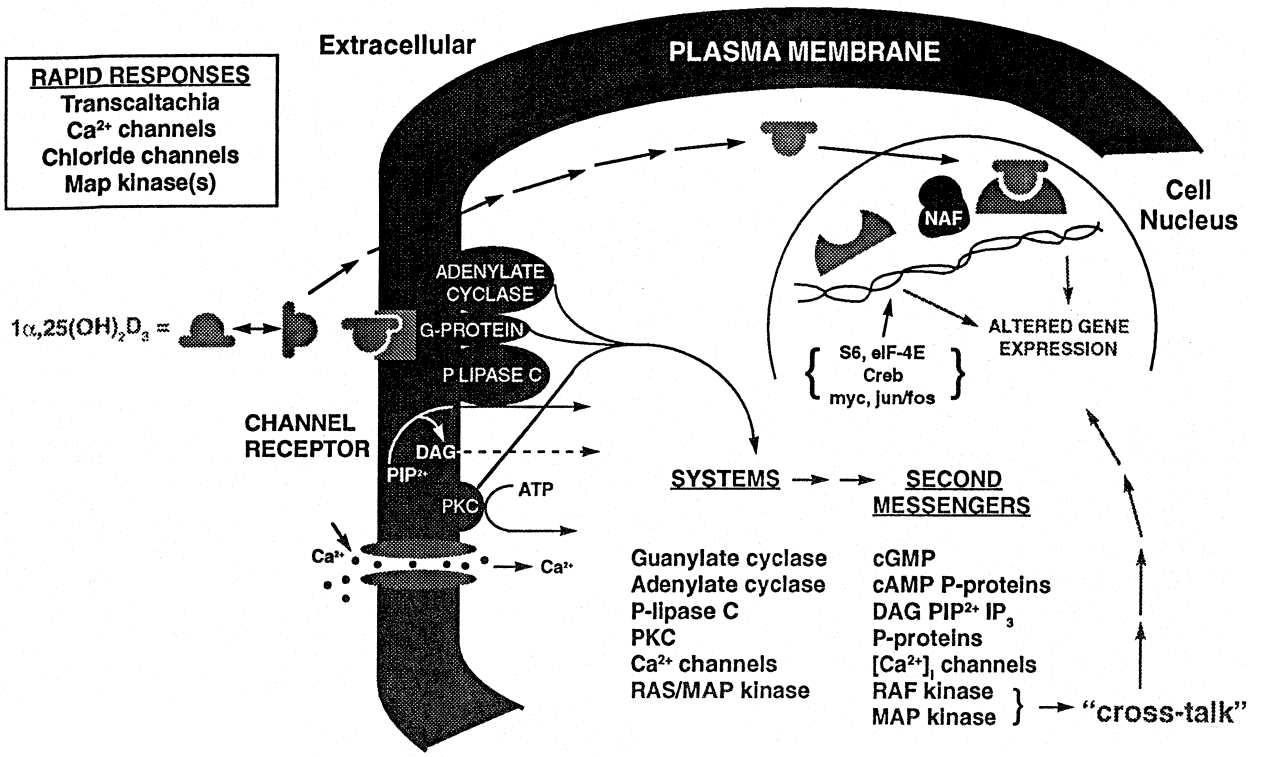

Figure 13 1α,25(OH)$_2$D$_3$ and signal transduction: a working model. The upper left inset lists the rapid responses generated by 1α,25(OH)$_2$D$_3$ whose actions are believed to be described by this schematic model. 1α,25(OH)$_2$D$_3$ can initiate biological responses via both its nuclear receptor and a putative cell membrane receptor (Nemere *et al.,* 1994), which generates rapidly the appearance of second messengers, some of which modulate via cross-talk selective events in the nucleus.

uniformly are significantly more potent than 1α,25(OH)$_2$D$_3$ with respect to their ability to inhibit cell proliferation and promote cell differentiation; all these analogs are currently being studied in animal models of the indicated cancer.

Based on the presence of the VDR$_{nuc}$ in all cells of the immune system, especially antigen-presenting cells (macrophages, and dendritic cells) and activated T lymphocytes, 1α,25(OH)$_2$D$_3$ has been shown to be a potent immunosuppressive agent (Lemire,1997). Thus it is not surprising that 1α,25(OH)$_2$D$_3$ analogs are proposed (ID) for clinical use in autoimmune graft rejection (Bertolini *et al.,* 1999) and the treatment of type I diabetes or prevention of destruction of transplanted islets in type 1 diabetes (Lemire, 1997).

Summary

A working model of a target cell for 1α,25(OH)$_2$D$_3$ is shown in Fig. 13. The signal transduction pathways linked to the VDR$_{nuc}$ and the VDR$_{mem}$ are illustrated

In contrast to classical steroid hormones, like estradiol, which have only one shape, it is apparent that 1α,25(OH)$_2$D$_3$ can generate at least three functionally different shapes, which effectively accommodate the ligand-binding domain requirements of the VDR$_{nuc}$, VDR$_{mem}$, and DBP proteins. With the identification of the target optimal shapes of ligands for the DBP, VDR$_{mem}$ and VDR$_{nuc}$, it is to be anticipated that chemists will continue their synthetic efforts to prepare conformationally restricted analogs that select one target shape for intensive biological studies. These new structures certainly will include nonsteroidal analogs that lack the classic A, seco B, C, D ring structure of 1α,25-(OH)$_2$D$_3$, but which still achieve a significant binding to the appropriate target protein; two examples of reports in this arena are already available (Boehm *et al.,* 1999; Verstuyf *et al.,* 1998). Future structure–function studies are awaited with interest.

It will also be interesting to observe over the next decade to what further extent the manipulation of 1α,25(OH)$_2$D$_3$ structure–function relationships is successful with regard to further development of new drugs that display target organ specificity of action but are devoid of undesirable calcemic effects.

CHAPTER 32

Vitamin D Gene Regulation

Sylvia Christakos

Department of Biochemistry and Molecular Biology, University of Medicine and Dentistry of New Jersey, New Jersey Medical School, Newark, New Jersey 07103

Vitamin D Metabolism

Vitamin D is a principal factor required for the development and maintenance of bone as well as for maintaining normal calcium and phosphorus homeostasis. In addition, evidence has indicated the involvement of vitamin D in a number of diverse cellular processes, including effects on differentiation and cell proliferation, on hormone secretion, and on the immune system (Darwish and DeLuca, 1993). For vitamin D to affect mineral metabolism as well as numerous other systems, it must first be metabolized to its active form. Vitamin D, which is taken in the diet or is synthesized in the skin from 7-dehydrocholesterol in a reaction catalyzed by ultraviolet irradiation, is transported in the blood by the vitamin D-binding protein to the liver. In the liver, vitamin D is hydroxylated at C-25, resulting in the formation of 25-hydroxyvitamin D_3[25(OH)D_3]. 25-Hydroxy-vitamin D proceeds to the kidney via the serum vitamin D-binding protein. In the proximal convoluted and straight tubules of the kidney nephron, 25(OH)D_3 is hydroxylated at the α position of carbon 1 of the A ring, resulting in the formation of the hormonally active form of vitamin D, 1,25-dihydroxyvitamin D_3 [1,25$(OH)_2D_3$]. The kidney can also produce 24,25-dihydroxyvitamin D_3[24,25$(OH)_2D_3$]. 24-Hydroxylase [24 (OH) ase] has been reported to be capable of hydroxylating the 24 position of both 25(OH)D_3 and 1,25$(OH)_2D_3$ (Darwish and DeLuca, 1993; Kumar, 1984) (see Fig. 1). Because the K_m value of 24(OH)ase for 1,25$(OH)_2D_3$ is 1/5 to 1/30 of the K_m value for 25(OH)D_3 (Inaba *et al.,* 1991; Tomon *et al.,* 1990), it has been suggested that the preferred substrate for 24(OH)ase *in vivo* may be 1,25$(OH)_2D_3$ rather than 25(OH)D_3 (Shinki *et al.,* 1992). Studies using mice with a targeted inactivating mutation of the 24(OH)ase gene [24(OH)ase] null-mutant mice] have provided the first direct *in vivo* evidence for a role for 24(OH)ase in the catabolism of 1,25$(OH)_2D_3$ (St-Arnaud *et al.,* 2000). Both chronic and acute treatment with 1,25$(OH)_2D_3$ resulted in an inability of 24(OH)ase-deficient mice to clear 1,25$(OH)_2D_3$ from their bloodstream. Impaired bone formation at specific sites (calvaria, mandible, clavicle, and periosteum of long bones) was also noted in the deficient mice. 24,25-Dihydroxyvitamin D_3 supplementation failed to correct most of the bone abnormalities. Because crossing 24(OH)ase-deficient mice to vitamin D receptor (VDR)-ablated mice totally rescued the bone phenotype, the authors suggested that elevated 1,25$(OH)_2D_3$ levels acting through VDR at specific sites and not the absence of 24,25$(OH)_2D_3$, were responsible for the abnormalities observed in bone development. Whether 24,25$(OH)_2D_3$ is an active metabolite has been a matter of debate. However, most studies indicate that 24,25$(OH)_2D_3$ appears to be relatively inactive when compared with 1,25$(OH)_2D_3$.

The production of 1,25$(OH)_2D_3$ and 24,25$(OH)_2D_3$ is under stringent control. Calcium and phosphorus deprivation results in enhanced production of 1,25$(OH)_2D_3$ (Henry and Norman, 1984). Phosphorus can have a direct effect on the kidney (Fukase *et al.,* 1982) and may also interact with a pituitary factor, which has been suggested to be growth hormone (Gray and Garthwaite, 1985). Elevated PTH resulting from calcium deprivation may be the primary signal mediating the calcium regulation of 1,25$(OH)_2D_3$ synthesis (Boyle *et al.,* 1972; Henry, 1985; Murayama *et al.,* 1999). However, high calcium has been reported to have a direct inhibitory effect on 1-hydroxylation (Fukase *et al.,* 1982). In addition to calcium and phosphorus, 1,25-dihydroxyvitamin D_3 also regulates its own production by inhibiting 1-hydroxylase. The synthesis of 24,25$(OH)_2D_3$ has been reported to be reciprocally regulated when compared with the synthesis of 1,25$(OH)_2D_3$ [stimulated by 1,25$(OH)_2D_3$, and inhibited by low calcium and PTH] (Henry and Norman, 1984). In addition to PTH, phospho-

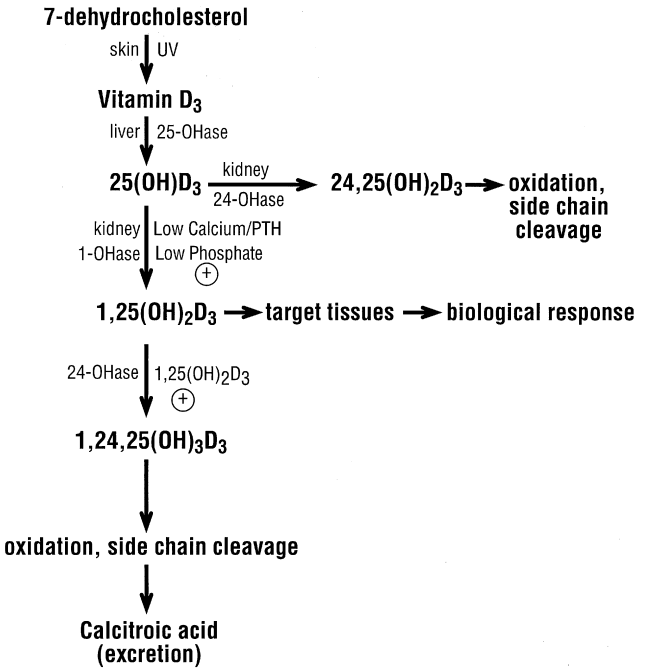

Figure 1 The metabolic pathway for vitamin D.

rus, calcium, and $1,25(OH)_2D_3$, it has been reported that sex hormones can influence production of the renal vitamin D hydroxylases. Estrogens alone or when combined with androgens have been reported to stimulate $1,25(OH)_2D_3$ production, and estradiol has been reported to suppress $24,25(OH)_2D_3$ synthesis in avian species (Pike *et al.,* 1978; Tanaka *et al.,* 1976). It is not clear, however, whether a similar relationship exists between sex steroids and vitamin D hydroxylases in mammalian species (Baski and Kenny, 1978).

Serum $1,25(OH)_2D_3$ levels and the capacity of the kidney to hydroxylate $25(OH)D_3$ to $1,25(OH)_2D_3$ have been reported to decline with age (Armbrecht *et al.,* 1980). In addition, an increase in renal 24-hydroxylase gene expression and an increase in the clearance of $1,25(OH)_2D_3$ with aging have been reported (Matkovits and Christakos, 1995; Wada *et al.,* 1992). These findings have implications concerning the etiology of osteoporosis and suggest that the combined effect of a decline in the ability of the kidney to synthesize $1,25(OH)_2D_3$ and an increase in the renal metabolism of $1,25(OH)_2D_3$ may contribute to age-related bone loss. Whether there is an interrelationship between the decline of sex steroids with age and age-related changes in the 1- and 24-hydroxylase enzymes remains to be determined.

Genomic Mechanism of Action of $1,25(OH)_2D_3$

1,25-Dihydroxyvitamin D_3, similar to other steroid hormones, is known to act by binding stereospecifically to a high-affinity, low-capacity intracellular receptor protein (vitamin D receptor or VDR), resulting in the concentration of the $1,25(OH)_2D_3$ receptor complex in the target cell nucleus and the activation or repression of the transcription of target genes (Darwish and DeLuca, 1993; Haussler *et al.,* 1998). Although the exact mechanisms involved in mediating the effects of $1,25(OH)_2D_3$ in numerous different systems are not clearly defined at this time, the VDR appears to be of major importance (Haussler *et al.,* 1998).

Role of $1,25(OH)_2D_3$ in Classical Target Tissues Bone

Exactly how $1,25(OH)_2D_3$ affects mineral homeostasis is a subject of continuing investigation. It has been suggested that the antirachitic action of $1,25(OH)_2D_3$ is indirect and the result of increased intestinal absorption of calcium and phosphorus by $1,25(OH)_2D_3$, thus resulting in their increased availability for incorporation into bone (Underwood and DeLuca, 1984; Weinstein *et al.,* 1984). Studies using VDR-ablated mice (VDR knockout mice)also suggest that a principal role of the vitamin D receptor in skeletal homeostasis is its role in intestinal calcium absorption (Li *et al.,* 1997; Yoshizawa *et al.,* 1997; Amling *et al.,* 1999). VDR knockout mice were found to be phenotypically normal at birth, but developed hypocalcemia, hyperparathyroidism, and alopecia within the first month of life. Rickets and osteomalacia were seen by day 35. When VDR knockout mice were fed a calcium/phosphorus/lactose-enriched diet, serum-ionized calcium levels were normalized, the development of hyperparathyroidism was prevented, and the animals did not develop rickets or osteomalacia, although alopecia was still observed. Thus, it was suggested that skeletal consequences of VDR ablation are due primarily to impaired intestinal calcium absorption. *In vitro* studies, however, have shown that $1,25(OH)_2D_3$ can resorb bone (Raisz *et al.,* 1972). Although $1,25(OH)_2D_3$ stimulates the formation of bone-resorbing osteoclasts, receptors for $1,25(OH)_2D_3$ are not present in osteoclasts but rather in osteoprogenitor cells, osteoblast precursors, and mature osteoblasts. Stimulation of osteoclast formation by $1,25(OH)_2D_3$ requires cell-to-cell contact between osteoblastic cells and osteoclast precursors and involves upregulation by $1,25(OH)_2D_3$ in osteoblastic cells of osteoclast differentiating factor (or osteoprotegerin ligand; see Chapter 7; Takeda *et al.,* 1999; Yasuda *et al.,* 1998a,b). Osteoclast differentiating factor/osteoprotegerin ligand, induced by $1,25(OH)_2D_3$, as well as by PTH, interleukin 11, and prostaglandin E_2 in osteoblasts/stromal cells, is a member of the membrane-associated tumor necrosis factor ligand family that enhances osteoclast formation by mediating direct interactions between osteoblast/stromal cells and osteoclast precursor cells. Osteoclastogenesis inhibitory factor/osteoprotegerin, a member of the tumor necrosis factor receptor family, is a soluble decoy receptor for osteoprotegerin ligand that antagonizes osteoprotegerin ligand function, thus blocking osteoclastogenesis. Osteoprotegerin is downregulated by $1,25(OH)_2D_3$ (Yasuda *et al.,* 1998a).

In addition to increasing the availability of calcium and phosphorus for incorporation into bone and stimulating

osteoclast formation, $1,25(OH)_2D_3$ also has a direct effect on osteoblast-related functions. For example, $1,25(OH)_2D_3$ has been reported to stimulate the production of osteocalcin (Price and Baukol, 1980) and osteopontin (Prince and Butler, 1987) in osteoblastic cells. The exact function of osteocalcin, a noncollagenous protein associated with the mineralized matrix, is not known. However, increased synthesis of osteocalcin has been positively correlated with new bone formation (Hauschka *et al.,* 1989; also see Chapter 5). Concerning osteopontin, also a major noncollagenous bone protein, it has been suggested that this secreted, glycosylated phosphoprotein is important for resorption of the bone matrix (the OPN-$\alpha_v\beta_3$ integrin interaction has been reported to be important for the adherence of the osteoclast to bone), as well as for mineralization (Denhardt and Guo, 1993; also see Chapter 15). Studies in OPN-deficient mice indicate significantly less osteoclasts in the deficient mice, confirming the *in vitro* findings of a role for OPN in osteoclast recruitment (Asou *et al.,* 1999). The Osf2/Cbfa1 transcription factor, identified as a transcriptional regulator of osteoblast differentiation, is involved in regulation of the expression of OPN and OC and has also been reported to be regulated by $1,25(OH)_2D_3$ (Ducy *et al.,* 1997; Javed *et al.,* 1999). Although the regulation of OPN, osteocalcin, and Osf2/Cbfa1 by $1,25(OH)_2D_3$ provides evidence for a role of $1,25(OH)_2D_3$ in osteoblast function, further studies are needed to define the interrelationship between the regulation by $1,25(OH)_2D_3$ of these proteins and the process of bone remodeling mediated by the osteoblast.

Intestine

In addition to its effect on bone, another extensively studied action of $1,25(OH)_2D_3$ is the stimulation of intestinal calcium absorption (Wasserman and Fullmer, 1995). Although the exact mechanisms involved in this process have still not been defined, it has been suggested that the calcium absorptive process occurs in three phases. The first phase, which may occur by nongenomic mechanisms, involves calcium transfer into the cell. The second phase occurs more slowly and involves the movement of calcium through the cell interior. It has been suggested that the interaction of $1,25(OH)_2D_3$ with the intestinal VDR and the genomic-mediated upregulation of a calcium-binding protein, known as calbindin, occurs during this phase. One of the most pronounced effects of $1,25(OH)_2D_3$ is increased synthesis of calbindin [for reviews see Christakos (1995) and Christakos *et al.* (1989)]. Two major subclasses of calbindin have been described: a protein of a molecular weight of ~9000 (calbindin-D_{9k}) and a protein with a molecular weight of ~ 28,000 (calbindin-D_{28k}). Calbindin-D_{9k} has two calcium-binding domains, has been observed only in mammals, and is present in highest concentration in mammalian intestine. Calbindin- D_{28k}, unlike calbindin-D_{9k}, is highly conserved in evolution and has four functional high-affinity calcium-binding sites. Calbindin-D_{28k} is present in highest concentrations in avian intestine and in avian and mammalian kidney, brain, and pancreas. There is no amino acid sequence homology between calbindin-D_{9k} and calbindin-D_{28k}. In VDR-ablated mice, which demonstrate impaired intestinal calcium absorption, calbindin-D_{9k} mRNA is reduced dramatically (Li *et al.,* 1998). It has been suggested that the role of intestinal calbindin in the second phase of the intestinal calcium absorptive process is to facilitate transcellular calcium diffusion (Wasserman and Fulllmer, 1995). Studies using analogs of $1,25(OH)_2D_3$ suggest that there need not be a direct correlation between calbindin induction and stimulation of intestinal calcium transport. Intestinal calbindin-D_{9k} mRNA but not intestinal calcium transport has been reported to be induced by $1,25(OH)_2D_3$ 24-homologues (Krisinger *et al.,* 1991). In addition, 1,25,28trihydroxyvitamin D_2 has been found to have no effect on intestinal calcium absorption but to result in a significant induction in rat intestinal calbindin-D_{9k} mRNA and protein (Wang *et al.,* 1993). These findings provide evidence that calbindin alone is not responsible for the $1,25(OH)_2D_3$-mediated intestinal transport of calcium. Although immunocytochemical evidence has indicated that calbindin is localized predominantly in the cytoplasm and is not associated with cellular membranes, evidence has suggested that some calbindin can be localized inside small vesicles and lysosome structures of the chick intestinal cell (Nemere *et al.,* 1991). Calbindin was also found to be associated with filamentous elements that can be isolated with tubules and microtubules of the chick small intestine (Nemere *et al.,* 1991). It was suggested that changes in the cellular localization of calbindin are involved dynamically in $1,25(OH)_2D_3$-dependent calcium transport in the intestine. In addition to acting as a facilitator of intestinal calcium diffusion, it is also possible that calbindin in the intestine may act as an intracellular buffer to prevent toxic levels of calcium from accumulating in the intestinal cell during $1,25(OH)_2D_3$-dependent transcellular calcium transport (Christakos *et al.,* 1989).

The third phase of $1,25(OH)_2D_3$-dependent intestinal calcium transport is calcium extrusion from the intestinal cell, which involves calcium transport against a concentration gradient. The intestinal plasma membrane calcium pump (PMCA-1) and PMCA-1mRNA have been shown to be stimulated by $1,25(OH)_2D_3$ in vitamin D-deficient rats and chicks, suggesting for the first time that the intestinal calcium absorptive process may involve a direct effect of $1,25(OH)_2D_3$ on calcium pump expression (Cai *et al.,* 1993; Wasserman *et al.,* 1992; Zelinski *et al.,* 1991). Although $1,25(OH)_2D_3$ has been reported to affect transcription of the intestinal PMCA gene, the mechanisms involved in this regulation remain to be determined. Further studies concerning the interrelationship between the vitamin D endocrine system and the intestinal calcium pump should result in a better understanding of additional factors involved in $1,25(OH)_2D_3$-mediated intestinal calcium transport.

Kidney

In addition to bone and intestine, a third target tissue involved in the regulation by $1,25(OH)_2D_3$ of mineral homeostasis is the kidney. Although there is some controversy

concerning the role of $1,25(OH)_2D_3$ in renal calcium transport, micropuncture data, as well as studies using a mouse distal-convoluted tubule cell line, have indicated that vitamin D metabolites can enhance the stimulatory effect of PTH on calcium transport in the distal nephron (Friedman and Gesek, 1993; Winaver *et al.,* 1980).Most recent studies have provided evidence that $1,25(OH)_2D_3$ increases PTH receptor mRNA and binding activity in distal tubule cells, providing a mechanism whereby $1,25(OH)_2D_3$ enhances the action of PTH (Sneddon *et al.,* 1998). In the mouse, both vitamin D-dependent calcium-binding proteins (calbindin-D_{9k} and calbindin- D_{28k}) have been reported to be localized in the distal nephron (distal convoluted tubule, connecting tubule, and cortical collecting tubule) (Rhoten *et al.,* 1985). Kinetic analysis has suggested that the two proteins affect renal calcium reabsorption by different mechanisms. Calbindin-D_{28k} stimulates the high-affinity system in the distal luminal membrane (Bouhtiauy *et al.,* 1994a), whereas calbindin-D_{9k} was found to enhance the ATP-dependent calcium transport of the basolateral membrane (Bouhtiauy *et al.,* 1994b). These findings provide evidence for a role for calbindins in vitamin D-dependent calcium transport processes in the kidney. Studies related to the cloning of a putative apical calcium channel in $1,25(OH)_2D_3$ responsive epithelia (the proximal duodenum as well as the distal tubule and placenta) have suggested a mechanism of calcium entry into $1,25(OH)_2D_3$ responsive epithelia (Hoenderop *et al.,* 1999; Vennekens *et al.,* 2000). It will be of interest in future studies to examine whether calbindin-D_{28k} affects calcium entry by interacting directly with an apical calcium entry channel or whether calbindin can affect other proteins involved in regulating the channel. Thus, $1,25(OH)_2D_3$ may affect calcium transport in the distal tubule by enhancing the action of PTH and by inducing the calbindins. In addition to calbindins, the plasma membrane calcium pump has also been localized immunocytochemically exclusively to the distal tubule and to the collecting duct (Borke *et al.,* 1988). However, the interrelationship between the renal calcium pump and $1,25(OH)_2D_3$ is not clear at this time. In addition to the suggested role of $1,25(OH)_2D_3$ in the tubular reabsorption of calcium, another important effect of $1,25(OH)_2D_3$ in the kidney is inhibition of the $25(OH)D_3$ 1α-hydroxylase enzyme and stimulation of the 24-hydroxylase enzyme. Both the 1α-hydroxylase and 24(OH)ase genes have been cloned, and studies indicate that they are regulated through liganded VDR (Takeyama *et al.,* 1997; Shinki *et al.,* 1997; Murayama *et al.,* 1999; Kerry *et al.,* 1996). Megalin, a member of the LDL receptor superfamily expressed in the neuroepithelium and on the apical surface of the proximal tubular epithelium, has been reported to play an important role in the renal uptake of $25(OH)D_3$ (Nykjaer *et al.,* 1999). In megalin knockout mice there was abnormal urinary calcium excretion of $25(OH)D_3$ that resulted in vitamin D deficiency and bone disease. These results suggest that megalin is essential to deliver the precursor for the generation of $1,25(OH)_2D_3$. Effects of vitamin D on phosphate reabsorption in the proximal tubule have also been suggested. Vitamin D has been reported to increase or decrease renal phosphate reabsorption depending on the parathyroid status and on experimental conditions. The gene for X-linked hypophosphatemic vitamin D-resistant rickets (PEX or HYP), a disease whose main feature is renal phosphate leak, has been identified (Rowe *et al.,* 1996). A putative vitamin D responsive element was noted in this gene, suggesting that $1,25(OH)_2D_3$ may play a role in regulating the HYP gene (Rowe *et al.,* 1996). The presence of a putative vitamin D responsive element in the promoter of the Na^+/phosphate cotransporter and regulation of this promoter by VDR and $1,25(OH)_2D_3$ also suggest a role for $1,25(OH)_2D_3$ in renal phosphate transport (Taketani *et al.,* 1997). In addition to modulation of the $25(OH)D_3$ hydroxylases and a few reports concerning effects on phosphate transport in the proximal tubule and enhancement of calcium transport in the distal nephron, in general, the effects of $1,25(OH)_2D_3$ in the kidney are not well understood. Although autoradiography indicated that the VDR was localized exclusively in the distal nephron (Stumpf *et al.,* 1980), studies using immunocytochemistry and reverse transcription polymerase chain reaction (RT PCR) have shown that VDR and VDR mRNA are also localized in glomeruli, proximal tubules and the collecting duct (Liu, *et al.,* 1996a), thus suggesting multiple genomically mediated actions of $1,25(OH)_2D_3$ within the kidney. Further research is needed in order to provide new insight concerning the renal effects of $1,25(OH)_2D_3$.

Parathyroid Glands

In the regulation of mineral homeostasis, the parathyroid glands are also an important target of $1,25(OH)_2D_3$ action. 1,25-Dihydroxyvitamin D_3 inhibits the secretion and synthesis of PTH. A direct action of $1,25(OH)_2D_3$ on the preproparathyroid hormone gene has been reported (Demay *et al.,* 1992; Mackey *et al.,* 1996).

Nonclassical Actions of $1,25(OH)_2D_3$

Effects of $1,25(OH)_2D_3$ on Differentiation and Proliferation

In addition to affecting tissues involved in mineral homeostasis, $1,25(OH)_2D_3$ has been reported to affect numerous other systems. Because $1,25(OH)_2D_3$ receptors have been identified in tissues not involved in calcium homeostasis, it has been suggested that the actions of $1,25(OH)_2D_3$ in these nonclassical target tissues are mediated, at least in part, by genomic mechanisms. One of the best characterized actions of $1,25(OH)_2D_3$ in a number of different normal and malignant cells is the ability of $1,25(OH)_2D_3$ to inhibit proliferation and to stimulate differentiation (Suda, 1989; Suda *et al.,* 1990). The effect of $1,25(OH)_2D_3$ on the inhibition of proliferation and the stimulation of differentiation is of interest because it has been related to the treatment of skin lesions found in psoriasis with $1,25(OH)_2D_3$ or analogs of $1,25(OH)_2D_3$ (this topic is discussed in detail in

Chapter 33). In addition to keratinocytes, $1,25(OH)_2D_3$ has been reported to inhibit the proliferation and induce the differentiation of leukemia cells (Suda, 1989) and to inhibit the proliferation of a number of malignant cells, including colon, breast, and prostate cancer cells (Kane *et al.,* 1996; James *et al.,* 1998; Wang *et al.,* 2000; Zhao *et al.,* 1997). A very active area of current investigation is the development of analogs of $1,25(OH)_2D_3$, which can inhibit cell growth and promote differentiation but do not affect serum calcium and the testing of their therapeutic potential in the treatment of leukemia and other malignancies.

Effects of $1,25(OH)_2D_3$ on Hormone Secretion

In addition to affecting the secretion of PTH, $1,25(OH)_2D_3$ has been reported to affect the secretion of other hormones that do not have a primary role in the regulation of mineral homeostasis. In the pituitary, $1,25(OH)_2D_3$ has been reported to enhance the secretion of both thyroid stimulating hormone (TSH) and prolactin (d'Emden and Wark, 1989; Murdoch and Rosenfeld, 1981). An induction of prolactin mRNA and transcription by $1,25(OH)_2D_3$ have also been reported in pituitary GH3 cells (Castillo *et al.,* 1999). Studies using VDR knockout mice have indicated that vitamin D is essential for full gonadal function in both sexes (Kinuta *et al.,* 2000). Although vitamin D plays a role in estrogen biosynthesis partially by maintaining calcium heomeostasis, direct regulation by $1,25(OH)_2D_3$ of the aromatase gene was suggested (Kinuta *et al.,* 2000). 1,25-Dihydroxyvitamin D_3 treatment can also enhance the secretion of insulin from the pancreas (Chertow *et al.,* 1983; Clark *et al.,* 1981; Norman *et al.,* 1980), the first nonclassical target tissue in which $1,25(OH)_2D_3$ receptors were identified (Christakos and Norman, 1979). Although normalization of insulin secretion by vitamin D has been observed in vitamin-deficient rats, it has been argued that this effect of vitamin D may be secondary to a primary effect of vitamin D on serum calcium or to other beneficial effects of vitamin D on growth and nutrition. This is still a matter of debate, however. It is indeed possible that $1,25(OH)_2D_3$ may act together with calcium to control insulin secretion. One of the earliest indications that the β cell may be a target for $1,25(OH)_2D_3$ came from immunocytochemical studies that localized calbindin-D_{28k} to the islet (Morrissey *et al.,* 1975). Studies using pancreatic islets from calbindin-D28k null-mutant mice (knockout mice) and β cell lines stably transfected and overexpressing calbindin have provided evidence for a role for calbindin in the modulation of depolarization-stimulated insulin release and suggest that calbindin can control the rate of insulin release via the regulation of intracellular calcium (Sooy *et al.,* 1999).

Effects of $1,25(OH)_2D_3$ on the Immune System

1,25-Dihydroxyvitamin D_3 has also been reported to affect the differentiation and function of cells of the immune system (Manolagas *et al.,* 1994).

Effects of $1,25(OH)_2D_3$ include inhibition of T-cell proliferation and regulation of the interleukins 1–3 and 6, regulation of interferon-γ, tumor necrosis factor, and granulocyte/macrophage colony-stimulating factor (6M-CSF). The effects of $1,25(OH)_2D_3$ on the suppression of T-cell proliferation and on the expression of certain cytokines are in contrast to the reported effect of $1,25(OH)_2D_3$ on the enhancement of macrophage phagocytic activity. Due to its immunosuppressive actions, it has been suggested that $1,25(OH)_2D_3$ or analogs of $1,25(OH)_2D_3$ may prevent the induction of certain experimental autoimmune disorders and may have beneficial effects when given in combination with immunosuppressive drugs such as cyclosporin A.

Transcriptional Regulation by $1,25(OH)_2D_3$

Vitamin D-Regulated Genes

The genomic mechanism of $1,25(OH)_2D_3$ action involves binding to specific DNA sequences in the promoter region of target genes. To date, more than 50 vitamin D-dependent genes have been identified in different target tissues in a number of species [see Hannah and Norman (1994) and Segaert and Bouillon (1998) for lists of vitamin D-dependent genes]. However, only a limited number of vitamin D responsive elements (VDREs) have been defined (Table I). On the basis of this small number of natural VDREs, in general, the VDRE consensus consists of two direct imperfect repeats of the hexanucleotide sequence GGGTGA separated by three nucleotide pairs.

CALBINDIN-$D_{9K,}$ CALBINDIN-D_{28K}

As mentioned previously, one of the most pronounced effects of $1,25(OH)_2D_3$ is increased synthesis of calbindin. Although sequence elements in the mouse calbindin-D_{28k} promoter (−200/−169) and in the rat calbindin-D_{9k} promoter (−489/−445) that respond to $1,25(OH)_2D_3$ have been identified, the response observed using the calbindin-D_{9k} or the calbindin-D_{28k} responsive sequences is modest (Darwish and DeLuca, 1992; Gill and Christakos, 1993). This modest response reflects previous *in vivo* findings that indicated that

Table I Vitamin D Responsive Elements Present in Vitamin-Regulated Genes

Rat 24-hydroxylase	AGGTGA gtg AGGGCG (−151/−137)
	CGCACC cgc TGAACC (−259/−245)
Mouse osteopontin	GGTTCA cga GGTTCA (−757/−743)
Human osteocalcin	GGGTGA acg GGGGCA (−499/−485)
Rat osteocalcin	GGGTGA atg AGGACA (−455/−441)
Mouse calbindin-D_{28k}	GGGGGA tgtg AGGAGA (−198/−183)
Mouse Calbindin-D_{9k}	GGGTGT cgg AAGCCC (−489/−475)
Avian integrin β_3	GAGGCA gaa GGGAGA (−770/−756)
Human p21	AGGGAG att GGTTCA (−779/−765)

$1,25(OH)_2D_3$ induces the expression of the calbindin-D_{9k} or the calbindin-D_{28k} gene by a small, rapid transcriptional stimulation followed by a large accumulation of calbindin mRNA long after $1,25(OH)_2D_3$ treatment (Christakos *et al.,* 1989). These findings suggest that the large induction of calbindin mRNA by $1,25(OH)_2D_3$ may be due primarily to posttranscriptional mechanisms. More recent studies noted the requirement of the homeodomain protein Cdx2, a transcription factor active only in intestinal epithelium, for calbindin-D_{9k} expression and that cooperation between the proximal calbindin-D_{9k} promoter and a distal element located in an open chromatin structure (−3600/−3400) is needed for vitamin D responsiveness (Colnot *et al.,* 1998). These studies suggest that the mechanism of action of $1,25(OH)_2D_3$ on calbindin regulation is more complicated than the conventional hormone-receptor transcriptional activation model. Calbindin-D_{9k} and calbindin-D_{28k} are regulated by a number of hormones in addition to $1,25(OH)_2D_3$. Calbindin-D_{9k} in rat uterus and calbindin-D_{28k} in mouse uterus, oviduct, and ovary have been reported to be regulated by estradiol [see Christakos (1995) and Christakos *et al.,* (1989) for review]. 1,25-Dihydroxyvitamin D_3 has no effect on calbindins in these female reproductive tissues. Glucocorticoid administration has been reported to inhibit the expression of intestinal calbindin-D_{9k} mRNA (Huang *et al.,* 1989; Li and Christakos, 1991). The inhibition of calbindin may be related to the decrease in intestinal calcium absorption, which has been observed with glucocorticoid treatment. Regulation of calbindin-D_{28k} by retinoic acid has also been reported (Wang and Christakos, 1995). In addition, neurotrophin 3, brain-derived neurotrophic factor, fibroblast growth factor, and tumor necrosis factor have all been observed to increase the expression of calbindin-D_{28k} in brain, suggesting regulation of calbindin by signal transduction, as well as by steroids [see Christakos (1995) for review]. Thus, it has become evident that calbindin is no longer considered a calcium-binding protein whose synthesis is dependent solely on vitamin D. Calbindin is present in a number of different tissues, may have multiple functions, and can be regulated by different ligands as well as by signal transduction.

OSTEOCALCIN, OSTEOPONTIN

Studies concerning the regulation by vitamin D of two other calcium-binding proteins, osteocalcin (OC) and osteopontin (OP), which are secreted by the osteoblasts, have resulted in the most information concerning transcriptional activation by $1,25(OH)_2D_3$. VDREs in both the human and the rat OC promoter (Demay *et al.,* 1990; Kerner *et al.,* 1989; Morrison *et al.,* 1989; Owen *et al.,* 1990; Ozono *et al.,* 1990) and in the mouse OP promoter (Noda *et al.,* 1990) have been well characterized. An AP1 site, which binds members of the Jun/Fos protooncogene family, has been reported to be closely juxtaposed to the VDRE in the human OC promoter (Ozono *et al.,* 1990). It has also been proposed that the rat OC VDRE contains an AP1 element within the VDRE (not juxtaposed as has been reported for the hOC VDRE) (Owen *et al.,* 1990). An AP1 site is not found within or juxtaposed to the mouse OP VDRE. It has been reported that the AP1 element can be involved in the synergistic enhancement of the $1,25(OH)_2D_3$-dependent transcriptional activation of the OC gene. However, expression of cjun and cfos in ROS 17/2.8 cells has been reported to suppress basal activity as well as the $1,25(OH)_2D_3$-induced response (Schule *et al.,* 1990). Thus it has been proposed that the AP1 site and AP1 proteins may play an important role in activating or suppressing both basal and $1,25(OH)_2D_3$-dependent OC transcription depending on the state of differentiation of the cell. In addition to an AP1 element, a glucocorticoid responsive element has also been identified overlapping the TATA box in both the rat and the human osteocalcin genes (Morrison *et al.,* 1989; Stromstedt *et al.,* 1991). Glucocorticoids, which dampen osteoblast activity, were reported to have a modest suppressive effect on the basal activity of the OC promoter but completely blocked the induction of OC promoter CAT expression by $1,25(OH)_2D_3$, providing a mechanism of glucocorticoid repression of the osteocalcin gene. More recent studies noted the importance of Cbfa transcriptional activators for basal and vitamin D responsive transcription of the OC gene (Javed *et al.,* 1999) and that the multifunctional transcriptional regulator YY1 represses $1,25(OH)_2D_3$ induced transcription of the OC gene (Guo *et al.,* 1997).

24-HYDROXYLASE

Most recently, vitamin D responsive elements have been identified in the rat 24-hydroxylase [24(OH)ase] gene (Kerry *et al.,* 1996; Ozono *et al.,* 1995; Zierold *et al.,* 1994). The 24(OH)ase gene is the first vitamin D-dependent gene reported to be controlled by two independent VDREs (at −259/−245 and at −151/−137). It has been suggested that the proximal VDRE is more responsive to $1,25(OH)_2D_3$ than the distal VDRE (Ozono *et al.,* 1995). A binding site for the Ras-activated Ets transcription factor has been identified downstream from the proximal VDRE, and this site was found to be critical for $1,25(OH)_2D_3$ mediated 24(OH)ase transcription (Dwivedi *et al.,* 2000). The most pronounced effects of $1,25(OH)_2D_3$ in intestine and kidney are increased synthesis of 24(OH)ase and calbindin (Matkovits and Christakos, 1995). However, unlike calbindin, which is only modestly transcriptionally responsive to $1,25(OH)_2D_3$, 24(OH)ase is strongly responsive to $1,25(OH)_2D_3$ at the level of transcription.

INTEGRIN $\alpha_v\beta_3$

1,25-Dihydroxyvitamin D_3 has also been reported to transcriptionally activate α_v and β_3 integrin genes. Integrin $\alpha_v\beta_3$ is expressed in the osteoclast plasma membrane, has been reported to bind to osteopontin through the amino acid sequence RGD, and has an important role in bone resorption (see Chapter 17). A vitamin D responsive element has been reported in the avian β_3 integrin gene (at −770/−756) (Cao *et al.,* 1993). The magnitude of the transcriptional response to $1,25(OH)_2D_3$ of the avian β_3 integrin gene is modest, similar to the transcriptional response of the calbindin genes to $1,25(OH)_2D_3$.

PARATHYROID HORMONE

The first demonstration of a negative VDRE was by Demay *et al.* (1992), who indicated that sequences in the human parathyroid hormone (PTH) gene (−125/−101) mediate transcriptional repression by $1,25(OH)_2D_3$. Only a single copy motif (AGGTCA) is identified within this region, and vitamin D receptor binding to this element does not require the retinoid X receptor (Mackey *et al.,* 1996). The response is tissue specific because the 25-bp oligonucleotide was reported to mediate transcriptional repression in GH4C1 cells but not in ROS 17/2.8 cells.

INTERLEUKIN-2 AND GRANULOCYTE/MACROPHAGE COLONY-STIMULATING FACTOR

Mechanisms involved in mediating the effects of $1,25(OH)_2D_3$ in systems other than those involved in maintaining mineral homeostasis have only recently begun to be explored. A decrease in the proliferation of T lymphocytes in the presence of $1,25(OH)_2D_3$ is correlated with a decrease in interleukin-2 (IL-2) mRNA and GM-CSF mRNA. Transcriptional repression of these genes contributes to the overall immunosuppressive effects of $1,25(OH)_2D_3$ (Alroy *et al.* 1995; and Towers *et al.,* 1999). Mechanisms involved in the repression by $1,25(OH)_2D_3$ of IL-2 and GM-CSF have been provided (Alroy *et al.,* 1995; Towers *et al.,* 1999). VDR can block the positive transcription factors NFATp and Jun/Fos, which bind to a composite site containing a consensus NFAT1-binding site. These findings provide novel insight concerning how $1,25(OH)_2D_3$ can act as an immunosuppressive agent and may provide a general mechanistic basis for how steroid receptors elicit immunosuppressive responses.

To provide insight concerning the mechanisms involved in the effect of $1,25(OH)_2D_3$ on the differentiation of leukemic cells into monocyte/macrophages, a cDNA library was prepared from the myelomonocytic U937 cell line and screened with probes generated from either $1,25(OH)_2D_3$-treated or untreated cells. The cyclin D-dependent kinase inhibitor p21 was found to be induced transcriptionally by $1,25(OH)_2D_3$, and a functional VDRE was identified in the p21 promoter (see Table I) (Liu, *et al.,* 1996b). Transient overexpression of p21 in U937 cells in the absence of $1,25(OH)_2D_3$ resulted in the expression of monocyte/macrophage-specific markers, suggesting that p21, which is involved in blocking cell cycle progression, may be a key factor involved in $1,25(OH)_2D_3$-mediated differentiation of leukemic cells.

Factors Involved in Vitamin D-Mediated Transcriptional Regulation

VITAMIN D RECEPTOR (VDR)

VDR Regulation Due to the importance of VDR in the molecular mechanism of vitamin D action, the regulation of VDR has been a focus of a number of studies. Upregulation of VDR by $1,25(OH)_2D_3$ has been shown in several different systems, including rat intestine (Strom *et al.,* 1989), pig kidney LLCPK-1 cells (Costa *et al.,* 1985), and HL-60 leukemia cells (Lee *et al.,* 1989). Whether the homologous upregulation of VDR involves an induction of VDR mRNA has been a controversial topic. However, it is not likely that an increase in VDR mRNA in response to $1,25(OH)_2D_3$ plays a major role in the regulation of the VDR. It has been suggested that homologous upregulation of the VDR is most probably due to increased stability of the occupied receptor (Lee *et al.,* 1989; Wiese *et al.,* 1992; Arbour *et al.,* 1993). VDR has also been reported to be regulated by a number of other factors, including activation of protein kinase A and protein kinase C. Treatment of NIHT3 mouse fibroblasts with $(Bu)_2$cAMP or forskolin (Krishnan and Feldman, 1992) and treatment of mouse osteoblasts (MC3T3-E1 cells) or rat osteosarcoma cells (UMR-106-01) with forskolin or PTH (Krishnan *et al.,* 1995) was reported to result in an induction in VDR abundance. Treatment of these cells with the phorbol ester, phorbol myristate acetate (PMA), whose actions are mediated by protein kinase C, resulted in a downregulation of VDR (Krishnan and Feldman, 1991; Krishnan *et al.,* 1995). Up- or downregulation of VDR in NIHT3 cells by forskolin or PMA, respectively, resulted in a corresponding induction or attenuation of reporter activity in cells transfected with the human OC VDRE fused to the reporter gene chloramphenicol acetyltransferase (Krishnan and Feldman, 1992). Treatment of UMR cells with PTH enhanced the $1,25(OH)_2D_3$-mediated induction of 24(OH)ase mRNA (Krishnan *et al.,* 1995; Armbrecht *et al.,* 1998). Thus the functional response corresponded to the change in VDR. However, opposite findings concerning the effect of activation of protein kinase A or protein kinase C on VDR have been reported by others (Reinhardt and Horst, 1990, 1994), suggesting that proliferation state, cell type, and stage of differentiation affect the interaction between $1,25(OH)_2D_3$ and signal transduction pathways. In general, studies suggest cooperativity between signal transduction pathways and $1,25(OH)_2D_3$. Effects of second messenger systems may be on the VDR. However effects on the promoter of the target gene or on other transcription factors that may be interacting with the VDR also need to be considered. Further studies related to the regulation of VDR will be facilitated by the preliminary analysis of the hVDR gene structure that spans more than 60 kb, consists of at least 14 exons, and is directed by two distinct promoters (Miyamoto *et al.,* 1997)

Phosphorylation of the VDR Although the VDR, similar to other steroid receptors, is phosphorylated, the exact functional role of phosphorylation of the VDR remains to be further elucidated. It has been suggested that phosphorylation may play a role in the binding of the receptor to DNA or in the interaction of VDR with other transcription factors. Phosphorylation of VDR was shown to involve serine residues. Serine-208 in the ligand-binding domain has been identified as a site of phosphorylation that accounts for at least 60% of the phosphorylation of the receptor (Hilliard *et al.,* 1994; Jurutka *et al.,* 1993). Casein kinase II has been reported to mediate VDR phosphorylation at serine-208 (Jurutka *et al.,* 1996). Although transcriptional activation by $1,25(OH)_2D_3$ is not dependent on serine-208 phosphorylation, studies have

shown that VDR phosphorylation by casein kinase II at serine-208 plays an important role in potentiating transcriptional activation (Jurutka *et al.,* 1996). These studies provide the first evidence of a functional role of phosphorylation of the VDR. Knowledge of the crystal structure of the VDR (Rochel *et al.,* 2000) will facilitate the definitive identification of other possible phosphorylation sites.

VDR Receptor Homodimerization vs Heterodimerization

Earlier reports indicated that the VDR functions primarily as a heterodimer with RXR for activation of gene transcription. Because VDR derived from Baculovirus (MacDonald *et al.,* 1991) or yeast (Sone *et al.,* 1990) systems or *in vitro*-translated VDR (Liao *et al.,* 1990) was not reported to interact directly with VDREs, it was suggested that VDR is unable to form natural homodimers. More recently, studies have indicated that purified VDR can bind as a homodimer to certain VDREs but that RXR was required for binding to other VDREs (Freedman *et al.,* 1994; Nishikawa *et al.,* 1994). However, the physiological relevance of VDR homodimers has been questioned. Cheskis and Freedman (1994) reported that VDR exists as a monomer in solution and homodimerization occurs upon binding to the OPN VDRE. 1,25-Dihydroxyvitamin D_3 was reported to destabilize homodimerization, resulting in VDR/RXR heterodimer formation (Fig. 2). Thompson *et al.* (1998) also reported that formation of the VDRE-complexed VDR-RXR heterodimer is strikingly dependent on the presence of $1,25(OH)_2D_3$. These studies suggest that although the VDR homodimer can exist in solution, the heterodimer is the functional transactivating species. 9-*cis*-Retinoic acid has been reported to decrease heterodimer formation by driving the equilibrium from the VDR heterodimer to the RXR homodimer or to the interaction of RXR with other receptors (Cheskis and Freedman, 1994; MacDonald *et al.,* 1993). Further studies using VDR mutants also suggest the importance of heterodimerization, as none of the mutants without the capability to form heterodimers showed $1,25(OH)_2D_3$-dependent transcriptional activation (Nakajima *et al.,* 1994). Although at this time the VDR homodimer does not appear to have a role in transcriptional activation, it is possible in future studies that VDR homodimers may be shown to have a functional role in enhancing the transcription of $1,25(OH)_2D_3$-dependent target genes yet to be identified.

Regions of VDR within the ligand-binding domain that may be crucial for heterodimerization have been suggested. Functional studies have indicated that the region in the C-terminal between amino acids 317 and 395 may have an important role in heterodimerization (Nakajima *et al.,* 1994; Jin *et al.,* 1996). A second interaction domain was reported between amino acids 244 and 263 (Rosen *et al.,* 1993; Whitfield *et al.,* 1995; Jin *et al.,* 1996). The two regions of VDR correspond to portions of helices 7–10 and 3–4, respectively. Although these studies are suggestive, a more complete understanding of the three-dimensional contacts between VDR and RXR will be obtained now that the crystal structure of the VDR ligand domain bound to its ligand has been published (Rochel *et al.,* 2000).

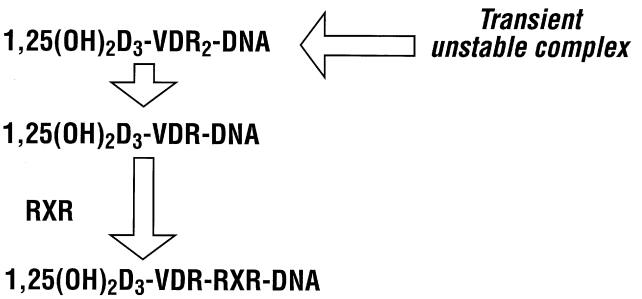

Figure 2 Proposed model of VDR homodimerization and heterodimerization with RXR. It has been reported that VDR exists as a monomer in solution and homodimerization occurs upon binding to the OPN VDRE. 1,25-Dihydroxyvitamin D_3 can destabilize homodimerization, resulting in VDR/RXR heterodimer formation (see Cheskis and Freedman, 1994).

INTERACTION OF VDR WITH TRANSCRIPTION MACHINERY

The mechanisms involved in VDR-mediated transcription following binding of the VDR-RXR heterodimer to DNA have begun to be investigated. Initiation of basal transcription involves binding of TFIID, which is composed of the TATA box-binding protein and associated TAFs, to the TATA element. After the binding of TFIID to the TATA element, other factors, including TFIIA, TFIIB, RNA polymerase II, TFIIE, TFIIF, and TFIIH, are recruited and associated with the complex. Studies have suggested that VDR can interact physically and functionally with TFIIB (Blanco *et al.,* 1995; Masuyama *et al.,* 1997).The interaction of TFIIB is with unliganded VDR, and the $1,25(OH)_2D_3$ ligand disrupts the VDR-TFIIB complex (Masuyama *et al.,* 1997). These findings suggest that VDR prerecruits TFIIB and, in the presence of ligand, TFIIB is released for assembly into the preinitiation complex to facilitate activated transcription.

Several TAFs have been suggested to be involved in VDR-mediated transcriptional activity. The TFIID subunit $TAF_{II}135$ potentiates the transcriptional activity of VDR (Mengus *et al.,* 1997). In addition, $TAF_{II}28$ (Mengus *et al.,* 2000) and $TAF_{II}55$ (Lavigne *et al.,* 1999) interact with two regions of the VDR (one region spanning α helices H3 to H5 of the VDR and a second region corresponding to α helix 8).Determinants for interaction with $TAF_{II}28$ or $TAF_{II}135$ are not identical. A mutation in the H3–H5 region that determines interaction with $TAF_{II}28$ was reported to abolish VDR-mediated transactivation (Mengus *et al.,* 2000), thus indicating that the specific amino acids within that region of the VDR ligand-binding domain are needed for transactivation.

SRC/P160 COACTIVATORS

Over the past few years a number of proteins known as p160 coactivators (based on one of the first identified members, the 160-kDa protein, steroid receptor coactivator-1;SRC-1) that bind to steroid receptors and enhance their activity have been identified. Three related family members, based on homologies, include SRC-1/NcoA1, GRIP-1/TIF-2, and ACTR/pCIP (for reviews, see McKenna *et al.,* 1999; Xu

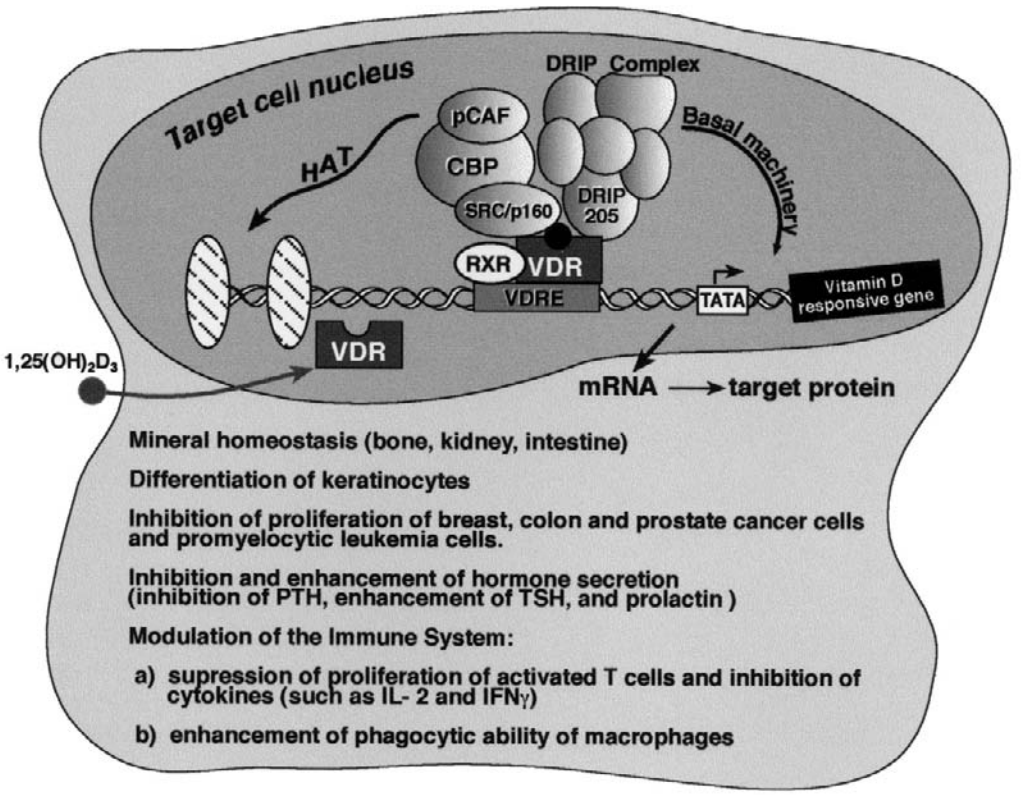

Figure 3 Genomic mechanism of action of $1,25(OH)_2D_3$ in target cells. 1,25-Dihydroxyvitamin enters the target cell and interacts with the nuclear VDR, which heterodimerizes with RXR. After interaction with the VDRE, transcriptional activation or repression proceeds through the interaction of VDR with coactivators and with the transcription machinery. Two models for the genomic action of $1,25(OH)_2D_3$ are shown. The histone acetyltransferase (HAT) activity-containing complex of SRC/p160 and CBP may be recruited first by VDR in response to the ligand. This would lead to DNA accessibility that would allow as a second step the binding of the DRIP complex (DRIP 205 subunit binds directly to VDR) and recruitment of RNA polymerase II (sequential model). Alternatively, there could be simultaneous chromatin remodeling and basal machinery recruitment (cooperative model). 1,25-Dihydroxyvitamin D_3 is known to affect mineral homeostasis, to differentiate keratinocytes, to inhibit the proliferation of cancer cells, to affect hormone secretion, and to modulate the immune system. Adapted with permission from Christakos *et al.* (1996).

et al., 1999). They interact with the AF2 domain of steroid receptors, including VDR (C-terminal helix 12 contains the core AF2) in a ligand-dependent manner. Studies indicate that helix 3 of the VDR is also important for interaction with p160 coactivators (Jimenez-Lara *et al.,* 1999; Kraichely *et al.,* 1999). These coactivators have histone acetylase (HAT) activity. This modification of histones is thought to destabilize the interaction between DNA and the histone core, liberating DNA for transcription. These coactivators can also form complexes with CBP (CREB-binding protein). CBP also has HAT activity. Thus the SRC/p160 family of coactivators can recruit CBP to the nuclear receptor, resulting in a multisubunit complex.

VITAMIN D RECEPTOR INTERACTING PROTEINS (DRIP) COMPLEX

In addition to the SRC/p160 family of coactivators, VDR-mediated transcription is also mediated by a coactivator complex, DRIP (Rachez *et al.,* 1998, 1999). These proteins are also called TRAP and ARC, depending on the transcription factor initially identified as the target (TR or androgen receptor, respectively), but are now thought to have broader target specificity due to their close identity. Studies have indicated that the complex does not have HAT activity but rather functions, at least in part, through recruitment of RNA polymerase II (Rachez *et al.,* 1999). The CBP/SRC coactivator complex may be needed first for chromatin remodeling followed by the recruitment of the transcription machinery by the DRIP/TRAP/ARC complex (sequential model) or there may be simultaneous chromatin remodeling and basal machinery recruitment (cooperative model) (Fig. 3).

Future Directions

New target genes, novel vitamin D responsive elements, and new factors involved in vitamin D-mediated transcription will undoubtedly be identified in numerous different systems, which are currently known to be affected by $1,25(OH)_2D_3$. Sequences divergent from the

current consensus VDRE may be observed, which should expand our understanding of the sequences involved in $1,25(OH)_2D_3$-mediated genomic responses. In addition to transcriptional regulation, it is likely that posttranscriptional mechanisms will be an important mechanism of control of a number of newly identified target genes. In addition to studies concerning the mechanisms involved in mediating the genomic actions of $1,25(OH)_2D_3$, further studies related to the physiological significance of target proteins are needed in the future. Finally, in the next few years, with the elucidation of the crystal structure of VDR, we will obtain an increased understanding of the structure of VDR in the presence and absence of ligand and/or protein partners. Based on the structural information, synthetic analogs of $1,25(OH)_2D_3$ may be designed that would selectively modulate specific $1,25(OH)_2D_3$ responses. Thus, new insight into the multiple roles of $1,25(OH)_2D_3$ will be obtained and selective modulation of $1,25(OH)_2D_3$ responses in bone and other target tissues may indeed be possible.

CHAPTER 33

Photobiology and Noncalcemic Actions of Vitamin D

Michael F. Holick
Boston University School of Medicine, Boston, Massachusetts 02118

Photobiology of Vitamin D

Photosynthesis of Previtamin D_3 and Its Conversion to Vitamin D_3

When human skin is exposed to sunlight, a photochemical process occurs that is essential for the maintenance of calcium homeostasis and a healthy skeleton. During exposure to sunlight, the ultraviolet B (UV-B; 290–315 nm) portion of the solar spectrum is responsible for photolyzing 7-dehydrocholesterol (the precursor cholesterol; provitamin D_3) to previtamin D_3(Holick, 1994). Once formed, previtamin D_3 undergoes an internal isomerization of its three double bonds to form a more thermodynamically stable, 5,6-cis-triene and is transformed in vitamin D_3 (Fig. 1). For warm-blooded animals, such as humans, this process would, under normal circumstances, take approximately 24 hr for 50% of previtamin D_3 to convert to vitamin D_3. However, in cold-blooded animals, this process could take several days (Holick *et al.,* 1980). It has now been found that there is membrane enhancement for the conversion of previtamin D_3 to vitamin D_3 in both cold-blooded and warm-blooded animals, including humans (Holick *et al.,* 1995). 7-Dehydrocholesterol is found principally in the cell membrane. Within the membrane, the hydrophobic side chain of 7-dehydrocholesterol is aligned with the hydrophobic chains of the fatty acids and cholesterol, thereby restraining the confirmation of previtamin D_3 when it is formed (Fig. 2). Thus, when 7-dehydrocholesterol is exposed to sunlight, 7-dehydrocholesterol is photolyzed to the s-*cis*, s-*cis* conformer of previtamin D_3. In an organic solvent, the s-*cis*,s-*cis*-previtamin D_3 conformer is thermodynamically unstable and immediately isomerizes to the s-*cis*, s-*trans* form. Because only the s-*cis*, s-*cis* conformer is able to isomerize to vitamin D_3, the entrapment of previtamin D_3 in its s-*cis*, s-*cis* form within the plasma membrane promotes a more than 10-fold increase in its rate of isomerization to vitamin D_3 when compared to the same reaction in an organic solvent (Tian *et al.,* 1994; Holick *et al.,* 1995). This process guarantees that the precious previtamin D_3 that is made in the skin is converted efficiently to vitamin D_3. In addition, as vitamin D_3 is being formed from previtamin D_3, its conformational change probably permits it to selectively exit from the membrane into the extracellular space.

Factors That Regulate Photosynthesis of Previtamin D_3 in Skin

SUNLIGHT-MEDIATED PHOTOLYSIS

It is well known that intense prolonged exposure to sunlight will not cause vitamin D intoxication. The reason for this is that during the initial exposure to sunlight, 7-dehydrocholesterol is converted to previtamin D_3. However, because previtamin D_3 is photolabile, when exposed to sunlight it is converted to lumisterol and tachysterol, which are thought to be biologically inert on calcium metabolism (Holick *et al.,* 1981) (Fig. 1). Once previtamin D_3 is isomerized to vitamin D_3, vitamin D_3 is also extremely photosensitive and is isomerized rapidly by sunlight to supersterol 1, suprasterol 2, and 5,6-transvitamin D_3 (Fig. 1), which are also thought to be either biologically inert or have less activity on calcium metabolism than vitamin D_3 (Webb *et al.,* 1989).

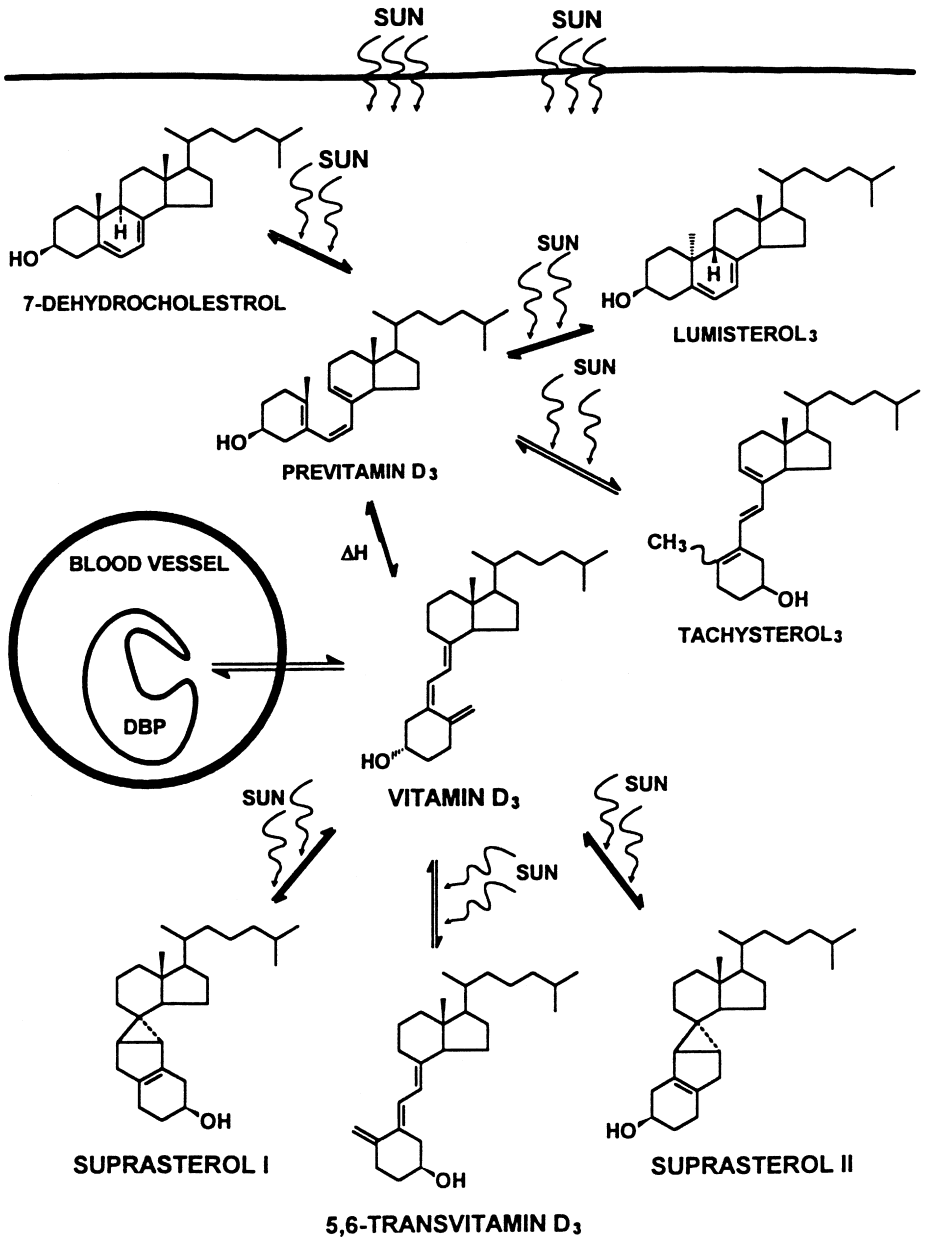

Figure 1 Photochemical events in the skin that lead to the production of vitamin D_3 and the regulation of vitamin D_3 in the skin. Reproduced with permission from Holick (1994).

MELANIN, SUNSCREENS, CLOTHING, GLASS, AND PLASTICS

Melanin is a natural sunscreen that effectively absorbs ultraviolet B radiation, thereby competing with 7-dehydrocholesterol for these photons. As a result, increased skin pigmentation requires longer exposure to sunlight to produce the same amount of previtamin D_3 as in a lighter-skinned individual (Clemens *et al.,* 1982).

Sunscreen use is highly recommended, especially for individuals who are prone to sunburning. Sunscreens such as melanin absorb ultraviolet B radiation. Therefore, the topical application of a sunscreen will substantially diminish or completely prevent the cutaneous production of previtamin D_3. When young adults were covered with a sunscreen preparation with a sun protection factor of 8 (SPF 8) followed by a whole body exposure to one minimal erythemal dose of simulated sunlight, they were unable to elevate their circulating concentrations of vitamin D above baseline values (Matsuoko *et al.,* 1987) (Fig. 3). Similarly, clothing absorbs most ultraviolet radiation and therefore prevents the cutaneous production of vitamin D_3 (Matsuoko *et al.,* 1994). Chronic use of a sunscreen will diminish circulating concentrations of 25-hydroxyvitamin D_3 as a measure of vitamin D status (Matsuoko *et al.,* 1992). In addition to sunscreens, exposure of the skin to sunlight that has passed through windowpane glass or Plexiglas will not permit any significant synthesis of vitamin D_3 in the skin because most glass and plastics absorb ultraviolet B radiation efficiently (Holick, 1994).

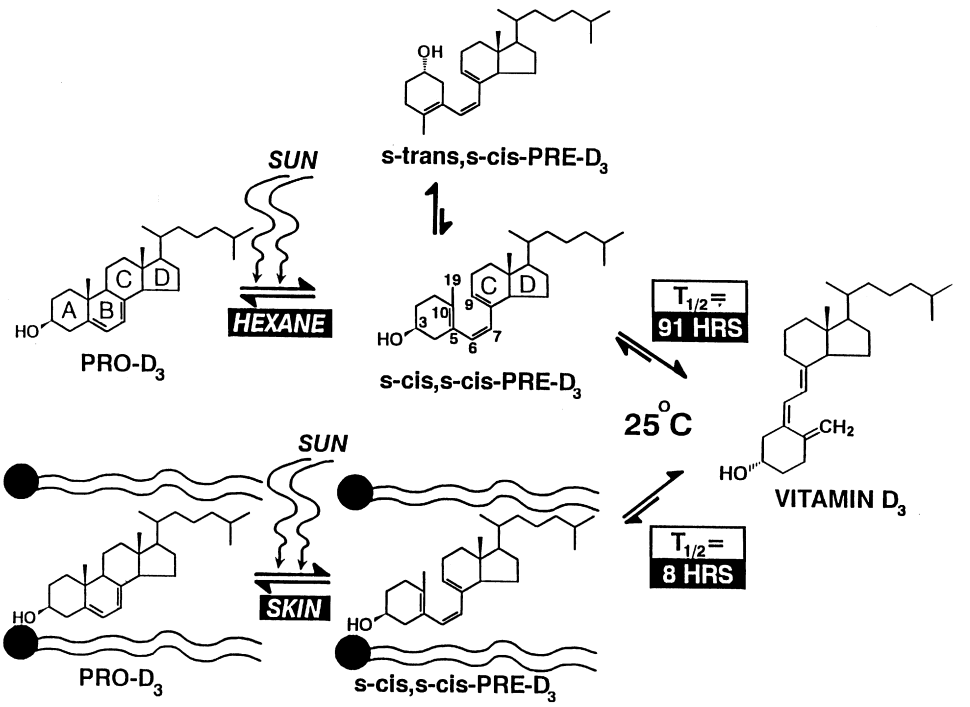

Figure 2 Photolysis of provitamin D_3 (pro-D_3) into previtamin D_3 (pre-D_3) and its thermal isomerization to vitamin D_3 in hexane and in skin. In hexane, pro-D_3 is photolyzed to s-*cis*,s-*cis*-pre-D_3. Once formed, this energetically unstable conformation undergoes a conformational change to the s-*trans*,s-*cis*-pre-D_3. Only the s-*cis*,s-*cis*-pre-D_3 can undergo thermal isomerization to vitamin D_3. The s-*cis*,s-*cis* conformer of pre-D_3 is stabilized in the phospholipid bilayer by hydrophilic interactions between the 3β-hydroxyl group and the polar head of the lipids, as well as by van der Waals interactions between the steroid ring and side chain structure and the hydrophobic tail of the membrane lipids. This "entrapment" significantly decreases its conversion to the s-*trans*,s-*cis* conformer, thereby facilitating the thermal isomerization of s-*cis*,s-*cis*-pre-D_3 to vitamin D_3. Reproduced with permission from Holick *et al.* (1995).

AGING

Aging influences a variety of metabolic processes. Therefore, it is not surprising that aging also markedly decreases the free concentrations of 7-dehydrocholesterol in the epidermis (MacLaughlin and Holick, 1985). When healthy young and elderly volunteers were exposed to the same amount of simulated sunlight, the circulating concentrations of vitamin D in the young volunteers (aged 22–30 years) increased to a maximum of 30 ng/ml within 24 hr after exposure, whereas the older subjects (aged 62–80 years) were only able to achieve a maximum concentration of 8 ng/ml (Holick *et al.,* 1989) (Fig. 4).

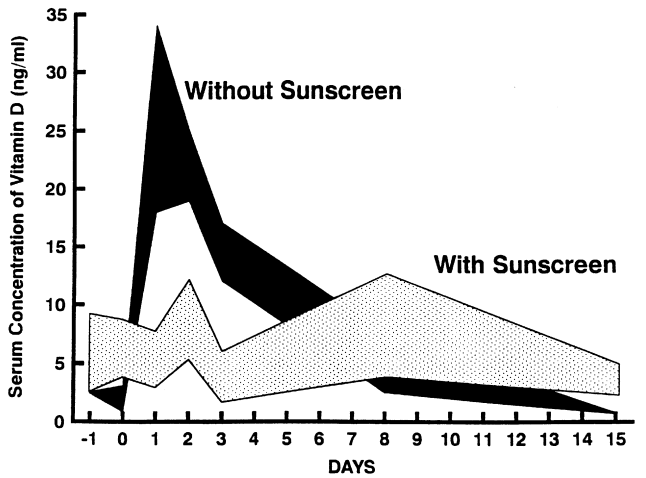

Figure 3 Circulating concentrations of vitamin D in healthy volunteers who applied an oil that contained a sunscreen with SPF-8 or no sunscreen over their entire bodies after a single exposure to one minimal erythemal dose of simulated sunlight. Adapted from Matsuoka *et al.,* 1987. Reproduced with permission from Holick, (1994).

SEASON, LATITUDE, AND TIME OF DAY

Season, latitude, and time of day can greatly influence the cutaneous production of vitamin D_3. As the zenith angle of the sun becomes more oblique, the ultraviolet B photons have to pass through the stratospheric ozone layer at a more oblique angle. This results in the ozone layer absorbing an increasing number of ultraviolet B photons. This can have a dramatic effect on the cutaneous production of previtamin D_3 (Webb *et al.,* 1988) (Fig. 5). In Boston, exposure to sunlight between the months of March and October is capable of producing previtamin D_3 in the skin. However, between the months of November and February, little if any cutaneous vitamin D_3 production can occur no matter how long one stays outdoors. The time of day also greatly influences the cutaneous production of vitamin D_3 (Fig. 6). During the summer in Boston, exposure of the skin to sunlight from

Figure 4 Circulating concentrations of vitamin D in response to a whole body exposure to one minimal erythemal dose in healthy young and elderly subjects. Adapted from Holick *et al.* (1989). Reproduced with permission from Holick (1994).

07:00 to as late as 17:00 hr eastern standard time (EST) resulted in previtamin D_3 production in human skin. However, in the spring and autumn, previtamin D_3 synthesis began at approximately 09:00 EST and ceased at approximately 15:00 EST.

Perspective on Utilization of Sunlight for Vitamin D

It is not well appreciated that casual exposure to sunlight provides most of us with our vitamin D requirement. With the exception of cod liver oil, fatty fish, and other fish liver oils, there are very few foods that have naturally occurring vitamin D. Although some foods are fortified with vitamin D, most notably milk, a recent survey of the vitamin D content in milk suggests that more than 50% of milk samples in the United States contained less than 80% of the vitamin D content stated on the label and approximately 15% contained no detectable vitamin D (Tanner *et al.,* 1988; Holick *et al.,* 1992; Chen *et al.,* 1993). The alarming increase in the incidence of skin cancer that has been directly related to an increased exposure to sunlight has prompted widespread use of sunscreening agents for preventing the damaging effects of sunlight on the skin. Because children and young adults will not routinely cover all sun-exposed areas with a sunscreen all of the time, there is no need for concern about the topical use of sunscreens in causing vitamin D

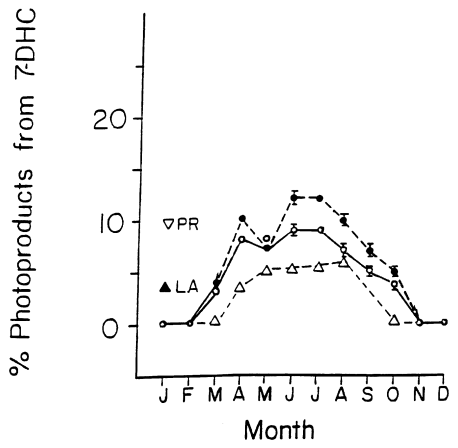

Figure 5 Photosynthesis of previtamin D_3 lumisterol, and tachysterol (photoproducts) after exposure of 7-dehydrocholesterol to sunlight in Boston (42°N) for 1 (○) and 3 (●) hr, Edmonton, Canada (52°N) after 1 hr (△) each month for 1 year, Los Angeles (34°N) (▲) and Puerto Rico (18°) in January (▽) Adapted from Webb *et al.* (1988).

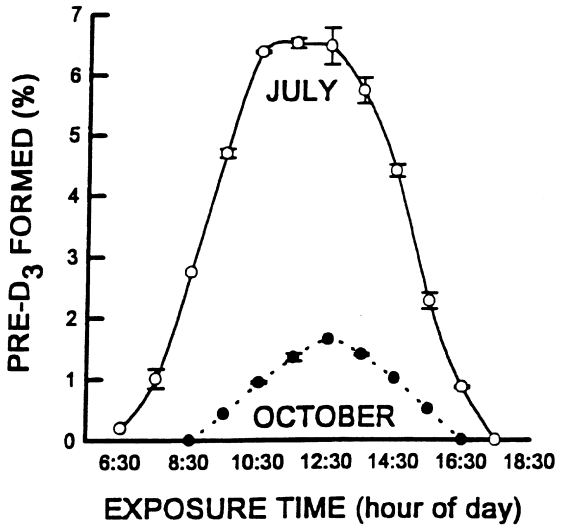

Figure 6 Photosynthesis of previtamin D_3 at various times on cloudless days in Boston in October and July. Adapted from Lu *et al.* (1992). Reproduced with permission from Holick. (1994).

deficiency in this population. However, elderly people, who have decreased capacity to produce vitamin D_3 in their skin, are concerned about developing wrinkles and skin cancer and will religiously topically apply a sunscreen on all sun-exposed areas before going outdoors. This can result in vitamin D insufficiency or overt vitamin D deficiency (Matsuoko *et al.,* 1988). People over 65 years of age who are not taking a vitamin D supplement can satisfy their bodies' vitamin D requirement by exposing their hands, arms, and face to suberythemal doses of sunlight (usually 5 to 15 min, depending on location and time of day) two to three times a week. For those who wish to stay outdoors for longer than the initial suberythemal exposure, it is recommended that they apply a sunscreen with a sun protection factor of equal to or greater than 15 to sun-exposed areas. Therefore, the intelligent use of sunlight to promote the cutaneous synthesis of vitamin D_3 and the topical use of sunscreening agents after the initial exposure prevent the damaging effects due to excessive chronic exposure to sunlight while providing it beneficial effect: vitamin D_3 (Holick, 1994).

Vitamin D Metabolism

Once vitamin D is made in the skin or ingested in the diet, it is bound to the vitamin D-binding protein (DBP). It travels to the liver where it is metabolized to 25-hydroxyvitamin D [25(OH)D]. Once formed, it leaves the liver bound to the DBP and is filtered in the gomerulus into the ultrafiltrate. 25(OH)D-DBP is reabsorbed from the ultrafiltrate by the tubules by the endocytitic receptor megalin (Nykjaer *et al.,* 1999). This endocytotic process is required to preserve 25(OH)D and to deliver it to the renal tubular cells for cytochrome P_{450} 25(OH)D-1α-hydroxylase (1α-OHase). This mitochondrial enzyme hydroxylates 25(OH)D on carbon 1 to form the biologically active form of vitamin D: 1,25-dihydroxyvitamin D [1,25$(OH)_2$D](Holick, 1999).

Originally, it was believed that the kidney was the sole source of 1α-OHase. This was based on the observation that anephric rats could not metabolize 25$(OH)D_3$ to 1,25$(OH)_2D_3$ (DeLuca, 1998; Holick, 1989b). This was also confirmed by many observations that low and undetectable concentrations of 1,25$(OH)_2D_3$ are present in patients who have no kidneys or no kidney function (Holick, 1989b). There is, however, compelling evidence that a wide variety of tissues also possess 1α-OHase activity. The first tissue demonstrated to have 1α-OHase was the skin (Bikle *et al.,* 1986). It has now been demonstrated that normal prostate and prostate cancer cells express 1α-OHase activity (Schwartz *et al.,* 1998). Using *in situ* hybridization and antibodies to 1α-OHase, it was found that 1α-OHase was present in the basal keratinocytes, hair follicles, lymph nodes, parasympathetic ganglion, pancreas, islet cells, adrenal medulla, brain (cerebellum and cerebral cortex), and placenta (Zehnder *et al.,* 2001).

Although the exact function of the extrarenal 1α-OHase is not well understood, it appears that this enzyme may be important for producing 1,25$(OH)_2D_3$ locally to act as a cellular growth modulator (Holick, 2001). To determine the effect of this enzyme on cellular growth and differentiation, we made a plasmid construct containing the 1α-OHase gene that was tagged with the green fluorescent protein gene (Flanagan *et al.,* 1999). A prostate cell line LnCaP that has a vitamin D receptor (VDR) but no 1α-OHase activity was transfected with the 1α-OHase plasmid. It was observed that cells expressed in their mitochondria a protein that had green fluorescence. These cells also had the capability of converting 25$(OH)D_3$ to 1,25$(OH)_2D_3$, whereas cells transfected with on empty vector were unable to produce any 1,25$(OH)_2D_3$. Cells transfected with the 1α-OHase construct were exposed to 25$(OH)D_3$, as were cells transfected with the empty vector construct. Cells transfected with 1α-OHase gene had decreased proliferative activity in the presence of 10^{-8} and 10^{-7} *M* 25$(OH)D_3$ whereas there was no effect in cells transfected with the empty vector (Flanagan *et al.,* 1999). These results suggest that 1,25$(OH)_2D_3$ may be produced locally in a wide variety of cells and that the function of 1,25$(OH)_2D_3$ is to regulate cell growth (Holick, 2001). This could be the explanation for why people who live at higher latitudes, and therefore make less vitamin D_3, are more likely to die of colon, breast, prostate, and ovarian cancer (Garland *et al.,* 1989, 1991; Ahonen *et al.,* 2000; Schwartz *et al.,* 1998). It may be that higher circulating concentrations of 25(OH)D are required in order for the extrarenal 1α-OHase to maximally function to produce 1,25$(OH)_2D_3$ locally to regulate cell growth and prevent metastatic activity of cells that become cancerous (Holick, 2000; Holick 2001).

Noncalcemic Actions of 1,25-Dihydroxyvitamin D_3

Nuclear Localization of ^{3}H-1,25$(OH)_2D_3$ in Noncalcemic Tissues

In 1979, Stumpf and colleagues reported that autoradiographic analysis of frozen sections of tissues from vitamin D-deficient rats that received an intravenous injection of [^{3}H-]1,25$(OH)_2D_3$ showed nuclear localization of [^{3}H-]1,25$(OH)_2D_3$ in a multitude of tissues that were not associated with calcium metabolism, including pituitary gland, thymus, gonads, stomach, breast, pancreas, and skin. Since this initial observation, a variety of investigators have reported that these tissues, as well as transformed cells and cancer cells, possess a vitamin D receptor (VDR) (Table I) (Eisman *et al.,* 1981; Colston *et al.,* 1981; Abe *et al.,* 1981; Tanaka *et al.,* 1982; Simpson *et al.,* 1985; Holick, 1995).

Noncalcemic Functions of 1,25-Dihydroxyvitamin D_3

CANCER CELLS

Initially, when normal tissues and cells such as the skin and immune cells were found to have receptors for 1,25$(OH)_2$D, it was thought that this was either an artifact or

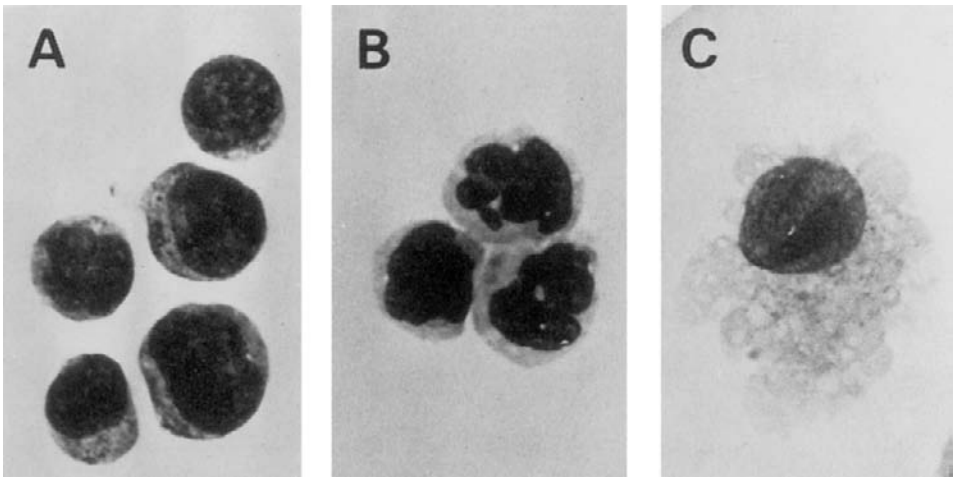

Figure 7 Morphologic changes in HL-60 cells treated with vehicle (A), 1.2×10^{-8} *M* of $1\alpha,25(OH)_2D_3$ (B), or 1.0×10^{-9} *M* of TPA (C) for 3 days. Stained by Wright–Giemsa procedures. From Suda *et al.* (1984), with permission.

was of little physiologic significance. In 1981, Eisman and co-workers reported that 80% of 54 breast cancer tissues possessed VDR activity. During the same year, Abe *et al.* (1981) and Feldman *et al.* (1981) reported that a mouse myeloid leukemic cell line (M-1) and melanoma cells, respectively, possessed a VDR (VDR+). Abe *et al.* (1981) showed a dose-dependent induction of differentiation of these myeloid leukemic cells by $1,25(OH)_2D_3$, and Colston *et al.* (1981) found that $1,25(OH)_2D_3$ inhibited melanoma cell proliferation. Cultured human promyleocytic leukemic cells (HL-60), which were VDR+, responded in a similar fashion (Fig. 7) (Tanaka *et al.,* 1982; Suda *et al.,* 1984). $1,25(OH)_2D_3$ was found to decrease cellular proliferative activity, reduce c-myc-mRNA, and induce the expression of monocyte-specific cell surface antigen 63D3 (Tanaka *et al.,* 1982). Of great interest was the *in vivo* observation that when M-1 leukemic mice were treated with $1,25(OH)_2D_3$ or 1α-hydroxyvitamin D_3 (1α-OH-D_3), their survival was enhanced substantially compared to the control group (Fig. 8) (Honma *et al.,* 1982). This suggested the possibility of using $1,25(OH)_2D_3$ or one of its analogs as an antiproliferative agent for the treatment of some leukemias and other malignant disorders.

IMMUNE SYSTEM

In the early 1980s, with the revelation that many tissues possessed a VDR, it was of great interest to determine whether cells of the immune system also possessed a VDR. Initial studies showed that resting T lymphocytes from the circulation did not possess VDR activity. However, upon stimulation with phytohemoglutinin or concanavalin A (Con A), these cells were induced to produce a VDR (Bhalla *et al.,* 1983; Tsoukas *et al.,* 1984). Once activated T lymphocytes developed VDR activity, they responded to $1,25(OH)_2D_3$ in a variety of ways, including decreased interleukin (IL)-2, interferon-γ, and GM-CSF production (Tsoukas *et al.,* 1984; Bhalla *et al.,* 1986; Binderup, 1992). Like resting T lymphocytes, resting B lymphocytes do not possess a VDR. When B cells were stimulated, a VDR was induced, which resulted in decreased DNA synthesis and

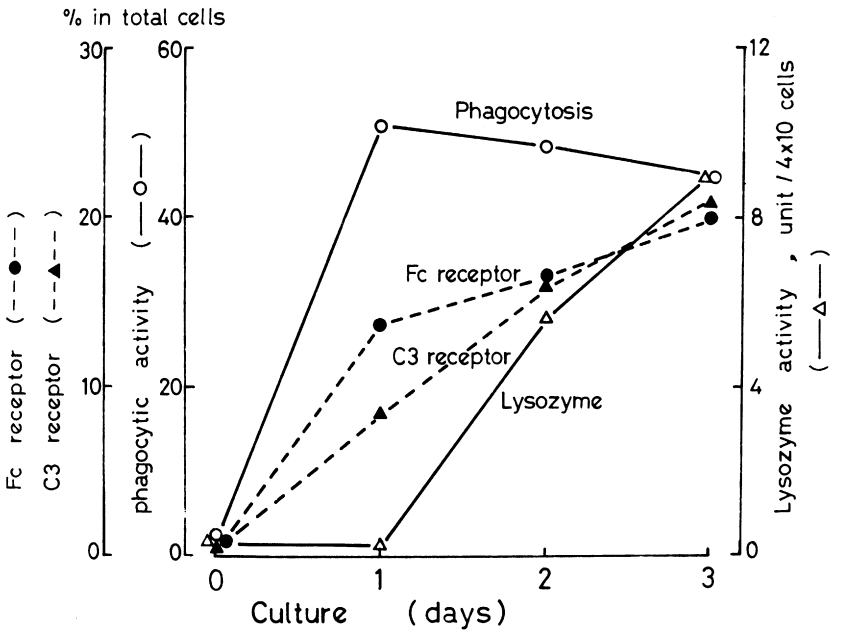

Figure 9 Time course of change in differentiation-associated properties of MI cells induced by $1\alpha,25(OH)_2D_3$. Cells were incubated with 1.2×10^{-8} *M* of $1\alpha,25(OH)_2D_3$ for 3 days. At indicated times, cells were harvested and their lysozyme activity was determined. In addition, percentages of phagocytic cells and of cells with Fc and C3 rosettes within the treated culture were determined. From Suda *et al.* (1984), with permission.

immunoglobulin production in response to $1,25(OH)_2D_3$ (Lemire *et al.,* 1984; Provvedine *et al.,* 1986). Circulating monocytes also possessed a VDR. In transformed and normal monocytes, $1,25(OH)_2D_3$ induced phagocytic activity in a time-and dose-dependent manner, increased OKII binding, augmented IL-1 production, enhanced lysosomal activity, and increased expression of cell surface antigens, including Fc and C_3 (Fig. 9) (Gray and Cohen, 1985; Amento, 1987; Suda *et al.,* 1984). When normal human monocytes were incubated with $1,25(OH)_2D_3$, cells developed morphologic and enzymatic changes consistent with their differentiation into macrophages (Provvedini *et al.,* 1986).

Therefore, it would appear that the immune system is potentially very sensitive to the modulating activities of $1,25(OH)_2D_3$. However, the exact physiological role of $1,25(OH)_2D_3$ on regulating the immune system is not well understood. An insight into the potential physiologic action of $1,25(OH)_2D_3$ on the immune system can best be seen in animals and patients with vitamin D deficiency and in patients with an inborn error in the metabolism of 25-OH-D to $1,25(OH)_2D$ or a defective VDR. Patients with vitamin D-deficient rickets have been noted to have recurrent infections, mainly of the respiratory tract (Lorente *et al.,* 1976). Vitamin D-deficient patients also have a depressed inflammatory and phagocytic response that is corrected by vitamin D replacement (Lorente *et al.,* 1976). A more subtle defect in the immune system is seen in patients with vitamin D receptor defects [vitamin D-dependent rickets type II (DDR II)]. Circulating mononuclear cells from these patients that had been stimulated previously with Con A did not respond to the same degree as normal monocytic cells to the antiproliferative activity of $1,25(OH)_2D_3$(Koren *et al.,* 1985). Furthermore, $1,25(OH)_2D_3$ and 1α-OH-D_3 treatment restored deficient macrophage and lymphocyte activities in vitamin D-deficient rats, in patients with vitamin D resistance, and in renal failure patients (Weintraub *et al.,* 1989; Binderup, 1992; Kitajima, 1989; Tabata *et al.,* 1988).

If $1,25(OH)_2D_3$ played a critical role in maintaining the immune system, then one might expect that patients with vitamin D deficiency or patients unable to either produce $1,25(OH)_2D$ (vitamin D-dependent rickets type I) or respond to $1,25(OH)_2D_3$ (DDR II) would be overcome by bacterial and viral infections. However, with the exception of some subtle recurrent infections in the respiratory tract, this is not so. Therefore, there is little evidence that $1,25(OH)_2D_3$ plays a critical role in maintaining a competent immune system.

$1,25(OH)_2D_3$ has a variety of *in vitro* and *in vivo* effects on the immune system. However, the *in vitro* observations do not necessarily predict *in vivo* outcomes. This may be due to the multitude of effects $1,25(OH)_2D$ has on T and B lymphocytes and monocytes. *In vivo,* the combination of these effects manifest themselves in numerous ways. In mice, $1,25(OH)_2D_3$ substantially reduces the development of autoimmune thyroiditis (Fournier *et al.,* 1990), encephalomyelitis (Lemire and Archer, 1991), and multiple sclerosis (Hayes *et al.,* 1997). $1,25(OH)_2D_3$ prolongs the survival of transplanted skin allografts in mice (Chiocchia *et al.,* 1991) and prevents the incidence of autoimmune diabetes in NOD mice (Mathieu *et al.,* 1994) (Fig. 10). Whereas *in vitro* $1,25(OH)_2D_3$ decreases immunoglobulin

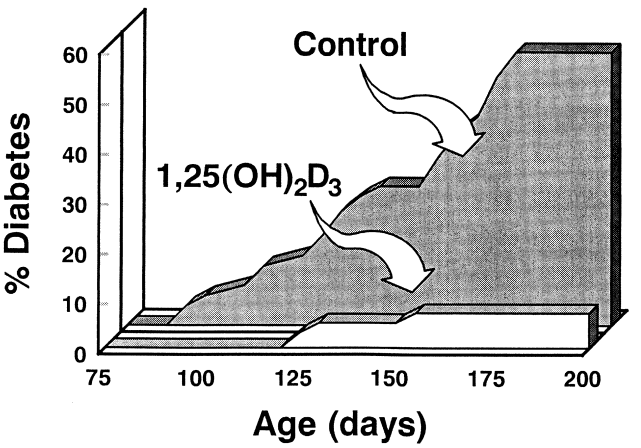

Figure 10 The effect of $1,25(OH)_2D_3$ on reducing the incidence of diabetes mellitus type I in NOD mice. Adapted from Mathieu *et al.* (1994).

synthesis in B lymphocytes, *in vivo,* its precursor analog, 1-α-OH-D_3, leads to an increase in primary antibody response (Komori *et al.,* 1985).

SKIN

The original observation that $[^3H]1,25(OH)_2D_3$ localized in the nuclei of cells in the basal layer of the epidermis has now been extended to include nuclei of cells in the outer root sheath of the hair follicle and in the stratum granulosum and stratum spinosum of the epidermis (Stumpf *et al.,* 1979, 1984). The presence of and amounts of VDR in keratinocytes appear to be related to the proliferative and differentiation activity of the cells; more VDR activity is observed in preconfluent proliferating cells than in postconfluent cells (Pillai *et al.,* 1987). VDR immunoreactivity has been detected in nuclei of dermal papilla cells and outer root sheath keratinocytes of the hair follicle. During hair follicle proliferation, the VDR immunoreactivity was enhanced significantly in both cell types, suggesting a potential role of $1,25(OH)_2D_3$ in regulating the hair cycle (Reichrath *et al.,* 1994). Although the physiologic function of $1,25(OH)_2D_3$ in these skin cells is not well understood, in cultured human and murine keratinocytes, $1,25(OH)_2D_3$ inhibited their proliferation in a dose-dependent fashion and caused them to terminally differentiate (Fig. 11) (Hosomi *et al.,* 1983; Smith *et al.,* 1986; Pillai *et al.,* 1987). Human skin fibroblasts also have VDR and respond to the hormone in a similar manner (Feldman *et al.,* 1982; Clemens *et al.,* 1983; Holick, 1995).

When cultured melanoma cells with VDR+ were incubated with $1,25(OH)_2D_3$, this hormone inhibited their proliferation and induced them to differentiate (Colston *et al.,* 1981). These data suggest that melanocytes may also be a target cell for $1,25(OH)_2D_3$. There is also immunohistochemical evidence for the presence of VDR in melanocytes from skin biopsies of patients with psoriasis (Milde *et al.,* 1991). However, there is no direct evidence that normal human melanocytes either possess a VDR or respond to $1,25(OH)_2D_3$ (Mansur *et al.,* 1988).

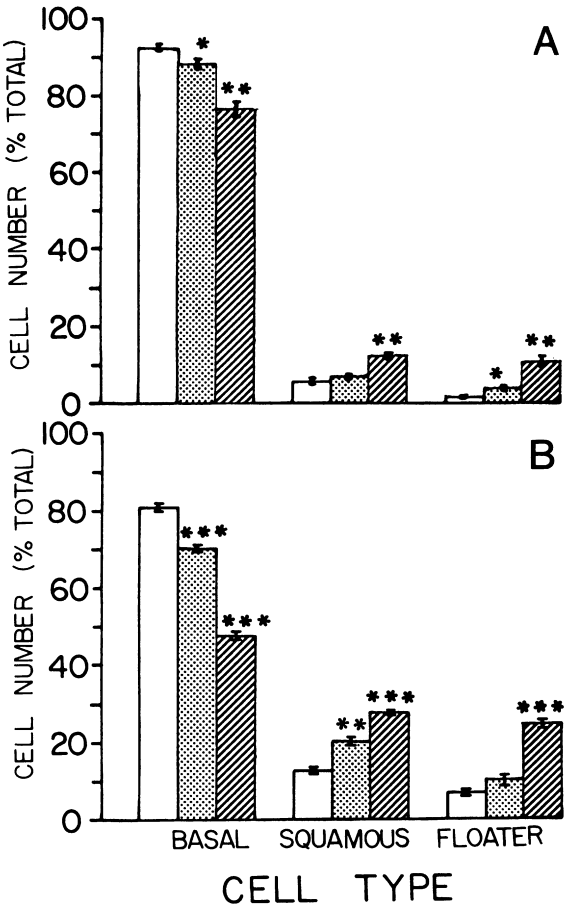

Figure 11 Effect of $1\alpha,25(OH)_2D_3$ on the morphologic differentiation of cultured human keratinocytes. The proportion of different keratinocyte cell types after 1 (A) or 2 (B) weeks of incubation with vehicle alone (open bar), $1\alpha,25(OH)_2D_3$ at 10^{-10} *M* (dotted bar), or $1\alpha,25(OH)_2D_3$ at 10^{-8} *M* (striped bar). Each bar represents the mean of triplicate determinations ± SEM. Student's *t* test was used to assess the level of significance ($^*p < 0.05$; $^{**}p < 0.001$). Reproduced with permission from Smith *et al.* (1986).

OTHER TISSUES

A wide variety of other cells and tissues from the brain to the gonads possess VDR (Clemens *et al.,* 1988). Cultured chick embryo skeletal myoblasts have receptor binding for $1,25(OH)_2D_3$ (Boland *et al.,* 1985). Furthermore, when cultured VDR+ myoblast cells (G-8 and H9c2) were incubated with $1,25(OH)_2D_3$, there was a dose-dependent decrease in cell proliferation and induction of terminal differentiation. When the cells became fused microtubules, VDR activity decreased (Simpson *et al.,* 1985). VDR is also present in rodent heart tissue, and when isolated cardiac muscle cells were exposed to $1,25(OH)_2D_3$, the hormone increased calcium uptake in a time - and dose-dependent fashion (Weishaar and Simpson, 1989).

Ovaries and testes have VDR activity. Sertoli cells in culture increase rapid uptake of calcium when exposed to $1,25(OH)_2D_3$ (Akerson and Walters, 1992). Of great interest was the observation that primary cultured prostate cells derived from normal, benign prostatic hyperplasia and

prostate cancer tissues possess VDR (Skowronski *et al.,* 1995). Prostate cancer cell lines and primary cultures of stromal and epithelial cells derived from normal and malignant prostate tissues respond in a dose-dependent fashion to the antiproliferative activity of $1,25(OH)_2D_3$.

β islet cells of the pancreas possess a VDR. There is some evidence that $1,25(OH)_2D$ may alter insulin secretion (Cade and Norman, 1986). The parathyroid glands possess VDR, and there is strong evidence that $1,25(OH)_2D_3$ suppresses preproparathyroid hormone mRNA levels (Naveh-Many and Silver, 1990).

Relevance of VDR and $1,25(OH)_2D_3$ in Noncalcemic Cells and Tissues

PHYSIOLOGIC ACTIONS

It is remarkable that most cells and tissues in the human body possess VDR and are therefore potential target tissues for $1,25(OH)_2D_3$ (Table I). Although there is very strong evidence *in vitro* and *in vivo* that $1,25(OH)_2D_3$ can have a wide range of noncalcemic activities that have an impact on the function of the immune system, skin, gonads, prostate gland, brain, skeletal and smooth muscle, and pancreas, the true physiologic function of $1,25(OH)_2D_3$ is not well understood. To put this into perspective, patients who are vitamin D deficient or patients who suffer from DDR II and are therefore totally resistant to the action of $1,25(OH)_2D_3$ do not seem to have major deficits in the physiologic function of most of the tissues described. There is subtle evidence that vitamin D deficiency causes muscle weakness and alters the immune system to make these patients more prone to some infections, and in the case of DDR II, the patients often suffer from alopecia (DeMay, 1995; Holick, 1995). They, however, do not have a higher incidence of cancer such as leukemia, they do not suffer from diabetes mellitus, and their skin appears to be normal with no evidence of hyperproliferation, such as psoriasis or pigmentation disorders.

PHARMACOLOGIC ACTIONS

The recognition in the early 1980s that $1,25(OH)_2D_3$ inhibited proliferation and induced differentiation of normal and tumor cells that possessed VDR was greeted with great excitement. The observation that mice with an M-1 cell leukemia had a marked prolongation in their survival when they received 1-α-OH-D_3 or $1,25(OH)_2D_3$ suggested that the antiproliferative activity of $1,25(OH)_2D_3$ and its analogs could be used to treat a variety of cancers (Honma *et al.,* 1982). Eighteen patients with myelodysplasia (preleukemia) were treated with 2μg of $1,25(OH)_2D_3$ for 12 weeks. A majority of the patients initially had a significant increase in their granulocyte, monocyte, and platelet counts, suggesting that $1,25(OH)_2D_3$ was inhibiting the proliferation and inducing terminal differentiation of the myelodysplastic cells. After 12 weeks of the study, however, there was no significant difference in the blood count for granulocytes, monocytes, and platelets compared to baseline and most patients progressed to acute myelocytic leukemia. In addition, most of the patients had developed hypercalcemia, limiting the amount of drug that could be used (Koeffler *et al.,* 1985). Three patients with myelofibrosis who received $1,25(OH)_2D_3$ (0.5 μg daily) had some improvement in their blood count indices after therapy (Arlet *et al.,* 1984).

When HL-60 cells are incubated with $1,25(OH)_2D_3$, most of the cells that have VDR respond to its antiproliferative and prodifferentiation activities. However, when $1,25(OH)_2D_3$ is removed from the culture, cells that did not commit to full differentiation reverted back to their original (anaplastic) state of activity (Bar-Shavit *et al.,* 1986). It is likely that in the population of leukemia cells, there are cells that have either defective or absent VDR. As a result, these clones of cells become the predominant cell type that may also be more blastic. There continues to be interest in developing potent analogs of $1,25(OH)_2D_3$ that have little calcemic activity and potent antiproliferative activity. These analogs could potentially be used as part of combination therapy for some cancers, such as colon, breast, prostate, and some leukemias.

Clinical Utility of Noncalcemic Actions of $1,25(OH)_2D_3$ and Its Analogs

Use of $1,25(OH)_2D_3$ and Its Analogs for Treatment of Skin Diseases

RATIONALE FOR THEIR USE

In the mid-1980s, there was mounting evidence that epidermal skin cells were very sensitive to the antiproliferative activity of $1,25(OH)_2D_3$ (Hosomi *et al.,* 1983; Smith *et al.,* 1986). Because psoriasis is a nonmalignant hyperproliferative disorder of the epidermis, it was reasoned that if psoriatic skin cells possessed a VDR, then it might be possible to use $1,25(OH)_2D_3$ or one of its analogs to decrease psoriatic keratinocyte proliferation, thereby treating this disorder. Before initiating a clinical trial to evaluate the therapeutic efficacy of $1,25(OH)_2D_3$, McLaughlin *et al.* (1985) obtained skin biopsies from six patients with psoriasis to determine whether cultured psoriatic fibroblasts responded to the antiproliferative activity of $1,25(OH)_2D_3$. It was found that psoriatic fibroblasts had a partial resistance to the antiproliferative activity of $1,25(OH)_2D_3$, and it was concluded that pharmacologic rather than physiologic amounts of $1,25(OH)_2D_3$ and its analogs could be used for the treatment of psoriasis (McLaughlin *et al.,* 1985) (Fig. 12). At the same time, Morimoto *et al.* (1985) treated an osteoporosis patient with 1α-OH-D and observed that this patient, who also suffered from psoriasis, had significant improvement in her disease while on therapy. There are now numerous reports that topical $1,25(OH)_2D_3$, as well as topical application of analogs of $1,25(OH)_2D_3$, including 1,24-dihydroxyvitamin D_3 and calcipotriene (Dovonex; Bristol-Meyers Squibb, Buffalo, NY), is safe and effective for the treatment of psoriasis

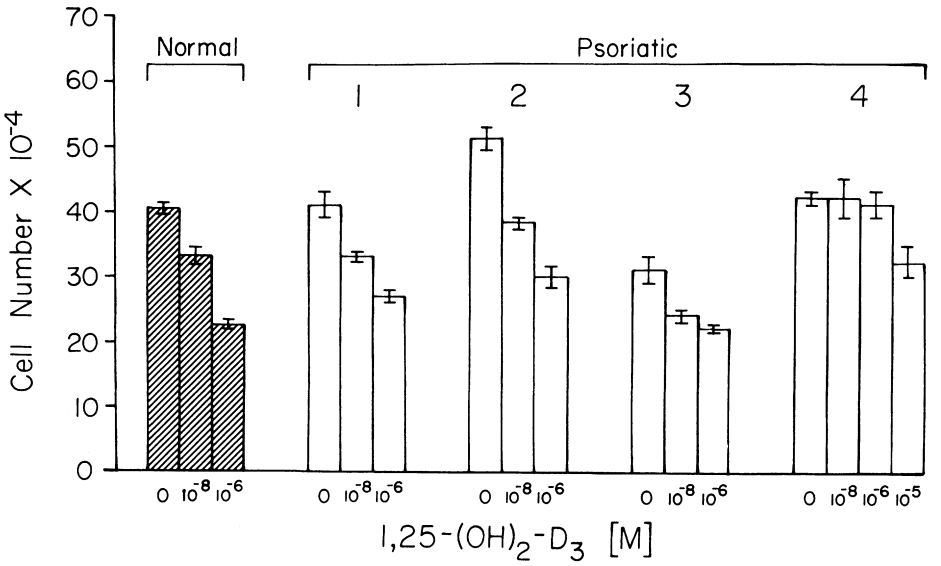

Figure 12 Effect of $1,25(OH)_2D_3$ on the growth of cultured dermal fibroblasts obtained from a normal adult or from four different patients with psoriasis. Fibroblasts were incubated in medium-containing vehicle alone or with $1,25(OH)_2D_3$ at 10^{-8}, 10^{-6}, or 10^{-5} mol/liter. After 7 days the cells were harvested and counted. Each bar represents the mean ± SEM cell number of triplicate cultures. Reproduced with permission from Smith *et al.* (1988).

(Kato *et al.,* 1986; van DeKerkhof *et al.,* 1989; Kragballe *et al.,* 1989; Staberg *et al.,* 1989; Langer *et al.,* 1992; Bourke *et al.,* 1993; Langer *et al.,* 1993; Holick, 1993; Bruce *et al.,* 1994; Perez *et al.,* 1996, 2001).

There has been great concern that in light of the earlier studies using $1,25(OH)_2D_3$ for treating preleukemia that caused severe hypercalcemia (Koeffler *et al.,* 1985) that $1,25(OH)_2D_3$ would not be a safe medication for treating psoriasis. However, for the most part, these concerns have not proven to be correct (Holick, 1993; Perez, *et al.,* 1996a,b).

Clinical Trials with Topical $1,25(OH)_2D_3$ and Its Analogs

The topical application of $1,25(OH)_2D_3$ (15 μg/g petrolatum) caused significant improvement by reducing scale, erythema, and plaque after 2 months of therapy (Fig. 13). After observing no untoward side effects from the therapy, 22 patients topically applied the $1,25(OH)_2D_3$ ointment over all of their lesions (2000–5000 cm^2), using up to 10 g of $1,25(OH)_2D_3$ ointment per day or 150 μg of the $1,25(OH)_2D_3$ daily. Scaling, plaque thickness, and erythema of psoriatic lesions showed excellent or moderate improvement in 90.9% of all cases with marked reduction in the psoriasis area severity index (PASI) score (Perez *et al.,* 1996). There was no change in serum $1,25(OH)_2D_3$ levels, which was also reflected in no significant change in either the 24-hr urinary excretion of calcium or the serum calcium concentration. This is quite remarkable when one considers that the kidney produces only about 2 μg of $1,25(OH)_2D_3$ each day. With the topical application of 70 times the total daily renal production of $1,25(OH)_2D_3$, one would have expected that some of the $1,25(OH)_2D_3$ would be transported across the skin into the circulation, causing hypercalciuria and hypercalcemia. This is especially true, as psoriasis causes a defect in the barrier function of the skin, thereby potentially enhancing the penetration of the drug. Although it is not known why there are no untoward side effects when using topical $1,25(OH)_2D_3$, it is likely that several mechanisms help prevent untoward toxicity. $1,25(OH)_2D_3$ probably partitions itself well between the petrolatum and the epidermis. Once the epidermal cells are exposed to $1,25(OH)_2D_3$, they turn on a cascade of metabolic processes to degrade $1,25(OH)_2D_3$ to a biologically inactive water-soluble calcitroic acid (DeLuca, 1988). It is also reasonable to consider that since the cellular components of the epidermis and dermis possess VDR, they act as an effective sponge to bind most of the $1,25(OH)_2D_3$, thereby preventing its entrance into the dermal capillary bed (Holick, 1987; Holick, 1993).

Several other analogs have been developed for the treatment of psoriasis. The most commonly used analog is calcipotriene (Dovonex). The strategy for developing this analog was to alter the side chain so that it would be metabolized rapidly and, therefore, less prone to developing hypercalciuria and hypercalcemia (Binderup and Braum, 1988; Kragballe *et al.,* 1989; Kragballe, 1991). Indeed, calcipotriene is metabolized and degraded rapidly (Binderup *et al.,* 1988; Sorensen *et al.,* 1990). Calcipotriene at 50 μg/g of ointment or cream is used worldwide for the treatment of psoriasis. Other analogs, including 1,24-hydroxyvitamin D_3 (Kato *et al.,* 1986) and hexafluoro-1,25-dihydroxyvitamin D_3 (Durakovic *et al.,* 2001), have been shown to be effective for treating psoriasis. However, calcipotriene can cause a dermatitis that occurs on very sensitive skin areas, such as

Figure 13 (A) Arms of a patient with a long history of plaque psoriasis before treatment with the topical form of 1,25-dihydroxyvitamin D_3. (B) The same patient who applied only petroleum jelly on the left forearm (at right) and petroleum jelly containing 15 μg/g of $1,25(OH)_2D_3$ on the right forearm (at left) for 3 months. Reproduced with permission from Holick (1994).

the face and genital regions (Yipp *et al.,* 1999), and very rarely hypercalcemia (Hoek *et al.,* 1994).

CLINICAL TRIAL WITH ORAL $1,25(OH)_2D_3$

For patients with more than 10% of their bodies affected with psoriasis, the topical application of $1,25(OH)_2D_3$ and other vitamin D analogs can be inconvenient. Eighty-four patients with psoriasis vulgaris or erythrodermal psoriasis were treated with 0.5 μg of $1,25(OH)_2D_3$ given at night and increased by 0.5 μg every 2 weeks as long as serum and urine calcium levels were normal. The usual therapeutic dose was between 1 and 3 μg each night. The treatment varied from 6 months to 3 years. Overall clinical assessment showed that 88% of all patients taking oral $1,25(OH)_2D_3$ had some improvement in their disease (Perez *et al.,* 1996b). Serum calcium concentrations did not increase outside of the normal range in most of the patients. Twenty-Four-hour urinary excretion increased, but was also not outside the normal range in most patients. Bone mineral density measurements and renal ultrasound scans for kidney stones at 6-month intervals for up to 4 years were unchanged from baseline (Perez *et al.,* 2001; Holick, 1996).

TREATMENT OF PSORIATIC ARTHRITIS WITH $1,25(OH)_2D_3$

It has been estimated that approximately 10% of patients with psoriasis suffer from psoriatic arthritis. In an open-label trial, we found that 10 patients with active psoriatic arthritis who received up to 2.5 μg of oral $1,25(OH)_2D_3$ each night had a statistically significant improvement in mean tender joint count and physician global assessment (Huckins *et al.,* 1991). Forty percent of patients had greater than 50% improvement in their disease and an additional 30% had greater than 25% improvement.

Conclusion

Casual exposure to sunlight provides most humans with their vitamin D requirement. Because vitamin D plays an essential role in the maintenance of a healthy skeleton, it is important that all vertebrates, including humans, have a steady supply of vitamin D. The skin is not only the site for the synthesis of this important calciotropic hormone, but is also a major target tissue for $1,25(OH)_2D_3$. The skin may also be a site for the metabolism of 25-OH-D to $1,25(OH)_2D$ (Bikle *et al.,* 1986). It is remarkable that $1,25(OH)_2D_3$ has so many potential biologic actions. As a result, $1,25(OH)_2D_3$ and its analogs have been developed for the treatment of a wide variety of clinical disorders. $1,25(OH)_2D_3$ and its analogs have been very effective in the treatment of hypocalcemic disorders and for the treatment of metabolic bone diseases associated with acquired and inherited disorders of 25(OH)D metabolism and VDR defects (DeMay, 1995; Holick, 1999). $1,25(OH)_2D_3$ and its analogs have also been shown to be of value for the treatment of osteoporosis (Tilyard *et al.,* 1992). What has been most intriguing about $1,25(OH)_2D_3$ is its potent antiproliferative properties. One might assume that because $1,25(OH)_2D_3$ is such a potent antiproliferative agent that its chronic use for the treatment of a hyperproliferative disorder would ultimately result in an atrophy of the treated tissues. For example, for the treatment of psoriasis, would the chronic use of $1,25(OH)_2D_3$ and its analogs cause senescence of the skin similar to topical steroids? All of the experience has suggested that $1,25(OH)_2D_3$ will not cause any thinning of the skin, unlike topical steroids. This suggests that $1,25(OH)_2D_3$ is able to sense the antiproliferative state and return the activity of the cell to normal. It is for this reason that $1,25(OH)_2D_3$ and its analogs hold such promise for the treatment of a wide variety of proliferative disorders, most notably some cancers.

The observations that many nonrenal tissues, including the skin, colon, and prostate, have 1α-OHase activity opens a new chapter in the vitamin D story (Holick, 2001). Why $1,25(OH)_2D$ would be produced locally in the skin, prostate, colon, and so on remains unknown but may be important in the regulation of cell growth (Fig. 14). The observation that the product of the Wilm's tumor gene modulates cellular proliferative activity of renal and hemopoetic cells and also regulates the expression of the VDR provides insight into the complexity of the function of $1,25(OH)_2D$ in cell growth (Mauer *et al.,* 2001).

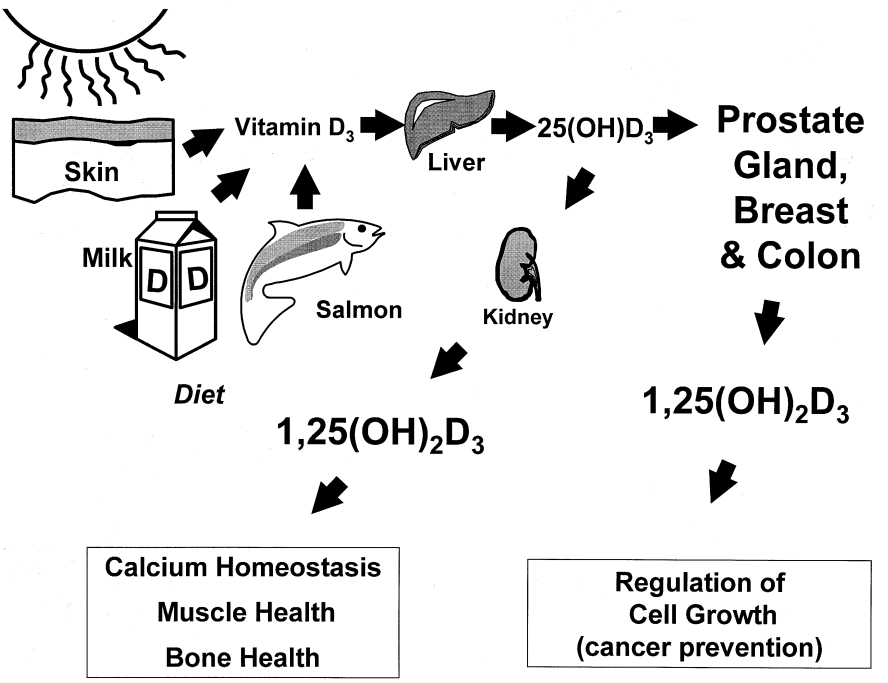

Figure 14 Metabolism of $25(OH)D_3$ to $1,25(OH)_2D_3$ in the kidney that is responsible for maintaining circulating levels of $1,25(OH)_2D_3$ on bone and muscle health and in tissues not related to calcium metabolism. This extrarenal metabolism may be important for regulating cell growth and decreasing malignant cell growth. Reproduced from Holick (2001), with permission.

$1,25(OH)_2D_3$ and its analog 1α-OH-D_3 have been used successfully during the past two decades for treating a variety of acquired and inborn errors in the metabolism of 25(OH)D to $1,25(OH)_2D$, as well as other hypocalcemic disorders (DeMay, 1995; Holick, 1995). The revelation that $1,25(OH)_2D_3$ has noncalcemic activities, including regulating proliferation and differentiation of cells and altering the immune function, sparked great interest in developing selective analogs of $1,25(OH)_2D$ that had the desirable noncalcemic actions of $1,25(OH)_2D$ without the potential toxic side effect on calcium metabolism. There are a very large number of analogs that have been synthesized and well reviewed by Bouillon *et al.* (1995). At the present time, there are very few analogs of $1,25(OH)_2D_3$ that are available commercially and have limited calcemic activity.

CHAPTER 34

Structure and Molecular Biology of the Calcitonin Receptor

Deborah L. Galson and Steven R. Goldring

Department of Medicine, Harvard Medical School, and Division of Rheumatology, Beth Israel Deaconess Medical Center, and the New England Baptist Bone & Joint Institute, Boston, Massachusetts 02115

Introduction

Calcitonin (CT) is a 32 amino acid peptide hormone that was originally identified as a hypocalcemic factor (Copp *et al.,* 1962). In mammals, these effects are attributed to inhibition of bone resorption and enhanced renal calcium excretion (Friedman and Raisz, 1965; Raisz *et al.,* 1967; Raisz and Niemann, 1967; Warshawsky *et al.,* 1980). The application of autoradiographic and radioligand-binding techniques with iodinated CT and, more recently, the use of reagents derived from cloned CT receptors (CTR) have permitted definitive identification and localization of the tissue and cellular distribution of CTRs. These results demonstrate that, in addition to receptors on osteoclasts and renal cells (Warshawsky *et al.,* 1980; Nicholson *et al.,* 1986), CTRs are widely distributed in diverse tissues and cell types, many of which are not involved in the regulation of mineral ion homeostasis. These include the central nervous system (Fischer *et al.,* 1981; Goltzman, 1985), placenta (Nicholson *et al.,* 1988), ovary (Azria, 1989), testis (Chausmer *et al.,* 1980), spermatozoa (Silvestroni *et al.,* 1987), lymphocytes (Marx *et al.,* 1974), and breast (Tverberg *et al.,* 2000). In addition, immunoreactive CT and CT mRNA expression have been colocalized in the mammary gland (Tverberg *et al.,* 2000), intestine, thymus, bladder, lung, testis, ovary, stomach, central nervous system, pituitary, and adrenal glands (Azria, 1989). The CTR is also expressed in a number of human cancer cell lines, including lung (Findlay *et al.,* 1980), prostate (Shah *et al.,* 1994), and breast origin (Findlay *et al.,* 1981) and was found in primary breast cancer cells (Gillespie *et al.,* 1997). This diverse tissue distribution of the ligand, as well as the receptor, indicates that CT may have a more complex function in addition to its activities in regulating calcium homeostasis.

There is good evidence that CT may function as a regulatory hormone in development. For example, in *Xenopus* embryos, addition of CT to the ambient water of the developing eggs produces larvae with multiple defects in oral–facial architecture and in the central nervous system (Burgess, 1982, 1985). These findings are consistent with faulty neural induction, perhaps resulting from effects of CT on migrating cells during gastrulation. It is interesting to speculate that these effects may be analogous to the inhibition of formation of polykaryons by CT during the generation of osteoclasts from mononuclear hematopoietic progenitors (Takahashi *et al.,* 1988b; Vaes, 1988). Further support for the role of CT in early vertebrate development is provided by the observations of Gorn *et al.* (1995a), who demonstrated that overexpression of procalcitonin in the two-cell stage of zebrafish embryos resulted in a variable axis duplication. Of interest, they were able to detect both CTR and CT mRNA at these tissue sites, consistent with an autocrine regulatory feedback system in the zebrafish embryo similar to that suggested by studies in mammalian species.

There are also observations that support a role for CT in mammalian development. For example, CT interaction with CTR (which is upregulated 25-fold between the one-cell and the eight-cell stage blastocyst) increases intracellular levels of calcium in preimplantation embryos and accelerates their development (Wang *et al.,* 1998). In addition, the murine embryonic teratocarcinoma cell line F-9 has receptors for CT that are functionally coupled to adenylate

cyclase (Evain *et al.,* 1981; Binet *et al.,* 1985). Treatment of these cells with dibutryl cAMP induces the cells to assume a neural-like morphology, which is accompanied by the loss of CTRs and a marked decrease in CT-induced cAMP responses (Evain *et al.,* 1981). Under these conditions, F-9 cells are induced to synthesize and secrete CT, suggesting that CT may act as an autocrine regulatory hormone during the differentiation process (Binet *et al.,* 1985).

Of particular interest, evidence shows that CT may have a role in early stages of embryonic bone formation or in the production of ectopic bone. For instance, CT has been shown to stimulate adenylate cyclase activity during the period of palatal fusion and oral–cranial development in golden hamsters (Waterman *et al.,* 1977). Farley and co-workers (1988) have shown that CT directly stimulates bone cell proliferation and bone formation in embryonic chicken skeletal tissues. These findings are consistent with an inductive effect of CT on mesodermal cells of osteoblast lineage or on osteoblasts themselves. It is still not clear, however, whether CT acts directly on bone-forming cells and their progenitors or indirectly through other target cells. CT has also been shown to produce effects in a model of ectopic bone formation. In these studies, administration of CT during early stages of endochondral bone formation induced by demineralized bone matrix results in increased bone formation that appears to be secondary to the enhanced proliferation of cartilage and bone progenitor cells (Weiss *et al.,* 1981). It is of interest that when CT was administered after bone formation was initiated, subsequent bone formation was suppressed, suggesting a differential response to this hormone, depending on the stage of cellular differentiation and the presence of different target cell populations.

CTR Protein Structure and Signaling

The CTR was initially cloned from the porcine renal epithelial cell line LLC-PK_1 (Lin *et al.,* 1991a,b). Analysis of the predicted 482 amino acid sequence of this cDNA demonstrated seven hydrophobic regions that could generate transmembrane (TM)-spanning domains. It has since been found that CTR is a member of a subfamily of the seven transmembrane domain G protein-coupled receptor superfamily termed $GPCR_{II}$. Members of this receptor family include receptors for parathyroid hormone/parathyroid hormone-related peptide (PTH/PTHrP) (Jüppner *et al.,* 1991; Abou-Samra *et al.,* 1992), corticotropin-releasing factor (Chen *et al.,* 1993), and, in addition, receptors for the glucagon family of peptides, glucagon (Jelinek *et al.,* 1993), secretin (Ishihara *et al.,* 1991), vasoactive intestinal peptide (Ishihara *et al.,* 1992), glucagon-like peptide 1 (Thorens, 1992), growth hormone-releasing hormone (GHRH) (Mayo, 1992), and pituitary adenylate cyclase-activating peptide (PACAP) (Pisegna and Wank, 1993). The most recent addition to this family is the so-called insect diuretic hormone receptor from adult *Manduca sexta* that stimulates fluid secretion and cAMP synthesis in the Malphighian tubules (Reagan, 1994). The peptide that activates this receptor belongs to the corticotropin-releasing factor peptide family (Chen *et al.,* 1993).

Analysis of the protein structure and amino acid sequences of the CTR (see Fig. 1) and related members of the family demonstrates that they share several common features. All of the predicted receptor proteins contain an extended extracellular amino (N)-terminal region that contains multiple potential glycosylation sites and conserved cysteine residues (Segre and Goldring, 1993). Glycosylation, particularly at Asn 78 and Asn 83 of the archetypal hCTR, is important for high-affinity binding of CT (Ho *et al.,* 1999). While the TM domain sequences are conserved (40–60% identical), the N-terminal domains are generally less than 25% identical. These observations suggest that the TM domain regions may have a more generic function, whereas the N-terminal domain fulfills specialized functions, such as ligand binding and receptor specificity. This speculation is supported by the functional consequences of site-directed mutagenesis of the receptors and the evaluation of both chimeric PTH/PTHrP-CT receptors and chimeric CT and PTH ligands (Jüppner *et al.,* 1993; Bergwitz *et al.,* 1996). Results indicate that the C-terminal portions of the ligands bind to the N-terminal extracellular domains of the receptors, whereas the N-terminal regions of the ligands interact with membrane-embedded domains to trigger receptor activation and signal transduction. With respect to the C-terminal intracellular domain of the receptors, except for the amino acid sequences immediately adjacent to the seventh TM domain, which are highly homologous and have been implicated in coupling to G proteins, the C-terminal regions are not conserved among $GPCR_{II}$ family members. One possibility is that the C terminus has different functions in the individual receptors. Alternatively, this region may not have a specific or critical function and is thus less constrained by selection and is more susceptible to sequence drift (Lok *et al.,* 1994).

The CTR is coupled to multiple signal transduction pathways through interaction with members of the heterotrimeric G protein family. Binding of CT to the CTR can stimulate activation of the adenylate cyclase/cAMP/ protein kinase A pathway (Chabre *et al.,* 1992; Force *et al.,* 1992) through the G protein G_s; the phosphoinositide-dependent phospholipase C pathway, which results in both Ca^{2+} mobilization (Teti *et al.,* 1995) and protein kinase C activation (Chakraborty *et al.,* 1994) via G proteins of the G_q family; and the phosphatidylcholine-dependent phospholipase D pathway, which also results in protein kinase C activation (Naro *et al.,* 1998) and can, under certain conditions, inhibit adenylate cyclase via the G_i subclass of G proteins (Shyu *et al.,* 1999). Of interest, the coupling of the CTR to specific G proteins and activation of individual signal pathways are affected by the stage of the cell cycle (Chakraborty *et al.,* 1991; Shyu *et al.,* 1999). In synchronized LLC-PK_1 cells, it has been reported that CTR-coupled G_i modulates the adenylyl cyclase activity stimulated by CTR-coupled G_s in the S

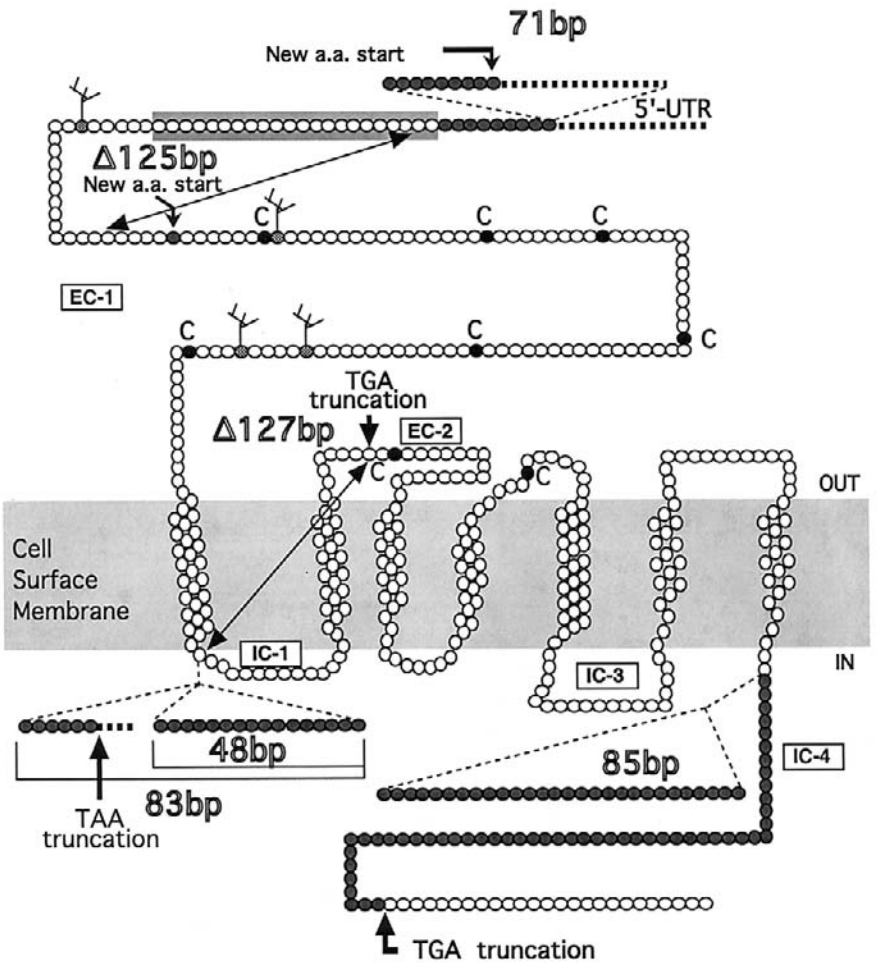

Figure 1 mRNA splice variants of human CTR depicted as expected protein translation products. White circles represent the amino acids (a.a.) of the archetypal human CTR isoform. The a.a. positions denoted as black circles with a C nearby are the conserved cysteines and shaded circles with the branch structure are the putative sites for N-glycosylation. Boxed circles denote the putative signal sequence. Gray circles represent amino acids added or changed by the addition or deletion of variably spliced mRNA regions as indicated. The domains of interest are noted as follows: IC-1, IC-3, and IC-4, first, third, and fourth intracellular domains, respectively; EC-1 and EC-2, first and second extracellular domain, respectively.

phase, but not in the G_2 phase of the cell cycle, and that this could be regulated by PKC-dependent negative regulation of the CTR-G_i-adenylyl cyclase coupling (Shyu *et al.,* 1999).

The CTR-mediated increases in cytosolic-free $[Ca^{2+}]$ ($[Ca^{2+}]_i$) and inositol phosphate production (Force *et al.,* 1992) are transduced by the activation of phospholipase C (PLC), which hydrolyzes phosphatidylinositol 4,5-biphosphate to generate two second messengers: inositol 1,4,5-triphosphate (IP_3) and diacylglycerol (DAG) (Rhee and Bae, 1997). The IP_3 generated binds to IP_3 receptors (ligand-gated ion channels) on the endoplasmic reticulum (ER), resulting in a release of the ER Ca^{2+} stores into the cytoplasm (Berridge, 1993). Prolonged elevation of $[Ca^{2+}]_i$ levels, beyond the initial transient resulting from the emptying of ER calcium stores, leads secondarily to an influx of extracellular Ca^{2+}. This sustained plateau phase of calcium mobilization is the outcome of capacitative calcium entry, a process that couples the depletion of intracellular stores to the influx of extracellular calcium through the specialized calcium channels (Findlay *et al.,* 1995; Teti *et al.,* 1995). Thapsigargin, an inhibitor of the endoplasmic reticulum Ca^{2+}-ATPase needed for repletion of calcium stores, induces a transient $[Ca^{2+}]_i$ increase by blocking reuptake, whereas ionomycin, a calcium ionophore, depletes the calcium stores directly. Both cause capacitative calcium entry in T cells. In HEK-293 cells stably transfected with rat or porcine CTRs (Findlay *et al.,* 1995) and the porcine renal tubular cell line LLC-PK_1 (Teti *et al.,* 1995), pretreatment with thapsigargin induced a transient increase and a sustained plateau, and further treatment with CT did not increase $[Ca^{2+}]_i$ over the thapsigargin-induced plateau. In HEK-293 cells transfected with a rat CTR, the CT-induced calcium influx was not inhibited by pertussis toxin, suggesting that although a G protein(s) may transduce the

CT signal, it is not a substrate for pertussis toxin ADP ribosylation (Findlay *et al.,* 1995).

The mechanism by which CT increases cAMP levels involves activation of adenylyl cyclase, a process that is dependent on interaction with the G protein G_s. In order to establish the molecular basis for G_s activation by CTR, a chimeric CTR/IGF II-R has been used to identify at least two distinct segments of the CTR, which have the capacity to interact with G_s proteins and activate cAMP (Orcel *et al.,* 2000). One segment is localized to residues 327–344 in the third intracellular loop (IC3) and the other to residues 404–418 in the membrane-proximal portion of the fourth intracellular domain (IC4). Similar regions of the predicted intracellular domains have been associated with G protein interactions in other members of the $GPCR_{II}$ family of receptors.

Signal pathways regulating the effects of CT on specific osteoclast activities have been studied extensively. However, interpretation of the role of the individual pathways responsible for the specific effects on osteclast function has been difficult because the results have often been dependent on the specific cell culture model employed and the species from which the cells were derived. In general, data indicate that activation of the adenylyl cyclase signal cascade induces the arrest of cell motility, in part, mediated by stimulation of the sodium pump. In contrast, a CT-induced elevation of $[Ca^{2+}]_i$ levels has been shown to be responsible for osteoclast retraction (Chambers *et al.,* 1985; Su *et al.,* 1992). We have observed that CT treatment of a chicken osteoclast-like cell line (HD-11EM) stably transfected with the archetypal human CTR induced changes in proliferation and cell shape (from cuboidal to stellate) and a loss of adhesion (Galson *et al.,* 1998). CT had a complex effect on cell growth with an early (within 4 hr) increase in proliferation followed by a block at G_2 (D. L. Galson, M. R. Flannery, and S. R. Goldring, unpublished results). All of these cellular responses to CT were independent of G_s signaling and adenylyl cyclase activation. PMA treatment was able to mimic much of the effects of CT treatment, implying that PKC activation regulated all of the CT-induced cellular responses observed. However, the PKC inhibitor Ro-31-8220 could only completely block the CT-induced loss of adhesion and partially block the CT-induced early proliferative response and had no effect on CT-induced cell morphology. These studies provide further evidence that CT effects on osteoclast function involve complex and independent signal pathways.

There is growing evidence of a role for CT and CTR signaling in modulating cell growth and for the general involvement of GPCR in regulating mitogen-activated protein kinase (MAPK) signaling networks (Gutkind, 1998). MAPKs, including Erk1/2, JNK, and SAPK, lie at the end of parallel protein kinase cascades and play important roles in many biological processes, including differentiation and normal and aberrant cell growth. Analysis of the effects of CT on cell proliferation has demonstrated that CT, paradoxically, can both contribute to mitogenesis and mediate growth suppression depending on the cellular context. For example, CT suppresses cellular proliferation of the human breast cancer cells lines T47D and MCF7 (Ng *et al.,* 1983), whereas it has a mitogenic action in primary human prostate cancer cells and a cell line LnCaP derived from prostate cancer (Shah *et al.,* 1994). The CT-induced suppression of T47D is thought to be mediated by the specific activation of the type II isoenzyme of the cAMP-dependent protein kinase (Ng *et al.,* 1983). However, CT increases both cAMP and $[Ca^{2+}]_i$ in the prostate cells (Shah *et al.,* 1994).

Cell lines stably transfected with CTRs have been used to gain further insights into the mechanisms by which CT regulates cell proliferation. Evdokiou *et al.* (1999) showed that CT suppressed the cellular proliferation of HEK-293 cells transfected with the rat or human CTR. No evidence of cell necrosis or apoptosis was detected, and growth inhibition appeared to be associated with an accumulation of cells in the G_2 phase of the cell cycle. The CT-induced G_2 block was associated with a rapid and sustained induction of the cyclin-dependent kinase inhibitor $p21^{WAF1/CIP1}$ mRNA and protein and reduction in p53 mRNA and protein.

In HEK-293 cells transfected with the rabbit CTR, CT induced Shc tyrosine phosphorylation, Shc-Grb2 association and phosphorylation, and activation of the MAPKs Erk1 and Erk2 (Chen *et al.,* 1998). Erk1/2 activation occurred through both a G_i pathway leading to activation of Ras and a G_q pathway, which raises $[Ca^{2+}]_i$ levels and activates PKC via a Ras-independent pathway. While the CT-induced increase in $[Ca^{2+}]_i$ levels was necessary, it was not sufficient for full activation of Erk1/2. CT-induced activation of the Erk1/2 MAPK pathway appears to be involved in CTR-mediated growth suppression. Raggatt *et al.* (2000) reported that inhibition of the CT-induced phosphorylation of Erk1/2 by the MEK inhibitor PD98059 in HEK-293 cells expressing the archetypal hCTR partially blocked the reported growth inhibitory effects of CT on these cells (Evdokiou *et al.,* 1999). These included blocking the associated accumulation of cells in G_2 and the CT induction of $p21^{WAF1/CIP1}$. These data suggest that activation of Erk1/2 by CT-liganded CTR is an important downstream effector in modulating cell cycle progression.

CT may exert its effects on cell shape and attachment via interactions of the CTR with the signal pathways linked to modulating the focal adhesion complex. CT stimulates tyrosine phosphorylation of the focal adhesion-associated protein HEF1, paxillin, and focal adhesion kinase (FAK) and their consequent complex formation by a mechanism dependent on both increased $[Ca^{2+}]_i$ levels and the activation of PKC (Zhang *et al.,* 1999). However, unlike the Erk1/2 response, CT-induced phosphorylation of HEF1 was completely pertussis toxin insensitive, suggesting that only activation of G_q is involved. Although the G_q pathway appears to be involved in the phosphorylations of Erk1/2 and of HEF1 and paxillin, the mechanisms by which these responses are transduced are largely independent (Zhang *et al.,* 2000). For instance, inhibition of MEK activity by

PD98059 reduced the CT-induced phosphorylation of Erk1/2 but not of HEF1 and paxillin. Also, unlike the CT-induced phosphorylation and activation of Erk1/2, the CT-induced phosphorylation of HEF1 was inhibited by cytochalasin D, suggesting that the actin cytoskeleton has a role in transducing the signal from the CTR to the focal adhesion-associated proteins. In addition to an intact cytoskeleton, cell attachment with engagement of integrins with extracellular matrix proteins and catalytically active Src are also required for CT-induced phosphorylation of HEF1 and paxillin. Regulation of the activity of these adhesion-related proteins may play a role in mediating CT induction of changes in cell shape and motility.

It has been demonstrated that the archetypal human CTR, when coexpressed with any of the three receptor activity-modifying proteins (RAMP1, 2, or 3), is also a receptor for the 37 amino acid peptide hormone amylin (Christopoulos *et al.,* 1999; Foord and Marshall, 1999; Muff *et al.,* 1999; Zumpe *et al.,* 2000). This peptide has effects on insulin release, glucose uptake, and glycogen synthesis in skeletal musculature (Wimalawansa, 1997). The RAMPs are a three member family of single TM proteins that act to modify the affinity of the CTR for the different peptide ligands of the CT family (CT, CGRP, amylin, and adrenomedullin). For instance, hCTR coexpressed with RAMP1 in COS-7 cells has higher affinity for human CGRPα and amylin and lower affinity for human CT than hCTR coexpressed with RAMP2 (Zumpe *et al.,* 2000). The interaction of the CTR with RAMPs represents an additional mechanism for modulating the function of the CTR and its response to ligands.

CTR Protein Isoforms Derived by Alternative mRNA Splicing

The CTR gene has a complex structural organization with several CTR protein isoforms derived from alternative splicing of transcripts from a single gene (Goldring, 1996). These isoforms, which are functionally distinct in terms of ligand-binding specificity and/or signal transduction pathway utilization, are distributed both in a tissue- and in a species-specific pattern (Lin *et al.,* 1991a; Gorn *et al.,* 1992, 1995b; Sexton *et al.,* 1993; Houssami *et al.,* 1994; Kuestner *et al.,* 1994; Yamin *et al.,* 1994; Zolnierowicz *et al.,* 1994; Albrandt *et al.,* 1995; Ikegame *et al.,* 1995; Shyu *et al.,* 1996; Galson *et al.,* 1996, 1997; Anusaksathien *et al.,* 2001). At least six different isoforms involving coding sequence exons of the human CTR (hCTR) have been described (Fig. 1). Each of these cDNAs would generate proteins with different predicted structural features.

Much of the understanding of the structure–function relationships in the hCTR have been gleaned from the analysis of two isoforms of the hCTR that differ by the presence or absence of a 48-bp exon (exon 7b) encoding 16 amino acids in intracellular domain 1 (IC1) (Fig. 1). These two isoforms exhibit significant differences in their pattern of coupling to signal transduction pathways and ligand-binding affinity (Gorn *et al.,* 1992, 1995b; Frendo *et al.,* 1994; Kuestner *et al.,* 1994). The hCTR isoform without the 48-bp exon (hCTR-48$^-$; "archetypal" hCTR) has lower binding affinity for salmon CT (sCT) (K_d 15 n*M*) than the 48-bp exon containing hCTR (hCTR-48$^+$) isoform (K_d 1.5 n*M*). In contrast, the hCTR-48$^-$ isoform demonstrates a much more significant ligand-mediated cAMP response to sCT and human CT (hCT) compared to the hCTR-48$^+$ isoform (Gorn *et al.,* 1995b). However, the ability of the hCTR-48$^+$ isoform to couple to adenylyl cyclase is affected differentially in different cell types (Nussenzveig *et al.,* 1994; Albrandt *et al.,* 1995; Gorn *et al.,* 1995b; Moore *et al.,* 1995). In contrast to the hCTR-48$^-$ isoform, the hCTR-48$^+$ isoform does not couple to PLC (Gorn *et al.,* 1992; Nussenzveig *et al.,* 1994; Moore *et al.,* 1995) nor to PLD (Naro *et al.,* 1998) and therefore does not induce PKC nor trigger an increase in $[Ca^{2+}]_i$ levels. When transfected into HEK-293 cells, the hCTR-48$^+$ isoform fails to transduce the CT-induced growth suppression signal mediated by the activation of Erk1/2 that was observed with the hCTR-48$^-$ isoform (Raggatt *et al.,* 2000). However, this group also reported that both the hCTR-48$^+$ and the hCTR-48$^-$ isoforms in HEK-293 could mediate CT-induced acidification of the extracellular medium by an unknown mechanism, suggesting that the hCTR-48$^+$ isoform may activate previously unrecognized pathways. The presence of the 16 amino acids in IC1 also inhibits ligand–receptor complex internalization (Moore *et al.,* 1995). Although in many tissues, the hCTR-48$^-$ isoform mRNA appears to be the predominant form, there are significant levels of the hCTR-48$^+$ mRNA in the osteoclast-like cells of giant cell tumor, CD34$^+$ cells from cord blood, placenta, and ovary (Gorn *et al.,* 1992, 1995b; Frendo *et al.,* 1994; Kuestner *et al.,* 1994; Albrandt *et al.,* 1995; Galson *et al.,* 1996). The porcine CTR (pCTR) also contains a variably spliced 48-bp exon encoding an additional 16 amino acids in IC1 (Zolnierowicz *et al.,* 1994). While the position of the variably utilized 16 amino acids in IC1 is identical with the hCTR, only two of the amino acids are conserved. The pCTR-1b (48+) is ~1000-fold less abundant in LLC-PK$_1$ cell mRNA than pCTR-1a (48−).

Both human (Gorn *et al.,* 1992, 1995b) (Fig. 1) and mouse CTRs (Anusaksathien *et al.,* 2001) (Fig. 2) contain a variably spliced exon that adds an in-frame upstream ATG with the potential to generate receptors with an additional 18 or 17 amino acids at the N terminus, respectively. Additionally, a hCTR mRNA has been identified that has a 125-bp deletion (hCTR-Δ125) from within exon 3 to mid exon 4, which includes the initiator Met (Albrandt *et al.,* 1995). Therefore, translation starts at an internal Met (M48), resulting in an N-terminal deletion of 48 amino acids. This N-terminally truncated hCTR isoform, which exhibits high binding affinity to sCT and a strong dose-dependent cAMP response to sCT, hCT, and human amylin, is expressed in mammary carcinoma cell lines (T47D and MCF-7), as well

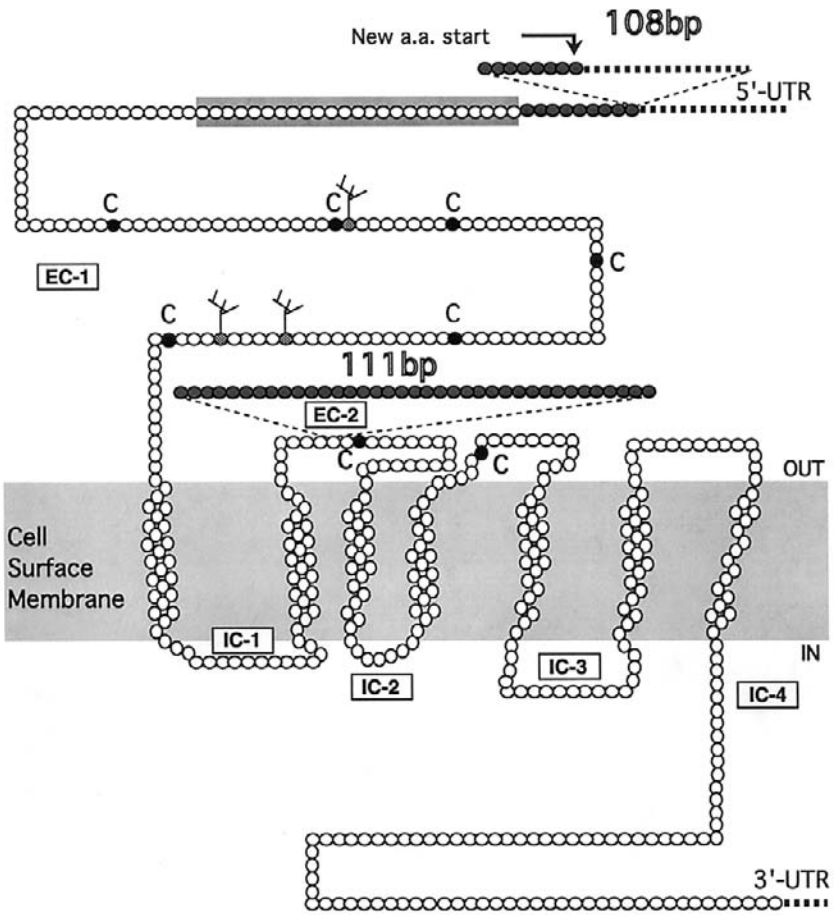

Figure 2 mRNA splice variants of murine CTR depicted as expected protein translation products. White circles represent the amino acids (a.a.) of the mCTR C1a isoform. The a.a. positions denoted as black circles with a C nearby are the conserved cysteines and shaded circles with the branch structure are the putative sites for N-glycosylation. Boxed circles denote the putative signal sequence. Gray circles represent amino acids added by the addition of variably spliced mRNA regions as indicated. The domains of interest are noted as follows: IC-1, IC-2, IC-3, and IC-4, first, second, third, and fourth intracellular domains, respectively; EC-1 and EC-2, first and second extracellular domain, respectively.

as in kidney, skeletal muscle, lung, and brain. The Δ125-bp and 71^{+}-bp isoforms of the hCTR exhibited modest alteration in ligand-binding affinity compared to the archetypal CTR isoform (hCTR-48^{-}), but the selectivity of ligand binding and activation of phospholipase C have not yet been tested.

Interestingly, two types of variably spliced mRNA products have been identified in hCTR that generate translation terminations shortly after transmembrane domain 1 (Moore *et al.,* 1995; Galson *et al.,* 1996), resulting in the putative expression of C-terminally truncated CTR proteins with a single transmembrane domain (Fig. 1). In one case (hCTR-83^{+}), there is an extra 35-bp exon (exon 7a) inserted just upstream of the 48-bp exon and in the other case (hCTR-Δ127), these 2 exons plus the next downstream exon (exon 8) were omitted. The potential physiological significance of these truncated isoforms is currently not known. Of interest, three truncated forms of the luteinizing hormone receptor have been identified, and these truncated isoforms exist as soluble binding proteins that are involved in the control of free hormone levels by competing with the membrane-associated luteinizing hormone receptor for ligand binding (Koo *et al.,* 1991).

Furthermore, we have identified a hCTR mRNA that contains a variably spliced novel 85-bp (named exon 13b) inserted between exons 13 (renamed 13a) and exon 14 whose presence results in a frameshift that creates a hCTR molecule with a completely novel intracellular domain 4 (IC4) at the C terminus (Galson *et al.,* 1997). This novel IC4 is only three amino acids longer than the archetypal IC4. CTR mRNA containing exon 13b was detected by reverse transcription-polymerase chain reaction (RT-PCR) technique in kidney, placenta, BIN67 (human ovarian cell line), and some giant cell tumor of bone samples. It was not found in brain, stomach, liver, and foreskin fibroblasts, although these samples were positive for other forms of hCTR mRNA. Functional studies using transient transfection into COS cells of a cDNA coding for the hCTR-$48^{-}85^{+}$IC4

isoform (which lacks the insert of 16 amino acids in IC1) indicate that the ability of this hCTR isoform to bind salmon CT is low. It does, however, signal through cAMP induction with the same EC_{50} as the archetypal hCTR, but the magnitude of the cAMP increase is markedly lower.

Rodent CTRs do not appear to contain the variably spliced exons found in the hCTR-coding sequence except, as mentioned earlier, the exon that inserts an upstream ATG start that adds 17 amino acids to the N terminus. However, rodent CTRs contain an additional variably spliced exon (111 bp exon 8b) within the coding sequence whose presence adds 37 amino acids to extracellular domain 2 (Fig. 2) and alters ligand specificity (Albrandt *et al.,* 1993; Sexton *et al.,* 1993; Yamin *et al.,* 1994; Inoue *et al.,* 1999). The two isoforms (termed C1a:insert negative and C1b:insert positive) bind salmon CT with high affinity, but the C1b receptors have a much lower affinity (negligible) for human and rat CT than the C1a receptors (moderate). This result is particularly surprising because it would be expected that CTR would bind the endogenous CT. Both the rat and the mouse C1b forms of CTR are expressed most highly in the brain. These findings indicate a role for the second extracellular domain in ligand-binding specificity and affinity. Additionally, the characteristics of the C1b receptors suggest that they may be the receptor for some as yet unidentified neurotransmitter resembling sCT (Sexton *et al.,* 1993).

Additionally, two CTR isoforms have been cloned from rabbit tissue. One form is structurally similar to the rodent C1a isoform and the other has a deletion of 14 amino acids in the seventh TM domain encoded by a distinct exon, designated 13 (CTRΔ13) (Shyu *et al.,* 1996). The expressed receptor exhibits a reduction of binding affinity for sCT and hCT by more than 10- and 2-fold, respectively. This isoform activates adenylate cyclase but not phospholipase C. The CTRΔ13 mRNA represents less than 15% of the CTR mRNA in osteoclasts, brain, and kidney, whereas at least 50% of the CTR transcripts are represented by this isoform in skeletal muscle and lung.

CTR Gene Organization

Analysis of the structural organization of CTR genes from different species has helped define the molecular basis for generation of the distinct receptor isoforms. In addition to the variable mRNA splicing that generates different CTR protein isoforms, multiple 5′-UTR structures have been described for both mCTR (Anusaksathien *et al.,* 2001) and hCTR (Nishikawa *et al.,* 1999; Hebden *et al.,* 2000) that arise from both variable splicing and alternative promoter usage.

Characterization of pCTR genomic organization was the first among the $GPCR_{II}$ family to be reported (Zolnierowicz *et al.,* 1994). This gene was found to span approximately 70 kb, and analysis revealed that the gene contained 14 exons with 12 exons encoding the actual receptor protein (Fig. 3). While the intron lengths are varied, there is one very long intron (>20 kb) between exons 2 and 3. The first and second exons and the first 30 nucleotides of the third exon represent the 5′-untranslated sequences. The remaining 51 nucleotides of the third exon encode a hydrophobic putative signal peptide. Exons 4–6 and exons 7–13 encode the N-terminal extracellular part of the receptor and the region of transmembrane domains, respectively. Exon 14 encodes the C-terminal intracellular region and the 3′-untranslated (3′ UTR) portion of the CTR transcript, which is very long (~2 kb). The 48-bp variably spliced exon (exon 8a in pCTR), resulting in an additional 16 amino acids in IC1, was found to arise from alternative use of two potential splice acceptor sites at the 3′ end of intron 7 located 48 bp apart so as to create two differently sized exons 8. Although there is a consensus exon/intron junction located in the EC2 region (E8/E9 pCTR) among all members of the $GPCR_{II}$ family, the presence of the 111-bp insertion in this region has been reported only in rat CTR and mCTR genes (Albrandt *et al.,* 1993; Sexton *et al.,* 1993; Yamin *et al.,* 1994).

Albrandt *et al* (1995) partially characterized the hCTR gene (gene name is CALCR) using a genomic clone that extended from intron 2 through exon 14. The exon/intron boundaries were located at similar positions to the pCTR gene, except that the 48-bp insert in IC1 is contained within a distinct exon (exon 7b) located 1 kb upstream of exon 8 (Moore *et al.,* 1995; Nussenzveig *et al.,* 1995; Galson *et al.,* 1996) (Fig. 3). The N-terminally deleted isoform of hCTR (Δ125 bp:EC1) occurs as a result of the deletion of part of exons 3 and exon 4 where it is bounded by the invariant GT/AG consensus-splicing motif for exon/intron splicing (Albrandt *et al.,* 1995). Further characterization by PCR (Moore *et al.,* 1995; Galson *et al.,* 1996) and analysis of the sequence in human BAC clone GS1-117O10 (GenBank accession number AC003078) from chromosome 7 have revealed that the alternatively spliced 35-bp exon (exon 7a) whose inclusion results in a C-terminal truncation six amino acids after TM1 is located 4.2 kb downstream of exon 7 and 2.35 kb upstream of the 48-bp exon 7b. The variably spliced 71-bp exon (termed 3a) that adds 18 amino acids to the N terminus is present 8.9 kb upstream of exon 3 (renamed 3b). The variably spliced 85-bp exon (Galson *et al.,* 1997) that alters the IC4 sequence (named 13b) is located 4.4 kb downstream of exon 13 (renamed 13a) and 3.15 kb upstream of E14.

Additional 5′-UTR hCTR cDNA sequences have been described. Nishikawa *et al.* (1999) isolated a hCTR cDNA containing the equivalent of the pCTR exons 1 and 2 by 5′-RACE using a human mammary tumor cell line, MCF-7. Interestingly, they also reported a novel hCTR 5′-UTR structure with a 288-bp osteoclast-specific exon (named Oc1 here) spliced to exon 3b (Fig. 3). This new exon (located at 168711–168422 in GenBank Accession Number AC003078) lies between exons 2 and 3a in the genomic structure. Using 5′-RACE, Hebden *et al.* (2000) also detected a hCTR 5′-UTR mRNA structure in T47D breast cancer cells, kidney, and osteoclastomas (with exons 1a and 2; 1392–1360 and 1174–957, respectively, in human BAC

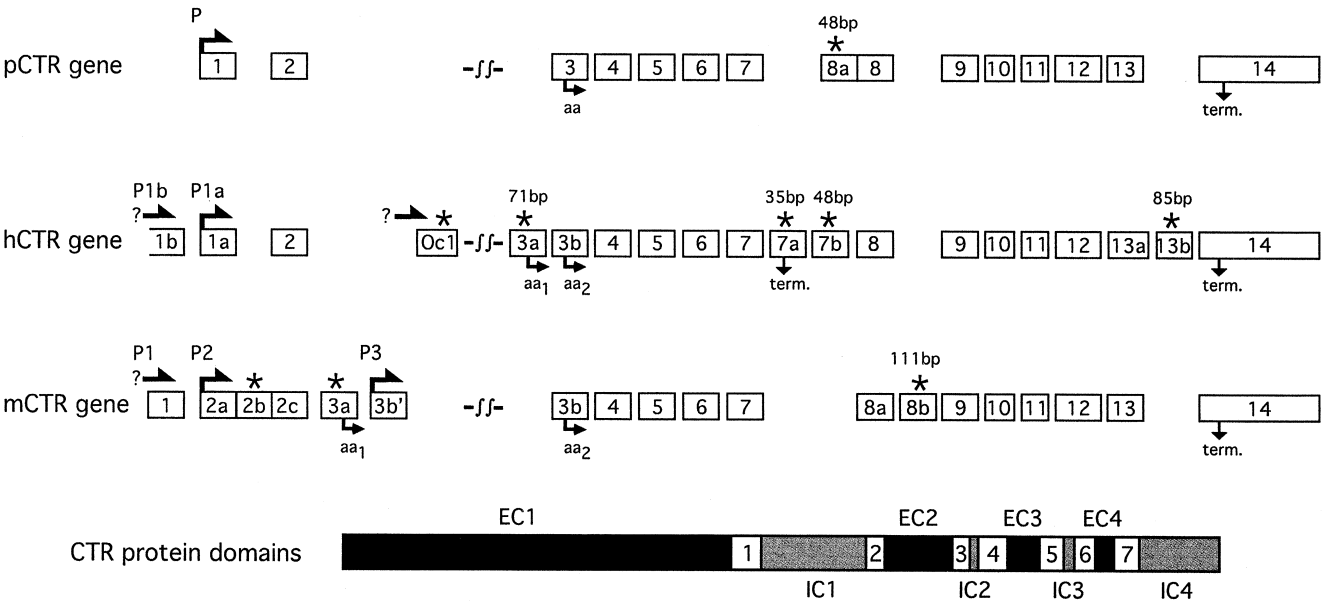

Figure 3 Genomic alignment of exons comprising porcine, human, and mouse CTR genes. Homologous exons are aligned vertically among the pCTR, hCTR, and mCTR genes (sizes are not to scale). Intron lengths are not represented, except that the position of the very long intron conserved among all three species is denoted by the double integral sign. Large gaps denote exons that have not been identified in all three species. Alternately, spliced exons are marked with an asterisk. Transcription starts of the putative promoters are indicated by arrows above the exons, and putative translation starts are indicated by arrows below the exons. Although they are not marked with an asterisk, exons used to initiate primary transcripts are always spliced out of transcripts that initiate upstream of them. Translation termini are also indicated below the exons. The hCTR exon 1b has no left side to indicate that the 5′ side has not been defined. Protein domains illustrated along the bottom show the correspondence between CTR exons and putative protein domains. The protein domains are denoted as follows: IC, intracellular domains (gray); EC, extracellular domains (black); and unprefixed numerals, transmembrane domains (white).

clone GS1-438P6, GenBank Accession Number AC005024), which resembles the pCTR 5′-UTR. While most of the 5′-RACE clones started within a few base pairs of the pCTR start, as might be expected for a TATA-less promoter, they detected multiple start positions for hCTR exon 1a, including some up to 43 bp upstream of those observed previously for hCTR and pCTR. Additionally, Hebden *et al.* (2000) reported the presence of a hCTR 5′-UTR structure that included a novel exon (named 1b) with a sequence homologous to the 5′ end of the mCTR cDNA reported by Yamin *et al.* (1994) spliced to exon 2. This novel hCTR exon lies upstream of exon 1a, but its 5′ end has not been defined. The 1059-bp intron region spliced out between exons 1b and 2 contained exon 1a. As discussed later, the presence of exon 1b or 1a in the mRNA reflects the alternative use of two different promoters in the hCTR gene. Analysis of sequence information available through the human genome sequencing project (GenBank accession numbers AC003078 and AC005024), the intron spliced out when exons 2 and 3b are joined in the mRNA is about 87 kb long and contains exons Oc1 (located ~14.8 kb 3′ of exon 2) and the 71-bp exon 3a (located 8.9 kb 5′ of exon 3b). Consequently, the length of the hCTR primary transcript initiated by the upstream hCTR promoter (from exon 1b) is at least 152 kb and contains 20 exons. The primary transcript initiated by the downstream hCTR promoter (from exon 1a) is 150 kb. It has not yet been determined whether the novel exon Oc1 represents the true 5′ end of an osteoclast-specific hCTR mRNA and thereby marks the presence of an osteoclast-specific promoter in the hCTR gene or reflects alternative splicing of a transcript generated from the upstream promoters.

Analysis of mCTR genomic clones revealed the exon structure of the original mCTR cDNA reported by Yamin *et al.* (1994) and showed that the locations of the exon/intron junctions within the coding region of the mCTR gene (exons 3–14) are identical to those of the pCTR and hCTR genes (Anusaksathien *et al.,* 2001) (Fig. 3). This includes the two putative translation start sites that are split between two exons in the murine (the 108-bp 3a and 3b) and human (the 71-bp 3a and 3b) CTR genes. Further analysis of mCTR transcripts identified novel cDNA sequences, new alternative exon splicing in the 5′-UTR, and three putative promoters (P1, P2, P3). Similarly to the hCTR 71-bp exon 3a, the mCTR exon 3a was found to be variably spliced. Some of the novel cDNA sequences add 512 bp to the 5′ side of the previously published cDNA (Yamin *et al.,* 1994), thereby extending exon 1 to 682 bp. In addition, three new exons were identified. Two of these novel exons are upstream of exon 2 and form a tripartite exon 2 (2abc) in which exon 2a is utilized by promoter P2 with variable splicing of exon 2b (which might also be considered a "retained intron"). Exon 2a is homologous to the pCTR exon 1 and the hCTR exon 1b. The third new exon (3b′) lies between 3a and 3b and is utilized by promoter P3. Exon 3b′ lies 689 bp downstream of exon 3a. The mCTR intron between exons 3b′ and 3b was found by analysis of

λ clones to be >13.9 kb and was found to be 29 kb in the mouse chromosome 6 genomic sequence (GenBank Accession number AC066688). This means that the intron spliced out between 2c and 3b is 40.2 kb. While 5′-RACE, primer extension, and RNase protection analysis combined to identify the 5′ end of mCTR exon 1, data also suggested that there might be another upstream exon in the P1 transcript. However, such an exon has not been found and the exact position of the mCTR P1 promoter remains to be determined. Therefore, the longest transcription unit, which is derived from promoter P1, is at least 77.4 kb and contains 19 exons.

Analysis of mCTR mRNAs has revealed that the three alternative promoters give rise to at least seven mCTR isoforms in the 5′ region of the gene and generate 5′-UTRs of very different lengths (from 93 bp to at least 955 bp). The structure of 5′-UTRs derived from P1 transcripts are 12c(+/−3a)3b, termed P1.1 (3a+) and P1.2 (3a−); P2 transcripts are 2a(+/−2b)2c(+/−3a)3b, termed P2.1 (2b−,3a+), P2.2 (2b−,3a−), P2.3 (2b+,3a+), and P2.4 (2b+,3a−); and the P3 transcript is P3.1 (3b′3b). Retention of the equivalent of the mCTR exon 2b (or "intron 2a") was not reported for pCTR and hCTR. This may be due to species differences or to differences in the experimental design employed. The alternatively spliced rodent-specific 111-bp coding exon (8b), which adds 37 amino acids to the extracellular domain 2 of mCTR, lies 886 bp downstream of exon 8a and 7.2 kb upstream of exon 9. The configuration of the seven mCTR 5′-UTR splice forms with the presence or absence of exon 8b has not been determined. Analysis by RT-PCR indicates that the P1 promoter (located upstream of an expanded exon 1) and the P2 promoter (located upstream of exon 2a) are utilized in osteoclasts, brain, and kidney, whereas the P3 promoter, located upstream of the novel exon 3b′, appears to be exclusively utilized in osteoclasts. Osteoclasts express all seven 5′-UTR mCTR isoforms. However, mRNA isoforms containing exon 3a are more abundant than their counterparts lacking exon 3a. It has not been possible to quantitate the relative promoter usage in osteoclasts. However, in kidney and brain, promoter P3 is not utilized and it appears that the kidney does not use exon 2b.

mCTR-P1 mRNAs have very long 5′-UTRs of >955 and >898 nucleotides that are slightly GC rich (53% GC) and contain seven AUGs before the AUG in exon 3a. Most have a pyrimidine at -3 that makes them poor translation candidates, although one such upstream ORF is 51 amino acids long (AUG at +252 in E1). One ORF (which encodes 14 amino acids) has an AUG (at +248 in E1) in a good Kozak context for translation. The occurrence of upstream AUG codons nearly always reduces the efficiency of initiation from downstream AUGs (Kozak, 1991). mCTR-P2 5′-UTRs have only 1 upstream ORF with its AUG in a poor Kozak context, range in size from 249 to 487 nucleotides, and are all GC rich (55–60% GC). The mCTR-P3 5′-UTR has no upstream AUGs, is only 93 nucleotides long, and is slightly AT rich (48% GC). One possible purpose of the generation of multiple mCTR 5′-UTRs is that mRNAs with different untranslated exons can differ in their stability, compartmentalization, and translational potential. When the translatability of mRNAs from the same gene with both a long and a short 5′-UTR has been compared, the short 5′-UTR is usually translated more efficiently (Nielsen *et al.,* 1990). Indeed, in some instances, the effect of 5′-UTR on translation can be so profound that a minor transcript from certain genes appears to be the major functional mRNA (Mitsuhashi and Nikodem, 1989; Horiuchi *et al.,* 1990). Additionally, the GC-rich, untranslated regions could have a mRNA secondary structure that may interfere with the translational process (Gehrke *et al.,* 1983; Kozak, 1986, 1989). Therefore, it is possible that translation of the seven mCTR cDNAs is regulated differentially and that the relative abundance of a particular mRNA isoform may not correlate with its contribution to the translated product.

Regulation of the CTR Gene

Although some of the human (Albrandt *et al.,* 1995), porcine CTR (Zolnierowicz *et al.,* 1994), and mouse (Anusaksathien *et al.,* 2001) genomic sequences have been cloned, little is known about the mechanism of transcriptional regulation for the CTR gene in osteoclasts or in other tissues in which it is expressed. Transfection analysis has been used to establish that the putative CTR promoters discussed earlier are functional (Zolnierowicz *et al.,* 1994; Anusaksathien *et al.,* 2001; Hebden *et al.,* 2000). A 657-bp fragment containing 357 bp of the pCTR promoter was demonstrated to drive expression of a luciferase reporter gene when transfected into the CTR-expressing porcine kidney epithelial cell line LLC-PK_1 (Zolnierowicz *et al.,* 1994). Hebden *et al.* (2001) transfected a series of hCTR-luciferase deletion constructs into human T47D breast cancer cells and demonstrated the presence of two functional promoters within the hCTR gene. As they deleted from −881 to −129 relative to exon 1a, they lost only about half the activity (the numbering has been revised to reflect +1 at the same position as pCTR). Deletions from the 3′ side were used to remove the downstream promoter (proximal to exon 1a) and define the position of the upstream promoter within a 2-kb region, which would suggest that hCTR E1b is at least 686 bp long. Using transiently transfected luciferase reporter constructs, Anusaksathien *et al.* (2001) demonstrated that the mCTR promoter P2 (proximal to exon 2a) is active in a murine kidney cell line (MDCT209), a chicken osteoclast-like cell line (HD-11EM), and a murine preosteoclast cell line (RAW264.7). Further investigation of the mCTR promoter P2 region by deletion analysis revealed that the −179 to +398 region contained maximal activity in all three cell lines. Most interestingly, the mCTR promoter P3 (proximal to exon 3b′) was only active in osteoclast-like cell lines (Anusaksathien *et al.,* 2001). Deletion analysis of the P3 promoter showed that −319 relative to exon 3b′ was sufficient for maximal activity. These transfection data con-

firmed the osteoclast specificity of mCTR promoter P3 observed by RT-PCR and provided the first evidence that the CTR gene is regulated in a tissue-specific manner by alternative promoter utilization.

The −319 mCTR promoter P3 contains five putative composite sites for the transcription factors NFAT and AP-1 (Galson *et al.,* 2000). Cotransfection of the mCTR-P3 reporter and a constitutively active NFAT (ΔNFAT; containing a deletion of the regulatory region, which allows it to localize in the nucleus independent of calcium signaling) into either uninduced RAW 264.7 or HD-11EM cells has been demonstrated to result in a large increase in activity. However, the widely expressed mCTR-P2 reporters were unresponsive to cotransfection with ΔNFAT in all three cell lines. DNA protein-binding analysis showed that the putative composite NFAT/AP-1 sites in the mCTR-P3 promoter can bind both NFAT and AP-1 proteins *in vitro*. Transient transfection of ΔNFAT into RAW 264.7 cells stimulated transcription from the endogenous CTR gene, as well as some other osteoclast-specific genes (e.g., TRAP). We conclude that calcium signaling via NFAT activation is important in regulating the expression of CTR in osteoclasts.

Comparison of the −179 mCTR-P2 region with the pCTR promoter sequence upstream from pCTR exon 1 (Zolnierowicz *et al.,* 1994) and a region of hCTR upstream of hCTR exon 1a revealed a high degree of homology and conserved sequence motifs for several transcription factors. The homology among the three species was very high in pairwise comparisons (~70%) for more than 2 kb further upstream (not shown). This would suggest that pCTR may also have the equivalent of the mCTR exon 1. Both mCTR P2 and P3 promoters lack many well-known transcription initiation site consensus sequences. These include a TATA box in the −30 region, an Inr element (YYANWYY) at +1 (Javahery *et al.,* 1994), a DPE site (RGWCGTG) downstream near +30 (Burke and Kadonaga, 1996; Orphanides *et al.,* 1996), and a BRE site (SSRCGCC) at approximately −38 relative to the start of transcription (Lagrange *et al.,* 1998). Both promoters possess a possible YY1-binding site (VKHCATNWB) at the putative transcription start, which could be involved in recruiting TFIIB (Houbaviy *et al.,* 1996; Usheva and Shenk, 1996). Typical for many TATA-less myeloid promoters, the proximal P2 promoter regions of the CTRs of all three species contain two putative Sp1 sites (Theisen and Bach, 1990), although their positions are not identical. All three mCTR-P2 homologous CTR promoters (mCTR-P2, hCTR-P1a, pCTR-P) are very GC rich and contain a high frequency of CpG dinucleotides indicative of the presence of a CpG island (Antequera and Bird, 1993). However, the P3 promoter region between exons 3a and 3b′ is only 36% GC and the −319 region is only 41% GC. The osteoclast-specific mCTR exon 3b′ is not homologous to the hCTR osteoclast-specific exon Oc1 (Fig. 3) nor do the proximal upstream regions to these exons have any significant homology.

The presence of alternative promoter usage and splicing, localized to the 5′ end of the CTR gene, may thus provide a mechanism for regulating the expression of this gene at both the translational and the transcriptional level. The existence of a mCTR promoter (P3) that is osteoclast specific is, perhaps, not surprising due to the fact that CTR is expressed in a restricted spectrum of tissues with developmental regulation. Upon proper stimulation, the osteoclast precursor, which is of monocyte/macrophage lineage, undergoes a program of cellular differentiation in which a distinct profile of genes are induced, including, for example, cathepsin K, β_3 integrin, acid phosphatase, and CTR. These genes encode protein products that confer upon the osteoclast the unique functional activities required for attachment and resorption of the mineralized bone matrix. The CTR gene appears to be induced during the terminal stages of osteoclast differentiation coincident with the acquisition of bone-resorbing capacity (Lee *et al.,* 1995). Characterization of molecular regulation of the CTR gene in osteoclasts could lead to novel approaches in treating osteoporosis, periodontal disease, inflammatory arthritis, and related bone disorders.

The function of pCTR (2.1 kb) and hCTR (4.9 kb) promoters has been assessed in transgenic mice (Jagger *et al.,* 1999, 2000). The hCTR fragment used contained both hCTR promoters defined by the transfection studies. It was found that although both of these promoters directed expression of the lacZ reporter in several embryonic and fetal tissues, which express endogenous mCTR, neither was sufficient to direct transcription in the adult kidney or bone of the transgenic mice. However, several of the tissues in which these CTR promoter-driven reporter genes were expressed represent previously unknown sites of CTR expression. Expression of the endogenous CTR gene was confirmed in each of the new sites.

The 2.1-kb pCTR*lacZ* transgene (Jagger *et al.,* 1999) was expressed in the embryonic brain and spinal cord at 11.5 days. At 15.5 days, expression was observed in the developing mammary gland, external ear, cartilage primordium of the humerus, and anterior naris (nostril). However, in the neonate and adult mouse, the transgene was only expressed in brain, spinal cord, and adult testis. No expression was observed in the kidney and osteoclasts. The 4.9-kb hCTR*lacZ* transgene (Jagger *et al.,* 2000) was expressed at additional sites not observed with the 2.1-kb pCTR*lacZ* transgene. The hCTR*LacZ* transgene was expressed at 8.5–10.5 days in the lateral side of cervical and occipital level somites and in lateral myotome and hypaxial muscle progenitors. At 11.5–16 days, expression was observed in limb buds, cornea, retina, skin, intercostal muscles, muscles of the limbs and face, and dorsal root ganglia, placenta, spinal cords, brain, anterior nares, and maxillary component of the first branchial arch. In the adult mouse, expression in the brain (olfactory bulbs, hippocampus, cerebellum, and cerebrum), ventral roots and dorsal horn of the spinal cord, nervous layer of the retina, and testis was observed. The difference in the pattern of expression of the two transgenes may be due to a species difference or to the additional amount of regulatory DNA available in the larger hCTR*LacZ* transgene. These data suggest that CTR may

play a role in morphogenesis. However, it is not clear which of the possible ligands is involved. Additionally, which CTR isoform is important is not yet known.

Homologous Downregulation of CTR

Although CT effectively inhibits osteoclast-mediated bone resorption after acute administration, continuous exposure to this ligand results in the development of a state of refractoriness, termed "escape," in which there is a loss of calcitonin-mediated inhibition of osteoclastic bone resorption. This phenomenon was first observed in bone organ cultures (Wener *et al.,* 1972; Tashjian *et al.,* 1978), but also occurs *in vivo* in patients receiving CT for the treatment of hypercalcemia and other high turnover states of bone remodeling, such as Pagets disease. Early studies suggested that the loss of responsiveness to CT was related to the downregulation of CT receptors on osteoclasts and the possible recruitment of osteoclasts that lacked CT receptors (Tashjian *et al.,* 1978; Krieger *et al.,* 1982; Nicholson *et al.,* 1987). The availability of cloned CT receptors has provided new reagents for studying regulation of the CTR and for defining the molecular mechanisms responsible for the development of refractoriness to calcitonin associated with the escape phenomenon.

The expression of the CTR appears to occur late in the sequence of osteoclast differentiation associated with the process of multinucleation and acquisition of the capacity to resorb bone (Takahashi *et al.,* 1988a,b; Hattersley and Chambers, 1989; Suda *et al.,* 1992, 1997). These findings have been confirmed in studies employing RNA samples from murine (Lee, *et al.,* 1995; Wada, *et al.,* 1995) or human (Takahashi *et al.,* 1995) bone marrow cultures that have been induced to form osteoclast-like multinucleated cells. Analysis of RNA samples prepared from cells at different stages of culture using RT-PCR with CTR-specific oligonucleotides demonstrates that the receptor is expressed in some mononuclear cells immediately prior to or in association with the process of multinucleation and competence to resorb bone.

Results from studies employing osteoclast-like cells generated in murine and human bone marrow cultures indicate that continuous treatment with CT results in the decrease in steady-state levels of CTR mRNA and downregulation of CTR binding attributed to receptor internalization (Rakopoulos *et al.,* 1995; Takahashi *et al.,* 1995; Wada *et al.,* 1995, 1996b, 1997; Inoue *et al.,* 1999; Samura *et al.,* 2000). Removal of CT from culture media results in a slow return of CTR message accompanied by the restoration of CT-binding activity (Samura *et al.,* 2000). In studies by Ikegame and co-workers (1996) using murine bone marrow cultures, they observed that the effect of CT treatment on CT binding was dependent on the stage of the cultures in which the CT was administered. If the calcitonin treatment was initiated at the beginning of the culture, osteoclasts developed normally, but these cells expressed minimally detectable levels of CTR as assessed by CT binding and CTR mRNA expression. If cultures were treated after day 6 of culture with CT, CTR mRNA levels declined rapidly and remained suppressed as long as CT was present. They speculated that the escape phenomenon was related to two independent mechanisms: one attributable to the development of osteoclasts with minimal or reduced CTR expression and the other related to the downregulation of CTR expression associated with receptor internalization and reduced receptor synthesis. It is of interest that the pattern of CTR mRNA expression after CT treatment is different in nonosteoclast lineage cells. In these cells, CT treatment only partially decreased steady-state CTR mRNA levels, although CT-binding activity was lost (Wada *et al.,* 1995; Findlay *et al.,* 1996). Removal of CT resulted in the gradual return of CTR mRNA to pretreatment levels with restoration of CT binding. In contrast, in murine bone marrow-derived osteoclasts treated in a similar fashion, CTR mRNA levels were not restored even after removal of CT. These results indicate that the regulation of CTR transcription and mRNA processing differs in osteoclasts and cells of nonosteoclast lineage.

Analysis of the intracellular signaling pathways responsible for the process of CT-induced desensitization has yielded conflicting results. This appears to be related to the source of the osteoclast-like cells employed in the experimental models. In osteoclast-like cells generated from murine bone marrow cultures, CTR downregulation appears to be principally dependent on activation of the protein kinase A pathway (Suzuki *et al.,* 1996; Wada *et al.,* 1996a). In contrast, Samura and co-workers (2000) demonstrated that in osteoclast-like cells prepared from human peripheral blood, CT-mediated desensitization was dependent on activation of the protein kinase C pathway. These findings indicate that the signaling pathways responsible for CTR regulation in human and murine osteoclasts may differ.

Studies have provided additional insights into the molecular mechanisms underlying the loss of CT responsiveness associated with CT treatment of osteoclasts. In studies by Wada *et al.* (1997), they observed that CT treatment of murine osteoclast-like cells derived from bone marrow cultures resulted in decreased steady-state levels of CTR mRNA that appeared to be principally related to increased rates of CTR mRNA decay. Nuclear run-on assays to assess the effects of CT treatment on CTR gene transcription indicated that CT treatment had no effect. They noted that the 3′-untranslated end of the murine CTR gene contained multiple copies of the AUUUA motif, as well as other A/U-rich sequences, which have been shown to regulate the stability of RNA transcripts. In contrast, studies by our own group in collaboration with Inoue and co-workers (1999) indicated that the downregulation of CTR mRNA levels by CT treatment was in part related to direct effects on gene transcription. Additional studies will be necessary to define the molecular mechanisms underlying CT-induced escape in osteoclasts.

In conclusion, cloning of the CTR has helped provide insights into the extreme diversity and pleiotropy of the *in vivo* activities of CT. These effects can be accounted for

based on the widespread distribution of CT receptors, including tissues not directly involved in the regulation of mineral ion homeostasis. The presence of multiple structurally and functionally distinct receptor isoforms that are expressed in a tissue- and cell-specific fashion provides a unique system for producing organ-specific responses to this ligand. The physiological relevance of many of these effects has not been established, but these activities potentially can be exploited for the development of novel applications for the use of CT in the treatment of disorders of skeletal and nonosseous tissues. The availability of new reagents derived from the cloning of the CTR gene will also permit further elucidation of the molecular mechanisms responsible for the regulation of the CTR gene. This should provide important insights into the mechanisms underlying the "escape"phenomenon and help define the possible role of CT in development.

CHAPTER 35

Calcitonin Gene Family of Peptides

Structure, Molecular Biology, and Effects

Kenneth L. Becker,[*] Beat Müller,[†] Eric S. Nylén,[*] Régis Cohen,[‡] Jon C. White,[*] and Richard H. Snider, Jr.[*]

Introduction

The physiopathology of calcitonin (CT) is of considerable pertinence to basic scientists and clinicians who are interested in bone and calcium metabolism. However, both the importance and the complexity of this topic have increased markedly due to the awareness that there are multiple peptides that originate from the "calcitonin gene family of peptides" and due to the finding that some of the precursors involved in the biosynthesis of these peptides possess great importance in normal physiological mechanisms as well as in human illness.

Mature human CT originates from the calcitonin-I (CALC-I) gene. CALC-I is a member of a family of genes: CALC-I, II, III, IV, and V. With the exception of CALC IV, which is on chromosome 12, all these genes are on chromosome 11. In addition to mature CT, the mRNAs, which originate from this gene family, produce other bioactive hormones: CT gene-related peptides I and II (CGRP-I and -II), adrenomedullin (ADM), amylin (see Fig. 1), and several other circulating precursor or derivative peptides, some of which also have biological functions.

Several common features characterize the classic hormones of the calcitonin gene family (Fig. 2). CT, the CGRPs, ADM, and amylin all contain two N-terminal cysteines that form a disulfide bridge, resulting in a ring structure at the amino terminus. Furthermore, the carboxyl-terminal amino acids of these peptides are amidated. The midregions of CGRP, CT, amylin, and ADM form an α-helical structure. Interestingly, when the sequences of CT, CGRP, and amylin are aligned with a gap introduced in the CT sequence to maximize homology, the 12 identical matches and five conservative amino acid substitutions suggest gene duplication of a common ancestral gene. Importantly, as will be discussed later, CT gene family peptides exert their bioeffects by binding to the same family of receptors.

Human Calcitonin and Its Preprohormonal Components

Biochemistry

Mature human CT is a single chain peptide of 32 amino acid residues (Fig. 2). The molecular mass of the hormone is 3418 Da. A disulfide bridge connects the cysteines at positions 1 and 7 to form a 7 amino acid ring structure at the amino terminus. At the carboxyl terminus, there is an amidated proline.

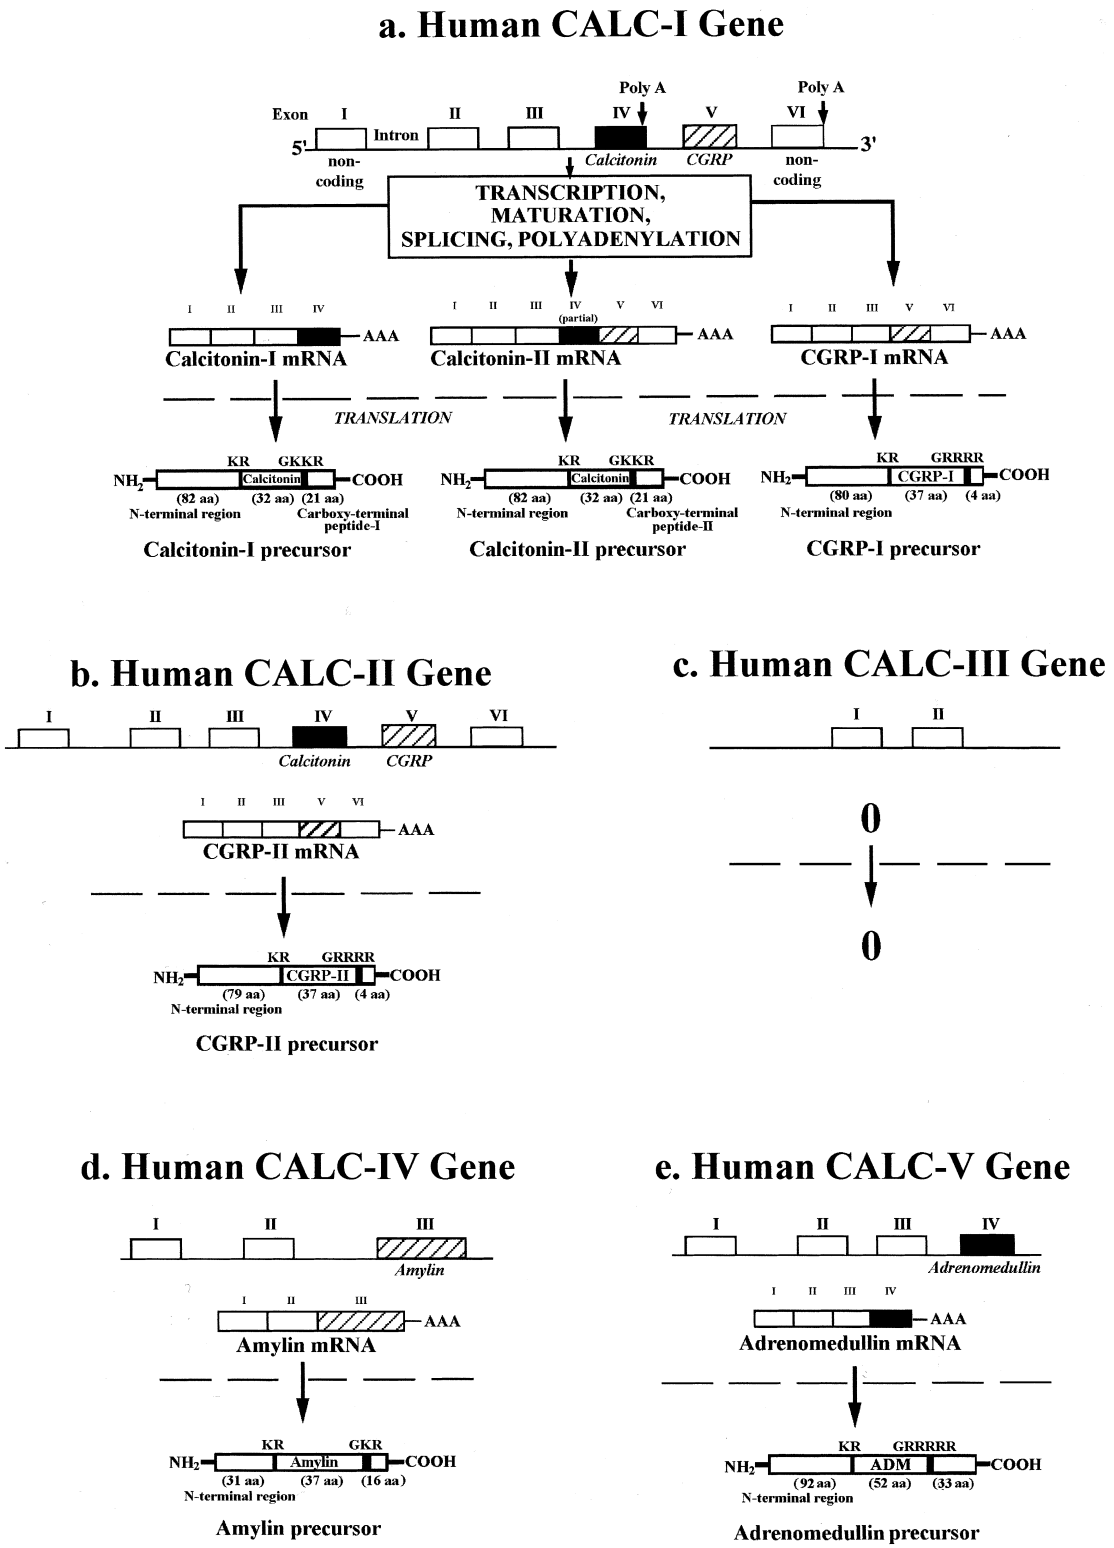

Figure 1 The human calcitonin (CT) gene family: organization of genes, mRNAs, and their hormone precursors. Based on their nucleotide sequence homologies, five genes belong to this family: CALC-I (CT/CGRP-I), CALC-II (CGRP-II), CALC-III, CALC-IV (amylin), and CALC-V (adrenomedullin) genes. (a) The CALC-I primary transcript is processed into three different mRNAs: CT, CT-II, and CGRP-I. The different products are generated by the inclusion or exclusion of exons by a mechanism termed splicing. Exons I – III are common for all mRNAs. Exon IV codes for CT, and exon V codes for CGRP-I. CT mRNA includes exons I + II + III + IV. CT-II mRNA includes exons I + II + III + IV (partial) + V + VI. CGRP-I mRNA is composed of exons I + II + III + V + VI. Each mRNA codes for a specific precursor. CT mRNA codes mainly for an N-terminal region, mature CT, and a specific C-terminal peptide (i.e., katacalcin, PDN-21, or CCP-I) that consists of 21 amino acids. The N-terminal region includes a signal peptide of 25 amino acids and an N-terminal peptide of 57 amino acids (i.e., NProCT or PAS-57). The CT-II precursor differs from the CT-I precursor by its specific C-terminal peptide, CCP-II. CCP-I differs from CCP-II by its last 8 amino acids. CGRP-I mRNA codes for an N-terminal region, mature CGRP-I, and a cryptic peptide. The commitment of the primary transcript in the different splicing pathways is determined, in part, by tissue specificity. Although there is some overlap, CGRP-I mRNA is expressed mainly in nervous tissue, and CT mRNA is the major mRNA product in thyroid tissue and other tissues, whereas CT-II was found to be expressed in liver. (b) The CALC-II gene codes only for a CGRP-II precursor. Its organization is similar to the CALC-I gene, containing 6 exons. Sequence

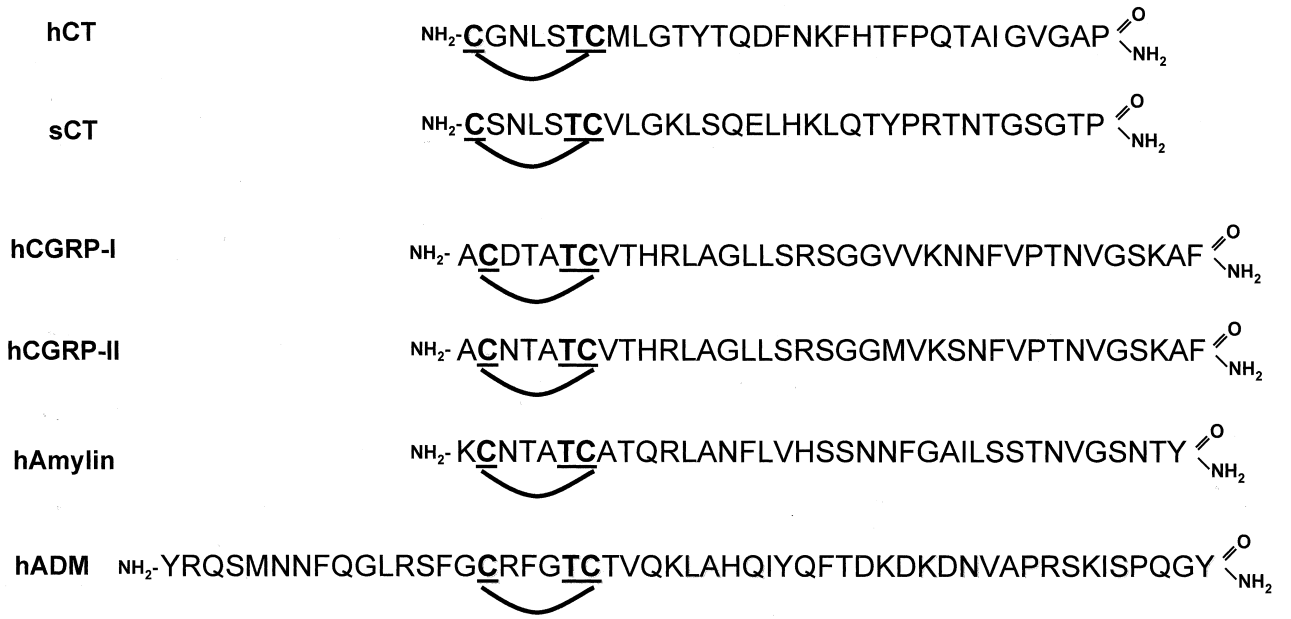

Figure 2 Amino acid sequences of human calcitonin (hCT), salmon CT (sCT), human CGRP-I (hCGRP-I), human CGRP-II (hCGRP-II), human amylin, and human adrenomedullin (hADM). Two structural features that are essential for full functional activity are conserved between the peptides: they contain two N-terminal cysteines that form a disulfide bridge resulting in an N-terminal loop and a C-terminal amide. Modified from Becker (2001).

The polypeptide precursor of CT, preprocalcitonin (Pre-ProCT) (molecular mass 15,466 Da), contains 141 amino acid residues (Le Moullec *et al.,* 1984) (Fig. 3). The CALC-I gene encodes information for its primary structure. The leader sequence (signal peptide) is composed of 25 amino acid residues.

As is common for leader sequences of all proteins, methionine (number 84 in Fig. 3) is the initial residue. Within the leader sequence, there is a customary stretch of mostly hydrophobic residues (amino acid residues 77–67 in Fig. 3). The function of the leader sequence is to assist in transport of the ribosomal precursor molecule into the cysternae of the rough endoplasmic reticulum.

Early in posttranslational processing, the leader sequence is cleaved from the Pre-ProCT precursor molecule by a signal peptidase. The resultant prohormone, procalcitonin (ProCT, also termed PAN-116), may be glycosylated. It consists of 116 amino acid residues (molecular mass 12,795 Da), which are folded into their appropriate three-dimensional conformation. At the amino terminus portion of ProCT, there is a 57 amino acid peptide called nProCT (also called PAS-57); its molecular mass is 6221 Da (Fig. 4). The immature CT, which is placed centrally within ProCT, consists of 33 amino acid residues, including a carboxyl-terminal glycine. There is a dibasic amino acid cleavage site (Lys-Arg), which is adjacent to the amino terminus side of immature CT. The final 21 amino acid residues comprise the CT carboxyl-terminal peptide-I (CCP); it is also termed carboxyl-terminal flanking peptide-I or PDN-21 (formerly called katacalcin). Human CCP occurs in two possible forms that differ by their terminal eight amino acid residues (CCP-I and CCP-II) (Fig. 4). These alternative structures arise from different forms of CT mRNA (Fig. 1). Situated between the amino terminus end of CCP-I or CCP-II and the carboxyl terminus of immature CT, there is a tribasic amino acid cleavage site (Lys-Lys-Arg).

Posttranslational Processing of Procalcitonin

The biosynthetic secretory pathway for CT involves a complex series of progressive modifications, which eventuate in the final exocytosis of the mature secretory product. Topographically, highly organized traffic from the endoplasmic reticulum must pass through the Golgi apparatus,

Figure 1 *(continued)*
homologies are important. Examination of the exon 4-like region of CALC-II indicates that CT mRNA is unlikely. Splicing at the site equivalent to the exon 3–exon 4 junction in hCT mRNA results in a stop codon within the reading frame of the precursor polypeptide. Although CALC-II appears to be a pseudogene for CT, it is a structural gene for CGRP-II. The CGRP-II hormone differs from CGRP-I by 3 amino acids. (c) The CALC-III gene contains only 2 exons. Their sequences have homologies with exons 2 and 3 of CALC-I and -II genes. The CALC-III gene does not seem to encode a CT- or CGRP-related peptide hormone and is probably a pseudogene, which is not translated into a protein. (d) The CALC-IV gene codes for a precursor containing the amylin peptide. This gene contains only three exons. The third exon codes for amylin. This 37 amino acid peptide has marked homology with CGRP peptides. It has been suggested that CT and CGRP exons are derived from a primordial gene and that the different CT/CGRP/adrenomedullin/amylin genes have arisen by duplication and sequence-divergent events. (e) The CALC-V gene is translated into adrenomedullin. This gene contains 4 exons. Adrenomedullin (ADM) is coded by the fourth exon. The amino-terminal peptides, encoded by exons 2 and 3, also have some bioactivity. Modified from Becker (2001).

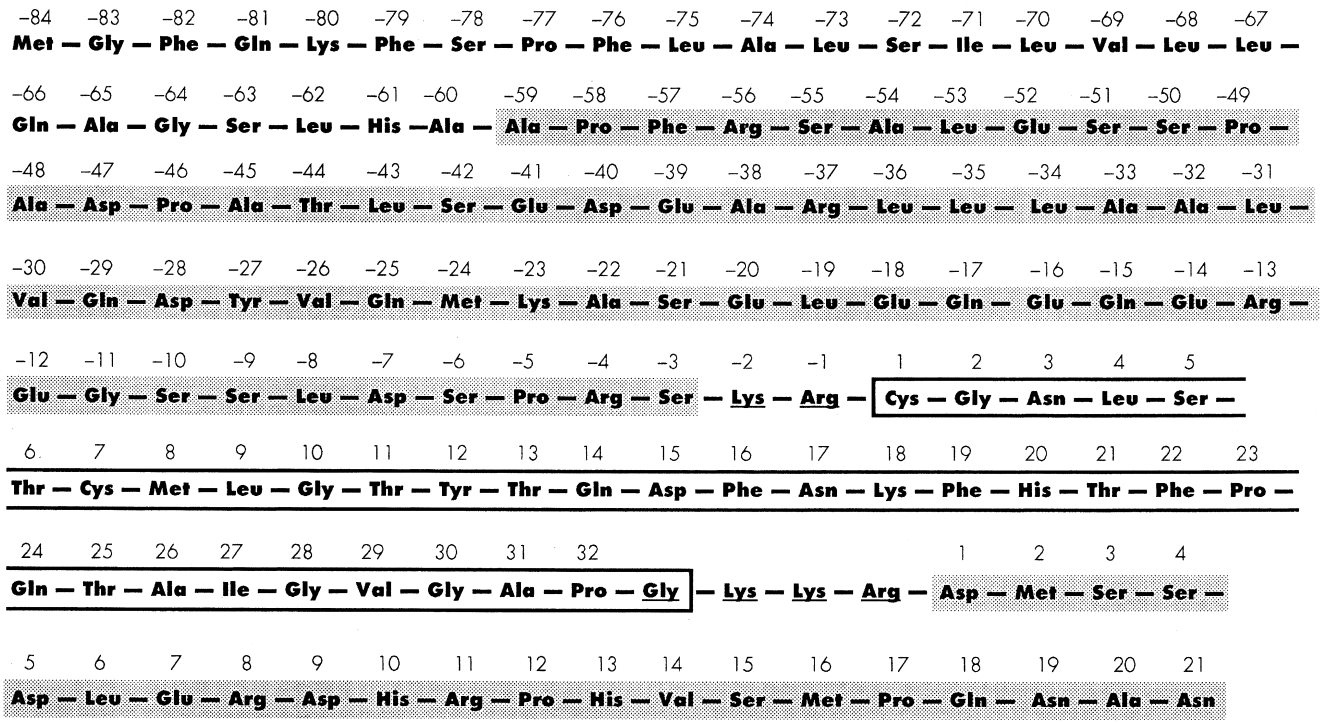

Figure 3 Sequence of human Pre-ProCT. This protein represents one of the two CT-containing molecules arising from the CALC-I gene and is the product of calcitonin-I mRNA (see Fig. 1). At the amino terminus, the first 25 amino acid residues comprise the signal peptide, the next 57 amino acid residues in the initial shaded area comprise N-procalcitonin (nProCT or PAS-57); the 33 amino acid residues in the bold enclosed area comprise immature CT; the underlined Gly residue at the carboxyl terminus of CT is removed during amidation of CT; the 21 amino acid residues in the final shaded area comprise calcitonin carboxyl peptide-I (CCP-I, PDN-21, or katacalcin). The underlined Lys and ARg residues between nProCT and immature CT and the underlined Lys, Lys, and Arg residues between immature CT and CCP-I are basic amino acid cleavage sites. The alternative Pre-ProCT that arises from calcitonin-II mRNA of the CALC-I gene differs only in the CCP portion (see Fig. 4). The amino acid sequence and numbering system were derived from Le Moullec *et al.* (1984).

the densecore secretory vesicles, and, eventually, the cell surface. This regulated secretory pathway for a CT molecule that is composed mostly of the mature, bioactive form differs from the constitutional, unregulated, secretory pathway by which, in all likelihood, mostly ProCT would be secreted. Although this constitutional pathway may be present to a small extent in normal persons, it seems to be paramount in certain disease states.

Regulated Secretion of Calcitonin and Its Precursor Peptides

The mechanisms by which the large precursor, ProCT, is serially processed and by which its component peptides are sorted into nascent secretory vesicles have not been fully clarified. However, much that has been learned from the study of other propeptides is also applicable to ProCT.

After the biosynthesis and folding of ProCT, subsequent proteolytic processing occurs, both within the Golgi apparatus and, later, within the secretory granules (Chanat and Huttner, 1991). Cisternae of the Golgi apparatus are arranged into a series of compartments, the final one being the *trans*-Golgi; this is the exit compartment of the apparatus. Immature secretion vesicles bud off from this compartment and, both here and within the vesicles, endoproteolytic cleavage occurs (Fig. 5). This cleavage of ProCT, and the consequent release of the immature CT, is accomplished by a prohormone convertase (PC) enzyme, which has not yet been identified. PC enzymes, which cleave propeptides preferentially at the carboxyl terminus of basic residues, are Ca^{2+} dependent; they often carry out their endoproteolysis in a strict temporal sequence. The appropriate order of proteolysis is, in part, modulated by autocatalytic self-activation, which, in turn, may be influenced by neuroendocrine "chaperone" peptides that aid in protein folding. For reasons detailed later, it is likely that the initial or preferential cleavage site of immature CT is at its amino terminus region, yielding a conjoined polypeptide of CT plus the CT carboxyl-terminal peptide (CT:CCP).

During early posttranslational processing, the nProCT segment may act as a signal for sorting its parent ProCT molecule to nascent secretion vesicles of the regulated secretory pathway; such a role has been demonstrated for the N-terminal 26 amino acid peptide of the prohormone of adrenocorticotropin (ACTH), pro-opiomelanocortin (POMC) (Cool and Loh, 1994). Furthermore, chromogranin B may function as a

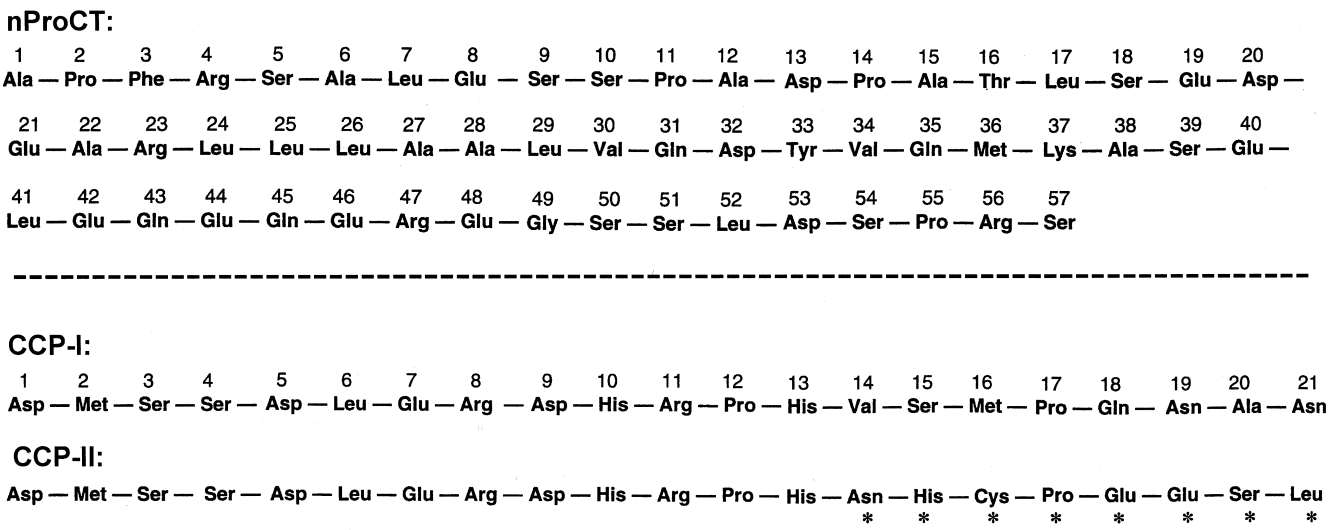

Figure 4 Sequence of human nProCT (top) and the two CCP peptides (bottom).

helper protein to favor *trans*-Golgi sorting to the regulated secretory pathway as it does for ACTH.

Within the newly formed secretion vesicles, proteolytic cleavage releases immature CT. Then, as amidation proceeds, mature CT is produced and is concentrated progressively within these vesicles (Treilhou-Lahille *et al.,* 1986). The ensuing tight aggregation of hormones within the vesicle causes its subsequent electron-dense appearance. These secretory vesicles are destined to serve as storage repositories for later secretion; without the appropriate external

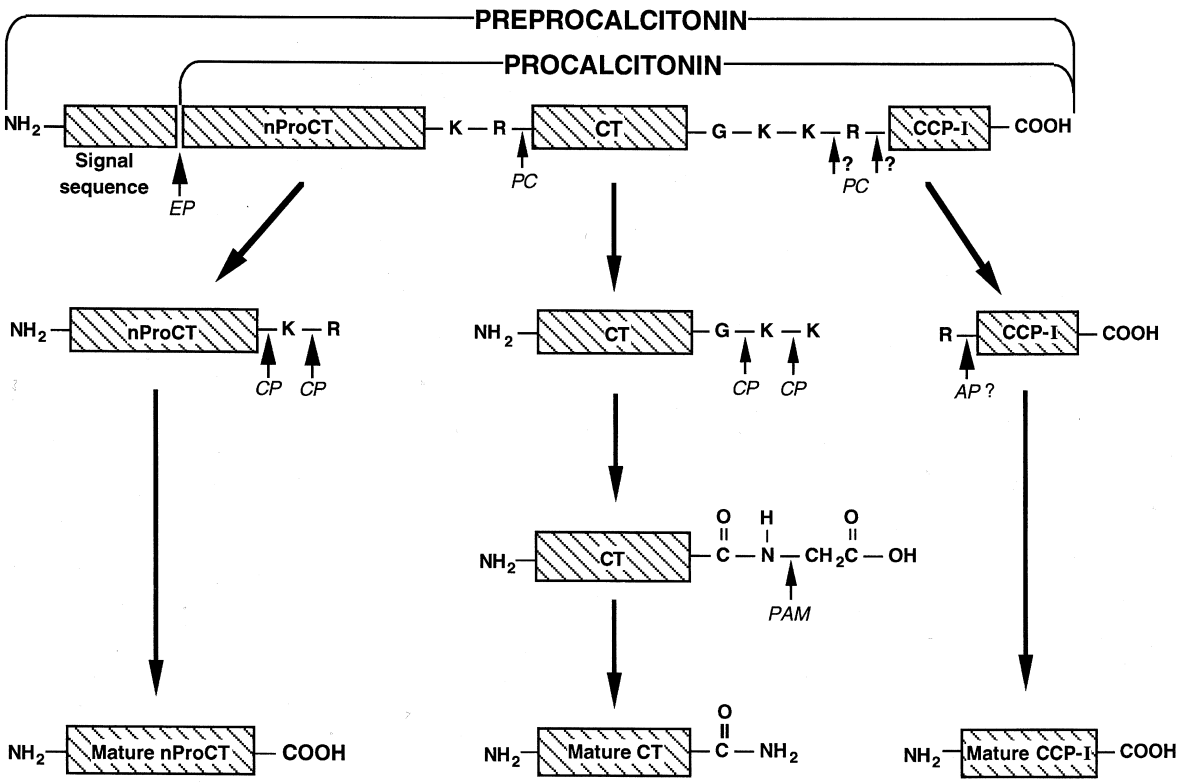

Figure 5 Enzymatic processing of Pre-ProCT and its constituents. EP, an endopeptidase; PC, a prohormone convertase; CP, a carboxypeptidase; AP, an aminopeptidase; PAM, peptidylglycine α-amidating monoxygenase and its constituent enzyme peptidyl-α-hydroxyglycine α-amidating lyase (PAL); K, lysine; G, glycine; R, arginine. The PC cleaves the propeptide at the carboxyl terminus of the dibasic paired Lys-Arg residues between nProCT and immature CT, and either between Lys and Arg or at the end of the Lys, Lys, Arg basic triplet, which is located at the junction between immature CT and CCP-I. If the cleavage is between Lys and Arg, an aminopeptidase enzyme would remove residual Arg. A carboxypeptidase removes residual Lys-Lys (or the Lys-Lys-Arg) from the immature CT prior to the action of PAM and removes Lys-Arg from the carboxyl terminus of nProCT.

stimulus, they have a relatively long half-life. Ultimately, in response to the appropriate signal at the plasma membrane, there is a brief increased concentration of cytosol-free Ca^{2+}; this induces secretion. In this process, the secretory vesicles further migrate via an intracellular microtubular system toward the periphery of the cell, fuse with the apical portion of the plasma membrane, and, by exocytosis, discharge their hormonal contents in a quantal release. Studies in normal humans suggest that these secretory vesicles contain, in addition to mature CT, nProCT, CT:CCP, and probably some free immature CT (Treilhou-Lahille *et al.,* 1986; Snider *et al.,* 1996).

Location of Calcitonin in the Body

Systematic studies have been made of immunoreactive CT (iCT) in tissues of humans and monkeys (Becker *et al.,* 1979, 1980a). In humans, the highest concentration of iCT is in the thyroid gland, where it is located within the C cells, mostly found in the central portion of each lobe. Scattered C cells may also be found in adjacent tissues (i.e., parathyroid glands and thymus). However, a survey of approximately 20 tissues of other regions of the human body has yielded iCT values for many tissues that are appreciably higher than in the blood. The highest levels have been found in small intestine, thymus, urinary bladder, lung, and liver. In both intact and thyroidectomized monkeys, these tissues also have considerably elevated levels. In the monkey, extrathyroidal tissue levels of iCT do not diminish following thyroidectomy (except for the high levels in the liver of the intact animal, which decrease markedly). When one considers the weights of most of these extrathyroidal tissues, their total iCT content is considerable. Gel filtration of several tissue extracts (e.g., lung, thymus, liver, stomach) demonstrates that the iCT consists primarily of mature CT, with very little of the peptide precursors. These patterns do not differ from that of the thyroid. In nearly all of the tissues where appreciable amounts of iCT are found, neuroendocrine cells have been identified, and in some of these tissues, immunohistochemical staining reveals the presence of iCT. These extrathyroidal neuroendocrine cell contents contribute to the serum content of iCT, and these cells can be induced to secrete both locally and distally under the influence of various stimuli.

In normal conditions, it is likely that the extrathyroidal iCT originates from iCT-containing neuroendocrine cells, as well as hormonal binding to receptor tissues. However, in several pathological conditions, iCT production and its corresponding mRNA are augmented greatly, emanating ubiquitously from nonneuroendocrine parenchymal cells (Müller et al., 2001).

Mature Calcitonin

A mature peptide may be defined as a final product of a precursor propeptide. If the peptide is a bioactive hormone, it must possess the required structure to exert an effect upon its receptor. An immature peptide hormone may be defined as one that either has not yet undergone proteolytic separation from its precursor propeptide or, if separated, has not yet undergone the final biochemical process(es) that is requisite for its full bioactivity.

As is the case for a very large number of bioactive peptides, mature CT possesses an α-amide moiety at its carboxyl terminus. In part, amidation may confer upon the hormone a structure or configuration that is important for its bioactivity and may also increase the resistance of the molecule to enzymatic degradation (Rittel *et al.,* 1976). Initially, prior to amidation, there usually is proteolysis at an endoproteolytic cleavage site (e.g., the Lys-Lys-Arg locus within the ProCT), and there is a prerequisite glycine residue at the carboxyl-terminal side of the amino acid residue that is to undergo the subsequent amidation.

The sequential steps leading to amidation are shown in Fig. 6. The parent enzyme that plays the key role in the amidation is peptidylglycine α-amidating monooxygenase (PAM) (Eipper *et al.,* 1992). The preliminary step performed by PAM is oxidation of the α-hydrogen of glycine to form an α-OH. Within the PAM protein, a second enzyme resides, peptidyl-α-hydroxyglycine α-amidating lyase (PAL). This enzyme acts on the intermediate molecule; it catalyzes amidation of the adjacent proline of CT, thus removing glycine in the form of a glyoxylate. The product of this two-step enzymatic action is mature 32 amino acid CT with an amidated proline at its carboxyl terminus. In most peptides that have been studied, amidation of the carboxyl terminus glycine residue occurs only after the prior complete proteolytic cleavage of the precursor molecule.

Bioactions of Calcitonin

The direct bioactivity of CT is linked inextricably to the location and nature of its receptors. In general, the relevant actions of CT in the human have been difficult to determine. Most of the *in vivo* and *in vitro* studies have been performed only in the laboratory animal; some of the study animals had been parathyroidectomized and some were intact; most investigators have utilized species of CT other than human (salmon, porcine, eel); and most investigators have utilized pharmacologic and not physiologic doses. Despite hundreds of studies, the precise physiologic role of CT remains uncertain. Nevertheless, it appears that biologically relevant effects occur in blood, bone, the central nervous system (CNS), the respiratory system, the gastrointestinal system, the reproductive system, and the kidney.

Calcitonin Effects on Serum Calcium and Phosphate

Acutely, CT decreases the serum calcium of laboratory animals. When human CT is administered to rats, this hypocalcemic activity is blunted by the deletion of the carboxyl-terminal amide group, by the shortening of the peptide chain, or by opening the disulfide ring (Rittel *et al.,* 1976). In human studies, the effects of CT on serum cal-

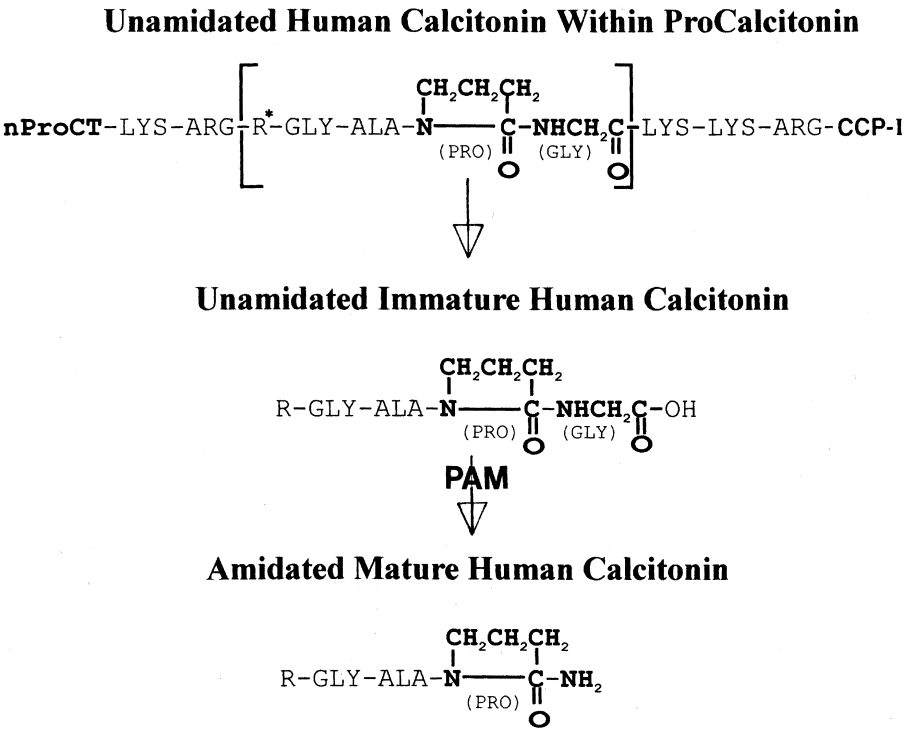

Figure 6 Sequential steps involved in the amidation of CT (see text). R^*, 29 amino acids of human CT not shown.

cium vary with the species of hormone used, its dosage, its method of administration, and the concurrent bone turnover rate of the human subject. In some studies of normal persons, CT is hypocalcemic (Gennari *et al.,* 1981), but, usually, it does not influence serum calcium levels (Gnaedinger *et al.,* 1989). However, in patients with high bone turnover, such as in Paget disease or in immobilized children, CT administration usually is hypocalcemic. In normal humans and dogs, pharmacologic doses of salmon CT result in hypocalcemia that is characterized by marked fluctuations, an occasional biphasic hypocalcemic response, and paradoxical above-baseline increases of serum calcium; these patterns may be partly due to parathyroid hormone overcompensation. In thyroparathyroidectomized humans and dogs, induced hypocalcemia may be more pronounced, but there still may be marked fluctuations to and above the baseline (Mohamadi *et al.,* 1975). Serum calcium is normal in hypercalcitonemic patients with medullary thyroid cancer (MTC).

The hypophosphatemic effect of CT is dose dependent and, in some studies, parallels the hypocalcemic effect.

CALCITONIN ACTIONS IN THE OSSEOUS SYSTEM

Mature CT plays an important role in skeletal homeostasis, being a key modulator of bone resorption (Zaidi *et al.,* 1994). The hormone inhibits bone resorption by inducing an acute quiescence of cell motility (Q effect); this occurs within 1 min and is followed by a more gradual retraction of the osteoclasts (R effect) (Moonga *et al.,* 1992; Alam *et al.,* 1993a). Retraction of the pseudopods, which occurs in most of the osteoclasts, is associated with the formation of intracellular retraction fibers and a cessation of membrane ruffling; the final result is a small, rounded, nonmotile cell (Gravel *et al.,* 1994). Both cyclic adenosine monophosphate (cAMP) and intracellular Ca^{2+} are second messengers for the Q and R effects, and both are G protein mediated. However, there are distinct differences: the Q effect is coupled to adenylate cyclase, acting via a cholera toxin-sensitive Gs; and the R effect is thought to be coupled to a pertussis toxin-sensitive G protein, resulting in an increased cytosolic-free calcium concentration (Alam *et al.,* 1993a). These studies have not determined whether there are one or two receptor complexes involved. Other investigators have demonstrated that protein kinase C participates in the effect (Su *et al.,* 1992). Chronic administration of CT reduces the number of osteoclasts.

CT inhibits other components of the osteoclast, such as the release of acid phosphatase. Carbonic anhydrase II is expressed at a high level in the osteoclast and plays an important role in the bone resorptive activity of osteoclasts. CT diminishes expression of this enzyme in a dose-dependent manner (Zheng *et al.,* 1994). Also, osteoclasts were reported to contain large amounts of focal adhesion kinase in their cytosol; this tyrosine kinase may assist in the maintenance of contact between the osteoclasts and the mineralized matrix upon which they act. CT inhibits this kinase (Berry *et al.,* 1994). Similarly, in the rabbit, expression of the bone matrix protein osteopontin, which participates in the attachment of osteoclasts to bone matrix, may be inhibited, acting via cAMP-dependent protein kinase and cal-

cium–protein kinase pathways (Kaji *et al.,* 1994). Thus, by various mechanisms, mature CT diminishes osteoclastic activity, a phenomenon that is so marked that its *in vitro* effect on bone resorption can be used as a bioassay to measure picomolar concentrations of the hormone (Zaidi *et al.,* 1994). The escape from CT inhibition of osteoclastic bone resorption appears to be due in large part to a rapid desensitization of the osteoclast (Samura *et al.,* 2000). As a reflection of the decreased bone turnover, CT reduces the excretion of urinary hydroxyproline, both acutely and chronically (Tolino *et al.,* 1993). The hormone appears to interact with the osteoprotegerin/osteoprotegerin ligand, thus influencing RANK (Mancini *et al.,* 2000). Some data suggest that CT may also exert a stimulatory effect on the osteoblast. The hormone increases the concentrations of IGF-I and IGF-II in cultures of human osteoblast cell lines in a dose- and time-dependent manner (Farley *et al.,* 2000). Also, it inhibits TNF-α production (Ballica *et al.,* 1999).

Vitamin D influences the osseous system, and the interrelationships between CT and this vitamin require further study. Several investigators have demonstrated that CT stimulates 1,25-dihydroxyvitamin D production *in vivo* in humans and in rats (Darger *et al.,* 1986) and, specifically, 1α-hydroxylase activity in the proximal straight tubule (Wongsuranat and Armbrecht, 1991). Furthermore, the 24-hydroxylase enzyme system, which participates in the deactivation of vitamin D metabolites in rat intestine, is diminished by CT administration (Beckman *et al.,* 1994). Conversely, in rats, the vitamin D status modulates the responsivity of the renal tubules to CT. For example, in this animal, an increased tubular reabsorptive capacity for calcium is induced by CT; this effect is blunted in vitamin D deficient animals (Su *et al.,* 1988).

Indirect evidence often cited for a relationship between CT and the osseous system relates to serum levels of the hormone. In general, normal men have higher levels than women. Some authors have reported lower levels in postmenopausal than in premenopausal women, and others have reported higher levels. In elderly women, there may be a low level of mature CT, with a consequent increased proportion of high molecular weight forms of CT (Bucht *et al.,* 1995). Notwithstanding, because of its inhibitory effects on the osteoclast, CT is used successfully in the therapy of disorders of bone loss or of rapid bone turnover and also to diminish the egress of osseous calcium into the blood in hypercalcemic conditions (see Chapter 82).

Further advances will undoubtedly emerge from the evaluation of the osteopenic CT gene knockout mouse model (Hoff *et al.,* 1998).

Calcitonin Actions in the Central Nervous System

CT has specific binding sites within the CNS. The intracerebral injection of CT suppresses food and water intake in rats (Chait *et al.,* 1995). Experimentally, the hormone also increases body temperature, acting on specific regions of the thalamus and hypothalamus (Sellami and de Beaurepaire, 1993). In the rat, intracerebral administration of CT decreases the frequency and amplitude of spontaneous growth hormone secretory pulses (Tannenbaum and Goltzman, 1985). In the human, large doses of salmon CT reduce the serum concentrations of testosterone, LH, and FSH, probably acting at the hypothalamic level (Mulder, 1993). CT activates the brain serotonergic system in rats, acting via a direct central effect and also via a hypocalcemic mechanism. In normal humans, salmon CT may decrease serum prolactin.

The antinociceptive activity of CT may be mediated in part via central cholinergic influences (Chen and Lee, 1995); also, the integrity of the brain serotonergic system is required for this analgesic effect (Coldado *et al.,* 1994). Furthermore, CT interacts with the opioid system (Martin *et al.,* 1993). Chronic administration of salmon CT to humans with migraine headaches increases the levels of β-endorphin, as well as ACTH and cortisol. In this respect, there have been many studies using pharmacologic dosages of CT for the control of pain secondary to osteoporosis (Pontiroli *et al.,* 1994) or painful osteolytic metastases or for other forms of pain not associated with bone involvement. Some of these studies have had convincing results, whereas some, particularly those involving nonosseous pain, have been less impressive.

Calcitonin and the Respiratory System

The total amount of iCT in normal lungs exceeds that of any tissue of the human body, including the thyroid gland (Becker *et al.,* 1979, 1984). The hormone is found within pulmonary neuroendocrine (PNE) cells, which are situated near the basement membrane and often extend to the lumen of the airway (Becker *et al.,* 1980b). In the newborn, they are grouped into strategically located organoid clusters and are termed neuroepithelial bodies (Becker, 1993). Similar cells are found in the trachea and larynx. The great number of PNE cells in the fetus and newborn and the response of these cells to stimuli such as cigarette smoke or hypoxia strongly suggest that CT plays a role in pulmonary maturation and pathophysiology (Tabassian *et al.,* 1989). CT affects transcellular and intracellular movements of calcium, and hence may exert an intrapulmonary paracrine action. The inhibition by CT of prostaglandin and thromboxane synthesis and its augmentation of prostacyclin production by endothelium may modulate local pulmonary blood flow. CT may increase cartilagenous growth (Burch, 1984) and hence may influence chondrogenesis of the bronchial tree. The hormone also interacts with other peptides; for example, CT blocks the bronchoconstrictor effects of bombesin-like peptides and substance P.

The molecular configuration of the iCT contained within normal PNE cells has been studied in the hamster; in this species, long-term cultures of the PNE cell have been established (Nylén *et al.,* 1987; Linnoila *et al.,* 1993). Hamster PNE cells appear to contain mature CT, perhaps in a dimeric form, and the iCT that is secreted by PNE cells following acute stimulation is mostly the mature hormone. In this regard, putative malignancies of the human PNE cells differ; both the bronchial carcinoid and the small cell lung

cancer store predominantly mature CT, but secrete predominantly precursor forms (Becker *et al.,* 1983; Nylén *et al.,* 1987).

GASTROINTESTINAL EFFECTS OF CALCITONIN

In humans, CT pharmacologically increases gastric acid and pepsin secretion, decreases pancreatic amylase and pancreatic polypeptide, and modulates small intestinal motility (Demol *et al.,* 1986). The effects of the hormone on gastrin release are variable. Human CT administration decreases serum levels of gastrin, insulin, and pancreatic glucagon. Serum motilin is decreased, as is gastric inhibitory peptide. Somatostatin levels in the serum are increased. The small intestinal secretion of potassium, sodium chloride, and water is augmented. Thus, at high concentrations, CT increases the net secretion of water and electrolytes from the human jejunum and ileum, and it has been postulated that these effects may be a cause of the diarrhea seen in some patients with medullary thyroid cancer (Gray *et al.,* 1976). Physiologic doses of CT do not appear to influence the gastrointestinal absorption of calcium or phosphate in humans.

CALCITONIN AND THE REPRODUCTIVE SYSTEM

In the human male, CT is over 10-fold higher in the seminal plasma than in venous plasma, strongly suggesting that it is produced within the genital tract (Davidson *et al.,* 1989). In this respect, neuroendocrine cells are found in the urethral epithelium and in the prostate gland. The CT of the seminal fluid consists predominantly of high molecular weight forms.

CT occurs in both the uterus and the placenta and has been reported to be secreted by human placental tissue (Balbanova *et al.,* 1987). In the rat, CT messenger RNA is found in the glandular epithelial cells of the uterus at the time of implantation. This expression is abolished by the antiprogestin drug mifepristone, a drug that blocks implantation. Furthermore, progesterone administration stimulates CT mRNA in the uteri of ovariectomized animals. Estrogen, which is inactive alone, is synergistic to this progesterone action (Ding *et al.,* 1994).

There are receptors to CT in the human placenta, both in the syncytiotrophoblast brush border that faces the mother and in the basal plasma membranes that face the fetus (Lafond *et al.,* 1994). In this respect, CT is known to induce an increase in human chorionic gonadotropin (hCG) secretion by human placental cells at term (Rebut-Bonneton *et al.,* 1992). The intraplacental presence of CT receptors, as well as cells containing iCT, suggests a role of CT in implantation (Kumar *et al.,* 1998) and in the regulation of placental function; nevertheless, little attention has been devoted to this important possibility. In one study, thyroidectomized pregnant ewes demonstrated an increased placental transfer of calcium from the dam to the fetus, a phenomenon that was abolished by the daily injection of the dams with salmon CT (Barlet, 1985).

The measurement of serum CT during pregnancy in the human has yielded inconsistent results, ranging from no appreciable change to an increase. These differences probably reflect the differing specificity of the antisera used.

Human breast milk contains large amounts of immunoreactive CT, much of it being composed of high molecular weight moieties (Bucht and Sjoberg, 1987). It is likely that these peptides emanate from the neuroendocrine cells of the breast ducts. The possible role of CT as a modulator of mineral and electrolyte concentrations of milk merits study.

CALCITONIN ACTIONS IN THE KIDNEY

The kidney is a principal site of CT degradation (Hysing *et al.,* 1991); much of this may be accomplished by the cell surface enzyme, neutral endopeptidase (NEP). In addition, the abundance of CT receptors in the kidney bears witness to the multiple actions of CT within this organ (Kurokawa, 1987). However, interpretations of some elicited actions are clouded by the fact that CT appears to activate both cAMP and protein kinase pathways, leading to opposite biological responses that depend on the phase in the cell cycle of the target renal cell (Chakraborty *et al.,* 1991). In humans, the intravenous administration of CT stimulates diuresis and increases the fractional excretion rates of sodium, chloride, magnesium, and potassium. Urinary calcium and phosphate excretion increases, as do the urinary levels of adenosine 3′,5′-cyclic monophosphate (Gnaedinger *et al.,* 1989) and *N*-acetyl-*β*-*D*-glucosaminidase. However, in some species (rat, mouse), CT stimulates the renal tubular reabsorption of calcium and magnesium, probably within the thick ascending limb of the Henle loop (Carney *et al.,* 1992). The CT stimulation of urinary excretion of phosphate occurs within the proximal tubule and may be due to the inhibition of Na/PO_4 cotransport (Muff *et al.,* 1994). Interestingly, high levels (up to 20-fold serum levels) of iCT (but not mature CT) are excreted in the urine. Urine iCT levels have been determined and characterized in normal adults (Snider *et al.,* 1978) and children (Silva *et al.,* 1981) and have been demonstrated to be useful for the detection and follow-up of medullary thyroid cancer and also to detect C-cell hyperplasia (Silva *et al.,* 1979a,b). Moreover, urine iCT levels are increased in some patients with lung cancer (Becker *et al.,* 1980c).

METABOLIC EFFECTS

CT increases plasma glucose and lactate in the rat and causes peripheral insulin resistance by inhibiting the insulin-stimulated incorporation of glucose into glycogen.

SUMMARY OF CALCITONIN ACTIONS

It is difficult to clearly delineate the biologically relevant roles that CT may play. However, although it is impossible to extirpate all iCT-producing cells in the body, the development of a CT gene knockout model (Zhang *et al.,* 2001) should make this task more feasible. The highest concentration of iCT is found within the thyroid gland, but not the highest total content. Also, the experimental effects of thyroidectomy vary considerably among different species. Although lower than

normal, serum and urine iCT levels usually remain measurable following thyroidectomy in the human (Silva *et al.,* 1978). However, in thyroidectomized humans, there is no response of iCT to a calcium infusion (Silva *et al.,* 1978) or to pentagastrin (Weissel *et al.,* 1991). Provided thyroid hormone is replaced, thyroidectomy in humans has little or no important biochemical or pathologic consequences, and calcium homeostasis remains largely intact. In addition, bone density is not affected (Hurley *et al.,* 1987). Nevertheless, when intravenous calcium is administered to patients with prior hypothyroidism or with thyroid ablation who are maintained on thyroid hormone, the subsequent return to normocalcemia is delayed as compared to persons with intact thyroid glands (Williams *et al.,* 1966). A cautious but still valid hypothesis, in part made nearly two decades ago, is that CT maintains bone mineral in emergency situations (i.e., to combat hypercalcemia) and may play a role in the conservation of body calcium stores in certain physiologic states (i.e., growth, pregnancy, lactation). Furthermore, immunoreactive CT is present in many normal tissues, and hence hemocrine, paracrine, neurocrine, and/or solinocrine (i.e., intraluminal) secretions of this hormone are undoubtedly important; its functions remain to be fully elucidated.

Physiopharmacologic Stimuli of Calcitonin Secretion

Many agents have been reported to stimulate the gene expression and secretion of CT. Often, the findings are difficult to extrapolate to the human because of the very diverse experimental conditions: e.g., *in vivo* vs *in vitro,* species of animal, different tissues being investigated, nature of the agent, pharmacologic vs physiologic dose of the stimulating agent, route of administration, acuity or chronicity of the stimulus, and assay used to quantitate the CT response. Furthermore, the effective pharmacologic secretagogues vary with the location of the hormone production.

In normal humans, an intravenous calcium infusion usually raises serum iCT (Silva *et al.,* 1974; Hurley *et al.,* 1988), as does pentagastrin (Guilloteau *et al.,* 1990). In normal persons, iCT persists in the serum, despite induced hypocalcemia (Body and Heath, 1983). Hypermagnesemia but not hyperphosphatemia induces iCT release from the thyroid gland.

The malignant C cell of the rat [i.e., medullary thyroid carcinoma (MTC)] exhibits an elevation of cytosolic-free Ca^{2+} in response to very small changes in extracellular Ca^{2+} (Fried and Tashjian, 1986). Such cytosolic changes induce secretion of CT. However, the response of the *nonmalignant* C cell to similar calcium perturbations may be considerably less (Selawry *et al.,* 1975). Endogenous hypercalcemia, such as that due to neoplasia, multiple myeloma, and sarcoidosis, often is associated with increases of serum iCT in humans; however, this increase may sometimes be related to the condition per se and not hypercalcemia. In hyperparathyroidism, serum iCT has been variably reported to be normal or increased.

The increase of serum iCT in response to gastrin, and perhaps to pancreozymin and glucagon, raises the question as to whether these or other gastrointestinal hormones regulate its secretion (Cooper *et al.,* 1971; Selawry *et al.,* 1975). In this respect, endogenous hypergastrinemia, as occurs in pernicious anemia, is associated with an increased serum iCT (Becker *et al.,* 1980d). Also, there is specific binding of 1,25-dihydroxyvitamin D to malignant human C cells (MTC), raising the possibility of the modulation of CT by this steroid hormone, but it is unknown whether this occurs in normal C cells.

In hamsters and in intact and thyroidectomized men, cigarette smoke increases serum iCT acutely and chronically probably due to the nicotine content of the smoke (Tabassian *et al.,* 1988, 1989, 1990, 1993). Nicotine per se increases serum CT in hamsters. Chronic exposure to cigarettes induces PNE cell hyperplasia. There are cholinergic–nicotinic receptors on the PNE cell, and cultured PNE cells of newborn hamsters secrete CT in response to nicotine (Nylén *et al.,* 1993). This alkaloid stimulates the growth of PNE cells and, in the hamster, also exerts this effect transplacentally on the fetus (Nylén *et al.,* 1988). Catecholamines do not appear to influence CT secretion (Epstein *et al.,* 1983).

Dietylnitrosamine, a carcinogenic agent with nicotinic characteristics, induces PNE cell hyperplasia in hamsters; pulmonary and serum levels of CT are increased; and hypercalcitonemia occurs (Linnoila *et al.,* 1984). The chronic exposure of hamsters to 60% oxygen for 3 months increases CT levels in the lungs and serum, probably due to PNE cell hyperplasia (Nylén and Becker, 1993). Also, in these animals, the combination of diethylnitrosamines with hyperoxia induces tumor-like hyperplasia of the PNE cells and increased serum iCT (Nylén *et al.,* 1990). In addition, the acute induction of hypoxemia in hamsters raises serum iCT (E. S. Nylén *et al.,* unpublished observations).

Measuring Mature Serum Calcitonin

Serum iCT has been measured by bioassay, radioreceptor assay, and immunoassay. Bioassay techniques (e.g., induced hypocalcemia in the laboratory animal, *in vitro* generation of adenylate cyclase from renal cell membranes, inhibition of ^{45}Ca release from prelabeled mouse calvaria) demonstrated that not all of the iCT that was immunologically detectable was bioactive. This is because the great majority of assays used prior to the 1990s cross-reacted with immature CT found within ProCT, within the free CT:CCP-I and CT:CCP-II conjoined peptides, and, alone, with the free immature form (Snider *et al.,* 1997) (see Fig. 5).

The principal clinical use of mature CT measurement is the detection and follow-up of patients with medullary thyroid cancer (MTC). It had been known since the 1970s that there was heterogeneity of calcitonin-containing peptides in the serum of MTC patients; therefore, mature CT was selected as the definitive marker to facilitate obtaining uni-

form normative and diagnostic criteria for C-cell hyperplasia as well as for medullary thyroid cancer.

The development of polyclonal antisera raised to specific regions of the mature CT molecule had provided useful normative data (Snider *et al.,* 1977); however, these values included the immature CT within the larger molecular weight precursors. In addition, early standard preparations for mature CT were insufficiently pure. Then, prior extraction and concentration of the serum with silica cartridges resulted in lower values that were more specific for mature CT (Body and Heath, 1983). The advent of monoclonal antisera further improved accuracy and specificity.

However, quantification of mature CT requires the specific detection of the amidated carboxyl terminal portion of the molecule. Usually, this utilizes a double-antibody method: one antibody reacts with the amidated carboxy terminus and the second one reacts with another portion of the molecule (usually the midportion). Such an assay will not cross-react with the immature CT within CT precursor molecules (Seth *et al.,* 1989; Guilloteau *et al.,* 1990; Motté *et al.,* 1988; Perdrisot *et al.,* 1990). This assay, which is available commercially, supersedes all others for the measurement of mature CT (Engelbach *et al.,* 2000). When using such an assay, the basal levels of mature CT are <10 pg/ml (<3 fmol/ml). Importantly, nearly all of the studies in the literature that have studied serum iCT levels relating to age, influence of the menstrual cycle, pregnancy, lactation, diurnal rhythm, influence of hormones, effect of secretagogues, physiopharmacologic manipulations, determinations of endogenous secretion rate (thought to be ~100 to 200 μg/day), half-life (thought to be ~10 min), degradation studies, and so on have not been verified using a specific and sensitive assay for mature CT.

Calcitonin Carboxyl-terminal Peptides I and II

CCP (Fig. 4) is the 21 amino acid peptide that, within the ProCT molecule, is connected to the carboxyl terminus of immature CT by the Lys-Lys-Arg cleavage site. CCP-I (molecular mass 2437 Da) is derived from the calcitonin-I mRNA. CCP-II (molecular mass 2505 Da) is derived from the calcitonin-II mRNA and is produced by splicing part of exon 4 to exon 5 of the CALC-I gene (Fig. 1). These two peptides differ in their last eight amino acid residues (Minvielle *et al.,* 1991; Cohen *et al.,* 1992). In their free forms, neither of these peptides are amidated. CCP-I is found in thyroid and MTC tissue and in the sera of normal persons and those with MTC (Born *et al.,* 1991). Although some investigators have reported that CCP-I is secreted in an equimolar amount with CT, other studies are not in accord. In several studies, serum CCP-I increased with calcium infusion. Some workers have found that serum levels increase in normal persons following a pentagastrin injection (Blind *et al.,* 1992). Serum levels of CCP-I have been used for detection and follow-up of patients with MTC. CCP-II has been found in thyroid, in MTC cells, in pituitary tumor, and in normal neurologic tissue (Cohen *et al.,* 1994). The serum level and bioactivity of CCP-II have not been studied sufficiently CCP-I does not influence osteoclast or serum calcium levels; its bioactivity is unknown (Zaidi *et al.,* 1991).

Clinical Conditions Characterized by Increased Serum Procalcitonin and Its Component Peptides

Normal persons secrete measurable serum levels of intact ProCT, nProCT, CT:CCP-I peptide, mature CT, and CCP-I (Snider *et al.,* 1997) (Fig. 7). Collectively, we refer to these precursor and component peptides as calcitonin precursors (CTpr).

Moreover, in several pathological states, there is an augmented biosynthesis and secretion of CTpr. These conditions include extrathyroidal neuroendocrine cell hyperplasia, medullary thyroid cancer, nonneuroendocrine tumors, and, last but not least, severe inflammation–infection–sepsis.

Extrathyroidal Neuroendocrine Cell Hyperplasia

In addition to C-cell hyperplasia of the thyroid (a sporadic or familial condition, which often eventuates in MTC), extrathyroidal neuroendocrine cell hyperplasia is also associated with increased serum iCT. Thus, the study of some chronic nonneoplastic pulmonary conditions with region-specific antisera has demonstrated a slight to moderate increase of serum iCT that is consistent with an apparent increase of CT-precursor forms. Usually, levels of free mature CT remain within the normal range. These conditions include patients with chronic bronchitis, chronic obstructive pulmonary disease, and chronic pulmonary tuberculosis (Becker *et al.,* 1981; Kelley *et al.,* 1994a). In this respect, iCT-containing PNE cells are hyperplastic in some chronic lung diseases (Becker *et al.,* 1980b, 1981; Johnson *et al.,* 1988). Similar phenomena have been induced in experimental animals (Linnoila *et al.,* 1984; Tabassian *et al.,* 1993). The authors have also encountered mildly increased levels of serum iCT in some patients with chronic intestinal disorders (e.g., regional ileitis). Insufficient studies have been performed to fully characterize the nature and distribution of the precursor forms secreted in extrathyroidal neuroendocrine cell hyperplasia.

Medullary Thyroid Cancer

The measurement of serum mature CT to detect and to follow the course of the neoplasm of the thyroid C cells, MTC, has proven to be a very important clinical procedure. In addition, it has had considerable usage to detect persons with the familial forms of MTC [although its use for this latter indication has been much diminished by the advent of its identification by RET protooncogene mutations (Mulligan *et al.,* 1995)]. The use of region-specific antisera and separatory techniques has demonstrated that MTC secretes

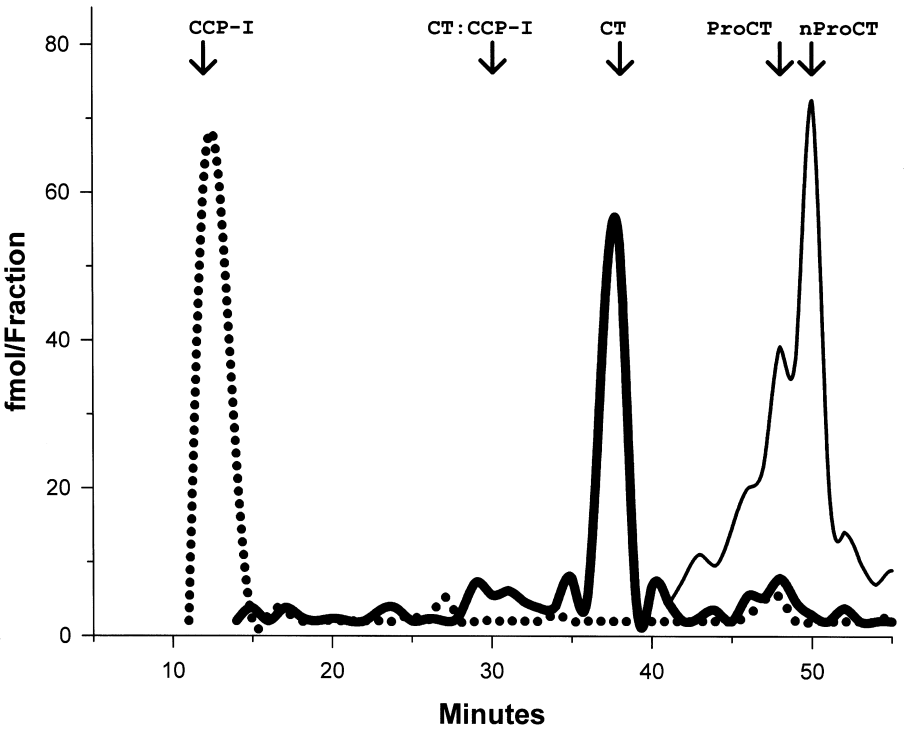

Figure 7 Procalcitonin and its component peptides in normal human serum. CT radioimmunoassay (thick line), CCP-I radioimmunoassay (dashed black line), and nProCT radioimmunoassay (thin line). Modified from Snider *et al.* (1997).

large amounts of high molecular weight forms of the hormone (i.e., CTpr) as well as considerable quantities of mature CT (Becker *et al.,* 1978; Ham *et al.,* 1980; Snider *et al.,* 1977) (Fig. 8).

Extrathyroidal Neuroendocrine Tumors

Two neoplasms of the lung, the highly malignant small cell lung cancer and the more benign bronchial carcinoid, are putative tumors of the PNE cells. Usually they secrete iCT (Becker and Gazdar, 1983, 1985). In these latter tumors, although serum levels of mature CT are increased, the proportion of high molecular weight forms usually is greater than in MTC (Becker *et al.,* 1978, 1983; Bertagna *et al.,* 1978; Nylen *et al.,* 1987). Other neuroendocrine tumors also may secrete iCT (e.g., pheochromocytoma, and pancreatic islet cell tumor).

Nonneuroendocrine Tumors

Increased levels of serum CTpr may occur in patients with nonneuroendocrine tumors. In such patients [e.g., epidermoid carcinoma of lung, breast cancer (Silva *et al.,* 1979)], it seems likely that hyperplasia of adjacent or intermixed neuroendocrine cells may play a role in this phenomenon (Kelley *et al.,* 1994).

Profile of Calcitonin Precursors Secreted by Tumors

Studies of patients with increased serum iCT due to various forms of neoplasia (Becker *et al.,* 1978; Snider *et al.,* 1977) demonstrated substantial amounts of high molecular weight iCT, which has been positively identified as CTpr (i.e., procalcitonin, nProCT, CT:CCP-I, CCP-I), as well as the mature CT hormone (Conton *et al.,* 1988; Ghillani *et al.,* 1989). Nearly always, the ratio of three of these large molecular weight CTpr (i.e., procalcitonin, nProCT, and CT:CCP-I), as compared with mature CT, is high (Becker *et al.,* 1978). Thus, in all of these tumors, synthesis and secretion of CTpr are increased, and posttranslational processing is incomplete. On a clinical level, when diagnosing or following MTC, a mature CT assay should be employed. However, when following the course of other neuroendocrine malignancies (e.g., small cell cancer of lung, carcinoid tumor) or of a nonthyroidal nonneuroendocrine malignancy (e.g. epidermoid carcinoma of the lung), an assay for CTpr should be used.

Increased Serum Calcitonin Precursors in Severe Inflammation–Infection–Sepsis

Marked insults, such as burns, trauma, surgical procedures, pancreatitis, or bacterial infections, commonly induce a hypersecretion of various proinflammatory cytokines,

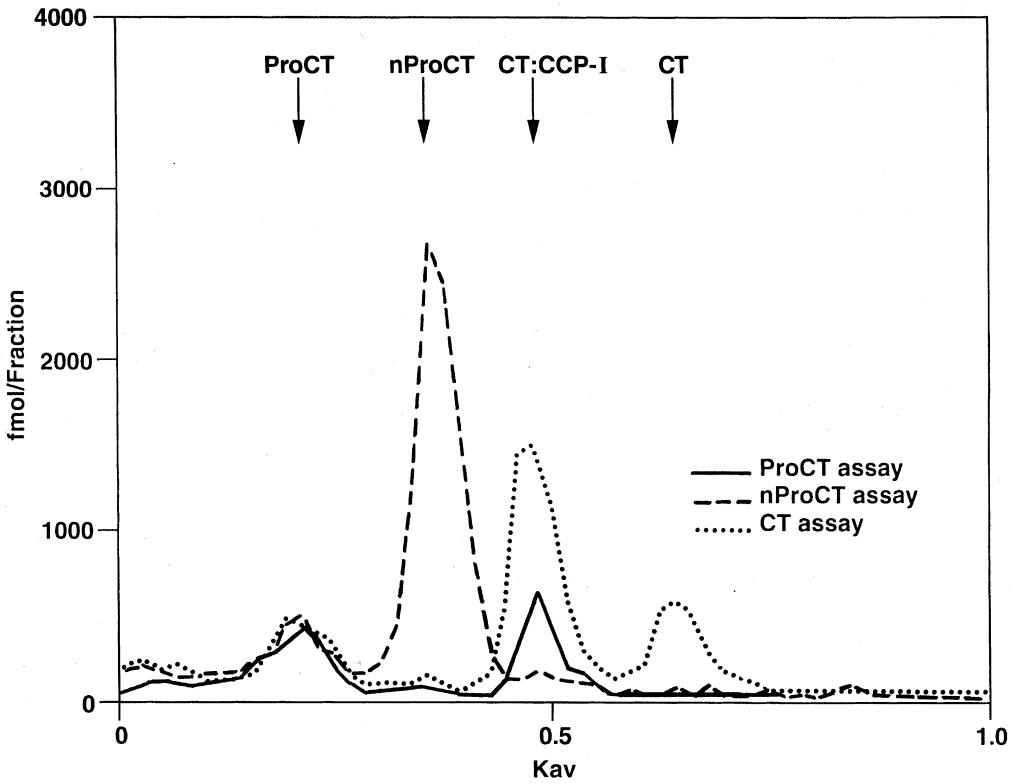

Figure 8 Gel filtration of serum of MTC patient. Note that the peak corresponding to the elution position of the CT:CCP-I peptide does not cross-react equally in both CT and ProCT assays. This may be due to the presence of some CT dimer (Tobler *et al.,* 1983), as it has a similar molecular mass.

arachidonic acid metabolites, and other humoral substances that cause a syndrome of systemic inflammation: vasodilation, chemoattraction of hematopoietic cells, activation of macrophages, and capillary endothelial leakage. The appellation of "sepsis" is given to this clinical condition (Bone, 1995). In severe cases, this may lead to "multiple organ dysfunction" characterized by myocardial insufficiency, circulatory hypoperfusion, hypoxemia, cerebral obtundation, renal failure, coagulopathy, and shock. Essentially, the patient becomes severely ill due primarily to a hyperresponsivity of the humoral reaction to the initial injury.

Calcitonin Precursors as a Marker for Severe Systemic Inflammation–Infection–Sepsis

In the United States, sepsis afflicts one-half million persons yearly and the mortality rate is 30 to 40%. Sepsis is defined as the systemic response to an injury that often is infectious (Bone, 1995). The systemic inflammatory response to an infection or marked injury originates from the elaboration by the host of a multitude of pro- and anti-inflammatory cytokines. Several studies over the past two decades have indicated that CTpr, including the ProCT prohormone, are increased markedly in severe inflammation and are often further augmented during microbial infection (Nylén *et al.,* 1992; Assicot *et al.,* 1993). In sepsis, circulating levels may be increased hundreds to thousands fold. In fact, CTpr are the most reliable markers of sepsis on an intensive care unit; they tend to correlate both with severity of illness and mortality and can be used to study the daily clinical course of the patient. Importantly, because of incomplete processing, there is very little or no elevation of serum mature CT. Assays for CTpr have become the best clinical marker for the presence, severity, and course of these conditions (Whang *et al.,* 1998; Müller *et al.,* 2000). The principal peptide components, which are increased, include the intact ProCT, the free nProCT, the free conjoined CT:CCP-I, and free CCP-I (Figs. 9 and 10). It is best to use an assay that measures more than one CTpr (e.g., Nylen *et al.,* 1992; Assicot *et al.,* 1993) because of the varying profiles of the increases occurring in the serum among different patients (Snider *et al.,* 1997).

The most proximal stimulus to increased CTpr in these conditions may be endotoxin, which, in turn, stimulates an increase of tumor necrosis factor α (TNF-α) and other cytokines. Indeed, in humans and experimental animals, injection of endotoxin or TNF-α results in a prolonged increase of serum CTpr (Preas *et al.,* 2001; Whang *et al.,* 2000). The initial hyperendotoxinemia may result from gram-negative bacterial infection or from translocation across the bowel wall of the *Escherichia coli* (or its endo-

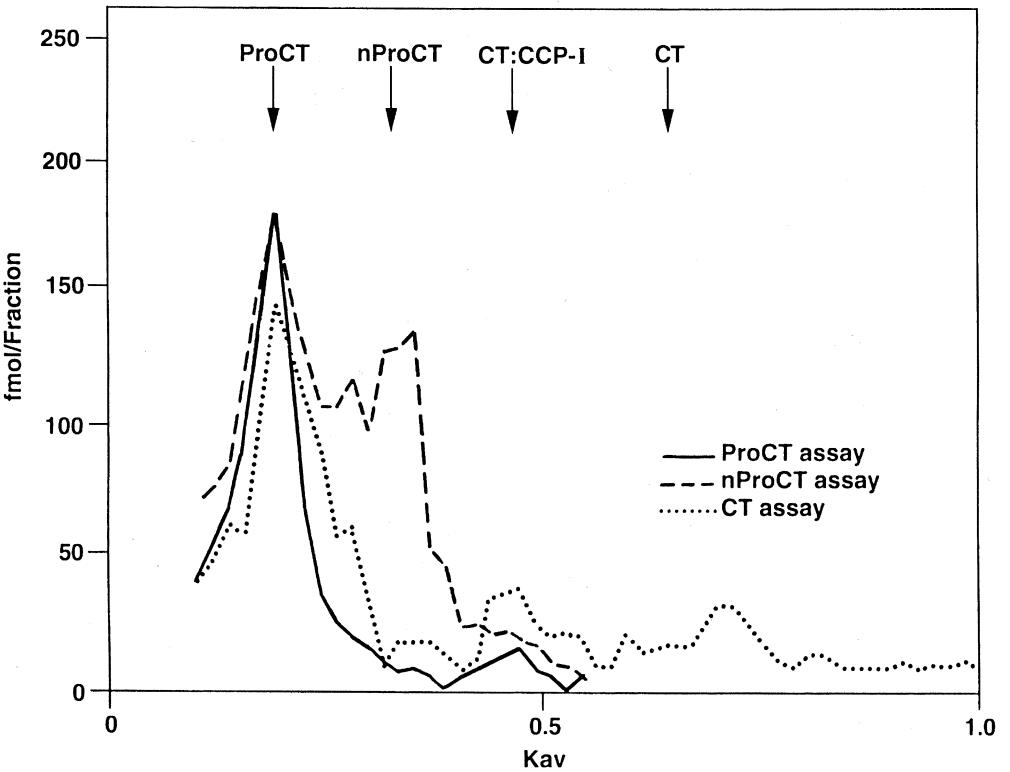

Figure 9 Gel filtration of serum of a septic burn patient with pneumonitis. No peak indicative of the presence of an uncleaved peptide-containing nProCT plus immature CT has been found in any of our studies to date. This suggests that the initial PC enzymatic cleavage may be at the basic amino acid cleavage site (Lys-Arg) situated between nProCT and the amino terminus of immature CT.

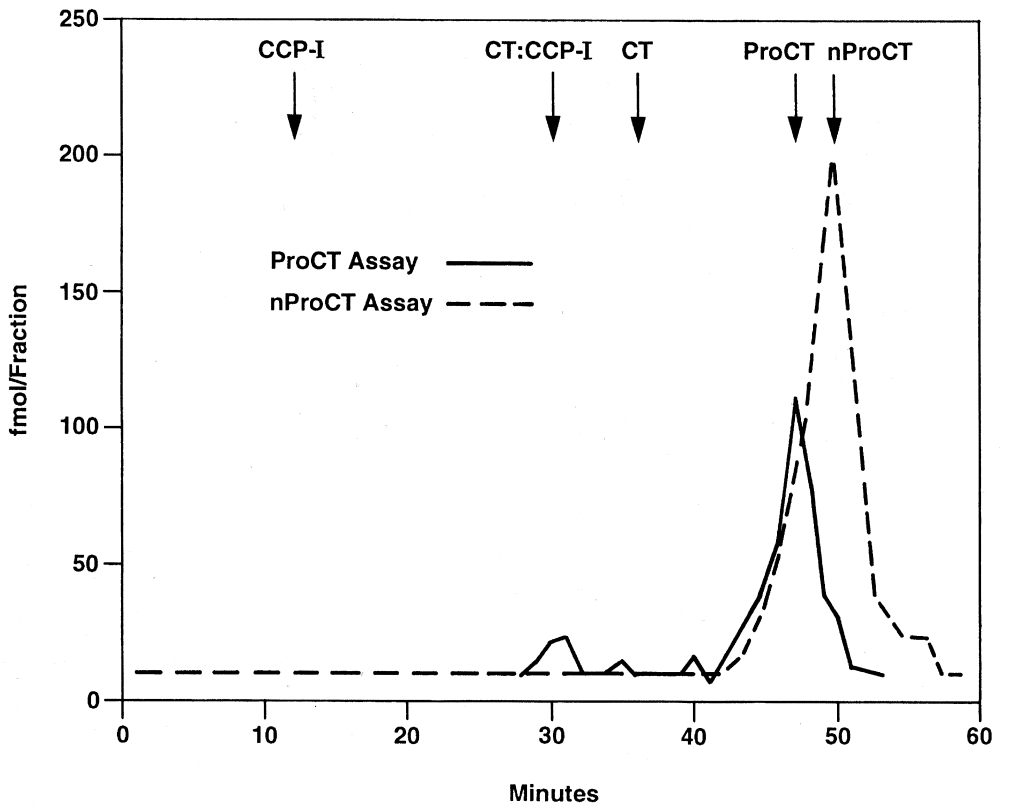

Figure 10 HPLC of serum from a burn patient with sepsis. Note the marked increase of nProCT and ProCT, as well as a moderate increase of the CT:CCP-I peptide.

toxin), which normally inhabit the gut (Ryan *et al.,* 1992). In this respect, burns and other severe injuries are known to induce such a translocation. However, sepsis induced by gram-positive bacteria also leads to an increase in circulating CTpr levels. Thus, other microbial products induce CTpr production.

Origin of Increased Calcitonin Precursors in Severe Systemic Inflammation

Studies in septic hamsters, pigs, and humans have revealed detectable CT mRNA not only in the thyroid gland, but also in all extrathyroidal tissues studied (brain, gut, kidney, liver, lung, testes, muscle, etc.) In contrast, in control animals, CT mRNA is detectable only in thyroid (i.e., C cells), and lung (i.e., PNE cells). In septic humans and animals, *in situ* hybridization studies have demonstrated that multiple cell types within these organs and tissues are involved. Thus, in sepsis, the entire organism is transformed into an endocrine gland (Müller *et al.,* 2001a). A similar phenomenon has been found for the expression of CGRP and ADM, two other peptides of the CALC gene family (Müller *et al.,* 2001b). It appears that increased gene transcription is induced by microbial infection-specific sepsis response elements in the gene promotor. Thus, these findings indicate that calcitonin gene products can follow either a classical hormonal expression or, alternatively, a cytokine-like expression pathway. In this regard, these gene products are a prototype of "hormokine" mediators (Müller *et al.,* 2001a,b).

Procalcitonin as a Toxic Factor in Systemic Inflammation

The correlation between serum CTpr levels and the severity of systemic inflammation/infection/sepsis suggested that one of these peptides, in particular ProCT, might be contributing to the morbidity and mortality of the host. Indeed, injection of ProCT into septic hamsters was found to increase mortality greatly. In follow-up studies, immunoneutralization of ProCT with antisera raised to different regions of the molecule has improved the clinical course of experimentally induced sepsis markedly (i.e., severe peritonitis) in hamsters and pigs (Nylén *et al.,* 1998; Wagner *et al.,* 2000). Studies in the septic pig have demonstrated marked amelioration of the disturbed physiologic and metabolic parameters among treated animals. The mechanism of the toxicity of ProCT in sepsis is under study.

Calcitonin Precursors and the Constitutive Pathway

The extraordinarily augmented and ongoing hypersecretion of CTpr in the face of a normal or only slightly increased serum level of mature CT in severe systemic inflammation indicates not only hypersynthesis, but also suggests a marked shift to the constitutive pathway of secretion, resulting in an incomplete processing of precursors.

As mentioned previously, the *trans*-Golgi normally identifies and selects certain proteins to be routed to two different secretory pathways: regulated and constitutive. The constitutive secretory pathway is present in all cells. Here, the vesicles that bud off from the *trans*-Golgi are less dense than those of the regulated pathway, and they migrate rapidly to the plasma membrane (Burgess and Kelly, 1987). Hence, in contrast to the slow transit time of the dense vesicles of the regulated system, which await periodic stimuli by their appropriate secretagogues for their exocytosis, the constitutive pathway vesicles are involved in a nonstoring, continuous secretion of newly synthesized peptide(s); it is a bulk-flow system. The vesicles fuse continuously with the plasma membrane, and the extrusion of their hormonal material may be calcium independent (Ma *et al.,* 1995). In severe systemic inflammation, a choice by the *trans*-Golgi to route ProCT to the constitutive pathway may be the major factor determining the exceptional spectrum of secreted components. Experimentally, such a shift to constitutional secretion has been shown to occur by the induction of dysfunctional prohormone convertase enzymes (Jung *et al.,* 1993; Naggert *et al.,* 1995), by the loss of Golgi recognition molecules (Bershadsky and Futerman, 1994; Chung *et al.,* 1989), by diminished intracellular calcium (Ma *et al.,* 1995), by alkalinization of cytoplasmic organelles (Scheele *et al.,* 1994; Xu and Shields, 1994), or by depolarization of the plasma membrane (Mostov, 1995; Schneeberger and Lynch, 1992; Simons and Van Meer, 1988; Simons and Wandinger-Ness, 1990). In this regard, septic serum, as well as some cytokines, may damage plasma membranes (Madara and Stafford, 1989; Todd and Mollitt; 1994).

Calcitonin Gene-Related Peptides I and II

The CALC-I gene produces either CT or CGRP-I. This is accomplished by alternative processing of the primary RNA transcript (Fig. 1) (Amara *et al.,* 1982) (see Chapter 36). CGRP-I (also termed CGRP-α) (molecular mass 3789 Da) is a 37 amino acid hormone, which, in humans, differs from CGRP-II (or CGRP-β) (molecular mass 3794) by three amino acids (Steenbergh *et al.,* 1985) (Fig. 2). CGRP-II originates from the CALC-II gene, for which there is no alternative processing of the RNA transcript. As is the case for CT, there is a carboxyl-terminal amide and a disulfide bridge at the amino terminus. CGRPs are biosynthesized from a larger Pre-ProCGRP, which has an nProCGRP that is very similar to nProCT. In addition, within the ProCGRP, there is a small carboxyl-terminal peptide that flanks the CGRP molecule.

CGRPs are predominantly neuropeptides; they are found mostly in the brain, ganglia, spinal cord, and peripheral nerves. They also are found in C cells and in PNE cells of the lung, where often they coexist with CT. Serum

levels are detectable in normal persons, and although values may be increased by induced hypercalcemia, this does not seem to be a physiologically relevant response. Values are commonly increased in the serum of patients with MTC, often in those with small cell cancer of the lung (Kelley *et al.,* 1994b).

CGRP may cause a slight diminution of bone resorption, the physiologic relevance of which is unknown (Owan and Ibraki, 1994) (see Chapter 36). The hormone inhibits osteoclast bone resorption by inducing quiescence (Zaidi *et al.,* 1987). This inhibition is mediated in part via cAMP (Akopian *et al.,* 2000). CGRP increases the number of bone colonies in cultured rat bone marrow (Bernard and Shih, 1990). In this respect, CGRP has been shown to have direct effects on osteoblast-like cells (Drissi *et al.,* 1997). Interestingly, CGRP increases intracellular-free Ca^{2+} concentrations in CGRP receptor-positive osteosarcoma cells (Drissi *et al.,* 1999). This increase is not coupled to adenylate cyclase, suggesting a downstream involvement of phospholipase C. CGRP-containing nerves appear to play a role in bone remodeling (Konttinen *et al.,* 1996). Although CGRP administration induces hypocalcemia in some laboratory animals, it does not do so in the human.

CGRP is a potent vasodilator and may diminish blood pressure. In this regard, it is noteworthy that the CT/CGRP gene knockout mouse model has elevated baseline blood pressure (Gangula *et al.,* 2000). The hormone may play a role in pulmonary pathophysiology. For example, there is an increase of CGRP-containing PNE cells in infants with fetal and neonatal lung disease. Serum CGRP is increased slightly in sepsis. Undoubtedly, the major physiologic role of CGRP is that of a neuromodulator. There are many receptor sites for CGRP in the nervous system and in peripheral tissues. CGRPs are discussed in greater detail in Chapter 36.

Amylin

The third hormonal member of the CALC gene family of peptides is amylin (Fig. 2), a 37 amino acid peptide (molecular mass 3903 Da) that was isolated from amyloid deposits in an endocrine pancreatic tumor and also in patients with type 2 diabetes mellitus (Cooper, 1994) (see Chapter 36). Amylin is produced from the CALC-IV gene located on chromosome 12. The hormone, which is cosecreted with insulin from pancreatic β cells, has an anti-insulin action; it diminishes insulin-stimulated glucose utilization (Castillo *et al.,* 1995). It inhibits the synthesis of glycogen in muscle and increases glycogen synthesis in the liver. Within the brain, amylin has an anorectic effect and also inhibits gastric acid secretion and gastric emptying (Samson *et al.,* 2000). In the kidney, the hormone stimulates plasma renin secretion. In common with CGRP, amylin exerts a vasodilator action. Amylin has an anti-inflammatory action, as do CT and CGRP (Clementi *et al.,* 1995).

Amylin affects osseous metabolism (Chapter 36). Intravenous administration of this hormone in dogs and in humans with Paget disease causes hypocalcemia (Wimalawansa *et al.,* 1992). In the dog, this hypocalcemia is associated with hypercalciuria; however, the increased urine calcium is insufficient to cause the decrease of serum calcium (Miles *et al.,* 1994). Amylin inhibits bone resorption by inducing quiescence of osteoclasts. In neonatal mouse calvariae, it reduces both basal and parathyroid hormone-induced bone resorption (Alam *et al.,* 1993b). Interestingly, amylin also influences bone formation; *in vitro,* it stimulates osteoblast proliferation in mice and increases mineralized bone volume (Cornish *et al.,* 1995). In young rats, the daily subcutaneous administration of amylin increases bone volume; there is no effect on ionized calcium (Romero *et al.,* 1995).

Serum levels of amylin are elevated in some patients with insulin resistance, in obesity, and in hypertension. It is unknown whether amylin contributes to an insulin-resistant state or whether the formation of islet amyloid noted in type 2 diabetes participates in the pathogenesis of this disease (Tenidis *et al.,* 2000).

Adrenomedullin

Adrenomedullin is a bioactive peptide that was originally found in pheochromocytoma tissue (Fig. 2) This 52 amino acid peptide (molecular mass 6029) is also amidated at the carboxyl-terminal and possesses an intramolecular disulfide bond between cysteine residues at positions 16 and 21, thus forming a 6-residue ring structure (Ishimitsu *et al.,* 1994a). These characteristics, plus its moderate amino acid identity with CGRP and a slight amino acid identity with amylin, suggest that it may be considered part of the CALC gene family (Wimalawansa, 1997). As is the case for CALC-I, -II, and -III genes, its gene is found on human chromosome 11. In contrast to CT and CGRP, which possess a disulfide ring structure at the amino terminus, and in contrast to amylin, which has a disulfide ring nearly at the amino terminus, adrenomedullin contains an additional 15 amino acid residues that are situated on the amino terminus side of its disulfide ring. However, much of this latter peptide extension is not needed for hormonal bioactivity. Within the proadrenomedullin molecule, there is an N-terminal 20-residue peptide that may be biologically active (Shimosawa *et al.,* 1995).

Adrenomedullin is found in adrenal medulla, heart, lung, kidney, vascular smooth muscle, endothelium, and plasma (Hinson *et al.,* 2000). The hormone activates adenylate cyclase through a G protein-coupled mechanism and mobilizes intracellular Ca^{2+}. Various pharmacologic stimulants of its secretion include cortisol, aldosterone, II-1α, TNF-α and-β, and lipopolysaccharide (Sugo *et al.,* 1995).

Adrenomedullin is a potent vasorelaxant; it dilates the pulmonary vascular bed, increases local blood flow, and produces a dose-related hypotension. Other actions include bronchodilation, inhibition of ACTH release from the pituitary gland, decreased angiotensin-induced aldosterone release, and natriuresis (Kanazawa *et al.,* 1994; Petrie *et al.,*

Table I Affinity of the CT Gene Family of Peptides According to the Type of Receptor and to RAMP Expression

Calcitonin receptor	
RAMP-1	CGRP and amylin; CT slight
RAMP-2	Calcitonin; CGRP and amylin slight
RAMP-3	Amylin; CGRP slight
Calcitonin receptor-like receptor	
RAMP-1	CGRP
RAMP-2	Adrenomedullin
RAMP-3	Adrenomedullin

2000). In the brain, adrenomedullin exerts vasorelaxant and antidipsogenic effects and may function as a neurotransmitter–neuromodulator.

In both *in vivo* and *in vitro* studies, adrenomedullin has been found to be a potent stimulator of osteoblasts (Cornish *et al.,* 1997). This has been postulated to play an important paracrine role in bone growth and maintenance (Hinson *et al.,* 2000). The effect of the hormone on the osteoclast is unknown.

Moderate increases of serum ADM occur in renal failure and in sepsis. The increased serum levels noted in patients with hypertension perhaps exert a protective role in this condition (Ishumitsu *et al.,* 1994).

Receptors of the Calcitonin Gene Family

Bioactivity of the peptides of the CT gene family is exerted by binding to their receptors. These receptors are G protein coupled; guanidine nucleotide guanosine triphosphate mediates their functions by binding to specific mediator proteins. There are two subgroups of receptors for the CT gene family: CT receptors (CRs) and CT receptor-like receptors (CRLRs) (see Chapter 34). Each of the CT gene family of peptides binds with differing affinities to these receptors. Consequently, some of their bioeffects overlap.

The complicated and unique overlapping of receptivity of CRs and CRLRs is due to their multipotentiality. Accessory proteins act upon these receptors, thus altering their specific responsivity and hence the physiologic profile of action of the CT gene peptides. These accessory proteins, which are called receptor activity-modifying proteins (RAMPs), alter the phenotype of the receptors, act on CRs by modification of its gene expression, and act on the CRLR by influencing transport to the plasma membrane. The presence, concentration, and/or timing of one or more of the three RAMPs (RAMP-1, -2, and -3) determines the specific cellular phenotype of the receptor that is ultimately expressed on the cell surface (Table I) (McLatchie *et al.,* 1998; Sumpe *et al.,* 2000; Martinez *et al.,* 2000). The profile of RAMP expression and activity is altered by the local milieu and is subject to humoral influences (Frayon *et al.,* 2000). This extraordinarily elegant system allows for a diversification of receptor function, thus modulating the action of the CT gene products according to ambient needs. Perhaps other receptors for individual members of the calcitonin gene family remain to be cloned.

Conclusion

CT was discovered in the early 1960s (Copp *et al.,* 1961; Hirsch *et al.,* 1963), at which time it was assumed to be a single hormone with a yet to be determined role in human physiology. Since then, it has been found to be only one peptide among a vast array of related circulating peptides comprising precursors, known hormones, and potential hormones. The discovery of this broad calcitonin gene family of peptides should provide great insight into the physiology of the human in health and disease.

CHAPTER 36

Amylin and Calcitonin Gene-Related Peptide

Ian R. Reid and Jill Cornish
Department of Medicine, University of Auckland, Auckland, New Zealand

Introduction

Calcitonin gene-related peptide (CGRP) and amylin are homologous 37 amino acid peptides, the genes for which have a common ancestral origin (see Fig. 1). Both have been reviewed recently (Wimalawansa, 1997). They have in common a 6 amino acid ring structure at the N terminus created by a disulfide bond between positions 2 and 7. In addition, C termini are amidated. CGRP-1 is generated by alternative processing of mRNA from the calcitonin gene, located on the short arm of chromosome 11. This gene has six exons, the first four of which produce the mRNA for the precursor of calcitonin, preprocalcitonin. This is subsequently converted to calcitonin itself and N- and C-terminal flanking peptides. An alternative mRNA for the CGRP precursor, preproCGRP, is formed from exons 1,2,3,5, and 6. This peptide is cleaved to produce an N-terminal flanking peptide similar to that from procalcitonin and CGRP-1 itself, which is coded by exon 5. The alternative splicing of calcitonin mRNA is tissue specific—in parafollicular cells of the thyroid, calcitonin mRNA is produced predominantly, whereas in the nervous system, CGRP-1 mRNA is produced predominantly. A second form of CGRP, CGRP-2, differs from CGRP-1 by only three amino acids in the human and one amino acid in the rat (see Fig. 1). It is produced by a separate gene also on the short arm of chromosome 11, thought to have arisen as a result of exon duplication (Zaidi *et al.,* 1987a). Both CGRPs have almost 20% homology with calcitonin, which is also amidated and contains a disulfide bridge.

Amylin has 43% sequence identity with CGRP-1, 49% with CGRP-2, and 13% with calcitonin in the human. It was originally isolated from amyloid deposits in the pancreases from patients with insulinoma or diabetes mellitus (Cooper *et al.,* 1987; Westermark *et al.,* 1987). Human amylin appears to be produced from a single gene on the short arm of chromosome 12, consisting of three exons. Like calcitonin and CGRP, amylin is synthesized as a prepropeptide, an 89 amino acid precursor that is subsequently processed to proamylin (67 amino acids) and hence to amylin itself. Amylin is the only known hormonal product of this gene.

Amylin is produced principally in β cells of the islets where its tissue content is less than 1% that of insulin. It is cosecreted with insulin, and evidence shows that insulin and amylin genes share transcriptional regulators (German *et al.,* 1992). Thus, hyperglycemia stimulates amylin secretion (O'Brien *et al.,* 1991), whereas hypoglycemia reduces it (Alam T *et al.,* 1992). Destruction of the β cell with streptozotocin reduces amylin secretion (Ogawa *et al.,* 1990). The excursion in circulating insulin levels following a glucose challenge appears to be greater than that seen with amylin (Mitsukawa *et al.,* 1990). Amylin secretion, however, may be more sustained following glucose administration (Mitsukawa *et al.,* 1990). In some experimental models, dissociation of the secretion of the two peptides has been achieved but this does not commonly occur *in vivo.*

Amylin has also been detected in tissues of the gastrointestinal tract, with tissue concentrations about 1% of those in the pancreas being found in the pyloric antrum (Nakazato *et al.,* 1989). Amylin or its mRNA has also been found in lung, dorsal root ganglion, hypothalamus, neuroendocrine tumors, and in an osteoblast cell line (Gilbey *et al.,* 1991).

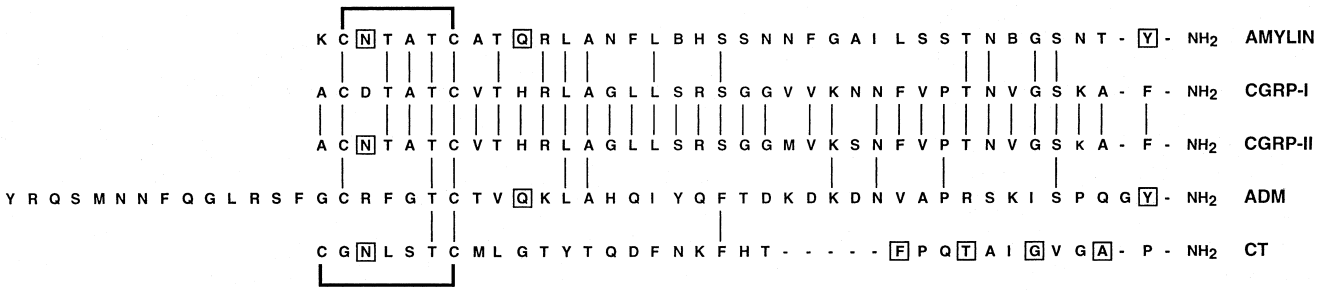

Figure 1 Amino acid sequences of amylin, CGRP, adrenomedullin (ADM), and calcitonin (CT) in humans. There is a disulfide bond in each peptide, as indicated by the dark line. Each peptide is amidated at its C terminus. Amino acids are identified as follows: A, alanine; C, cysteine; D, aspartic acid; E, glutamic acid; F, phenylalanine; G, glycine; H, histidine; I, isoleucine; K, lysine; L, leucine; M, methionine; N, asparagine; P, proline; Q, glutamine; R, arginine; S, serine; T, threonine; V, valine; Y, tyrosine. Identical amino acids are indicated by vertical lines and squares.

Extraskeletal Actions of Amylin and CGRP

Fuel Metabolism

The effects of amylin and CGRP on fuel metabolism appear to be comparable. In skeletal muscle the primary effects are probably on glycogen synthesis (which is inhibited) and glycogenolysis (which is stimulated). Thus, muscle glycogen stores are decreased by amylin or CGRP, and this is accompanied by diminished glucose uptake and increased glycolysis, leading to increased lactate production. In the liver, glucose output is increased, probably as a result of increased gluconeogenesis. This may be contributed to the increased flow of lactate from skeletal muscle, but has also been observed in some studies of isolated hepatocytes, implying an additional direct effect of amylin on liver cell function. Thus, in both skeletal muscle and liver, amylin and CGRP act as noncompetitive antagonists of insulin and produce insulin resistance (Young *et al.,* 1992). Amylin does not influence adipocyte metabolism, however, so the insulin resistance it produces is selective and could lead to a redirection of fuel from carbohydrate storage in liver and muscle to triglyceride storage in adipose tissue.

As well as antagonizing the actions of insulin (Hettiarachchi *et al.,* 1997; Gebremedhin *et al.,* 1998), amylin also reduces its secretion (Furnsinn *et al.,* 1994), possibly by altering glucose sensing at the β cell (Wagoner *et al.,* 1993). Overexpression of the amylin gene results in the development of diabetes in transgenic mice (Verchere *et al.,* 1996), but paradoxically, an amylin analog (pramlintide) reduces postprandial blood glucose excursion, probably by retarding gastric emptying (Thompson *et al.,* 1997). In some species, amylin can, in certain conditions, polymerize to form the β-pleated sheets characteristic of amyloid. Amyloid is toxic to pancreatic β cells (Lorenzo *et al.,* 1994), and its presence in type 2 diabetes may contribute further to reduced insulin secretion in that condition. Amino acids 25–29 in human amylin appear to be critical for amyloid formation. There is no homology between amylin and CGRP in this region, which may account for the failure of CGRP to form amyloid deposits.

Cardiovascular System

CGRP is one of the most potent vasodilators known and its receptors are distributed widely throughout the vascular system. In some vessels, it appears to act directly on smooth muscle, whereas in others, CGRP receptors are on endothelial cells, which release a diffusible mediator, probably nitric oxide. CGRP-containing nerves are also present in the heart, and CGRP exerts both positive inotropic and positive chronotropic effects. The wide distribution of CGRP-containing nerves throughout the vascular system makes it likely that CGRP has an important role in the regulation of regional blood flow, including renal and cerebral blood flow. CGRP administration is associated with a fall in systemic blood pressure. Amylin shares the vasodilatory of CGRP but it is significantly less potent (Young *et al.,* 1993). Both peptides cause hypertrophy of cardiomyocytes (Bell *et al.,* 1995).

Nervous System

CGRP is distributed throughout the nervous system, being found in sensory, motor, and autonomic nerves, as well as in the hypothalamus, thalamus, and hippocampus. It is one of the most abundant peptides in the nervous system and it is frequently colocalized with other neuropeptides, such as substance P. This suggests that it may have a neuromodulatory role, acting in concert with other neurotransmitters. CGRP modulates pain perception and also appears to act centrally as an anorexiant (Lutz *et al.,* 1994).

Amylin also appears to have a role in the nervous system. It is found in some sensory neurons (Mulder *et al.,* 1995) and modulates appetite, memory, and motor function (Morley *et al.,* 1995; Clementi *et al.,* 1996). Through the formation of oligomers, it may produce neuronal apoptosis (Tucker *et al.,* 1998).

Other Tissues

These peptides increase renin secretion (Wookey *et al.,* 1996) and may also interact with other hormonal axes, as circulating amylin concentrations are higher in patients with

primary hyperparathyroidism (Valdemarsson *et al.,* 1996), and CGRP is a growth hormone secretagogue (Nakamura *et al.,* 1998). They reduce gastric acid secretion (Rossowski *et al.,* 1997) and inhibit gastric emptying (Kolterman *et al.,* 1995; Young *et al.,* 1995). There is also evidence that both peptides can modulate inflammatory responses (Clementi *et al.,* 1995).

Peptide Access to the Bone Microenvironment

The principal route by which amylin reaches bone is the circulation, which, in turn, derives its amylin from pancreatic secretion. Circulating amylin levels are of the order of 5 pmol/liter, rising to 10–20 pmol/liter following a meal. Amylin secretion is pulsatile, with peaks occurring at about 5-min intervals (Juhl *et al.,* 2000). Levels are probably higher in obese subjects and those with type 2 diabetes (Butler *et al.,* 1990; Mitsukawa *et al.,* 1990; Hartter *et al.,* 1991; Sanke *et al.,* 1991; Reid *et al.,* 1993), but appear to be decreased by leptin (Karlsson *et al.,* 1998). There is one report of amylin production from a human osteoblast-like cell line (Gilbey *et al.,* 1991), raising the possibility of amylin production locally within the bone microenvironment, but we have been unable to confirm the presence of amylin mRNA in primary rat osteoblasts (D. Naot *et al.,* unpublished data).

Early reports suggested that CGRP circulated in concentrations of 30–40 pmol/liter (Zaidi *et al.,* 1986; Schifter, 1991), but it has been suggested more recently that the concentration is closer to 1 pmol/liter (Born *et al.,* 1991). Circulating concentrations are increased by sex hormone replacement therapy in postmenopausal women (Spinetti *et al.,* 1997). Some circulating CGRP may be secreted by the parafollicular cells of the thyroid and the balance is released by nerve endings. It is likely that bone may be exposed to significantly higher concentrations of CGRP as a result of local release of CGRP from nerve terminals. Sensory nerve fibers containing CGRP are widely distributed in bone, including bone marrow (Bjurholm, 1991; Hukkanen *et al.,* 1992; Ahmed *et al.,* 1994). Innervation is richest at the epiphysis and periosteum (Hill and Elde, 1991). When defects are created surgically, the development of CGRP-containing nerves is noted several days later, often in association with new blood vessels (Aoki *et al.,* 1994), suggesting a role in callus formation and bone healing. Similar responses are seen following fractures (Hukkanen *et al.,* 1993). It is interesting to note that CGRP-containing nerves are also seen in the growing deer antler (Gray *et al.,* 1992) and surrounding developing teeth (Fristad *et al.,* 1994). It is possible that CGRP aids bone growth in all these circumstances through its direct effects on osteoblast function. The intimate association of these nerves with blood vessels suggests that they may also have a role in regulating blood flow to sites of bone healing or growth.

There has been a report of CGRP mRNA in osteosarcoma cell lines and in human osteoblasts, raising the possibility that this peptide is produced locally in bone (Drissi *et al.,* 1997).

Effects on Osteoclasts

CGRP

Following the discovery of CGRP, its common origin and sequence homology with calcitonin led to an investigation of its effects on bone resorption. This was first approached by injection of the peptide into intact animals (Tippins *et al.,* 1984). Tippins and colleagues (1984) found that CGRP had a calcitonin-like effect in the rat and rabbit, lowering circulating calcium concentrations. In the rabbit, it was approximately equipotent with calcitonin, although in the rat, concentrations 100- to 1000-fold higher than those of calcitonin were required to produce hypocalcemia. However, in the rabbit, higher concentrations of CGRP produce hypercalcemia. In the chicken, the peptide causes only hypercalcemia.

These results led to more detailed assessments of CGRP effects on bone resorption. Yamamoto *et al.* (1986) studied the effect of human CGRP on ^{45}Ca release from prelabeled neonatal mouse calvariae (Fig. 2). CGRP produced a comparable degree of inhibition of both basal and parathyroid hormone-stimulated resorption, but the half-maximal concentration of CGRP was 500-fold higher than that for human calcitonin. Others have produced similar results in fetal rat bone organ cultures (D'Souza *et al.,* 1986; Roos *et al.,* 1986; Tamura *et al.,* 1992; Zhang *et al.,* 1994). The antiresorptive effect of CGRP blocks the stimulation of bone resorption produced by a variety of osteolytic factors.

Studies of disaggregated neonatal rat osteoclasts have confirmed that both CGRP-1 and CGRP-2 directly inhibit bone resorption in these cells (Fig. 3). These two peptides are equipotent, but the effect requires nanomolar concentrations, in contrast to calcitonins, which require only picomolar

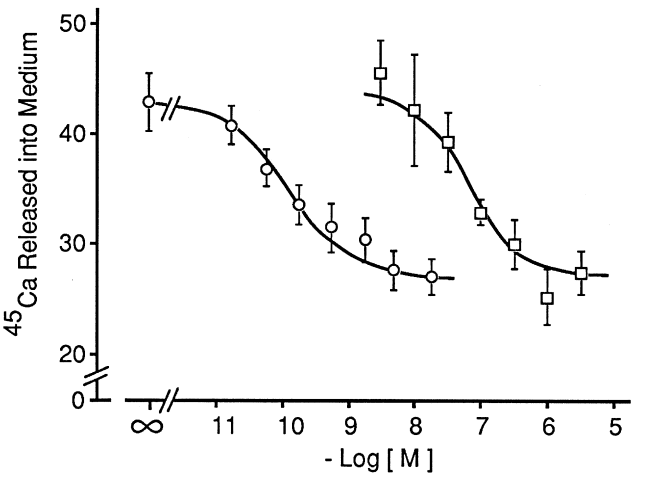

Figure 2 Effect of human calcitonin and human CGRP on PTH-stimulated bone resorption in neonatal mouse calvariae. Data are mean ±SE, $n = 6$. From Yamamoto *et al.* (1986), with permission.

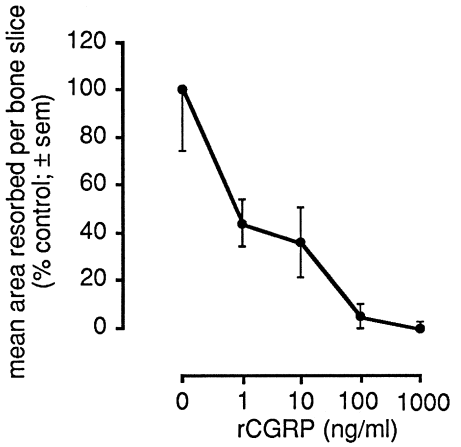

Figure 3 Effect of rat CGRP on bone resorption by isolated rat osteoclasts; 1 ng/ml CGRP = 0.26 nmol/liter. From Zaidi *et al.* (1987), with permission.

concentrations to produce comparable inhibition (Zaidi *et al.,* 1987b,c). More recent studies in isolated osteoclasts have further characterized the effects of CGRP on these cells (Alam *et al.,* 1991, 1993a,b). It inhibits osteoclastic bone resorption by inhibiting cell motility, probably via cylic AMP production, as this effect is reproduced by forskolin. Inhibition of cell motility is blocked by the CGRP fragment, CGRP-(8-37). Osteoclast retraction, which appears to be mediated by changes in intracellular calcium, is not seen with CGRP, although it is produced by calcitonin. These data imply that CGRP activates only the cyclic AMP intracellular messenger system, whereas calcitonin also acts on osteoclasts via changes in intracellular calcium. This may contribute to the greater potency of calcitonin in inhibiting bone resorption.

CGRP has also been shown to be active in other osteoclast models. Tamura *et al.* (1992) demonstrated cyclic AMP production in osteoclast-like multinucleated cells formed in cocultures of mouse osteoblasts and bone marrow cells in the presence of calcitriol. Concentrations 60-fold higher than those of human calcitonin were required, and CGRP in high concentrations displaced calcitonin from its specific binding site.

Evidence also suggests that CGRP may act on osteoclast precursors. Specific binding of CGRP to mouse bone marrow cells (Mullins *et al.,* 1993) and macrophages has been demonstrated, and CGRP inhibits the development of osteoclasts in macrophage–osteoblast cocultures (Owan and Ibaraki, 1994). We have addressed this question in cultures of mouse bone marrow, where CGRP inhibits the formation of mononuclear cells staining with tartrate-resistant acid phosphatase, as well as inhibiting the subsequent fusion of these cells to form multinucleated osteoclasts. Similar effects were seen with calcitonin at 1000-fold lower concentrations (Cornish *et al.,* 2001). Akopian *et al.* (2000) have reported reduced formation of human osteoclasts following treatment with CGRP. These data suggest that CGRP binds

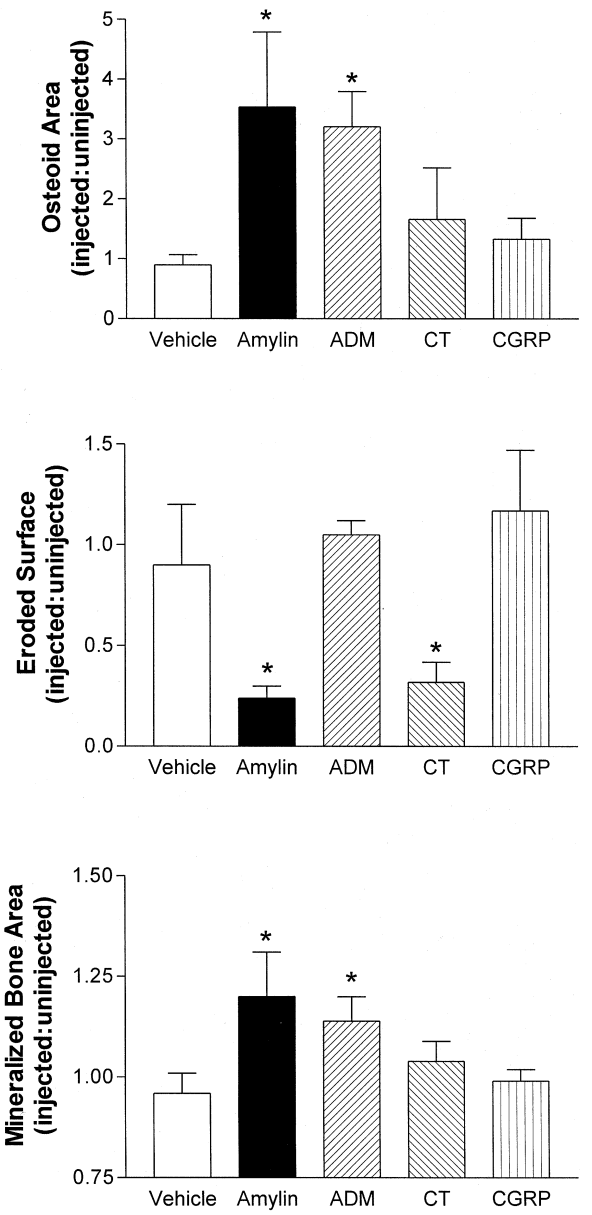

Figure 4 Comparison of the *in vivo* effects of rat amylin, human adrenomedullin, rat calcitonin (CT), and rat CGRP on bone histology in adult mice. Animals were injected daily with 4.1×10^{-9} mol of each peptide over the periosteum of one calvaria for 5 days and then sacrificed 1 week later. Data are expressed as the ratio of each index measured in the injected hemicalvaria to that measured in the contralateral, uninjected hemicalvaria. $n = 5$ in each group. Data are mean ±SE. Significant differences ($p < 0.05$) between injected and uninjected hemicalvariae are indicated by asterisks. From Cornish *et al.* (1999d), with permission.

specifically to osteoclast precursors and regulates osteoclast development.

Despite this consistent evidence of an effect of CGRP on osteoclastic resorption *in vitro*, a study of *in vivo* injection of CGRP over the calvariae of adult mice detected no significant inhibition of resorption (Cornish *et al.,* 1995) (Fig. 4). However, Valentijn *et al.* (1997) have demonstrated incomplete suppression of post-ovariectomy increases in bone

resorption in rats with CGRP treatment. This required the use of CGRP in a dose 500 times higher than that of calcitonin, which produced a greater therapeutic effect. Thus CGRP is antiresorptive *in vivo*, but its low potency suggests that this is unlikely to contribute to normal skeletal physiology except, possibly, in the region immediately adjacent to CGRP-producing cells.

Amylin

Within a short time of the description of amylin, its effect on indices of bone resorption had been assessed in studies paralleling those just described for CGRP. Thus its hypocalcemic actions in rats (Datta *et al.,* 1989; MacIntyre, 1989; Zaidi *et al.,* 1990), rabbits (Datta *et al.,* 1989), and humans (Gilbey *et al.,* 1991b; Wimalawansa *et al.,* 1992) were reported (Fig. 5), and similar effects have been described in the goat (Min *et al.,* 1999). In the rat, 30-fold higher doses of amylin were required to produce comparable hypocalcemia to that from calcitonin, and human studies showed a similar trend. The effects of amylin on serum calcium in the rat, however, were significantly greater than those of CGRP (Zaidi *et al.,* 1990).

More detailed studies of the action of amylin on isolated osteoclasts have shown that its actions are qualitatively similar to those of CGRP. Thus amylin inhibits the motility of mature osteoclasts by way of increasing intracellular cyclic AMP concentration. It is 10-fold more potent than CGRP but an order of magnitude less potent than human calcitonin (Alam *et al.,* 1993b). Amylin does not produce the osteoclast retraction seen with calcitonin. In contrast, CGRP and amylin were equipotent in stimulating cyclic AMP production in osteoclasts produced by coculture of osteoblasts and bone marrow cells (Tamura *et al.,* 1992), although 60-fold less potent than human calcitonin. In the putative osteoclast precursor, the macrophage, amylin stimulated cyclic AMP production but was 100-fold less potent than CGRP (Owan and Ibaraki, 1994). This effect was blocked by the CGRP antagonist, CGRP(8-37). We have also studied the effect of amylin on osteoclast development in mouse bone marrow cultures (Cornish *et al.,* 2001). As with CGRP, there is an inhibition of both the formation of mononuclear osteoclast-like cells and the fusion of these cells.

Amylin has also been shown to reduce bone resorption in organ culture. It is approximately equipotent with CGRP in inhibiting calcitriol-stimulated resorption in fetal rat long bones (Tamura *et al.,* 1992). Amylin reduces both basal and parathyroid hormone-stimulated bone resorption in neonatal mouse calvariae, and cyclic AMP production is also stimulated in this model (Pietschmann *et al.,* 1993; Cornish *et al.,* 1994). In the studies of Cornish and co-workers (Fig. 6), inhibition of resorption was seen at concentrations as low as $10^{-9}M$.

These results should be interpreted in the light of the marked propensity for amylin to adhere to the surfaces of laboratory plasticware (Young *et al.,* 1992), suggesting that the actual concentrations of amylin in all *in vitro* experiments may be one to two orders of magnitude less than the amount added to the media. Thus, both osteoclast and calvarial studies imply that amylin may regulate bone resorption at physiological concentrations. This activity is dependent on the presence of the carboxyl-terminal amide group. In its absence, the potency of amylin in reducing osteoclastic resorption is comparable to that of CGRP (Datta *et al.,* 1989; Alam *et al.,* 1993b). Amlyin's inhibition of bone resorption in neonatal mouse calvariae only occurs with the intact molecule, in contrast to the situation with amylin action on osteoblasts. Amylin fragments, which act as antagonists in the osteoblast, do not modify the effect of amylin on osteoclasts (Cornish *et al.,* 1998b).

The effect of amylin on resorption *in vivo* has been studied histomorphometrically in several different models. Cornish

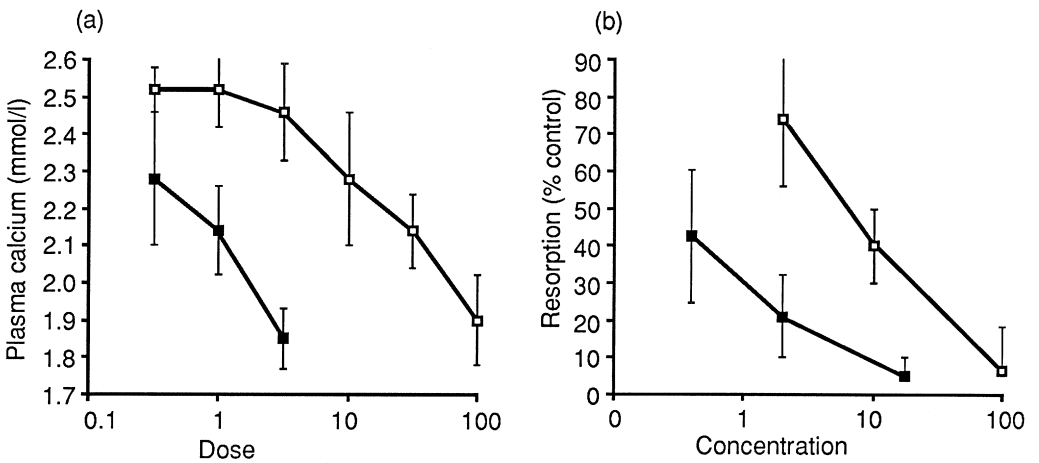

Figure 5 Effect of human amylin and human calcitonin on (a) plasma calcium in the rat and (b) bone resorption by isolated osteoclasts *in vitro.* Doses are given in pmol/rat (a) and in pmol/liter (b). Data are mean ±SE. From MacIntyre (1989), with permission.

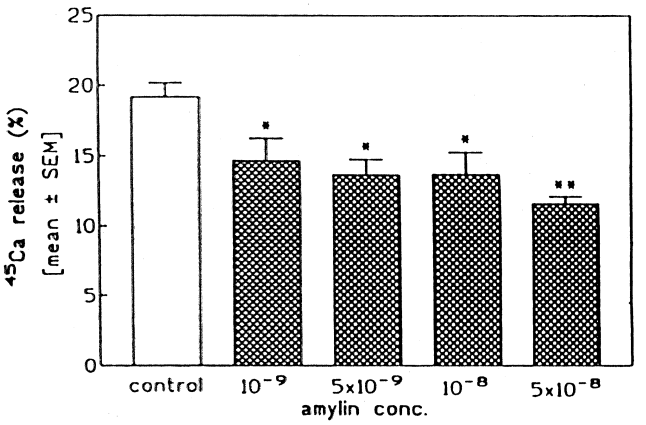

Figure 6 Effect of amylin on basal bone resorption in neonatal mouse calvariae. Based on data in Cornish *et al.* (1994).

et al. (1995) demonstrated 60–70% reductions in indices of bone resorption following daily local administration of amylin over the calvariae of adult mice. Very similar changes in resorption indices were seen following systemic administration of amylin to adult male mice for 1 month (Cornish *et al.,* 1998a), although the aminoterminal octapeptide of amylin is without effect on resorption in the same model (Cornish *et al.,* 2000). In ovariectomized rats, intact amylin reduces urinary excretion of deoxypyridinoline and reduces bone loss (Horcajada-Molteni *et al.,* 2000) (Fig. 8). In contrast, the earlier experiment of Romero *et al.* (1995), in which amylin was administered systemically to rats, showed only a nonsignificant trend toward reduced resorption, and Borm *et al.* (1999) found no change in resorption markers in 23 diabetic patients receiving the amylin analogue pramlintide for 1 year. The latter study needs to be interpreted with caution, as it used an amylin analog of unknown activity on bone and it was uncontrolled.

Effects on Osteoblasts

CGRP

At the time that the effects of CGRP as a calcitonin analog in bone were being investigated, data began to emerge suggesting that it may also have an effect on osteoblasts. Michelangeli *et al.* (1986) demonstrated that CGRP increased cyclic AMP formation in an osteogenic sarcoma cell line (UMR 106-01) that had an osteoblastic phenotype and was not calcitonin responsive. The same group subsequently studied mixed bone cell cultures obtained by sequential digestion of neonatal chicken, rat, or mouse calvariae and again demonstrated the presence of a cyclic AMP response to CGRP when none to calcitonin was detectable (Michelangeli *et al.,* 1989). Other studies have demonstrated CGRP binding (Seitz *et al.,* 1986; Datta *et al.,* 1990) and cyclic AMP production (Thiebaud *et al.,* 1991; Bjurholm *et al.,* 1992; Tamura *et al.,* 1992) in normal or transformed osteoblast-like cells. Aminoterminal peptides and the disulfide bridge were both necessary to maintain activity of CGRP on osteoblasts (Thiebaud *et al.,* 1991).

A variety of other effects of CGRP on osteoblasts have been demonstrated. Cornish *et al.* (1995) showed small increases in osteoblast proliferation in response to CGRP but only at concentrations 1000-fold higher than those of amylin required to produce an effect (Fig. 7). Gupta *et al.* (1994) demonstrated a stimulation of Na^+/H^+ exchange in UMR 106 cells. From these studies, they concluded that activation of more than one intracellular second messenger pathway is necessary to account for their findings and, in particular, that cyclic AMP generation alone is not an adequate explanation. Subsequently, Kawase *et al.* (1995) have demonstrated an effect of CGRP on intracellular calcium concentrations and on potassium fluxes and membrane polarization (Kawase and Burns, 1998) in the same cell line. In another osteoblast cell line, CGRP increases intracellular calcium concentrations but has no detectable effect on cyclic AMP (Drissi *et al.,* 1999).

There is also evidence that CGRP may act on preosteoblasts (Thiebaud *et al.,* 1991; Tamura *et al.,* 1992), influencing their development from precursor cells (Mullins *et al.,* 1993). Bernard and Shih (1990) have demonstrated that the number and size of bone colonies developing in bone marrow cultures are increased by CGRP and that systemic treatment with CGRP increases the number of bone colonies developing in marrow cultures.

The effects of CGRP on cytokine/growth factor production have been assessed. Sakagami *et al.* (1993) found that CGRP increased cyclic AMP and interleukin-6 production in a preadipocyte-like stromal cell line. CGRP also inhibited the proliferation of these cells. In primary osteoblasts, however, CGRP increased IGF-1, IGF-2, and osteocalcin mRNA, and this effect on IGF-1 has been confirmed by others (Vignery and McCarthy, 1996). In primary rat osteoblast cultures, CGRP has also been shown to substantially reduce tumor necrosis factor-α production and to weakly stimulate interleukin-6 production by these cells (Millet and Vignery, 1997). Thus CGRP may regulate the function of both precursor cells and mature osteoblasts by modulating the production of cytokines and growth factors.

The small amount of data regarding the effects of CGRP on osteoblast function *in vivo* is conflicting. Cornish *et al.* (1995) found no significant effect of local injection of CGRP on osteoblast indices in adult mice (Fig. 4). Valentijn *et al.* (1997) found no change in bone formation rates in ovariectomized rats treated with CGRP, but observed increases in bone formation indices, bone volume, and bone density of mice with osteoblasts overexpressing CGRP (Ballica *et al.,* 1999).

We have raised the possibility that these relatively weak effects of CGRP on osteoblast function may be mediated by receptors that have a higher affinity for amylin than for CGRP (Cornish *et al.,* 1999b). In cultures of fetal rat osteoblasts, amylin increased cell number, thymidine, and phenylalanine incorporation at 100-fold lower concentrations

than those of CGRP and its maximal effects were about twice as great as those of CGRP. There was no additivity between maximal doses of the peptides on these indices. The CGRP receptor blocker, CGRP-(8-37), completely blocked the effect of CGRP at blocker concentrations $\leq 10^{-9}\,M$. In contrast, the amylin receptor blocker, amylin-(8-37), completely blocked the effects of CGRP when the blocker was present in concentrations as low as $10^{-11}M$. In converse experiments studying the blockade of maximal doses of amylin, amylin-(8-37) $10^{-10}M$ was effective, whereas a 100-fold greater concentration of CGRP-(8-37) was necessary to achieve the same effect. It was concluded that amylin and CGRP probably act through a common receptor to stimulate osteoblast growth and that this receptor has a higher affinity for amylin than for CGRP.

Amylin

The binding of amylin to osteoblast-like cells was demonstrated soon after the discovery of the peptide (Datta *et al.,* 1990), and binding of amylin and stimulation of cyclic AMP production were also demonstrated in a pre-osteoblastic cell line (Tamura *et al.,* 1992). However, these studies did not demonstrate cyclic AMP production in response to amylin in primary osteoblast cultures, although CGRP produced cyclic AMP in these cells (Tamura *et al.,* 1992). Cornish *et al.* (1995) demonstrated stimulation of proliferation of fetal rat osteoblasts by amylin in concentrations as low as $10^{-11}M$, as shown in Fig. 7. Similar effects have been shown in human osteoblasts by Villa *et al.* (1997) and by ourselves (unpublished data). Amylin-(1-8) also stimulates osteoblast proliferation, although its half-maximally effective concentration is 10-fold higher than that of the intact peptide (Cornish *et al.,* 1998b). This peptide also stimulates thymidine incorporation in neonatal mouse calvariae (Cornish *et al.,* 1999c).

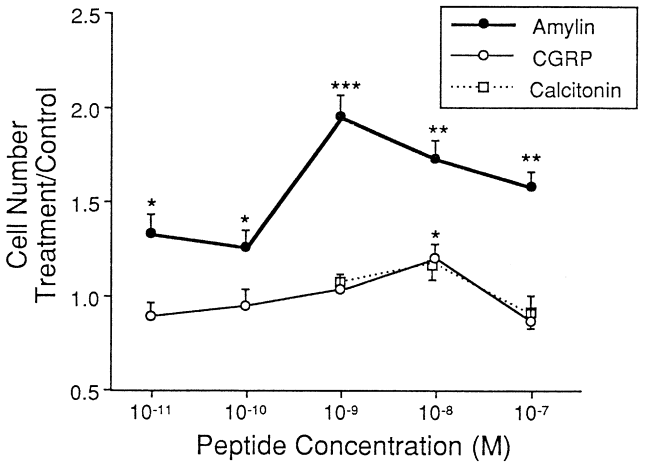

Figure 7 Dose dependence of the effects of rat amylin (●) rat CGRP-1(○), and rat calcitonin (□) on numbers of primary rat osteoblast-like cells in culture over 24 hr. $n = 6$ in each group. Data are mean ±SEM. Statistical significance of differences from control: $^{*}p \leq 0.05$; $^{**}p < 0.005$; $^{***}p < 0.001$. Reprinted with permission from Cornish *et al.* (1995).

In vivo studies of the effect of amylin on osteoblastic function are now available. Jacobs *et al.* (1992) commented on an increase in cortical endosteal osteoblast numbers in normal rats treated with amylin, but not in diabetic rats similarly treated. Subsequently, the same group showed a transient elevation of serum osteocalcin in rats given daily injections of amylin (Romero *et al.,* 1995). Cornish *et al.* (1995) (Fig. 4) have shown two- to four-fold increases in histomorphometric indices of osteoblast activity in adult mice to whom amylin was administered locally over the calvariae daily for 5 days, and we have now shown 30–100% increases in these indices following daily systemic administration of amylin

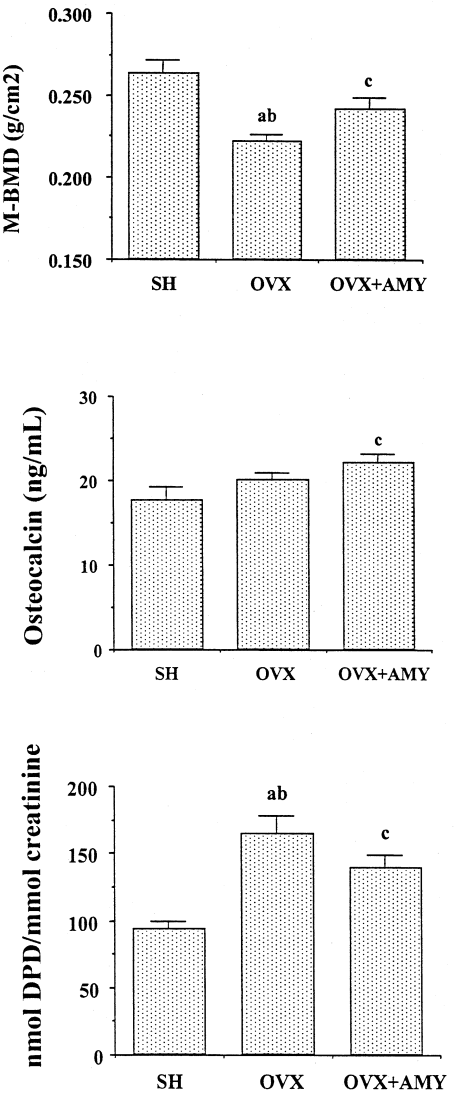

Figure 8 Effects of daily systemic administration of amylin (3 μg/100 g) to ovariectomized rats for 90 days. Indices assessed were distal metaphyseal bone mineral density of the femur (M-BMD), serum osteocalcin concentration, and urinary excretion of deoxypyridinoline (DPD). SH, sham operated; OVX, ovariectomized; AMY, amylin. a, significantly different from sham animals, $p < 0.01$; b, significantly different from amylin-treated group, $p < 0.05$; c, significantly different from sham, $p < 0.05$. Data from Horcajada-Molteni *et al.* (2000), with permission.

over 1 month (Cornish *et al.,* 1998a). Horcajada-Molteni *et al.* (2000) demonstrated increases in serum osteocalcin concentrations in ovariectomized rats treated systemically with amylin (Fig. 8), although the small human study with pramlintide did not detect any changes in osteoblast function (Borm *et al.,* 1999).

These *in vivo* studies have now been extended to amylin-(1-8). When administered by local injection over the calvariae of female mice, this peptide increased the double-labeled surface threefold. The effect was dose dependent from 0.4 to 40 n*M* and greater than that of an equimolar dose of hPTH-(1-34). The mineral apposition rate was increased by 40 n*M* amylin-(1-8) but not by hPTH-(1-34). Daily systemic administration of this peptide to sexually mature male mice for 4 weeks almost doubled histomorphometric indices of osteoblast activity (Cornish *et al.,* 2000). Thus, a number of studies have found evidence of an anabolic action of amylin and its amino terminus in osteoblasts.

Effects on Bone Mass

Studies in which the effects of these peptides on the total amount of mineralized tissue in bone has been assessed have mostly been referred to already. In the study of Cornish *et al.* (1995) involving local injection of intact amylin over the calvariae of adult mice, there was a substantial decrease in bone resorption, an increase in bone formation, and a 20% increase in mineralized bone area after only five daily injections (Fig. 4). An equimolar dose of CGRP in the same model produced no significant effects on any of these parameters. By comparison, calcitonin inhibited resorption but did not significantly affect formation and caused a small, nonsignificant increase in mineralized bone area.

Romero and colleagues (1995), administered amylin systemically to normal male rats for 18 days, producing no changes in histomorphometric indices of formation or resorption but increasing cancellous bone volume of the proximal tibia by 25%. In diabetic animals, a similar upward trend in bone volume was evident but was not statistically significant. In a similar study in normal male mice, Cornish *et al.* (1998a) showed increases in total bone volume in the proximal tibia of 70% (Fig. 9), and there were also increases in cortical width, tibial growth plate width, tibial length, body weight, and fat mass. A similar experiment using amylin-(1-8) increased bone volume by 36%, tibial cortical thickness by 8%, and resulted in increased bone strength as assessed by three-point bending (Cornish *et al.,* 2000). There were no between-group differences in soft tissue mass in the study with the amylin octapeptide, but growth plate width was again increased, suggesting an effect on chondrocytes also. This effect has now been confirmed *in vitro* in studies demonstrating the increased proliferation of canine and human chondrocytes in response to amylin, amylin-(1-8), and adrenomedullin (Cornish *et al.,* manuscript submitted). In the study of systemic administration of intact amylin to ovariectomized rats, reported by

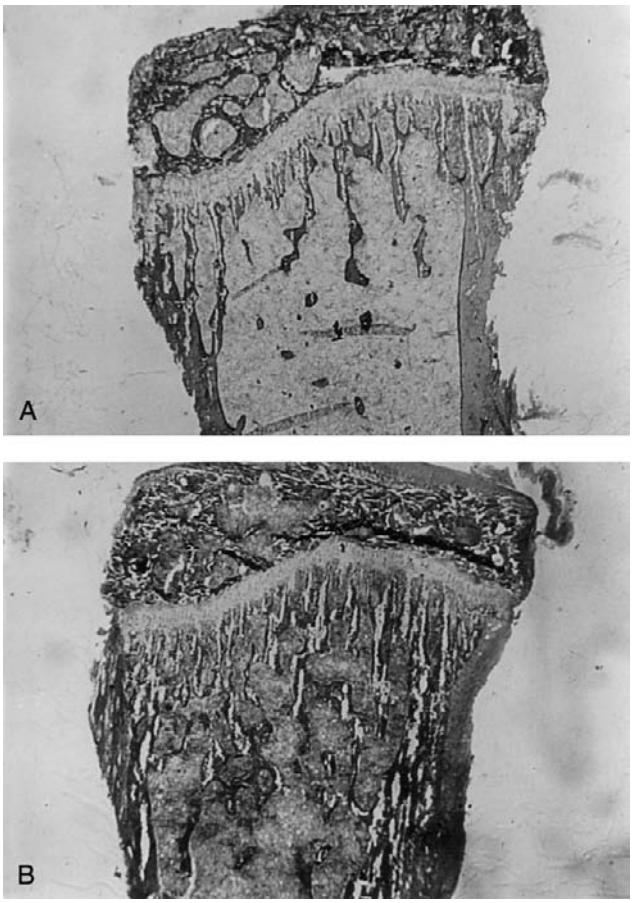

Figure 9 Photomicrographs of proximal tibiae of mice treated systemically with (A) vehicle or (B) amylin 10 μg/day for 4 weeks. Trabecular bone volume is increased 70% in amylin-treated animals. Reprinted from Cornish *et al.* (1998), with permission.

Horcajada-Molteni *et al.* (2000), both distal metaphyseal and total femoral bone densities were higher in animals receiving peptide (Fig. 8). The negative result of the uncontrolled study with pramlintide in patients with type I diabetes has already been referred to (Borm *et al.,* 1999).

In the study of Valentijn *et al.* (1997), ovariectomized rats were given daily subcutaneous injections of CGRP-α for 28 days. This treatment decreased bone resorption and caused a modest reduction in postovariectomy bone loss from 60 to 46%. In a study of transgenic mice overexpressing the CGRP gene in osteoblasts, Ballica *et al.* (1999) demonstrated a 5% increase in distal femoral bone density at the age of 12 weeks, confirming the potential impact of these peptides on bone mass, but also suggesting that the impact of amylin is greater. A quite different approach to determining the effect of CGRP on bone mass was used by Hill *et al.* (1991). Reasoning that most of the CGRP that gains access to bone does so via sensory nerves, they studied the effect of sensory denervation using capsaicin treatment in rats. This intervention produced no change in tibial histomorphometry although the osteoclast surface in the mandible was decreased. Whether this is attributable to loss of CGRP or to other effects of capsaicin treatment is not known.

Effects on Calcium Metabolism *in Vivo*

The most apparent effect of amylin and CGRP on systemic calcium metabolism is the induction of hypocalcemia, which has been demonstrated in a number of species, as discussed earlier. This is probably substantially attributable to inhibition of osteoclastic bone resorption. However, amylin, like calcitonin, may have a direct calciuretic effect on the kidney. Rat amylin binds to the renal porcine calcitonin receptor with an affinity comparable to that of porcine calcitonin itself. Both peptides comparably stimulate cyclic AMP production via this receptor (Sexton *et al.,* 1994). CGRP does not compete for binding to this receptor. However, in rat renal tubular membranes, CGRP and amylin stimulated cyclic AMP production with comparable half-maximal concentrations, and the effects of both peptides were blocked by CGRP(8-37) (Osajima *et al.,* 1995). Consistent with these results is the finding of Miles *et al.* (1994) that amylin infusion doubles urinary calcium excretion in dogs. However, the increased urinary loss of calcium accounted for less than 10% of the fall in serum calcium, suggesting that reduced osteoclastic resorption was the principal contributor to the hypocalcemic effect. These changes were accompanied by a doubling of PTH but no change in circulating calcitonin concentrations.

In the rat, CGRP, like amylin, is hypocalcemic with a potency slightly greater than that of amylin (Young *et al.,* 1993). However, in the chicken it has the opposite effect, elevating serum calcium within 20 min of administration (Ancill *et al.,* 1990; Bevis *et al.,* 1990). The mechanism of this effect has not been elucidated.

Adrenomedullin

It is not appropriate to discuss the actions of amylin and CGRP on bone without mentioning those of the closely related peptide, adrenomedullin, a 52 amino acid peptide (Kitamura *et al.,* 1993). It was originally identified in 1993 in a human pheochromocytoma and has since been found to be present in normal adrenal medulla and in many other tissues, including the atria, ventricles, endothelial cells, lungs, brain, kidneys, and bone (Ichiki *et al.,* 1994; Montuenga *et al.,* 1997; Hinson *et al.,* 2000). It circulates in picomolar concentrations in both rats and humans (Kitamura *et al.,* 1994; Hinson *et al.,* 2000). It is a potent vasodilator, acting directly on the renal, cerebral, mesenteric, pulmonary, and systemic circulations, including the vascular supply of the skeleton (Kato *et al.,* 1996). Its hemodynamic effects are probably mediated via receptors on vascular smooth muscle cells and possibly endothelial cells. Binding to a number of other tissues, including lung, heart, kidney, and hypothalamus, has also been demonstrated (Hinson *et al.,* 2000). Adrenomedullin shows approximately 20% sequence identity with amylin and CGRP and slightly less with calcitonin (Muff *et al.,* 1995). Like amylin and CGRP, it has an N-terminal ring created by a disulfide bond and is amidated at its C terminus. Adrenomedullin differs from the others in that it has a linear N-terminal extension, consisting of 15 amino acids in the human and 13 in the rat.

Because of its structural similarity to amylin and CGRP, the effects of adrenomedullin on the skeleton were assessed (Cornish *et al.,* 1997). At concentrations of 10^{-12} *M* and greater, adrenomedullin dose dependently increases cell number and [^{3}H]thymidine incorporation in cultures of fetal rat osteoblasts. This effect was also seen with adrenomedullin(15-52), adrenomedullin(22-52), and adrenomedullin(27-52) but not with adrenomedullin(40-52). Adrenomedullin also increases [^{3}H]thymidine incorporation into cultured neonatal mouse calvariae and phenylalanine incorporation into both isolated osteoblasts and calvariae (Cornish *et al.,* 1997), and we have also shown that it stimulates proliferation of primary cultures of human osteoblasts (J. Cornish *et al,* unpublished observations). Adrenomedullin injected daily for 5 days over the calvariae of adult mice increased indices of bone formation two- to threefold and increased mineralized bone area (Cornish *et al.,* 1997). When administered systemically to mice for 4 weeks, it produces very similar effects to those of amylin-(1-8). Like that peptide, adrenomedullin is without effect on osteoclast activity, and its effects on osteoblasts are blocked by amylin receptors blockers, such as amylin-(8-37). These similarities suggest that the actions of amylin and adrenomedullin on the osteoblast might share a common mechanism.

Receptors

In nonosseous tissues, there are believed to be separate specific receptors for amylin and CGRP, with some evidence pointing to more than one class of receptor for the latter. Amylin, CGRP, and calcitonin are able to displace each other from specific binding sites, implying significant cross-reactivity of each with the receptors of other peptides. Whether this leads to significant biological effects at the peptide concentrations found *in vivo* is unknown.

The fact that the actions of amylin on osteoblasts and osteoclasts can be dissociated, suggests that they may be mediated by different receptors. Data available at the present time are consistent with the actions of amylin and CGRP on bone resorption being mediated by the calcitonin receptor. As noted earlier, current data suggest that the actions of amylin, CGRP, and adrenomedullin on osteoblasts may all be mediated by a common receptor, which has a lower affinity for CGRP than for the other two peptides. We have shown that the proliferative effects of amylin and adrenomedullin are dependent on the presence of the IGF-1 receptor, although neither of these peptides appear to compete for binding to this receptor, implying a less direct mechanism for its involvement (Cornish *et al.,* 1999a).

Uncertainty still surrounds the identities of the receptors for this family of peptides in nonbone cells. A CGRP receptor was identified in 1995 by Kapas and Clark, but work by

McLatchie *et al.* (1998) casts doubt on the significance of this receptor. They suggest that the principal CGRP receptor is in fact the so-called calcitonin receptor-like receptor (CRLR). Cells expressing this receptor alone are relatively unresponsive to CGRP, but in the presence of a peptide they have termed receptor activity modifying protein-1 (RAMP1), the CRLR is both glycosylated and translocated to the cell surface, conferring CGRP sensitivity. Separate proteins, RAMP2 and RAMP3, interact with this receptor to produce an adrenomedullin receptor. Other groups have confirmed that these CRLR-based receptors account for most of the specific binding of adrenomedullin and CGRP in a variety of rat tissues (Chakravarty *et al.,* 2000). When RAMPs 1 or 3 interact with the calcitonin receptor, an amylin receptor is created (Christopoulos *et al.,* 1999; Muff *et al.,* 1999). Primary rat osteoblasts express mRNAs for all three RAMPs, the calcitonin receptor-like receptor, and the putative adrenomedullin receptor identified by Kapas *et al.,* (1995), but not that for the calcitonin receptor (Naot *et al.* 2000). Thus, the nature of the receptor mediating the osteoblast effects described earlier is uncertain, but it could be an adrenomedullin receptor.

The receptors referred to earlier are all seven transmembrane G protein-coupled receptors, thought to act via adenylyl cyclase and/or calcium-inositol signaling pathways. It should be noted that the effects of these peptides on cyclic AMP concentrations in osteoblasts are modest (in comparison with parathyroid hormone, for instance) and that amylin and adrenomedullin activate mitogen-activated protein kinase in osteoblasts (Abrahamsen *et al.,* 2000). Further work is needed to delineate fully the second messenger pathways mediating their effects in bone.

Si1gnificance in Calcium Metabolism

What role amylin and CGRP play in normal bone metabolism and bone pathology remains to be determined. It has been hypothesized that amylin secretion following a meal directs the absorbed calcium and protein from the meal into new bone synthesis by increasing bone growth at a time when the substrates are available (MacIntyre, 1989; Zaidi *et al.,* 1993). Amylin may also contribute to the relationship between body mass and bone density. Body mass, or more particularly fat mass (Reid *et al.,* 1992a,b), is the principal determinant of bone density in women. While this might be mediated to some extent by the effect of weight on skeletal load bearing and by adipocyte production of estrogen, neither of these explanations is adequate to explain the published results (Reid *et al.,* 1992a,b, 1993, 1994, 1995). Because both insulin and amylin are hypersecreted in obesity and because both may potentially act directly or indirectly to increase bone mass, they may contribute significantly to this relationship. Indeed, circulating insulin levels are directly related to bone density in normal postmenopausal women (Reid *et al.,* 1993), and because amylin is cosecreted with insulin, it would seem likely that a similar relationship for this peptide exists.

Because most of the CGRP gaining access to bone does so via sensory nerves, it is likely that this peptide is involved in the response of bone to injury and to other stimuli, such as exercise. The association of CGRP-containing nerves with healing and growing bone supports this contention.

The effects of both amylin and CGRP are, broadly, to increase bone formation and reduce bone resorption. As such, they are attractive candidates for the treatment of the generalized bone loss of osteoporosis and to promote healing of local bone defects. Their efficacy has now been demonstrated in several different animal models, although much remains to be done in determining which fragments or analogs are the most promising candidates and what their other effects might be. Further studies are under way that should determine whether compounds mimicking the effects of amylin and CGRP will find a place as therapeutic entities.

Introduction

Since the publication of the first edition of this book in 1996, the field of estrogen and progestin action has witnessed several major advances that impact bone, which are the emphasis of this chapter. Estrogen (E) is the major sex steroid affecting the growth, remodeling, and homeostasis of the skeleton, whereas the importance of progesterone (P) is less well defined. It is becoming increasingly clear that E regulates the processes of osteoblast (OB)-mediated bone formation and osteoclast (OC)-mediated bone resorption at multiple levels; including progenitor cell recruitment, proliferation, differentiation, and programmed cell death. Additionally, a second estrogen receptor distinct from the classical receptor has been identified, and loss-of-function mutations for these two receptor isoforms produce different skeletal phenotypes in mice. Taken together, these findings demonstrate that the effects of E on bone and cartilage are highly complex. Similar receptor isoforms for progesterone receptor have been identified in OBs, which also contribute to the varying actions of P on the skeleton. Added to these variables are the existence of steroid receptor coregulators; nuclear transcription factors that modulate steroid receptor interactions with the transcriptional machinery. Nevertheless, the actions of E and P at the molecular, cellular, and bone tissue level are currently being elucidated.

The topics covered in this chapter include estrogen and progesterone receptor structure and function, roles of the receptor isoforms and receptor coregulators, receptor isoform expressions in bone tissues, effects of E and P treatment on bone cells *in vitro* and on the skeleton *in vivo,* and consequences of estrogen and progesterone receptor gene deletions on skeletal structure and bone metabolism. Additionally, due to the increasing clinical and scientific interest in these hormones, the actions of E-related compounds [selective estrogen receptor modulators (SERMs), E metabolites, and phytoestrogens] on the skeleton and bone cells are discussed.

General Estrogen Actions on the Skeleton

Mechanism of Action of Steroid Hormones

Estradiol and progesterone are the principle circulating sex steroids in females, which also function in males. All steroids are thought to diffuse passively into cells and are retained intracellularly by complexing specific receptor proteins, which are steroid and target tissue specific. The steroid receptor (ER and PR) concentration in bone is low relative to reproductive tissues and suggests a more limited range of actions. Steroid hormone receptors are a subclass of a larger (100 member) family of zinc finger-containing, nuclear hormone receptors that function as transcriptional regulators (Tsai and O'Malley, 1994). The ligands are bound with high affinity (K_d 10^{-10} to 10^{-8} M), but reversibly, to their respective receptors. Binding to the receptors triggers a receptor "activation," which induces a conformational change, dissociation of accessory proteins, receptor dimerization and oligomerization, and, in some cases, posttranslational modifications such as phosphorylation. The activated receptors either bind directly to regulatory DNA elements (hormone response elements) in the promoters of target genes or bind indirectly with other DNA-binding transcription factors (e.g., AP-1 factors) via protein–protein interactions, which then bind to the promoter. Once bound to the DNA, directly or indirectly, the activated receptor complex recruits transcription factors and/or coregulator proteins, which in turn bind to the core proteins of the transcriptional

activation complex to regulate gene transcription (Bevan and Parker, 1999; McKenna *et al.,* 1999; Robyr *et al.,* 2000).

The diffusion of steroids into the cell and the formation of the ligand–receptor complex are rapid, occurring within minutes of the injection of the steroid into an animal. Following steroid–receptor complex formation (1–4 min posttreatment), this complex binds to nuclear acceptor sites (2–5 min). This nuclear binding apparently, directly or indirectly, regulates the transcription of "early" (5–30 min) or "late" (2–4 hr) genes. Changes in protein profiles due to changes in "late" gene expression begin to occur 6–8 hr posttreatment. The major physiological effects of steroids in reproductive and skeletal tissues begin to occur by 12 to 24 hr after steroid treatment. Cell and tissue responses that occur at 36 to 72 hr after treatment probably represent secondary effects of steroid regulated paracrine/autocrine factors. The 2 to 3-hr period elapsing between the steroid receptor binding to the nuclear acceptor sites and the delayed, but major, transcriptional response of the late structural genes has been termed the "lag" phase. This is a period during which early response genes, coding for transcription factors and other proteins, are activated to subsequently regulate late gene expression. The latter process has been termed "the cascade model of steroid hormone action" (Landers and Spelsberg, 1992).

Estrogen Receptor Isoforms

Receptor Isoforms

The discovery of a second isoform of the ER, termed ERβ, as the product of a different gene in addition to that of the first described and extensively studied ERα, has added a new level of complexity to our understanding of E action (Kuiper *et al.,* 1996; Mosselman *et al.,* 1996). As depicted in Fig. 1, ERα and ERβ possess a high degree of homology in their DNA-binding domains and a moderate degree of conservation in their C-terminal ligand-binding domains (Kuiper and Gustafsson, 1997). The former explains why the two receptor isoforms interact with the same DNA response elements and the latter explains why both isoforms bind many natural estrogens, SERMs, and antiestrogens often with the same, but sometimes different, affinities (Kuiper *et al.,* 1997). In contrast, ERα and ERβ are most divergent in their N-terminal A/B domains, which harbor the ligand-independent AF-1 transactivation function and which interact with proteins of the core transcriptional machinery to regulate gene expression. The molecular size and tissue/cell type distribution of ERα and ERβ also differ significantly. Concentrations of the β isoform are high in prostate, ovary, vasculature, brain, and bladder, but are low or absent in uterus, breast, kidney, pituitary, and epididymis (Kuiper *et al.,* 1996, 1997). Interestingly, the latter tissues contain high levels of the ERα species. In certain cell types, transfection-reporter gene analysis using an E-response element reporter gene construct indicates that ERβ is a weaker regulator of gene transcription than ERα (Kuiper *et al.,* 1996, 1997; Paech *et al.,* 1997; Hall and McDonnell, 1999). It has also been shown that in response to E treatment, ERα interacts with AP-1 factors and binds to AP-1 regulatory elements, a site where ERβ is inactive when complexed with E (Paech *et al.,* 1997). In contrast, ERβ activates AP-1 regulatory elements in response to treatment with SERMs, e.g., tamoxifen and raloxifene (Paech *et al.,* 1997). Similar results for ERα and ERβ with these ligands have also been noted for transactivation through Sp1 elements (Saville *et al.,* 2000). Studies indicate that ERβ may function as a transdominant inhibitor of ERα at subsaturating E levels, and that in some systems the partial agonist activity of tamoxifen manifested through ERα is completely abolished upon coexpression of ERβ (Hall and McDonnell, 1999).

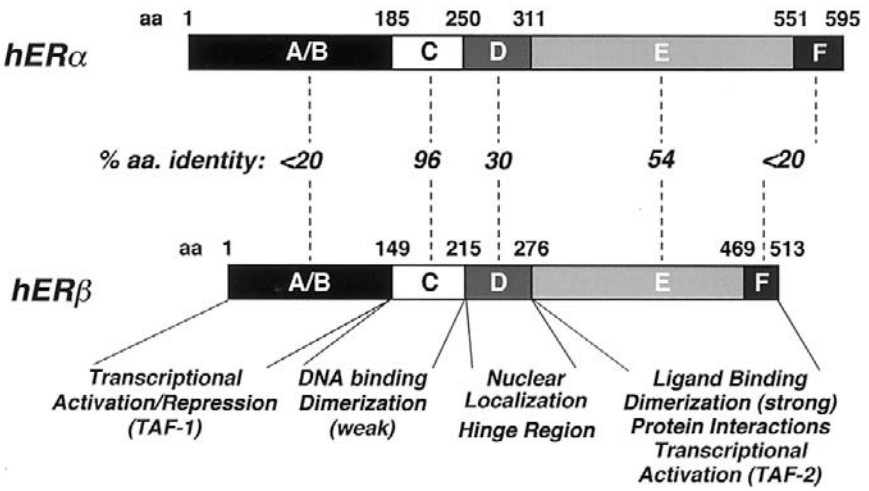

Figure 1 Model of human estrogen receptor isoforms, their domains, functions, and homologies to each other.

STEROID RECEPTOR COREGULATORS

The activity of steroid nuclear receptors is modulated by the family of steroid receptor coregulators, which is composed of coactivators and corepressors (Bevan and Parker, 1999; Robyr *et al.,* 2000; McKenna *et al.,* 1999). Each receptor isoform (ERα and ERβ, or A and B isoforms of the progesterone receptor, PR) adopts a unique conformation that is dependent on the particular isoform and the agonist/antagonist/mixed agonist nature of the ligand (Brzozowski *et al.,* 1997; Paige *et al.,* 1999). It is the unique conformation adopted by each receptor isoform on ligand binding that determines the relative interaction of the receptor with either coactivators or corepressors and thereby the differential transactivation of hormone-responsive promoters. Coactivators, when bound to "active" receptor conformations (usually formed with agonists), mediate favorable interactions with the basal transcriptional machinery, stabilize the preinitiation complex and, overall, stimulate gene transcription. Conversely, corepressors bind preferentially to "inactive" receptor conformations (usually formed with antagonists or unliganded receptor) and prevent the interaction of the receptor with coactivators, thus resulting in nonproductive transcription factor complexes, which suppress gene transcription.

As an example, the opposing transcriptional activities of the two isoforms of PR have been demonstrated to be due, on the one hand, to preferential binding of the coactivators GRIP1 and SRC-1 by agonist-bound PR_B and, on the other hand, by the ability of PR_A to bind the corepressor SMRT but not coactivators (Giangrande *et al.,* 2000). Given the weaker transactivating activity of ERβ (Hall and McDonnell, 1999), an analogous pattern of coregulator interaction may occur with ERα and ERβ. Interestingly, in the presence of mixed agonist/antagonists, when the receptor adopts conformations that are intermediate between active and inactive states, the relative level of coactivators to corepressors can determine transcriptional responses. In this regard, changing the coactivator/corepressor ratio has been shown to modulate ERE promoter activity in the presence of 4-hydroxytamoxifen and ERα (Smith *et al.,* 1997). Consequently, it is plausible that alterations in the expressions of the various coregulators in bone cells, e.g., during differentiation, would affect the responsiveness to E and P.

Expression and Distribution of ERα and ERβ in Bone Cells and Skeletal Tissue

OSTEOBLASTS AND OSTEOBLAST PROGENITOR CELLS

While the effects of E on bone growth and turnover are well documented, the inability to detect estrogen receptors in bone cells fostered the belief that E acts indirectly on bone via other calciotropic hormones, such as parathyroid hormone, 1,25-dihydroxyvitamin D_3, or calcitonin. However, in 1988, two groups reported the detection of high-affinity ERs (now known to be ERα) in cultured normal human osteoblastic (hOB) cells (Eriksen *et al.,* 1988), as well as human (TE85) and rat (ROS 17/2.8) osteosarcoma cell lines (Komm *et al.,* 1988). In additon, both groups were able to detect ER mRNA and E effects on endogenous gene expression in osteoblastic cells. Subsequently, others have reported the presence of ERα in human SaOS (Etienne *et al.,* 1990), mouse MC3T3-E1 (Masuyama *et al.,* 1992), and rat UMR-106-01 (Davis *et al.,* 1994) osteoblastic cells. Available evidence indicates that the expression of both ERα and ERβ increases during OB differentiation *in vitro*. Thus, in fetal rat calvarial-derived OB cultures, the level of ERα mRNA was initially low in proliferating cells but increased at the onset of alkaline phosphatase expression and progressively increased thereafter to reach a maximum level in fully differentiated OBs (Bodine *et al.,* 1998). In a human fetal OB line, expression of ERβ mRNA was also found to increase steadily as cells differentiated and then deposited a mineralized matrix (Arts *et al.,* 1997). However, the level of ERβ transcripts in primary rat calvarial cultures was maintained at a high level throughout differentiation (Onoe *et al.,* 1997). Overall, various sensitive techniques have demonstrated the presence of ERs in normal and transformed osteoblastic cells in culture from several species.

It remains uncertain whether osteoblast progenitor cells express ERα and/or ERβ and thus represent additional targets for E action. However, because the expression of both ER isoforms appears to increase during OB differentiation, the receptor levels in progenitor cells would be expected to be low. ERα mRNA has been detected in a murine bone marrow stromal cell line, and the levels were upregulated by 1,25-dihydroxyvitamin D3 (Bellido *et al.,* 1993). More recently, the expression of ERα mRNA was found to be increased upon glucocorticoid-induced differentiation of human bone marrow stromal cells (Oreffo *et al.,* 1999), consistent with findings from rat calvarial OBs. There have been few reports on the effects of E on OB progenitor cells. Although E modulates the expression of certain OB marker genes in an osteogenic murine stromal cell line (Mathieu and Merregaert, 1994), proliferation and osteogenic differentiation of primary rat bone marrow stromal cells were unaffected by E (Rickard *et al.,* 1995).

OSTEOCLASTS

E may also exert direct effects on cells of the osteoclast (OC) lineage. The expression of ERα mRNA and protein has been reported in isolated avian and human OCs and giant cell tumors of bone (Oursler *et al.,* 1991, 1994). The human leukemic cell line FLG 29.1, which can be induced by phorbol esters to cells exhibiting many features typical of OCs, was also shown to possess ERα and estrogen/raloxifene-binding sites (i.e., E receptors) (Fiorelli *et al.,* 1995, 1997). In addition, OC precursors present in murine hemopoietic blast cell cultures have been shown to express ERα mRNA (Kanatani *et al.,* 1998). The presence of ERβ in mature OCs or their precursors has not been reported.

Skeletal Distribution

Available evidence suggests that only a subset of osteogenic cells in bone tissue express ER. Although the distribution of ERα or ERβ in bone is incompletely known at present, the pattern of expression of the two isoforms appears to overlap considerably. Both ERα and ERβ have been localized to hypertrophic chondrocytes in growth plate cartilage (Ben-Hur *et al.,* 1993; Nilsson *et al.,* 1999), although ERα is additionally present in chondrocytes of the proliferating zone (Ben-Hur *et al.,* 1993; Kusec *et al.,* 1998). In bone, the general consensus for ER distribution is that both receptor isoforms are localized predominantly to osteoblasts and lining cells of trabecular bone, with lower levels in osteocytes and low to undetectable levels in osteoclasts. However, other patterns of distribution of ERα have been obtained. For example, immunofluorescence detection of ERα in human female and pig bone revealed strongest reactivity in about 50% of the osteocytes with indistinct staining of OBs and lining cells (Braidman *et al.,* 1995). Using a more sensitive *in situ* reverse transcriptase (RT) polymerase chain reaction (PCR) technique to identify ERα mRNA in actively remodeling human fracture callus, Hoyland *et al.* (1997) reported that OBs opposing bone surfaces expressed the highest levels of ERα, whereas osteocytes and OCs expressed lower levels. These results were confirmed in another study in which the ERα mRNA and protein were similarly predominantly localized to osteoblasts and lining cells of trabecular bone from human and rabbit, with no clear expression in osteocytes or OCs (Kusec *et al.,* 1998).

The *in situ* RT-PCR technique has been used to demonstrate a loss of ERα mRNA expression from OBs and osteocytes in males with idiopathic osteoporosis, suggesting a case of estrogen resistance (Braidman *et al.,* 2000). In an immunolocalization study of mouse and human trabecular bone and fracture callus, ERβ was identified in OBs, osteocytes, and OCs, with the latter cells exhibiting cytoplasmic rather than nuclear immunoreactivity (Vidal *et al.,* 1999). Similar results were obtained for ERβ mRNA in neonatal rat bone in which the transcripts were expressed predominantly by OBs covering metaphyseal trabecular bone surfaces with lower signals in osteocytes and bone marrow (Windahl *et al.,* 2000b). In rats, the relative levels of ERα and ERβ mRNA have been reported to be lower in cortical compared to trabecular bone, with ERα being the dominant species in both locations (Lim *et al.,* 1999; Onoe *et al.,* 1997). The weak expression of ERβ in cortical bone is an intriguing observation given that the most striking skeletal phenotype in ERβ knockout mice is an increase in cortical bone mineral content in postpubertal females (Windahl *et al.,* 1999). In any case, these *in vitro* and expression studies indicate that the concentrations of ERα are higher than ERβ in bone tissue, as well as in the OBs at different stages of differentiation. It is unclear, however, what concentration of each receptor isoform is required for responsiveness in OB cells and whether one isoform modulates the activity of the other when both are expressed, as has been reported in other cell types.

In Vivo Effects of Estrogens and Progestins on Bone

Introduction

Sex steroids influence most if not all aspects of bone development, growth, and remodeling. The physiological actions of sex steroids contribute to (a) sexual dimorphism of the skeleton, (b) timing of epiphyseal closure, (c) determination of peak bone mass, (d) maintenance of mineral homeostasis during reproduction, and (e) maintenance of bone mass, architecture, and mineral homeostasis in adults. The important role of gonadal hormones in bone metabolism is well established. Despite the recognition that gonadal insufficiency is the most important risk factor for osteoporosis, the mechanisms of action of sex steroids on bone *in vivo* are poorly understood and have received surprisingly moderate attention by investigators. Because human studies have provided a very limited understanding regarding the underlying cellular and molecular mechanisms that mediate hormonal action, studies in laboratory animals have proven extremely useful in identifying an impressive range of physiological actions of gonadal hormones on bone and mineral homeostasis. Additionally, a common contemporary use of animals involves preclinical studies evaluating the effectiveness of pharmaceuticals as interventions to prevent or treat bone loss. The strengths and weaknesses of the most well-established animal models for osteoporosis have been reviewed (Turner *et al.,* 2000).

This section emphasizes the effects of sex steroids on the skeleton of placental mammals. The reader is referred to a prior review for a discussion of the important and unique effects of sex steroids on the skeleton during reproduction in oviparous vertebrates (Turner *et al.,* 1994a).

Effects of Sex Steroids on Bone Mass

Ovariectomy leads to a bone deficit in adult rodents and primates (Kalu *et al.,* 1991; Lindsay *et al.,* 1978; Jayo *et al.,* 1990). These changes are due to endocortical bone modeling, destructive cancellous bone modeling, and remodeling (Wronski *et al.,* 1988a; Turner *et al.,* 1987b). Similar changes occur in rats (Goulding and Fisher, 1991) and monkeys (Mann *et al.,* 1990) following administration of GnRH agonists, a chemical intervention that decreases serum estradiol levels comparable to ovariectomy. This important role of E in mediating skeletal changes is further implicated by the observation that the skeletal changes following treatment of rats with ICI 182,780, a potent estrogen receptor antagonist, are similar to ovariectomy (Sibonga *et al.,* 1998). This conclusion is further supported by the consistent finding that the skeletal changes that follow ovariectomy are antagonized by pharmacological replacement with E. The physiological role of other ovarian hormones is less clear. The progesterone antagonist RU486 was reported to not alter cancellous bone volume and turnover in female rats whereas administration of androgen and P to animals had variable results (Abe *et al.,* 1992; Barengolts *et al.,* 1991; Kalu *et al.,* 1991; Schmidt *et al.,* 2000).

Alterations in Bone Architecture in Gonadal Hormone-Deficient Laboratory Animals

CORTICAL BONE

The volume of the medullary canal in rat tibiae is enlarged following ovariectomy due to a net increase in bone resorption (Kalu *et al.,* 1989; Turner *et al.,* 1987a). Osteoclast number is increased (Turner *et al.,* 1987b) and bone formation remains unchanged or increased (Turner *et al.,* 1987a,b, 1990c). In contrast, there is an increase in bone formation at the periosteal surface (Turner *et al.,* 1987a). As a result of the opposing changes in radial growth and endocortical modeling, the cortical bone volume changes little in ovariectomized rats (Turner *et al.,* 1987a,b, 1990b,c). It may, in fact, increase in rapidly growing rats because the increase in periosteal addition of bone exceeds the increase in endocortical resorption (Turner *et al.,* 1990b). The cellular mechanism for the differential response of the periosteal and endocortical bone surfaces of the midshaft appears to be related to the different functions and populations of cells that comprise the two bone envelopes in the rat model.

The periosteum is responsible for radial bone growth. Under normal circumstances, bone resorption is associated with developing vascular spaces. Osteoclasts are uncommon at other locations on the periosteum and are not notably increased following ovariectomy. This low level of focal resorption is contrasted with the endocortical surface, which undergoes aggressive bone modeling during growth to increase the volume of the marrow cavity. Estrogen suppresses growth (Turner *et al.,* 1994b) and ovariectomy results in reestablishment of radial bone growth in adult rats. A similar periosteal expansion occurs in aging humans. It is important to note that one of the limitations of rat and mouse studies is that the skeleton of small rodents does not undergo cortical bone remodeling. Ovariectomy increases endocortical bone resorption surface and cortical porosity in dogs (Karambolova *et al.,* 1987). However, no net loss of cortical bone was also reported in this species (Martin *et al.,* 1987). Studies in other large animals with an estrus cycle more similar to the human menstrual cycle (e.g., nonhuman primates) are necessary to adequately characterize the possible effects of sex steroids on Haversian (cortical) bone remodeling.

CANCELLOUS BONE

Ovariectomy results in severe cancellous osteopenia in long bones and vertebrae of rats (Wronski *et al.,* 1989) and vertebrae of monkeys (Jerome *et al.,* 1986; Longcope *et al.,* 1989). The response to ovariectomy in dogs has been less consistent, with no change (Snow and Anderson, 1986) and bone loss (Martin *et al.,* 1987) reported. The rate of bone loss from rat vertebrae occurs more slowly than from long bones (Wronski *et al.,* 1988b, 1989). There appears to be a regional difference within bones. Cancellous osteopenia is more prominent in the proximal tibial metaphysis than the distal metaphysis or proximal epiphysis. It is important to note that the rate of bone loss may be related to differences in bone marrow and prevailing levels of mechanical loading (Westerlind *et al.,* 1997). Additional evidence suggests that there is overlap between mechanical signaling and estrogen action on bone (Damien *et al.,* 1998; Tomkinson *et al.,* 1998).

Ovariectomy results in increases in the osteoblast-lined perimeter, OC-lined perimeter, and OC size in long bones of rats (Wronski *et al.,* 1986; Turner *et al.,* 1988). There are simultaneous increases in the mineral apposition and bone formation rates, suggesting that ovariectomy results in chronic high bone turnover. Cancellous bone turnover remains elevated in rats a year or more after ovariectomy (Wronski *et al.,* 1989; Sibonga *et al.,* 2000). Bone formation is increased in ovariectomized monkeys (Jerome *et al.,* 1986; Longcope *et al.,* 1989), suggesting the bone loss in nonhuman primates is also associated with increased bone turnover. Dempster *et al.* (1995) reported temporal changes in cancellous bone architecture of the distal rat femur after ovariectomy. These investigators demonstrated that the primary mechanism of ovariectomy-induced bone loss is osteoclastic perforation and removal of the trabecular plates. Generalized, gradual trabecular thinning was not observed. Interestingly, a similar process is responsible for removal of the most distal trabeculae during normal bone elongation (Frost, 1963).

Effects of Estrogen Replacement on Bone Metabolism in Ovariectomized Laboratory Animals

Estrogen treatment of ovariectomized rats prevents the increase in medullary area by preventing the increase in OC number (Turner *et al.,* 1987a,b). Similarly, E replacement prevents the increase in periosteal bone formation (Turner *et al.,* 1987a,b). Estrogen reduced the number of preosteoblasts in S phase of the cell cycle, suggesting that the hormone inhibits the production of OBs. At the same time, E decreased steady-state mRNA levels for bone matrix proteins and IGF-I, bone matrix synthesis, reduced OB number, and increased the population of bone-lining cells (Turner *et al.,* 1990a; Turner *et al.,* 1992). E inhibits bone growth by decreasing bone formation, as well as bone resorption, and these changes are associated with a decreased expression of OC survival factors such as IGF-I. E treatment can result in an osteosclerotic response in ovariectomized as well as ovary intact mice. This nonphysiological response can limit the usefulness of the mouse as a model for the analyses and understanding of E action on human bone (Turner, 1999).

Estrogen replacement stabilizes cancellous bone volume in ovariectomized rats by reducing the rate of bone turnover, by reestablishing a neutral or positive balance between bone formation and bone resorption; and by preventing the destruction of trabecular plates (Kalu *et al.,* 1991; Turner *et al.,* 1988; Wronski *et al.,* 1988b, 1993). Estrogen accomplishes these actions in part by reducing the initiation of new bone remodeling. Osteoclast number is reduced in estrogen-treated rats. The hormone probably acts via decreasing the fusion of the OC precursors (Turner *et al.,* 1994b), as well as reducing OC life span (Kameda *et al.,* 1997). The effects of

E on cancellous bone formation are more controversial. There is general agreement that the inhibitory effects of the hormone on initiation of bone remodeling leads to an overall coupled decrease in bone formation as well as improved bone remodeling balance. The latter change may be due to an increased OB life span (Gohel *et al.,* 1999). However, some investigators have reported that E has separate direct stimulatory actions to increase OB number and bone formation (Takano-Yamamoto and Rodan, 1990; Chow *et al.,* 1992). Most investigators, however, have reported that E inhibits indices of bone formation, including OB number and activity (Kalu *et al.,* 1991; Turner *et al.,* 1988, 1993; Wronski *et al.,* 1988b; 1993). Studies to investigate this controversy failed to reveal any evidence for an anabolic action of estrogen on bone formation (Westerlind *et al.,* 1993). Furthermore, time course studies have shown that E results in rapid decreases in mRNA levels for bone matrix proteins and collagen synthesis (Turner *et al.,* 1999). Finally, E does not increase bone volume in adult rats with established bone loss (Wronski *et al.,* 1993).

Skeletal Phenotypes of Mice with Targeted Disruption of ER Genes

The development of mice exhibiting targeted gene deletions (knockout) in ERα, ERβ, or both genes simultaneously has been achieved. Although the complete analysis of the skeletal phenotypes for some of the genotypes has yet to be reported, certain mutants have been examined in detail. As a note of caution, the mutant phenotype of knockout animals may result from multiple influences that occur as a consequence of the targeted mutation, and therefore the mechanisms responsible for the phenotype may not be restricted solely to that mutation. In this regard, disturbing ER signaling in all tissues by ER isoform gene ablation may destabilize the feedback loops regulating the synthesis of other sex steroids in addition to E, thereby leading to changes in the circulating levels of these hormones, some of which also possess major osteotropic activity. For example, the ERαKO female mouse has been reported to have markedly elevated levels of E, whereas the male ERαKO has increased levels of testosterone (Couse and Korach, 1999). As a further complexity, phenotypes in single ER gene mutants may arise as a result of the β isoform being able or unable to either compensate for the loss of the α isoform or, alternatively, suppress ERα activity. In the latter case, loss of ERβ could conceivably enhance rather than suppress E responsiveness in a cell type that normally expresses both ER isoforms.

ERα Knockout Mice

Homozygous deletion of the ERα gene results in reduced cortical bone density and cortical bone formation in both male and female mice, suggesting that E stimulates cortical bone formation via ERα (Korach *et al.,* 1997). Although there is delayed closure of the epiphyseal growth plate, linear bone growth in long bones is generally reduced, which is more pronounced in females (Korach *et al.,* 1997; Schmidt *et al.,* 1999). The effect of ERα knockout on trabecular bone, however, is less certain. Using independently generated animals, trabecular bone has been reported to be either modestly decreased in both sexes (Korach *et al.,* 1997) or unaffected in females and showing an age-related increase as a result of reduced bone turnover in males (Sims *et al.,* 2000). Consequently, the lack of marked trabecular bone loss suggests that ERβ compensates for loss of ERα in this tissue. Female ERαKO mice lose bone following OVX to the same extent as the wild type. However, estrogen responsiveness in the ERαKO female is reduced, as higher estrogen concentrations are required to prevent the bone loss compared to OVX wild-type mice (Ederveen and Kloosterboer, 1999).

Interestingly, both a man with aromatase P450 deficiency (causing complete E deficiency) and a man with a mutation in the ERα gene (causing partial E resistance) exhibited continued longitudinal bone growth due to delayed epiphyseal growth plate ossification in addition to marked trabecular osteopenia (Carani *et al.,* 1997; Smith *et al.,* 1994). From these findings it is therefore apparent that (1) E has opposite effects on longitudinal bone growth in humans and mice and (2) ERα mediates at least some of the effects of E on trabecular bone remodeling in both species.

ERβ Knockout Mice

Deletion of the ERβ gene, as with ERα, results in delayed growth plate closure, but in adult female ERβKO mice, the longitudinal bone growth for some long bones is increased rather than decreased (Windahl *et al.,* 1999). Studies suggest that the cortical and trabecular bone parameters of male ERβKO are not significantly different from wild type (Vidal *et al.,* 2000). In contrast, whereas the trabecular bone of female ERβKO mice is unaffected, there is increased whole body bone mineral content due to increased cortical bone, although this is only observed in postpubertal females (Windahl *et al.,* 1999). The increased cortical bone is a result of elevated periosteal (radial) bone formation, indicating that ERβ is required for pubertal feminization of the skeleton.

Although trabecular bone is unaffected in ERβKO animals at sexual maturity, older (~4 months to 1 year) female ERβKO mice are partially protected against age-related trabecular bone loss, as these animals exhibit higher trabecular bone density and volume than either male ERβKO or wild-type animals (Windahl *et al.,* 2000a; Ederveen *et al.,* 2000). The increase in trabecular bone is thought to be due to enhanced bone formation rather than to changes in growth plate kinetics or altered bone resorption because OB markers and ERα transcript levels are elevated (Windahl *et al.,* 2000a). It has been suggested that increased trabecular bone in female ERβKO mice is caused by the removal of the dominant-negative function of ERβ on ERα activity (Sims *et al.,* 2000). Female ERβKO animals lose cortical and trabecular bone after OVX similarly to wild type (Windahl *et al.,* 1999). Moreover, E treatment prevents OVX-induced bone loss in ERβKO female mice to the

same extent as in wild-type mice in contrast to the weaker E responsiveness of ERαKO females (Ederveen *et al.,* 2000; Ke *et al.,* 2000). Thus, ERβ seems to be nonfunctional in the skeleton of male mice, whereas in females, ERβ mediates the suppression of periosteal bone growth. Further, in female mice, ERβ is not required for the maintenance of trabecular bone in the presence of ERα, but is required in the absence of ERα. In support of the hypothesis that ERβ does not mediate E responses in trabecular bone, at least in males, testosterone, but not E, completely prevents the decrease in bone density at trabecular sites in orchidectomized ERαKO males (Vandenput *et al.,* 2000). An apparent discrepancy, however, is that if ERβ is truly nonfunctional in the male mouse skeleton, then why does the ERαKO male not exhibit E resistance characterized by elevated bone turnover rates and osteopenia rather than the unaltered or slightly increased trabecular bone density that is in fact observed (Sims *et al.,* 2000)?

ERα/β KNOCKOUT MICE

Deletion of both ER isoforms in double knockout mice (ER$\alpha\beta$KO) generates a skeletal phenotype in the male very similar to that caused by ERα single deletion; namely, postpubertal longitudinal and periosteal (cortical) bone growth are reduced, but trabecular bone is unaffected (Vidal *et al.,* 2000). Interestingly, the reduced bone growth in the male has been correlated with decreased serum IGF-1 levels (Vidal *et al.,* 2000). Similarity of the skeletal defects resulting from ERα or ERα plus ERβ gene inactivation in the male knockout is further evidence for the lack of involvement of the β isoform in growth and remodeling of the male skeleton.

In contrast, in females the bone defects in the ER$\alpha\beta$KO mouse are distinct from those produced by deletion of either ER isoform alone, thus supporting a role for both isoforms in the female skeleton. In postpubertal ER$\alpha\beta$KO females, both cortical thickness and trabecular bone density are reduced due to decreased bone formation without effects on osteoclast surface (Sims *et al.,* 2000). Because female ERαKO animals fail to exhibit trabecular bone loss, this finding therefore demonstrates that ERβ in females can compensate for the loss of ERα and that both ER isoforms participate in normal trabecular remodeling.

CONCLUSIONS

Overall it is becoming clear that ERα and ERβ likely perform different functions in cortical and trabecular bone and that the relative importance of the two isoforms at these sites differs between the sexes. However, it is of course questionable whether the ER isoforms perform identical functions during skeletal growth and turnover in humans. Perhaps the most surprising result arising from the ER knockout analysis is that double ER$\alpha\beta$KO mice are viable with grossly normal skeletons, demonstrating that both ER isoforms are dispensable for the normal development of cartilage and bone.

Skeletal Phenotype of Mice with Disruption of PR Genes

Mice have been generated with a homozygous mutation of the PR locus in which expression of both A and B isoforms of PR is prevented. The PR-B has been shown to be the dominant player in gene regulation in P target cells (Giangrande *et al.,* 1999). PRKO mice (i.e., PR-A/B knockouts) exhibit multiple reproductive abnormalities and homozygous females are infertile (Lydon *et al.,* 1995). Female PRKO mice have been analyzed histomorphometrically for possible skeletal defects. Although aged animals had cortical and trabecular bone densities that were not significantly different from age-matched wild-type animals (Bain *et al.,* 1997), subtle abnormalities were evident at earlier ages. Young postpubertal PRKO mice exhibited increased cortical bone thickness with no changes in trabecular bone, whereas rapidly growing prepubertal PRKO mice possessed elevated trabecular bone density and formation without effects on cortical bone (Rickard *et al.,* 1999). Linear bone growth was unaffected at all ages examined. These findings suggest that progesterone may be involved in the early growth and sexual dimorphism of the female skeleton. Studies on PR_AKO female mice showed that progesterone displayed a major effect in reproductive tissue in these PR_AKO mice compared to the wild type (Mulac-Jericevic *et al.,* 2000). This suggests that PR_A may play a dominant-negative role in the actions of PR_B. It will be most interesting to examine the skeleton in these PR_AKO female mice.

Effects of Estrogen on Bone Cells *in Vitro*

Osteoblasts

ESTROGEN REGULATION OF EARLY AND LATE RESPONSE GENES IN OSTEOBLASTS

As outlined briefly earlier, sex steroids regulate the expression of early response genes within 30 min to 2 hr following hormone exposure. The best examples of this are the nuclear protooncogenes, including c-myc, c-jun, jun-B, c-fos, N-myc, and the TGFβ-inducible early gene, TIEG (Spelsberg *et al.,* 1992; Tau *et al.,* 1998). These genes are expressed and regulated by sex steroids in many different reproductive (Murphy *et al.,* 1987; Fink *et al.,* 1988) and bone tissues (Eriksen *et al.,* 1988; Harris *et al.,* 1995; Tau *et al.,* 1998; Oursler *et al.,* 1991, 1994). Thus these genes are excellent markers for steroid actions and interactions. Because these genes are regulated rapidly by steroids in all tissues containing their receptors, and most of these early gene products in turn regulate the gene expression of late genes, a role for nuclear protooncogenes as early response ("regulatory") genes in a cascade model of steroid action in bone and reproductive tissues has been proposed (Landers and Spelsberg, 1992; Spelsberg *et al.,* 1992).

In contrast to these rapidly induced genes, which are universal markers of steroid actions, many late responsive (24–48 hr) structural genes are specific to different tissues and some, like the growth factor/cytokine genes, mediate the effects of E on these tissues. Control of late gene expression by E has been investigated in numerous osteoblast cell culture systems. Unfortunately, despite extensive efforts, only a few putative target genes have shown consistent regulation. The most reliable responses are increases in type I collagen, transforming growth factor (TGF)-β, and insulin-like growth factor (IGF)-1 production (for a review, see Spelsberg *et al.,* 1999). In fact, E has been shown to induce TGFβ production by both OBs and OCs (Oursler, 1998). These factors may mediate some of the anabolic effects of E on bone. For example, TGFβ plays an important role in chondrogenesis and osteogenesis, as both TGFβ and IGF-1 promote the proliferation and differentiation of OB precursors, and TGFβ inhibits the formation of OCs. In addition to regulating IGF-1 synthesis, E may modulate IGF bioactivity by regulating the production of IGF-binding proteins, including IGFBP-2, 3, and 4, which in turn enhance or suppress the activities of IGF-1 and IGF-II. TGFβ and IGF-1 are both sequestered in bone matrix at relatively high concentrations. See Fig. 2 for a detailed list of E responses in OB and OC cells.

Estrogen Regulation of Cytokine Synthesis in Osteoblasts

In bone, a hallmark of E deficiency is an elevated rate of bone turnover in which both OC-mediated bone resorption and, perhaps secondarily, OB-mediated bone formation/activity occurs at an increased rate. See Fig 3 for a model illustrating the known and putative mechanisms of OB–OC interactions. A considerable amount of evidence demonstrates that release of an E-imposed suppression of bone-resorbing cytokine synthesis is responsible for the accelerated bone turnover. The OB and/or monocyte/macrophage lineage release of numerous cytokines that are capable of increasing OC formation, differentiation, or activity has been shown to be inhibited by E. However, which of the cytokines is/are most important for mediating the actions of E remains unresolved. One theory maintains that bone marrow monocyte/macrophage-derived interleukin (IL-1) and tumor necrosis factor (TNF) induce the production of other cytokines, including macrophage colony stimulating factor (M-CSF), granulocyte-macrophage CSF (GM-CSF), and IL-6 by osteoblasts and hematopoietic cells, which together promote osteoclast resorptive activity. Evidence in support of this pathway is as follows: (1) release of IL-1, TNF, and GM-CSF by peripheral blood monocytes from untreated osteoporotic women is higher than from E-treated osteoporotics and nonosteoporotics (Pacifici *et al.,* 1989, 1991), (2) production of M-CSF by osteoblastic/stromal cells is increased by OVX in mice and is dependent on bone marrow synthesis of IL-1 and TNF (Kimble *et al.,* 1996), (3) neutralization of TNF activity either by the inhibitory TNF-binding protein (TNFbp) or by expression of an inhibitory soluble TNF type I receptor in mice prevents OVX-induced bone loss (Ammann *et al.,* 1997), (4) type I IL-1 receptor-null mutant mice fail to lose bone following OVX (Lorenzo *et al.,* 1998), and (5) simultaneous blockade of both IL-1 and TNF activity by IL-1 receptor antagonist (IL-1ra) and TNFbp completely prevents OVX-induced bone loss in rats (Kimble *et al.,* 1995, 1997).

An alternative, but not exclusive, proposed pathway favors IL-6 as the mediator of bone loss in an E-deficient state. Evidence for this pathway is as follows: (1) production

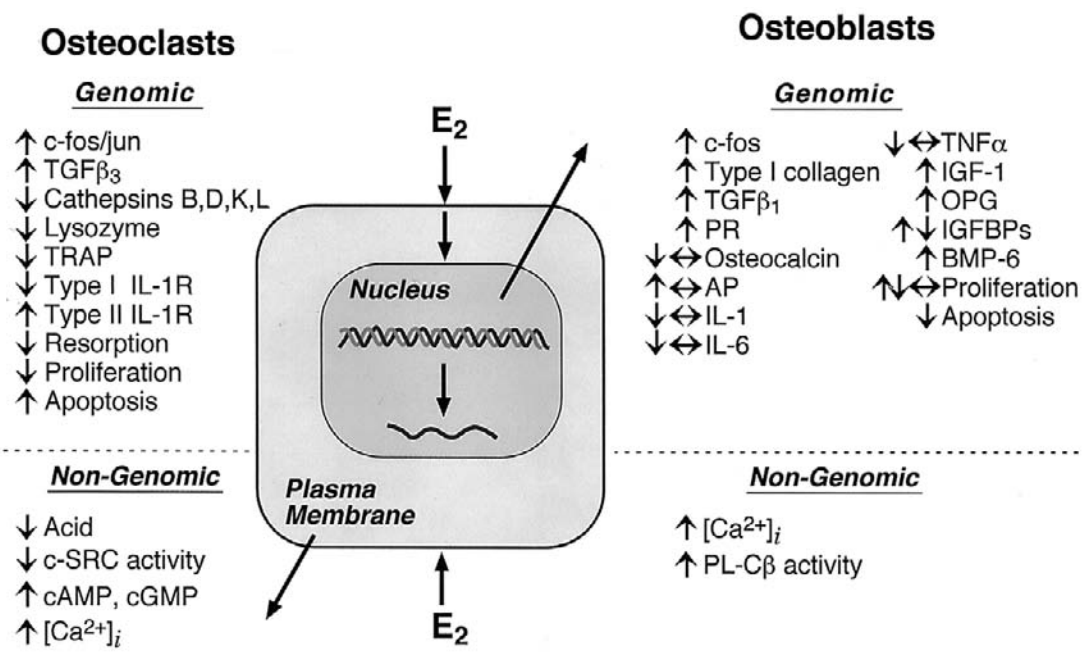

Figure 2 Model outlining all the reported effects of estrogens on osteoblast and osteoclast functions. Arrows indicate the changes induced by estrogen. Double/triple arrows indicate published differences in reported responses.

of IL-6 is inhibited by E in cells of the stromal/osteoblast lineage *in vitro* (Girasole *et al.,* 1992; Passeri *et al.,* 1993), although this is not a universal finding (Rickard *et al.,* 1992; Rifas *et al.,* 1995), (2) the production of IL-6, as well as the number of OC precursors and osteoclast formation, is increased in *ex vivo* bone marrow cultures from OVX mice compared to sham control animals (Miyaura *et al.,* 1995), (3) all of these effects, as well as the increased population of osteoclasts present in trabecular bone of OVX mice, can be prevented by treatment with E or an anti-IL-6 antibody (Jilka *et al.,* 1992), (4) E may reduce the responsiveness of OB lineage cells and possibly also OCs to IL-6 by decreasing expression of the ligand-binding gp80 and signal-transducing gp130 subunits of the IL-6 receptor (Lin *et al.,* 1997), and (5) IL-6-deficient mice are protected from OVX-induced bone loss (Poli *et al.,* 1994).

Other factors such as osteoprotegerin (OPG), a soluble member of the TNF receptor family, may also mediate the inhibitory effect of E on bone resorption. OPG binds to and inhibits the activity of OPG ligand (OPGL or RANKL), a TNF-related cytokine produced by bone marrow stromal cells and OBs (among other cell types), which has been shown to be essential for OC formation. Among the bone-active cytokines, OPG is unique because deletion of the OPG gene in mice generates severe osteopenia in both cancellous and cortical bone (Bucay *et al.,* 1998), whereas mice overexpressing OPG develop osteopetrosis and do not lose bone as a result of sex hormone deficiency (Simonet *et al.,* 1997). E has been shown to increase OPG expression in OBs overexpressing the ERα gene (Hofbauer *et al.,* 1999), and this effect may be indirect via TGFβ, which has been shown to increase OPG production by bone marrow stromal OB precursor cells (Takai *et al.,* 1998). Assuming these effects also occur *in vivo*, OPG may be a key mediator of the antiresorptive effects of E. A summary of the mechanisms for the control of bone resorption by E is shown in Fig. 4.

Molecular Mechanism of Estrogen Regulation of Cytokine and Other Gene Promoters

The molecular mechanisms involved in the E regulation of several cytokine/late gene promoters have been elucidated. Many of these promoters lack consensus estrogen response elements (EREs) and thus have revealed alternative mechanisms of transcriptional control by the ER, which in some instances does not require direct binding of the ligand-activated ER to DNA. Instead, ER interacts with other transcription factors and coregulators to modulate the binding affinity of these proteins to their cognate regulatory sites in the DNA. For example, repression of the IL-6 promoter by E occurs because protein–protein interactions between the ligand-activated ERα and NF-κB and C/EBPβ prevent binding of the latter factors to their respective sites on DNA (Stein and Yang, 1995; Galien *et al.,* 1996). In contrast, E stimulates transcription from the IGF-1 promoter via enhanced binding of fos/jun heterodimers to AP-1 elements by interaction with activated ERα (Umayahara *et al.,* 1994). Numerous genes, including

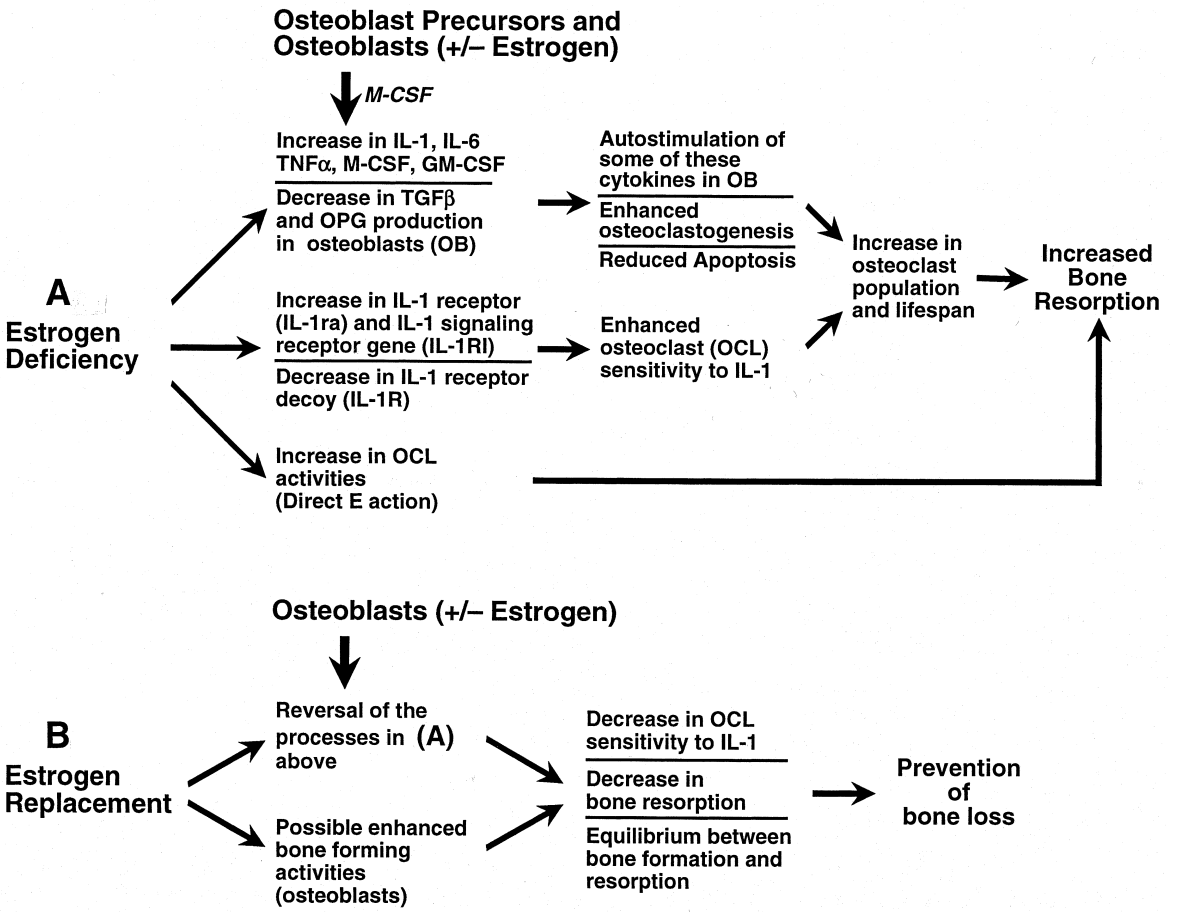

Figure 4 Outline of the potential pathways in estrogen regulation of bone resorption. Reproduced with permission from Spelsberg *et al.* (1999).

retinoic acid receptor-α1 (RAR-α1), c-fos protooncogene, cathepsin D, IGFBP-4, and the epidermal growth factor receptor gene, among others, are modulated by E through the binding of ER/Sp1 transcription factor complexes with either Sp1 sites alone or Sp1/ERE half-sites (Rishi *et al.,* 1995; Krishnan *et al.,* 1994; Salvatori *et al.,* 2000).

Estrogen Regulation of Proliferation, Formation and Apoptosis of Osteoblasts

Osteoblast Proliferation Similar to the conflicting reports on the E regulation of numerous late response genes in bone-forming OBs, there is a lack of a general consensus with regard to the effects of E treatment on OB cell proliferation. While E has been reported to stimulate cell proliferation in primary and immortalized fetal rat calvarial cells (Ernst *et al.,* 1989), normal adult human OBs (Scheven *et al.,* 1992), mouse MC-3T3E1 cells (Majeska *et al.,* 1994), and synchronized human osteosarcoma cells (Ikegami *et al.,* 1994), E has been shown to have no effect on some primary cultures of normal adult OBs (Keeting *et al.,* 1991; Rickard *et al.,* 1993) or to inhibit cell growth in OBs stably transfected with the ERα gene (Watts *et al.,* 1989; Kassem *et al.,* 1996; Robinson *et al.,* 1997).

The effect, if any, of E on the proliferation of OB progenitor cells is also currently unclear. Whereas the proliferation rate of bone marrow-derived OB precursor cells, isolated from OVX rats, was increased compared to cells from sham-operated animals (Modrowski *et al.,* 1993), the *in vitro* treatment of rat bone marrow stromal cells with E showed no effect on cell growth (Rickard *et al.,* 1995).

Osteoblast Formation *In vivo*, OB and OC formation appears to be tightly coupled due, at least in part, to (1) the dependence of OC precursor development on support from cells of the stromal/OB lineage through the provision of cytokines and other stimuli and (2) of OB precursor development on factors released from bone matrix by OC activity. It has been suggested that E deficiency causes not only increased OC formation [as a result of increased production of bone-resorbing cytokines (discussed earlier)], but also stimulates OB formation (Manolagas, 1999). In support of this, ovariectomy of rodents increases the number of bone marrow-derived OB progenitor cells (Scutt *et al.,* 1996; Jilka *et al.,* 1998). In mice, this increase was transient and partially independent of increased bone resorption, suggestive of a possible direct action of E on OB proliferation and/or differentiation (Jilka *et al.,* 1998). Such mechanisms may therefore account for the elevated bone turnover immediately after OVX/menopause. However, the stimulated rates of OC and OB formation due to sex steroid deficiency are only tempo-

rary, and with time after OVX/menopause, bone remodeling declines to levels approximating premenopausal rates.

Apoptosis It is becoming increasingly clear that E also has major effects on the apoptosis of OBs and OCs. E has been shown to have opposite effects on apoptosis in OCs and OBs. In OCs, apoptosis is stimulated by E via a TGFβ-mediated mechanism (Hughes *et al.,* 1996; Kameda *et al.,* 1997). However, apoptosis is prevented by E in osteocytes (Tomkinson *et al.,* 1997, 1998) and OBs (Gohel *et al.,* 1999; Manolagas *et al.,* 1999). The enhancement of OC apoptosis could contribute to the antiresorptive effects of E, and the prevention of OB apoptosis could contribute to the reported anabolic effects of E on the skeleton. As mentioned earlier, the increased formation of OBs and OCs observed after OVX is only temporary, and eventually the opposing effects of E on OB and OC apoptosis are believed to return to dominance. Consequently, an imbalance between bone resorption and formation will be maintained, only now resulting in the net slow rate of bone loss that persists once the initially high bone turnover of the perimenopausal period has subsided.

NONGENOMIC EFFECTS OF ESTROGEN ON OSTEOBLASTS

The cascade model explains many apparent nongenomic actions of steroids, which are, in fact, genomic processes. However, there is a growing body of evidence that steroids also influence the cell surface by nongenomic effects, which involve responses to steroids within minutes and are too rapid to be explained by genomic processes (Moss *et al.,* 1997; Revelli *et al.,* 1998). For instance, a possible cardioprotective effect of E has been shown to occur through the induction of endothelial nitric oxide synthase in human vascular endothelial cells via a ligand-dependent interaction between ERα and phosphatidylinositol-3-OH kinase (Simoncini *et al.,* 2000). In OBs, treatment with E has been shown to cause a rapid (within seconds) increase in intracellular calcium ion concentration due to influx across the plasma membrane and release from intracellular stores (Lieberherr *et al.,* 1993). Additionally, E stimulates the hydrolysis of phosphatidyl inositol phospholipids with the generation of diacylglycerol and inositol 1,4,5-trisphosphate, which in turn activate other second messenger pathways. In female rat OBs, this effect of E has been shown to be mediated by the activation of phospholipase C-β2 via a pertussin toxin-sensitive G protein's $\beta\gamma$ subunits, further supporting the existence of a nonclassical membrane ER (Le Mellay *et al.,* 1999). Activation of MAP kinases and increases in cAMP and cGMP have also been reported in osteosarcoma cells (Endoh *et al.,* 1997).

A nongenomic mechanism involving the *src* tyrosine kinase and MAP kinase signaling pathway has recently been demonstrated to mediate the antiapoptotic effects of E on primary and immortalized OB and osteocytic cells (Kousteni *et al.* 2001). Intriguingly, the antiapoptotic effect of both E and the androgen dihydroxytestosterone were mediated equivalently via both ER (α and β) or by the androgen receptor (AR). Furthermore, only the ligand-binding domain of the receptor protein appeared to be required and the antiapoptotic function was dissociated from the receptors' transcriptional activity (Kousteni *et al* 2001). One possible interpretation of these observations is that ER and/or AR proteins localized at the plasma membrane exhibit unique properties and perform distinct functions to that of the nuclear localized receptor.

The response of the target cell to E may therefore be a superimposition of genomic and nongenomic effects, although the physiological importance of the nongenomic effects is still unclear. The putative membrane receptors for steroid hormones remain unidentified.

Osteoclasts

In addition to indirect effects of E on the formation, differentiation, and activity of OCs via regulation of cytokine synthesis by OBs, E may also have direct actions on osteoclasts and their precursors (see Fig. 2). The bone-resorbing activity of avian, rabbit, and human OCs is decreased by treatment with E, which is due in part to a reduced population of OCs via apoptosis (Kameda *et al.,* 1997; Hughes *et al.,* 1996). E may further inhibit bone resorption by acting directly on OC progenitors to reduce OC formation, as demonstrated by (1) the ability of E to reduce proliferation and increase apoptosis of FLG 29.1 preosteoclastic cells (Zecchi-Orlandini *et al.,* 1999), (2) the antagonism by E of the differentiation of murine hemopoietic blast cells into multinucleated OCs induced by GM-CSF and PTH/PTH-related peptide (Kanatani *et al.,* 1998), and (3) the finding that E suppresses the production of TRAP-positive, multinucleated OCs from primary murine bone marrow myeloid progenitors and the mouse monocytic cell line RAW 264.7 cultured in the presence of soluble RANKL (OPGL) and M-CSF but in the absence of stromal/OB support cells (Shevde *et al.,* 2000). This latter effect of E may be due to downregulation of OPGL-induced JNK activity in OC progenitors (Srivastava *et al.,* 1999).

Additionally, E has been reported to inhibit the expression/secretion of matrix-degrading agents by isolated OCs, including acid and the lysosomal enzymes cathepsin B, D, K, and L, and lysozyme (Kremer *et al.,* 1995; Mano *et al.,* 1996; for a review, see Oursler, 1998). Similar to the studies on OBs, the effects of E on isolated avian OCs *in vitro* appear to be limited by the level of ERα (Pederson *et al.,* 1997). Further, the antiresorptive effects of E on OCs may in part be mediated by reducing the responsiveness of OCs to resorption-stimulatory cytokines through the modulation of cytokine receptor levels and/or postreceptor signaling. For example, in isolated human OCs, E directly reduces mRNA expression of the signaling type I IL-1 receptor while simultaneously increasing levels of the "decoy" type II IL-1 receptor and release of soluble IL-1RII (Sunyer *et al.,* 1999). The IL-1 pathway is a stimulator of OC bone resorption.

Several nongenomic effects of E in OCs have also been reported. Treatment of isolated chick OCs with E inhibited the basal and PTH-stimulated production of acid within 15 min (Gay *et al.,* 1993). This effect appears to be mediated at the plasma membrane because membrane-impermeable conjugates of E produced the same response (Brubaker and Gay,

1994). E treatment of avian OCs is also associated with rapid and transient changes in cell shape and the level of phosphotyrosine proteins at the plasma membrane (Brubaker and Gay, 1999). One of the phosphorylated proteins has been identified as pp60src, a tyrosine kinase required for the bone resorptive function of OCs. Treatment with E affects the degree of phosphorylation, and hence activity, of src as well as its subcellular distribution (Pascoe and Oursler, 2001). However, translocation of the src protein both to (Brubaker and Gay, 1999) and away (Judd and Oursler, 1994) from the cell surface has been reported. Active src kinase phosphorylates many substrates, including ras and the MAP kinases, which have been shown to be stimulated via a nongenomic pathway in E-treated MCF-7 breast cancer cells and rat osteosarcoma cells (Migliaccio *et al.,* 1996; Endoh *et al.,* 1997). Interestingly, constitutive activation of src decreases lysosomal enzyme secretion similarly to treatment with E, further implicating src as an intermediate in the action of E in OCs (Pascoe and Oursler, 2001). Finally, specific cell surface-binding sites for E have been reported in chick OCs and FLG 29.1 human preosteoclastic cells in which treatment with E affected intracellular calcium ion concentrations and pH within seconds to minutes (Brubaker and Gay, 1994; Fiorelli *et al.,* 1996).

Effects of Selective Estrogen Receptor Modulators, Estrogen Metabolites, and Phytoestrogens

SERMs

Despite the success of hormone replacement therapy in the treatment of postmenopausal osteoporosis, prolonged treatment with E, even when supplemented with a progestin, is associated with an increased risk of breast and uterine cancer. Consequently, there has been a tremendous effort to develop synthetic tissue-specific, partial estrogen agonists that possess the desirable estrogen agonist properties in bone and the cardiovascular system without the undesirable growth-promoting effects in reproductive tissue. One such nonsteroidal analog, the benzothiophene derivative, raloxifene (LY139481 HCl), appears to satisfy many/all of these criteria in both laboratory animals and postmenopausal women.

Although raloxifene binds with similar affinity to ERα and ERβ (Kuiper *et al.,* 1998), the compound induces distinctly different conformational changes in ERα (Brzozowski *et al.,* 1997) and ERβ (Paige *et al.,* 1999) when it binds to the ligand-binding domain. Because the conformational differences affect the coregulatory factors recruited by each receptor, this provides the molecular explanation for the divergent effects of E and raloxifene on gene transcription from various E-inducible promoters (eg., AP-1 sites) depending on which ER isoform is present (Paech *et al.,* 1997; Watanabe *et al.,* 1997). Thus, the tissue-selective responses to raloxifene and other partial E agonists may be explained by a combination of the relative level of ERα to ERβ, the repertoire of coregulators present in the cells (described earlier), and the type of DNA response element present in the promoter.

In the OVX rat model of postmenopausal osteoporosis, raloxifene prevented bone loss from sites of both cancellous and cortical bone, reduced serum cholesterol, but did not stimulate uterine hyperplasia (Black *et al.,* 1994; Turner *et al.,* 1994). Interestingly, in growing rats, the effects of E and raloxifene on bone growth and remodeling are not identical. Similar to E, raloxifene prevented the increases in longitudinal and radial bone growth as well as cancellous bone resorption that were induced by OVX, but, in contrast to E, did not prevent the OVX-induced increase in cancellous bone formation (Evans *et al.,* 1994). In adult rats with established osteopenia, raloxifene prevented additional bone loss but, as with estrogen, is unable to replace lost bone (Evans *et al.,* 1996). The prevention of cancellous bone loss by raloxifene occurred by a mechanism mimicking the antiresorptive action of estrogen in which osteoclast numbers and eroded trabecular surfaces were reduced.

More recently, analogs of raloxifene that are more potent antagonists in the uterus have also been shown to prevent OVX-induced bone loss when administered to rats immediately following OVX, as well as block continued bone loss when administered to osteopenic animals (Li *et al.,* 1998). It has also been shown that raloxifene only partially inhibits bone loss during the high turnover phase after OVX, but completely prevents bone loss during the subsequent slower phase of post-OVX bone loss. In clinical trials of postmenopausal women, raloxifene reduced markers of bone resorption and formation and increased bone mineral density relative to patients receiving the placebo, comparable to the effects of conjugated estrogens (Draper *et al.,* 1996; Delmas *et al.,* 1997). Additionally, raloxifene therapy reduced the serum concentrations of total and low-density lipoprotein (LDL) cholesterol but, unlike estrogen, did not stimulate the endometrium.

Although the *in vivo* effects of raloxifene have been studied extensively and in bone appear to closely parallel those of estrogen, comparatively little is known about the cellular and molecular effects of SERMs on bone cells *in vitro* (Bryant *et al.,* 1999). In OB lineage cells, raloxifene has been reported to stimulate creatine kinase activity (Fournier *et al.,* 1996), total protein and type I collagen α-chain synthesis (Qu *et al.,* 1999), and the expression of TGFβ3 mRNA (Yang *et al.,* 1996). To date, the few known actions of raloxifene on OC lineage cells are very much analogous to those of E. Treatment of OVX mice with raloxifene decreased the number of bone marrow-derived preosteoclasts (GM-CFU) (Liu *et al.,* 2000). This effect of raloxifene may be direct given that specific high-affinity-binding sites for raloxifene have been demonstrated in a human leukemic preosteoclastic cell line (Fiorelli *et al.,* 1997). Furthermore, raloxifene suppressed osteoclastic differentiation induced by a combination of M-CSF and OPGL in the osteoclastogenic mouse monocytic cell line RAW264.7 (Shevde *et al.,* 2000).

Estrogen Metabolites

Even though postmenopausal women lose bone at different rates, the levels of serum E do not differ among them (Riis, 1995). However, the serum levels of adrenal androgens

and the conversion of these androgens and estradiol to other estrogen metabolites do differ among individuals and certain races of the population and may play a role in maintaining bone mass in certain individuals.

Studies have shown that the predominant postmenopausal estrogen estrone (E_1) is metabolized through two mutually exclusive hydroxylation pathways (Fishman *et al.,* 1984; Martucci and Fishman, 1993). The catalytic conversions of estrone by 2-hydroxylase or 16α-hydroxylase enzymes results in the formation of either 2-hydroxyestrone (2-OHE_1) or 16α-hydroxyestrone (16α-OHE_1), respectively. The 16α-OHE_1 has been shown to bind covalently and noncovalently to the estrogen receptor (ERα), but with reduced affinity compared to E. However, its lack of binding to the serum-binding globulin makes it more available for E target tissues (Swaneck and Fishman, 1988; Fishman and Martucci, 1980). In addition, 16α-OHE_1 serves as an estrogen agonist in reproductive tissues (Fishman and Martucci, 1980; Schneider *et al.,* 1984). In contrast, 2-OHE_1 also binds very weakly (even less than 16α-OHE_1) to the ER (Fishman and Martucci, 1980) and has been shown to have no estrogenic activity and, in some cases, to act as an antiestrogen (Schneider *et al.,* 1984; Vandewalle and Lefebvre, 1989).

Lim *et al*. (1997) reported that urinary levels of 16α-OHE_1 were lower and 2-OHE_1 levels were higher in postmenopausal osteopenic individuals than in nonosteopenic individuals. Furthermore, the 16α-OHE_1/ 2-OHE_1 ratio was correlated positively with bone mineral density. African-American women, who are at lower risk for developing osteoporosis, reportedly have increased 16α-hydroxylation and therefore have a higher 16α-OHE_1/2-OHE_1 ratio compared to Caucasian women (Coker *et al.,* 1997). When OVX rats were treated with 16α-OHE_1, the cancellous bone turnover associated with ovariectomy was prevented in a similar manner as E (Westerlind *et al.,* 1998). However, 2-OHE_1 displayed no estrogenic activity on trabecular bone turnover in OVX rats. In agreement with these findings *in vivo*, 16α-OHE_1, but not 2-OHE_1, mimicked the effects of E on the regulation of alkaline phosphatase activity and osteocalcin secretion in an E responsive osteoblast cell line stably expressing ERα (Robinson *et al.,* 2000).

Another naturally occurring estrogen metabolite is 2−methoxyestradiol (2−MeO-E_2), produced primarily by the liver. This metabolite has very low affinity for ER (ERα) and because of this its physiological effects are thought not to be mediated through the ER pathway. 2-MeO-E_2 has antitumorigenic activity and may act as a physiological tumor suppressor (Zhu and Conney, 1998). Tumor cell proliferation is inhibited, possibly through the disruption of tubulin polymerization, and angiogenesis is reduced via increased senescence and apoptosis of endothelial cells by 2-MeO-E_2 (Fotsis *et al.,* 1994). The administration of high concentrations of 2-MeO-E_2 to rapidly growing rats has been demonstrated to inhibit longitudinal bone growth but have no effect on either radial bone growth or cancellous bone turnover (Turner and Evans, 2000). This suggests that the metabolite reduces proliferation and/or stimulates apoptosis of rapidly dividing growth plate chondrocytes.

Phytoestrogens

There are three main classes of phytoestrogens: isoflavones, lignans, and coumestans. They are found principally in plants or their seeds, and a single dietary source often contains more than one class of phytoestrogens. Using a competition-binding assay, Kuiper *et al.* (1998) found that although the binding affinity of the phytoestrogens for either ERα or ERβ was lower than that of E, the relative binding affinity of phytoestrogens toward ERβ was significantly greater than that toward ERα. In contrast to phytoestrogens, the relative binding affinity of the SERMs, tamoxifen, and raloxifene, was greater for ERα than for ERβ. Using a reporter gene construct, the phytoestrogens tested were able to activate both ER subtypes, although the overall potency of these compounds was approximately 1/100th to 1/1000th that of E (Kuiper *et al.,* 1998).

The most convincing evidence for phytoestrogen effects on bone comes from animal studies. To date, there have been 13 published studies (11 in rats, 1 in mice, and 1 in macaques) examining effects of various phytoestrogens on bone loss, with generally positive findings. In addition to these animal studies, some preliminary studies in postmenopausal women demonstrate possible efficacy of phytoestrogens in the prevention of bone loss (Potter *et al.,* 1998). The principal issue is whether the actions of phytoestrogens on bone are identical to those of E or the SERMs. In support of this, both genistein in mice and coumestrol in rats prevented post-OVX bone loss by reducing bone resorption and osteoclast number in a manner very similar to E (Ishimi *et al.,* 1999; Draper *et al.,* 1997). However, in contrast, other studies have demonstrated that the reduction of bone loss following OVX in rats by genistein or by soy protein was associated with unchanged parameters of bone resorption but increased bone formation rates (Fanti *et al.,* 1998; Arjmandi *et al.,* 1998; Harrison *et al.,* 1998). These data thus indicate that there may be important differences between phytoestrogen and E effects on bone and, in fact, between the skeletal effects of different phytoestrogens. It has been suggested that some effects of phytoestrogens in different tissues may be due to ER-independent mechanisms, i.e., through protein tyrosine kinases or other mechanisms (Tham *et al.,* 1998).

Progesterone

Introduction

Progesterone is often given in conjunction with E during hormone replacement therapy of postmenopausal women to minimize some of the undesirable effects of E on reproductive tissues. However, the effects of P on bone physiology have not been examined to the large extent that E effects have been studied (for a review, see Prior, 1990). P exerts its effects on cells via mechanisms analogous to E; by binding and activating the progesterone receptor (PR), a member of the steroid nuclear receptor transcription factor family, which subsequently binds to the regulatory regions of target genes,

classically at progesterone response elements (PREs), to modulate gene transcription. Nongenomic effects of P in OBs have also been documented (Le Mellay and Lieberherr, 2000; Grosse *et al.,* 2000).

Progesterone Receptors in Bone Cells

In human, rat, and rabbit, PR exists as two isoforms, A and B (see Fig. 5), that are transcribed from the same gene using different promoters (Kastner *et al.,* 1990). Both PR promoters are estrogen inducible. The PR_B isoform is generally a stronger activator of gene transcription than PR_A, and in certain conditions, PR_A can reduce the transactivation stimulated by PR_B and other steroid receptors, including the ER (Giangrande *et al.,* 1999; Kraus *et al.,* 1995). Because of these important functional distinctions between the two PR isoforms, it is of interest to determine their relative expression level in target cells. The presence of PR mRNA and protein has been demonstrated in primary cultures of human OBs (Eriksen *et al.,* 1988) and in several OB cell lines (HOS TE85, MG-63, and SaOS-2) (Wei *et al.,* 1993; MacNamara *et al.,* 1995), including transcripts for both PR isoforms (MacNamara and Loughrey, 1998). In some cases, but not all, E stimulates the level of PR expression (Eriksen *et al.,* 1988; Harris *et al.,* 1995; MacNamara and Loughrey, 1988). Consequently, some of the effects on bone metabolism that have been attributed to E may in fact be mediated by P.

Effects of Progesterone on OBs and OCs

Progesterone has been reported to affect OB and OB precursor cell proliferation and differentiated functions, but some data are conflicting. Canalis and Raisz (1978) initially demonstrated that P inhibited proliferation and collagen synthesis by fetal rat calvarial cells. In contrast, Slootweg *et al.* (1992) found that whereas P alone did not affect proliferation of SaOS-2 cells, it stimulated cell growth synergistically with E. However, P alone has been found to stimulate the proliferation of TE85 osteosarcoma cells and normal human OBs (Tremollieres *et al.,* 1992). Other studies have shown stimulatory effects of P on the proliferation of normal and transformed osteoblastic cells (Scheven *et al.,* 1992; Verhaar *et al.,* 1994; Manzi *et al.,* 1994). More recently, P has been shown to increase the number of alkaline phosphatase-positive colonies—and hence osteogenic development—of a subclass of osteoprogenitor cells isolated from rat vertebral bone explants (Ishida and Heersche, 1997, 1999). P treatment of primary human OB and TE85 osteosarcoma cells was reported to increase IGF-II secretion (Tremollieres *et al.,* 1992) and inhibit IL-6 secretion in primary human OBs and mouse bone marrow stromal cells (Girasole *et al.,* 1992). P may regulate further aspects of the IGF system in bone because P stimulates expression of IGFBP-5 by a transcription-dependent mechanism in human osteosarcoma cells (Boonyaratanakornkit *et al.,* 1999). IGFBP-5 is unique among the various IGFBPs and *in vitro* it enhances the mitogenic activity of both IGF-1 and IGF-II in OBs.

Effects of Progesterone on Bone Physiology

ANIMALS

A number of experimental animal studies have indicated significant effects of P on bone metabolism. Thus, P has been shown to stimulate mineralization of newly induced bone in rats (Burnett and Reddi, 1983) and to increase the cortical bone formation rate in spayed Beagle dams (Snow and Anderson, 1985). Moreover, P was able to prevent ovariectomy-induced bone loss in rats, with inhibition of resorption indices, but persistently elevated bone formation rates (Barengolts *et al.,* 1990, 1996). In addition, the high circulating levels of P in pseudopregnant rats were associated with preservation of bone mass despite E levels comparable to ovariectomized rats (Bowman and Miller, 1996). However, these studies contrast with histomorphometric analyses, which have failed to detect a beneficial action of

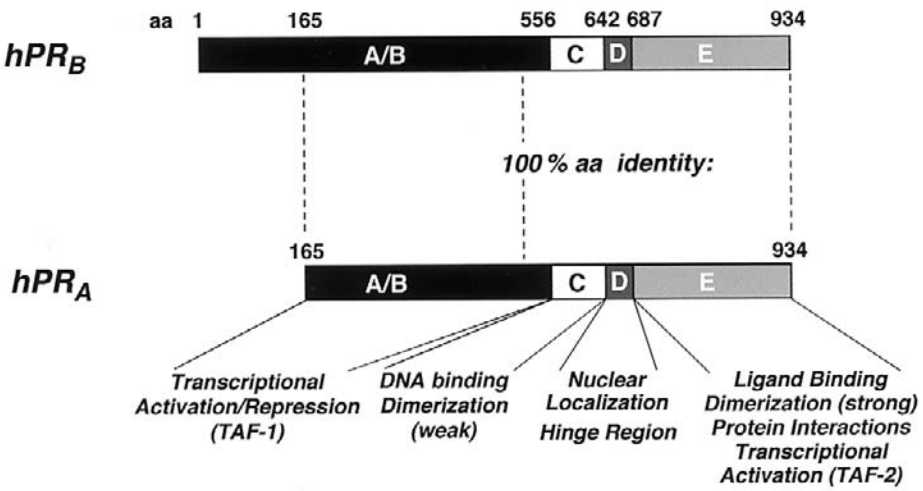

Figure 5 Model of human progesterone receptor isoforms with defined domain functions and homologies.

P on cancellous bone with or without coadministration of E (Kalu *et al.,* 1991; Fujimaki *et al.,* 1995). A more recent study in rats has reported that P has a significant stimulatory effect on bone formation and acts synergistically with estrogen to inhibit bone resorption (Schmidt *et al.,* 2000).

HUMANS

Despite some ongoing controversy (Waller *et al.,* 1996; De Souza *et al.,* 1997), the bulk of evidence from human studies is consistent with a significant role for P in bone metabolism. Thus, women with ovulatory disturbances related to luteal phase defects have been shown to lose bone mass over 1 year compared to women with normal menstrual cycles (Prior *et al.,* 1990) and to have increases in bone mass in response to P therapy during the luteal phase (Prior *et al.,* 1994). Several studies have found that P treatment of postmenopausal women protects against bone loss, particularly at cortical sites (McNeely *et al.,* 1991; Gallagher *et al.,* 1991; Grey *et al.,* 1996). Although some studies have shown that treatment of postmenopausal women with either P alone or combination therapy of E with P is as effective as E alone in the prevention of bone loss (McNeeley *et al.,* 1991; Grey *et al.,* 1996), other trials have demonstrated a lesser effect (PEPI, 1996; Prior *et al.,* 1997). Progesterone reduces postmenopausal bone loss in part by a suppression of bone resorption (Mandel *et al.,* 1982; Lobo *et al.,* 1984).

Conclusions

As described earlier, numerous major advances have occurred in recent years in the area of estrogen action on bone. It is now evident that E affects bone formation and bone resorption at all levels of cellular regulation: progenitor cell proliferation, differentiation, bone metabolism, and bone cell apoptosis. Consequently, the control by E of bone growth and remodeling at the tissue level is now realized to be extremely complex. How E elicits its effects within the cell, as well as the range of possible responses, is also more diverse than previously thought. The latter is due, in part, to the identification of the second ER isoform, ERβ, exhibiting an activity and expression distinct from the classical ERα. In addition, the presence of steroid receptor coregulators adds to the diverse responses. The differential expression and activities of the ER isoforms and the receptor coregulators provide explanations for the cell- and tissue-selective actions of the SERMs.

However, the answers to several important questions remain incomplete. For example, do the two ER isoforms regulate the same target genes? Are the two isoforms coexpressed in OBs and OCs? Does the relative ratio of ERα to ERβ change during differentiation and, if so, is E responsiveness affected? Is E responsiveness in OBs and OCs also determined by alterations in the relative levels of the steroid receptor coactivators and corepressors? Further analysis of the various ER mutant mice should provide answers as to whether the effects of E at particular skeletal sites (such as trabecular surfaces, periosteum, and growth plate) are mediated primarily by one or both ER isoforms. In addition, the generation of bone cell lines from each of the various ER-deficient genotypes should prove valuable in addressing many of the questions just posed.

Advances in our understanding of the actions and importance of P in bone growth and remodeling have, unfortunately, been more modest. The availability of PR-deficient mice will make it possible to examine the interaction between E and P in bone, such as the potential involvement of P and PR as regulators of certain skeletal effects of E. Lastly, and in analogy to studies with ERs, investigation into possible exclusive roles of the A and B isoforms of PR may reveal heretofore unrecognized effects of P on bone.

CHAPTER 38

Selective Estrogen Receptor Modulators

Douglas B. Muchmore

Geoffrey Greene
Ben May Institute for Cancer Research, University of Chicago, Chicago, Illinois 60637

Introduction

Selective estrogen receptor modulators (SERMs) act via estrogen receptors to mediate estrogen agonist effects in some systems (e.g., inhibition of bone resorption) while exerting estrogen antagonist effects in other systems (e.g., inhibition of estrogen-dependent endometrial stimulation). Given the recently appreciated complexity of estrogenic mechanisms, it is not surprising that SERMs with differing profiles of target tissue action have been discovered. The major targets demonstrating this heterogeneity of ligand action are nonskeletal, and thus this chapter, while focusing on skeletal effects, discusses both skeletal and selected nonskeletal effects of SERMs in order to illustrate similarities and differences between SERMs. SERMs of primary interest are those that have been released for clinical use.

Mechanism of Action of SERMs

Mechanisms of Estrogen Action

As implied by their name, SERM effects are mediated through specific, high-affinity interactions with estrogen receptors, and thus a current understanding of SERM biology depends on insights developed from the rapidly evolving field of estrogen receptor biology. Estrogen receptors are members of a superfamily of nuclear transcription factors, comprising over 150 members. The superfamily consists of type I receptors responsible for steroid hormone action (estrogens, androgens, progestagens, glucocorticoids, and mineralocorticoids), type II receptors responsible for nonsteriodal hormone action (thyroid hormones, vitamin D receptor ligands, and retinoids), and so-called orphan receptors, which do not have identified cognate ligands (Tsai and O'Malley, 1994).

The "classical" model of estrogen action involves ligand binding to a nuclear estrogen receptor with a resultant conformational change in the receptor that alters its affinity for associated proteins (e.g., heat shock proteins), allowing dimerization of two liganded receptor monomers (Clark *et al.,* 1992). In turn, these dimers interact with transcriptional coactivators or corepressors (McKenna *et al.,* 1999) and then bind directly to specific DNA promoter sequences [estrogen response elements (EREs)], resulting in the modulation of transcription and translation of the corresponding gene products. The ERE promoter is involved in the activation of numerous classical estrogen-responsive genes, including many pathways involved in reproductive processes.

The potential clinical relevance of transcriptional modulators in steroid receptor action has been underscored by the report of a case of androgen insensitivity in a phenotypic female with normal levels of testosterone, as well as normal expression of unmutated androgen receptors. However, the subject's fibroblasts failed to show transcriptional activation in a reporter gene assay using a transfected androgen receptor derived from her own genetic material, from normal subjects, or from a subject with "classical" androgen insensitivity due to an androgen receptor mutation. Conversely, fibroblasts from either normal males or

the female with classical androgen receptor mutation demonstrated normal reporter gene activation using the androgen receptor derived from either normals or the subject with variant androgen insensitivity but not from the subject with androgen receptor mutation. The authors were able to show that the subject's defect likely results from a failure to respond to the transactivation signal from the AF-1 region of the androgen receptor (Adachi *et al.,* 2000). Although not yet described, it is likely that variable target tissue sensitivity to estrogen may also be due to variations in transactivation protein structure or function.

The basic model of steroid hormone action is still applicable to many of the actions of estrogens. However, progress in estrogen receptor biology has provided substantial detail at the molecular level in understanding this process, while also identifying new, alternate pathways of estrogen action. These new insights have provided a framework for understanding the seemingly contradictory abilities of SERMs to act as estrogen agonists in some systems yet to lack estrogen agonism in other systems while partially or completely antagonizing the action of estrogens themselves.

In addition to ERE-dependent pathways, it is now known that estrogens mediate gene transcription through a number of other promoter sequences, including the AP-1 promoter (Paech *et al.,* 1997), the retinoic acid receptor-α1 promoter (Elgort *et al.,* 1996), the transforming growth factor-β (TGF-β) promoter (Yang *et al.,* 1996a), the SF-1 response element (Vanacker *et al.,* 1999), the SP1 response element (Xie *et al.,* 2000), and the NF-κB response element (Inadera *et al.,* 2000). Also complicating the picture was the discovery of ERβ (Kuiper *et al.,* 1996), a distinct ER subtype with homology to the classical estrogen receptor, now known as ERα. Differential activation or inhibition of the various estrogen pathways, depending on which ligands (agonist, antagonist, or SERM), which receptor subtype (ERα or ERβ), and which coactivators and/or corepressors may be present in a given target, provides for a richly complex menu of tissue-specific estrogen responses. In terms of bone, these estrogenic responses lead to modulation of various cytokine levels, which leads to alterations in osteoblast and osteoclast function (see Chapter 39).

Antagonist Actions of SERMs

Antagonist actions of SERMs can now be explained at the molecular level. The key breakthrough which led to this understanding was the elucidation of the crystallographic structure of the ligand-bound estrogen receptor (Brzozowski *et al.,* 1997). The estrogen receptor consists of six sequence domains (A–F), which are associated with various functional correlates, including ligand binding (part of the E domain), DNA binding (the C and D domains), and coactivator/corepressor binding (the A/B domain, which contains the transactivation function-1 or AF-1 region, and the E domain, which contains the AF-2 region). AF-1 and AF-2 regions have been demonstrated via a variety of techniques to be important modulators of estrogen-responsive gene transcription. Thus, various mutagenesis experiments have demonstrated that modifications of the sequence of AF-2 can turn agonists into antagonists and vice versa (Montano *et al.,* 1996; Nichols *et al.,* 1998).

Crystallographic studies have demonstrated that the structures of the various functional regions of the estrogen receptor ligand-binding domain (LBD) are conferred by the three-dimensional conformation of the 12 α-helical segments of the LBD. Helices 1–11 of either the ERα or the ERβ LBD assume similar positions regardless of the ligand (estrogen or SERM) that is bound (Brzozowski *et al.,* 1997; Pike *et al.,* 1999). Of note, the ligand-binding pocket of the receptor is relatively promiscuous (Pike *et al.,* 1999), allowing high-affinity binding of a diverse group of compounds ranging from natural estrogens to several chemical classes of pharmaceutical SERMs (Fig. 1).

The ability of the ligand-binding pocket to accommodate molecules that possess bulky sidechain substituents is key to the antagonist action of many SERMs because binding of these compounds results in a repositioning of helix 12 compared to its position when estradiol is bound. When an estrogen such as diethylstilbesterol (DES) is bound to the receptor, helix 12 assumes a stable position, lying across the entry to the ligand-binding pocket (Fig. 2A, see also color plate). This appears to "lock" the ligand in place and, importantly, results in creation or completion of the AF-2 region of the receptor. As noted earlier, the AF-2 region is an area of the receptor that interacts with certain transcriptional coactivators, which, in turn, modulate estrogen target gene transcription. Thus, the appropriate nuclear receptor interaction domain of the coactivator (e.g., GRIP1 NR box II) makes contact via an LXXLL motif with helices 3, 4, 5, and 12 of the ER LBD (Fig. 2A).

In contrast, when a SERM such as raloxifene (Brzozowski *et al.,* 1997) or 4-hydroxytamoxifen (Shiau *et al.,* 1998) is bound, helix 12 repositions itself to occupy the hydrophobic cleft defined by helices 3, 4, and 5 (Fig. 2B, see also color plate), which alters the conformation of the AF-2 surface and blocks the hydrophobic cleft. An LXXML motif in helix 12 mimics the LXXLL motif of the p160 coactivator (e.g., GRIP1). This reorientation effectively prevents transcriptional modulators, such as the p160 coactivators, from interacting with the AF-2 surface. Conversely, certain corepressors, such as NCo-R, may be recruited to the SERM–ER complex (Jepsen *et al.,* 2000). Given that estrogen and SERMs compete for high-affinity binding to the same ligand-binding domain of the estrogen receptor, the SERM-mediated blockade of AF-2 by helix 12 results in antagonism of estrogen action on target genes that depend predominantly on AF-2.

Additional potential antagonist mechanisms of SERM modulation of estrogen activity have been described. As noted, estrogen receptors depend on dimerization in order for successful stimulation of classical gene targets. The synthetic "pure" estrogen antagonist ICI 164,384 destabilizes ER dimers (Arbuckle *et al.,* 1992) as well as the ER

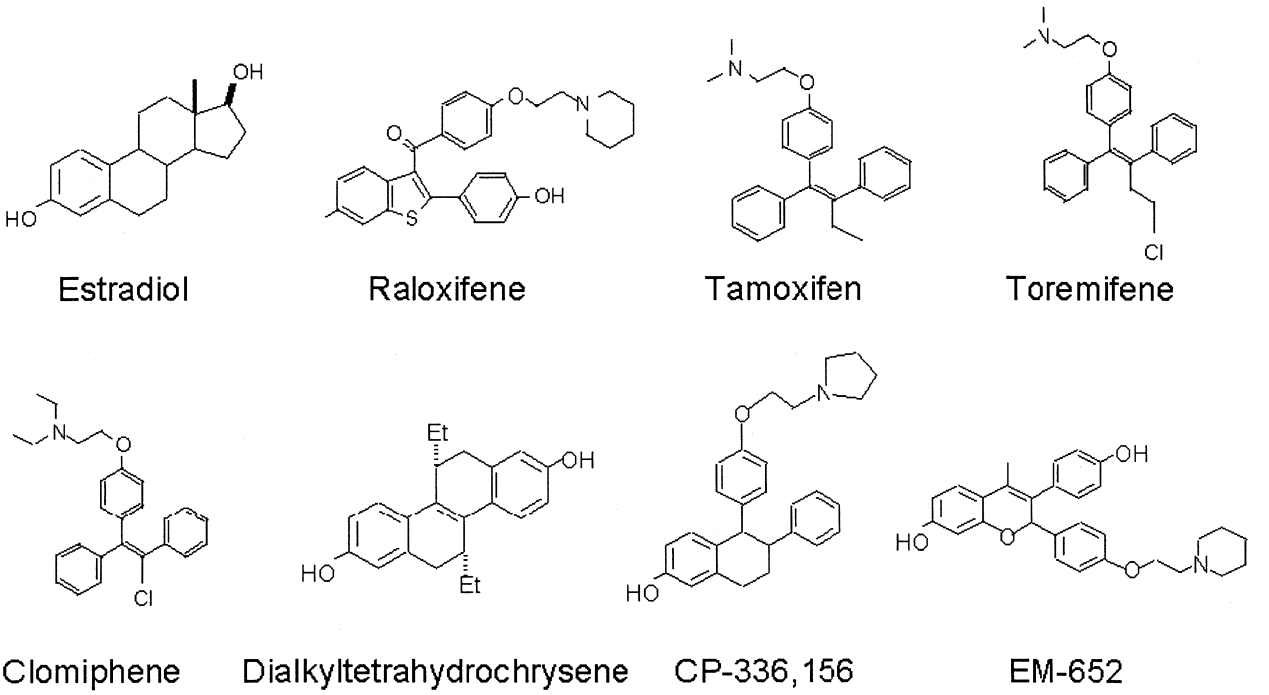

Figure 1 Chemical structures of estradiol and various SERMs representing several chemical classes, including benzothiophenes (raloxifene), triphenylethylenes (tamoxifen, toremifene, and clomiphene), chrysenes (dialkyltetrahyrdochrysene; Meyers *et al.,* 1999; Sun *et al.,* 1999), tetrahydronapthalenes (CP-336,156; Ke *et al.,* 1998), and benzopyrenes (EM-652; Labrie *et al.,* 1999).

protein itself, which may explain its potent antagonist activity *in vivo*. Tamoxifen may also destabilize ER dimers, which have been shown to reduce estrogen-stimulated gene transcription in a yeast model (Wang *et al.,* 1995). Further, ERα and ERβ are capable of forming heterodimers (Pace *et al.,* 1997) in which ERβ can act as a transdominant inhibitor of ERα activity under subsaturating hormone concentrations when both receptor subtypes are cotransfected into a test cell system (Hall and McDonnell, 1999). Given that ER receptor subtypes may respond differently to the

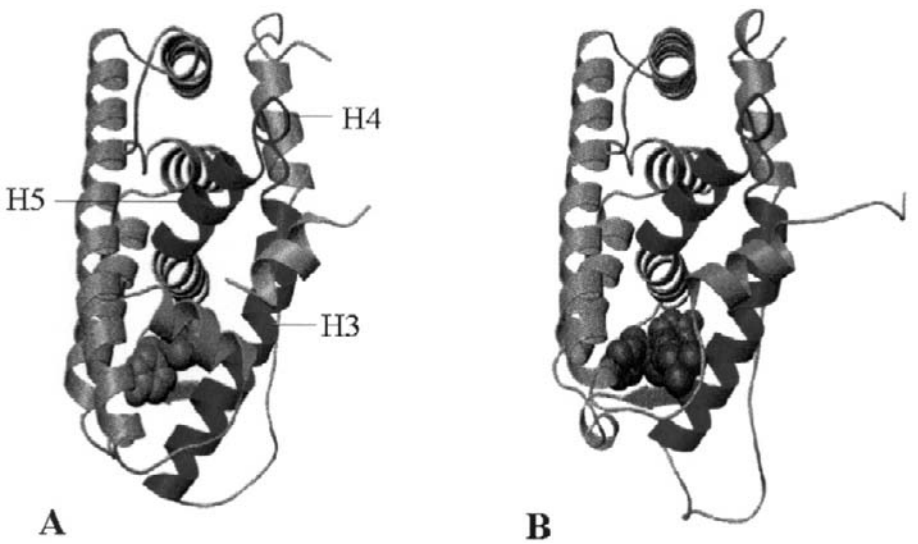

Figure 2 Structures of the DES-ERα LBD-GRIP1 NR box II peptide complex (A) and the OHT-ERα LBD complex (B) [adapted from Shiau *et. al.* (1998), with permission from Elsevier Science]. (A) The GRIP1 coactivator peptide and the DES-ERα LBD are shown as ribbon drawings. The peptide is shown in gold, and helix 12 (residues 538–546) is shown in magenta. Helices 3, 4, and 5 (labeled H3, H4, and H5, respectively) are colored blue. DES, colored green, is shown in space-filling representation. (B) OHT-ERα LBD is depicted as a ribbon drawing. As in A, helix 12 (residues 536–544) is shown in magenta, and helices 3, 4, and 5 are shown in blue. OHT, in red, is shown in space-filling representation. (See also color plate.)

same ligands (Paech *et al.,* 1997), the structural and/or functional interactions between the different ligand-bound receptor subtypes afford a mechanism by which SERMs may alter estrogen action.

Agonist Actions of SERMs

Whereas SERMs may act primarily in classical estrogen pathways as estrogen antagonists, they are known to have intrinsic estrogenic activity in nonclassical pathways. One such pathway (TGF-β) was identified as a candidate gene for estrogen pathways in bone because TGF-β has antiresorptive action and is stimulated *in vivo* by estrogen (Yang *et al.,* 1996b). Because of these properties, Yang *et al.* (1996a) investigated the molecular regulation of TGF-β transcription. Their results showed that whereas estradiol itself had little ability to stimulate TGF-β3 promoter sequence-dependent transcription in a transient transfection assay, raloxifene had potent activity in this regard. Interestingly, a variety of naturally occurring estrogen metabolites were also active, suggesting that this alternate pathway of estrogen action may well have physiological relevance under normal conditions. The lack of effect seen with estradiol itself suggests that the production and distribution of estrogen metabolites may provide regulatory control opportunities for estrogen action in bone (or elsewhere).

Yang *et al.* (1996a) expanded these studies by investigating the effects of using various deletion mutants of the estrogen receptor in the transfection assay. Raloxifene retained transcriptional stimulatory activity even when the DNA-binding domain of the estrogen receptor (but not the ligand binding domain) was deleted. This suggested that the classical ERE consensus sequence was not involved in this estrogen receptor-mediated transcriptional activity and that SERMs may exert some of their agonist activity by stimulating alternate estrogen pathways.

Work investigating the impact of AF-1 and AF-2 truncation mutations of a naturally occurring estrogen receptor mutant (D351Y) that confers estrogen agonist activity to raloxifene or tamoxifen has emphasized the importance of AF-1 in mediating agonist activity of SERMs (Webb *et al.,* 2000). In previous work using receptor chimeras, McInerney *et al.* (1998) demonstrated that whereas SERMs such as tamoxifen were antagonists using wild-type ERβ, these agents would act as agonists when the ERα receptor A/B domain was used to replace the N-terminal sequence of the ERβ receptor, again implicating AF-1 in SERM-mediated estrogen agonism. The extent to which the differences in AF-1 between ERα and ERβ have an impact on SERM activity *in vivo* is uncertain but one potential determinant of the clinical spectrum of activity of a SERM may be distribution of the estrogen receptor subtypes, which is known to vary from tissue to tissue (Couse *et al.,* 1997; Kuiper *et al.,* 1997).

Receptor subtype distribution and function may have specific importance in bone, as a knockout mutation of the two receptor subtypes has different phenotypic effects. ERα knockout female mice exhibit an increase in bone resorption and remodeling, an effect consistent with a role of ERα in the maintenance of skeletal dynamics (Couse and Korach, 1999). ERα knockout mice also demonstrate disproportional body growth, with decreased appendicular, but not axial, growth (Vidal *et al.,* 1999). ERβ knockout female mice have increased adult bone mass, which may be due to lack of maturation-associated inhibition of bone growth during adolescence (Windahl *et al.,* 1999), an effect not seen in ERα knockout female mice (Vidal *et al.,* 1999).

In the male, ERα plays an important role in human skeletal health; an ERα-deficient man was reported to suffer osteoporosis at age 28 (Smith *et al.,* 1994). ERα knockout male mice develop impairment of longitudinal skeletal growth, which is associated with decreased levels of IGF-1, an effect not seen in ERβ knockout male mice (Vidal *et al.,* 2000). The applicability of these mouse model findings to human physiology may be limited because of substantial differences in skeletal homeostasis between mice and men (Couse and Korach, 1999). However, because the effects of SERMs depend on the complement of estrogen receptor subtypes present in a target tissue, there may be clinical implications for SERM action (as yet unrecognized) that are attributable to variation in receptor subtype expression in bone.

Summary of SERM Mechanisms and Further SERM Development

SERMs are now recognized as a specific, new class of pharmacologic agents. Advances in receptor biology now allow coherent, if incomplete, models for how SERMs are able to act simultaneously as agonists, partial agonists, and/or antagonists in different tissues. These insights have been aided greatly by the crystallographic determinations of estrogen receptor structure when bound to one or another ligand (Fig. 2).

These advances may also pave the way for new drug discovery. As an example, coactivators that modulate transcription at the AF-2 region have been shown to depend on the sequence motif LXXLL for AF-2-binding activity (Chang *et al.,* 1999). More recently, Paige and colleagues (1999) demonstrated that peptides containing this motif demonstrate differential receptor-binding patterns ("fingerprints") depending on which ligand is bound to the receptor. This finding supported the previous hypothesis of McDonnell *et al.* (1995) that different SERMs result in ligand-specific differences in receptor conformation (subsequently directly demonstrated via crystallography). The relevance of the differential binding patterns of these peptides was underscored by further work, which demonstrated that cells that are induced to express LXXLL-containing peptides show modulation of estrogen and SERM transcriptional activity (Norris *et al.,* 1999).

These findings have since been extended to demonstrate that flanking sequences of the LXXLL motif also affect the transcriptional response to ligands (Chang *et al.,* 1999). By systematically studying a large panel ($>10^8$) of peptides synthesized by combinatorial methods, these investigators

were able to identify three classes of LXXLL peptides, one of which proved to have specific ERβ antagonist activity (Chang *et al.,* 1999). This approach, as well as others, may lead to the development of estrogen receptor subtype-specific SERMs. Indeed, Sun *et al.* (1999) and Meyers *et al.* (1999) have reported the development of ERα-specific agonist compounds (see Fig. 1 for an example structure). The clinical utility of these ER subtype-specific SERMs is uncertain, but such developments may result in increasingly selective clinical tools.

Physiologic Effects of SERMs

Animal Models

BONE

Tamoxifen was the first SERM to be used on a broad scale in the clinic. Originally identified as an "antiestrogen," it has more recently been recognized as a SERM. Initially developed in the mid-1960s (Harper and Walpole, 1966), tamoxifen was investigated for possible use in contraception. Because of its impact on the hypothalamic/pituitary/ovarian axis, it actually resulted in induction of ovulation (Klopper and Hall, 1971; Williamson and Ellis, 1973), and, in fact, a related compound (clomiphene) is used clinically for induction of ovulation. Following recognition of its antitumor activity in animal models (Jordan, 1974; Nicholson and Golder, 1975), it has been developed for treatment of metastatic breast cancer, for adjuvant treatment of early breast cancer, and for reduction in the incidence of primary breast cancer in high-risk women.

Early preclinical work on tamoxifen in bone models was based on the potential concern that an "antiestrogen" may result in harm to the female skeleton. However, tamoxifen was found to inhibit parathyroid hormone-mediated bone resorption in rat fetal long bones (Stewart and Stern, 1986). Further studies gave conflicting results, and a reduction in bone mass compared to vehicle was seen in a study of ovariectomized rats (Feldmon *et al.,* 1989), although bone mass was maintained in mature and ovariectomized rats in another study (Turner *et al.,* 1987). Additional conflicting data were adduced in studies of bone turnover: a study of calcitriol-induced bone resorption in rats failed to show a beneficial effect of tamoxifen (Goulding *et al.,* 1990), but another study showed reduction of bone resorption by tamoxifen in the ovariectomized rat (Turner *et al.,* 1988). Although mixed results were seen, it was clear that the initial fears that "antiestrogens" would have uniformly unfavorable skeletal effects were not borne out by these studies.

The most extensively studied SERM with respect to skeletal effects is raloxifene. Studies in ovariectomized rats have shown normalization of bone markers by raloxifene (Frolik *et al.,* 1996). Long term studies (up to 12 months) in ovariectomized rats showed raloxifene to be comparable to estrogen in inhibition of cancellous bone loss as determined by densitometry (Black *et al.,* 1994; Sato *et al.,* 1995) and by histomorphometry (Evans *et al.,* 1996). Raloxifene also preserved bone strength both at the femur and at the lumbar spine in ovariectomized rates as effectively as estrogen (Turner *et al.,* 1994). In a primate model (Jerome and Lees, 1996), raloxifene reduced bone turnover and increased bone mass relative to placebo, but the control ovariectomized animals in this study gained bone mass during the course of the experiment, suggesting that the model using recently captured feral animals may not be fully applicable to the human condition.

These preclinical bone results for tamoxifen and raloxifene (as well as results for other SERMs that have been in development) have supported estrogen agonist properties for these SERMs in this target system and, in the case of raloxifene, provided the basis to support a clinical development program for the prevention and treatment of postmenopausal osteoporosis.

CARDIOVASCULAR SYSTEM

Preclinical studies of tamoxifen have focused on effects of lipids, although it has also been characterized as an antioxidant (Wiseman, 1995). Studies of tamoxifen treatment in intact female rats fed an atherogenic diet showed reductions in LDL cholesterol from 29 to 45% (Vinitha *et al.,* 1997). In ovariectomized rats, tamoxifen reduced total cholesterol by approximately 50% (Sato *et al.,* 1996). However, a study of the dilator responses of atherosclerotic epicardial coronary arteries in cynomolgous monkeys to acetylcholine or nitroglycerin showed tamoxifen to be antiestrogenic. Whereas tamoxifen caused a constriction response to acetylcholine, there was no effect of estrogen. Additionally, estrogen caused a relaxation response to nitroglycerin; there was no similar response in tamoxifen-treated animals (Williams *et al.,* 1997).

Raloxifene has been studied systematically for preclinical effects on both lipid and nonlipid cardiovascular effects in animal systems. The results demonstrated a 50–60% reduction in total cholesterol by raloxifene in ovariectomized rats (Sato *et al.,* 1996). Raloxifene has also been shown to have potentially beneficial estrogenic activities in a number of nonlipid animal systems, including increasing rabbit coronary artery nitric oxide activity (Figtree *et al.,* 1999) and reducing neointimal thickening following balloon injury in ovariectomized rats (Kauffman *et al.,* 2000). Further, raloxifene reduced aortic cholesterol accumulation in cholesterol-fed rabbits by a mechanism that likely involved both lipid and nonlipid components (Bjiarnason *et al.,* 2000). In a cholesterol-fed primate model, raloxifene did not show a reduction in coronary atherosclerosis (Clarkson *et al.,* 1998), although a number of explanations related to the experimental conditions may explain this result (Bryant *et al.,* 1998).

The results of preclinical studies of these SERMs are generally consistent with potentially beneficial estrogen agonist activity in both lipid and nonlipid cardiovascular effects.

BREAST

Tamoxifen has been studied very extensively with regard to estrogen antagonist effects in a multitude of breast cancer models, including viral, chemical or radiation-induced carcinogenesis (Jordan *et al.,* 1980, 1993; Gottardis and Jordan, 1987; Welsch *et al.,* 1981). Of interest, long-term tamoxifen exposure may lead to resistance to or dependence on tamoxifen for further growth; the mechanistic basis for this resistance syndrome remains an issue of considerable interest, although comprehensive molecular and biochemical explanations are lacking. At least in a rat model, mutation of the estrogen receptor at the Asp-351 residue has been shown to convert SERMs from antagonists into agonists (Levenson and Jordan, 1998), although mutations of this type are uncommon in clinical cancer (Hopp and Fuqua, 1998). Raloxifene has been shown to markedly reduce the appearance of breast tumors in carcinogen-treated intact rats (Anzano *et al.,* 1996) and to block the proliferation of MCF-7 breast cancer cells, an estrogen-dependent process (Wakeling *et al.,* 1984).

REPRODUCTIVE TRACT

The reproductive tract is a target of particular interest because different SERMs have demonstrated markedly different biological effects in this system. As such, the reproductive tract should offer the possibility to identify, in a clinically relevant way, the mechanisms by which SERMs differ in their *in vivo* actions.

Tamoxifen has demonstrated uterine stimulatory effects in ovariectomized rats (Sato *et al.,* 1996), including modest increased uterine wet weight (25% compared to 300% for estrogen control), endometrial thickness (250%), and myometrial thickness (30%) with changes in endometrial histology consistent with a strong estrogenic effect (pseudostratified columnar epithelium). Similar results were reported by other authors (Ke *et al.,* 1997). Raloxifene demonstrates a substantially different profile (Sato *et al.,* 1996), with a modest increase in uterine wet weight (35%), but only the lowest dose of raloxifene showed a measurable increase of endometrial thickness (60% at a 0.1-mg/kg dose but no increase at 1.0- and 10-mg/kg doses). Also, in contrast to tamoxifen, raloxifene had no effect on myometrial thickness or on eosinophilic infiltratiion (a marker of estrogenic activity in the ovariectomized rat model). These data support that these two SERMs have differential profiles of estrogen receptor-mediated effects, with similar agonist effects in bone and lipid markers along with similar antagonist effects in breast models but divergent effects in the reproductive tract.

Clinical Data

Given the panoply of potential SERM uses, it is not surprising that these compounds have been considered for a variety of clinical indications. Approved clinical uses of SERMs include treatment and prevention of osteoporosis (raloxifene), treatment of breast cancer (tamoxifen, toremifene), reduction in risk of breast cancer in high-risk women (tamoxifen), and induction of ovulation (clomiphene). Many other potential indications for use (e.g., reduction in cardiovascular disease risk in women, treatment of mastalgia, endometriosis or uterine fibroids, multiple uses in men) have been considered or are under study for these or other, newer SERMs.

RALOXIFENE

Bone Studies Of the SERMs approved for human use, raloxifene has been studied to the greatest extent in the skeletal system, including studies of bone remodeling, bone turnover markers, bone histomorphometry, and vertebral fracture risk reduction. Using calcium tracer kinetics in a controlled environment, Heaney and Draper (1997) showed that either cyclic hormone replacement therapy or raloxifene (60 mg/day) led to a positive calcium balance and with reduction in bone resorption at both 4 and 31 weeks compared to untreated controls. The effect of estrogen on bone resorption was greater than that with raloxifene at the 31 week point. Calculated indices of bone formation showed no change with either agent at 4 weeks, but at 31 weeks this was reduced with hormone replacement therapy but not with raloxifene. These results suggested that hormone replacement therapy suppressed bone turnover to a greater extent than raloxifene, although the overall calcium balance was not significantly different between the therapies. Findings consistent with these were reported in a bone biopsy study comparing raloxifene to estrogen treatment (Prestwood *et al.,* 2000).

Several large studies of the effects of raloxifene on both bone turnover markers and bone density have been performed, both in women without osteoporosis and, among women with osteoporosis, in those with or without prevalent vertebral fracture. A study conducted in Europe (Delmas *et al.,* 1997) randomized 601 early postmenopausal women (2–8 years since last menstrual period) without osteoporosis by bone mineral density (BMD) criteria (lumbar spine BMD from 2.0 SD above to 2.5 SD below mean value for young adult normal females) to one of four treatment groups: 30, 60, and 150 mg/day of raloxifene or placebo. All women received 400–600 mg/day of supplemental elemental calcium; vitamin D supplements were not provided. Bone turnover markers were significantly suppressed compared to placebo (Fig. 3), with reductions at 24 months in the range of 15–35% for bone-specific alkaline phosphatase, serum osteocalcin, and urinary C-telopeptide of type I collagen. Raloxifene treatment brought these measurements down to approximately the middle of the normal premenopausal range. At 24 months the BMD in the raloxifene groups was significantly above placebo ($p < 0.001$) at the spine, hip, and total body, with an increment above placebo in the range of approximately 2 to 2.5% at all sites.

Similar results for bone turnover markers and BMD were seen in a study of somewhat older French women (Meunier *et al.,* 1999) with either low bone density or osteoporosis (average BMD T score $= -2.8$) who were

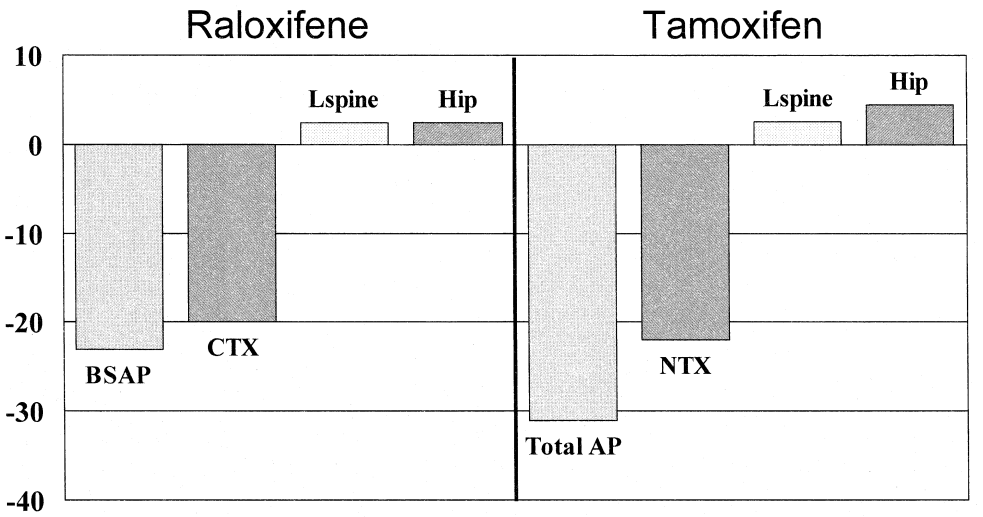

Figure 3 Comparison of the bone effects of 60 mg/day raloxifene (RLX) and 20 mg/day tamoxifen (TAM). Direct comparative data are not available; data presented are percentage difference from placebo at 2 years from separate studies (Delmas *et al.,* 1997, Chang *et al.,* 1996) showing results from similar assays. Generally similar effects are seen for these drugs on bone formation indices (bone-specific alkaline phosphatase shown for RLX, total alkaline phosphatase for TAM), bone resorption indices (C-telopeptide of type 1 collagen/creatinine ratio for RLX and N-telopeptide of type 1 collagen/creatinine ratio for TAM), and BMD response at the hip and spine. Insufficient fracture data for tamoxifen have been reported to allow comparison to raloxifene for this end point.

treated with either 60 or 150 mg raloxifene vs placebo; in this study, all subjects received both calcium and vitamin D supplements.

Two studies of women with osteoporosis have reported on the bone marker and BMD effects of raloxifene. The first (Lufkin *et al.,* 1998) was a small (143 subject) study of 1- year duration that randomized subjects to 60 or 120 mg of raloxifene versus placebo; all subjects received both calcium and vitamin D supplements and had osteoporosis by both BMD (hip or spine BMD below the 10th percentile for premenopausal females) and vertebral fracture criteria (one or more vertebral deformities with >15% height loss compared to adjacent vertebra). As in the previous studies, bone-specific alkaline phosphatase decreased approximately 10–15%, osteocalcin decreased approximately 15–20%, and urinary C-telopeptide of type I collagen/creatinine decreased by 24–30% compared to placebo. BMD at the spine, ultradistal radius, and hip showed modest increases at 1 year of about 1.5–2.5% compared to placebo.

The largest clinical bone study of raloxifene has been the Mulitple Outcomes of Raloxifene Evaluation (MORE), involving 7705 women from 25 countries (Ettinger *et al.,* 1999). The study was stratified into two parts: approximately one-third of women had prevalent vertebral fracture and approximately two-thirds of women had osteoporosis by BMD criteria alone (femoral neck or lumbar spine *T* score less than or equal to −2.5). Subjects were randomized to receive raloxifene 60 or 120 mg/day versus placebo; all subjects received both vitamin D and calcium supplementation. Results of bone markers at 36 months were consistent with the shorter term study findings, with reductions by both doses of raloxifene of about 20% for osteocalcin and 25% for C-telopeptide of type I collagen compared to placebo ($p<0.001$ for all comparisons). Three-year BMD results showed increases compared to placebo at both femoral neck and lumbar spine in the range of approximately 2–3% ($p<0.001$).

The MORE study was designed to evaluate vertebral fracture risk as its primary end point (Ettinger *et al.,* 1999). New vertebral fractures among women without prevalent fracture at study entry were reduced by 50% compared to placebo (2.3% cumulative incident fracture among raloxifene-treated women versus 4.5% for those on placebo); among those with prevalent fracture at study entry the reduction in new fractures was 30% (cumulative incident fracture among raloxifene-treated women was 14.7% for the 60-mg group and 10.7% for the 120-mg group versus 21.2% for those on placebo). These vertebral fracture reductions were statistically significant. A nonsignificant trend was seen for reduction of the secondary end point parameter of all nonvertebral fractures (9.3% cumulative incidence on placebo versus 8.5% cumulative incidence on raloxifene).

Cardiovascular End Point Studies A number of studies have looked at effects of raloxifene on surrogate markers for coronary heart disease. In a phase 1B, 8-week study of raloxifene 200 or 600 mg per day involving 251 women, serum LDL cholesterol decreased by 9.5 and 12.6%, respectively, compared to baseline (Draper *et al.,* 1996). The European osteoporosis prevention study of 601 women (Delmas *et al.,* 1997) in which 30, 60, or 150 mg of raloxifene was provided daily for 2 years showed reductions of total cholesterol (6.4 and 9.7%, respectively) and LDL cholesterol (10.1 and 14.1%) without significant changes in either HDL cholesterol or triglycerides with any dose of raloxifene.

The first focused clinical trial designed specifically to analyze the effects of raloxifene on cardiovascular surrogate markers was a 6-month study of 390 early postmenopausal subjects, comparing hormone replacement therapy, raloxifene 60 or 120 mg/day to placebo. (Walsh *et al.,* 1998). Raloxifene at either dose significantly reduced LDL cholesterol by 12% compared to placebo; a similar fall of 14% was seen with HRT. However, HDL cholesterol rose a significant 11% with HRT but did not change with raloxifene. HDL_2 cholesterol increased significantly by about 16% with raloxifene, compared with a significantly greater increase of 33% with HRT. Similarly, Lp(a) decreased a significant 4% compared to placebo with both doses of raloxifene, but it fell an even greater 16% with HRT. There was a significant (20%) increase in triglycerides with HRT, an undesirable effect, whereas triglycerides fell by 4% with 60 mg raloxifene. Finally, raloxifene lowered fibrinogen (12 and 14% with 60 and 120 mg/day, respectively), in contrast to no effect with HRT. Serum fibrinogen is an epidemiologically identified risk factor for coronary heart disease, although prospective studies demonstrating a clinical benefit of lowering fibrinogen have not been reported. Additional cardiovascular risk factors include homocysteine and C-reactive protein; raloxifene lowered homocysteine levels significantly and similarly to HRT (Walsh *et al.,* 2000), but unlike HRT, it did not increase C-reactive protein levels (Walsh *et al.,* 2000; Blum *et al.,* 2000). Raloxifene was qualitatively similar to estrogen in its modest lowering of several cell adhesion molecules in postmenopausal women (Blum *et al.,* 2000).

These studies of surrogate cardiovascular markers indicate that the SERM raloxifene has effects that are generally similar to estrogens (i.e., agonist actions), effects that would be predicted to have beneficial effects on clinical end points. In some instances, the magnitude of positive effects is less than that seen with estrogen [e.g., HDL, HDL-2, Lp(a)], but in some instances it is similar to or greater than HRT (e.g., LDL, fibrinogen, homocysteine). The ability of these types of studies to predict clinical outcomes is limited, as evidenced by the controversy surrounding the cardiovascular benefits and risks of estrogens themselves. A recent publication has demonstrated that the adverse results seen the Heart Estrogen/Progestin Replacement Study (HERS) of secondary event prevention are entirely compatible with prior observational data, which showed a substantial benefit conferred by estrogen use; this apparent contradiction is explainable if one hypothesizes an early, adverse effect of estrogen use followed by a late, sustained beneficial effect (Blakely, 2000). As in the case of estrogen, it is essential to conduct large-scale clinical end point trials to affirm the clinical effects of SERMs on the cardiovascular system. The ongoing Raloxifene Use in the Heart (RUTH) trial (Barrett-Connor *et al.,* 1998), which recently achieved its planned enrollment of 10,000 subjects, should provide definitive evidence regarding the cardiovascular effects of raloxifene in postmenopausal women at risk for cardiovascular events.

Effects of Raloxifene on the Breast The major osteoporosis trials (Delmas *et al.,* 1997; Meunier *et al.,* 1999; Lufkin *et al.,* 1998; Ettinger *et al.,* 1999) and the study of cardiovascular surrogate markers (Walsh *et al.,* 1998) have shown no increase in reports of mastalgia or other breast abnormalities with raloxifene compared to placebo. In the MORE study, breast cancer incidence was a specified secondary end point, and data reported through a median duration of 40 months (Cummings *et al.,* 1999) showed that raloxifene was associated with a 76% reduction (RR = 0.24; CI = 0.13–0.44). There was no difference in between the two dosage groups (60 and 120 mg/day). As would be expected for an estrogen receptor active agent, this therapy benefit was restricted to cases of estrogen receptor positive tumors (RR = 0.10; CI = 0.04–0.24); there was no increase in estrogen receptor negative tumors either (RR = 0.88; CI = 0.26–3.00). Patients enrolled in the MORE trial are being followed for an additional 4 years beyond its initial 4 year duration in the Continuing Outcomes for Raloxifene Evaluation (CORE) trial for the primary purpose of continuing to monitor breast cancer incidence with long-term raloxifene versus placebo. Additionally, a large (22,000 subject) study known as the Study of Tamoxifen and Raloxifene (STAR) comparing the breast cancer incidence in high risk postmenopausal women is currently enrolling.

Effects of Raloxifene on the Uterus Because of the differences noted between different SERMs in the preclinical model effects on the reproductive tract, it is critical to review the clinical effects of these agents on the uterus. The raloxifene clinical trials completed to date have enrolled well over 10,000 postmenopausal women, more than two-thirds of whom had an intact uterus at study entry. The results of several raloxifene clinical trials that employed systematic uterine monitoring (Delmas *et al.,* 1997; Lufkin *et al.,* 1998; Walsh *et al.,* 1998; Cohen *et al.,* 2000) were summarized (Cohen *et al.,* 2000; Davies *et al.,* 1999) to review its effects on the uterus in approximately 1500 postmenopausal women. There were no differences between raloxifene and placebo in relation to reports of vaginal bleeding or change in endometrial thickness as assessed by endometrial ultrasonography after 12, 24, or 36 months of treatment. Another study conducted in 415 postmenopausal women for 12 months (Goldstein *et al.,* 2000) also found no differences between raloxifene and placebo using the additional monitoring methods of saline-infused sonohysterography and scheduled, routine endometrial histologic sampling.

Systematic uterine monitoring was undertaken in a large subset of women in the MORE trial (Cummings *et al.,* 1999). Transvaginal ultrasound results showed a clinically insignificant (0.3 mm) increase in endometrial thickness in women treated with raloxifene compared to placebo. Importantly, there has not been an increase in reports of endometrial carcinoma in the large cohort (5957 subjects with an intact uterus at randomization); at 40 months of follow-up there had been four cases of endometrial cancer

reported in the placebo group versus six cases in the combined raloxifene groups for a RR = 0.8 (CI = 0.2–2.7).

Other Effects of Raloxifene Like estrogen (Daly *et al.,* 1996; Jick *et al.,* 1996; Grodstein *et al.,* 1996), raloxifene is associated with an approximate three-fold increased risk of venous thromboembolic disease (Cummings *et al.,* 1999). Although the mechanism of this risk is not fully understood, it would appear to be an estrogen agonist action shared by the major SERMs, including tamoxifen (Lipton *et al.,* 1984; Fisher *et al.,* 1998; Fisher and Redmond, 1992). In contrast to estrogen but similar to tamoxifen, raloxifene increases the risk of hot flashes (Delmas *et al.,* 1997; Ettinger *et al.,* 1999; Cohen and Lu, 2000), presumably as an estrogen antagonist effect at the hypothalamic/pituitary level.

In summary, raloxifene demostrates a SERM profile in the human, with major estrogen agonist actions in the bone and cardiovascular systems but major estrogen antagonist actions in the breast and uterus.

TAMOXIFEN

Bone Studies Because tamoxifen was originally identified as an "antiestrogen," it was initially assumed that it may have adverse effects on estrogen target tissues beyond the breast. However, cross-sectional and small prospective studies of tamoxifen (Ward *et al.,* 1993; Kristensen *et al.,* 1994; Gotfredson *et al.,* 1984; Love *et al.,* 1988; Fornander *et al.,* 1990; Fentiman *et al.,* 1989; Turken *et al.,* 1989; Ryan *et al.,* 1991) were reassuring in that no adverse effects on bone were demonstrated. The first sizable (140 postmenopausal women with node negative breast cancer) prospective, randomized, placebo-controlled 2-year-long clinical showed significant improvement in spinal bone density with tamoxifen, (10 mg twice daily) vs placebo (Love *et al.,* 1992a). Consistent with an estrogen agonist effect, markers of bone turnover, including serum osteocalcin and total alkaline phosphatase, decreased significantly ($p<0.001$) in response to tamoxifen. Lumbar spine BMD increased by 0.61% per year with tamoxifen compared with a decrease of 1.00% per year with placebo ($p<0.001$). Follow-up of this same cohort at 5 years showed the bone benefit of tamoxifen to be durable (Love *et al.,* 1994).

Further support for the beneficial effects of tamoxifen on the bone of postmenopausal women with breast cancer came from a study utilizing histomorphometry (Wright *et al.,* 1994). In this study, 21 women who had received at least 15 months of tamoxifen underwent transiliac bone biopsy, and these results were compared to 19 untreated controls. A significantly lower tissue-based formation rate and a longer remodeling period were noted in the treated women, consistent with an estrogen agonist action resulting in reduced bone turnover.

In addition to studies of women with breast cancer, tamoxifen has also been prospectively evaluated in women without breast cancer (Grey *et al.,* 1995a; Powles *et al.,* 1996). Among 57 women randomly assigned to 20 mg/day of tamoxifen versus placebo (Grey *et al.,* 1995a), bone turnover markers (serum alkaline phosphatase and urinary hydroxyproline, N-telopeptide of type I collagen and calcium) all declined significantly on tamoxifen compared to placebo. Also, lumbar spine BMD increased with tamoxifen treatment by 2.1% over placebo at 2 years, although there was no statistically significant difference between treatment groups at the proximal femur. In another study, 54 healthy postmenopausal women were randomized to 20 mg/day tamoxifen or placebo for 3 years; tamoxifen-treated women experienced 2–3% improvements in BMD at spine and hip by 3 years compared to small losses in women receiving placebo ($p<0.002$, spine; $p<0.05$, hip) (Powles *et al.,* 1996). This study also examined the effect of tamoxifen on the BMD of premenopausal women, which declined at both the hip and the spine compared to placebo. This latter effect is compatible with a partial estrogen agonist effect of tamoxifen on BMD.

As shown in Fig. 3, the bone metabolic effects of raloxifene and tamoxifen are generally similar (subject to the understanding that raloxifene has been systematically studied to a far greater degree in bone).

Effects of Tamoxifen on Fracture Risk A reduction in osteoporotic fracture has not been the primary end point of any tamoxifen studies to date. However, two studies have examined the effect of tamoxifen on fracture risk as a secondary end point. In the Danish Breast Cancer Cooperative Group (Kristensen *et al.,* 1996), 1716 high-risk women were randomized to no treatment or to radiation therapy and tamoxifen (30 mg per day). The study examined the occurrence of hip fractures during the first year of treatment; no data were obtained on vertebral deformities or other nonvertebral fractures. Overall, there was no difference in the rates of hip fracture between treatment groups, although a subset analysis showed an increase in intertrochanteric fracture on tamoxifen versus placebo during the first year (RR = 2.12; CI = 1.12–4.01). Clinical fracture occurrence was a secondary end point of the large Breast Cancer Prevention Trial (Fisher *et al.,* 1998) conducted by the National Surgical Adjuvant Breast and Bowel Group (NSABP). This trial randomized 13,388 high-risk women to either tamoxifen (20 mg/day) or placebo. During the 36-month follow-up of the trial there was no difference in the occurrence of all reported clinical fractures (483 subjects on placebo and 472 on tamoxifen). The treatment group difference approached statistical significance when only those fractures likely to be osteoporotic (hip, distal radius, and clinical spine fractures) were included in the analysis (RR=0.81; CI=0.63–1.05).

Effects of Tamoxifen on Cardiovascular End Points As in the case of bone studies, most data on lipid and cardiovascular end points with tamoxifen derive from breast cancer studies. Tamoxifen has been associated with reductions in total cholesterol and LDL cholesterol in the ranges of approximately

5–15% and 5–30%, respectively (Ilanchezhian *et al.,* 1995; Grey *et al.,* 1995b; Saarto *et al.,* 1996; Thangaraju *et al.,* 1994). Similar to raloxifene, the effect of tamoxifen on HDL has been neutral (Saarto *et al.,* 1996; Shewmon *et al.,* 1994; Biloma and Jordan 1996). Also similar to raloxifene, reductions in both fibrinogen (Love *et al.,* 1992b) and Lp (a) (Shewmon *et al.,* 1994) have been reported. Tamoxifen has either no effect (Grey *et al.,* 1995b) or increases triglycerides (Love *et al.,* 1990). This profile of activities is generally estrogen agonist and would be predicted to be generally favorable.

Data regarding tamoxifen effects on myocardial infarction come from breast cancer treatment and prevention trials, including the Scottish Cancer Trials Breast Group (McDonald and Stewar 1991), the Stockholm Breast Cancer Study Group (Rutqvist and Mattson, 1993), the NSABP B-14 trial (Costantino *et al.,* 1997), and NSABP BCPT (Fisher *et al.,* 1998). In the Scottish studies the risk of myocardial infarction was reduced significantly and there was a trend toward reduction of other ischemic events in tamoxifen users vs nonusers (McDonald and Stewart, 1991). The Swedish study also reported a significant reduction in cardiac disease with tamoxifen (Rutqvist and Mattson, 1993). The NSABP B-14 breast cancer treatment study showed a similar, but not statistically significant, 34% reduction in fatal heart disease (Costantino *et al.,* 1997). These breast cancer treatment studies are, however, confounded by a high death rate from breast cancer. The BCPT prevention trial did not show a reduced incidence of ischemic heart disease events, but this study was conducted in a younger population and the overall number of cardiac events was very low (Fisher *et al.,* 1998). As for both estrogens and other SERMs, definitive data supporting a cardiovascular benefit for tamoxifen have not been presented.

Effects of Tamoxifen on the Breast Tamoxifen has a widely studied and well recognized role in the treatment of breast cancer. This experience was summarized in an overview analysis (Early Breast Cancer Trialists' Collaborative Group, 1998) covering data on 37,000 women enrolled in 55 randomized clinical trials evaluating the effects of tamoxifen in patients with breast cancer. From the perspective of SERM biology, a key finding was the observation that tamoxifen benefits in breast cancer are restricted to cases of estrogen receptor-positive disease. Tamoxifen has been shown to have an optimum treatment duration for breast cancer treatment of 5 years; continuing the therapy longer results in a slight increase in recurrent tumor development compared to stopping after 5 years. This may be due to the emergence of tamoxifen-resistant (or, perhaps, tamoxifen-dependent) cell clones; the mechanism of this effect has not been clarified but may, at least in some cases, be attributable to somatic mutation of the estrogen receptor conferring an estrogen agonist profile to an antagonist drug.

Tamoxifen was the active treatment arm for the large NSABP BCPT study (Fisher *et al.,* 1998). This study showed that tamoxifen reduced the risk of invasive breast cancers by 49% and noninvasive cancers by 50% after 3 years of follow-up. Interestingly, this effect was approximately the same in magnitude for both pre- and postmenopausal women enrolled in this trial; this suggests a modulating role in the appearance of clinical breast cancers in both estrogen-replete and estrogen-deficient women. As seen in the MORE trial for raloxifene, there was no difference between placebo and tamoxifen in the incidence of estrogen receptor-negative tumors.

Results that conflict with the North American BCPT trial results have been reported from two smaller European breast cancer prevention studies (Powles *et al.,* 1998; Veronesi *et al.,* 1998). Many methodologic and study group differences between the trials (such as family history, use of HRT during trial, frequency of hysterectomy, loss to follow-up during study) could explain these differences, and the results of the North American study are generally considered to be sound. One area of much discussion is whether the results from studies like the MORE trial and the BCPT trial represent early treatment of preexisting lesions versus true "prevention" of cancer. Although the clinical implications of a substantial delay in progression of a preexisting lesion may well be beneficial, a true "prevention" effect would have a greater long-term health impact. A recent publication used modeling techniques to simulate tumor growth rate and thus to estimate the clinical appearance time of "new" versus "preexisting" tumors based on the BCPT clinical results (Radmacher and Simon, 2000), and the results suggested that the duration of the BCPT was sufficient for a substantial portion of the tumors that had been prevented from appearing in the tamoxifen arm had, indeed, truly been prevented from forming in the first place. As noted earlier, longer term observations of SERM treatment, as being conducted in the CORE trial, will provide further evidence to support or refute a true "prevention" effect of SERMs in breast cancer.

Effects of Tamoxifen on the Uterus Many years elapsed between the clinical introduction of tamoxifen and recognition of its potentially harmful effects in the uterus, largely due to a lack of systematic surveillance in early studies. It is now known that tamoxifen increases the risk of uterine bleeding and of both benign and malignant disease of the uterus (Fisher *et al.,* 1994, 1998; Cohen *et al.,* 1993; Cook *et al.,* 1995). Abnormalities such as adenomyosis, endometrial hyperplasia, and benign polyp formation are more common with tamoxifen treatment than with placebo treatment. Most importantly, the relative risk of endometrial cancer with tamoxifen treatment increases between 2.5- and 7.5-fold (Cosman and Lindsay, 1999). In the BCPT (Fisher *et al.,* 1998), the relative risk for uterine cancer was 2.53 ($p < 0.05$). In this study, the excess incidence of these cancers was only in women over age 50 (i.e., postmenopausal women). The endometrial cancers associated with tamoxifen use generally cause symptoms early (i.e., vaginal bleeding), and thus all of the endometrial cancers seen in the tamoxifen treatment arm in the BCPT were identified at an early stage of disease.

Other Effects of Tamoxifen Like raloxifene and estrogen, tamoxifen is associated with an approximate three-fold increase in the incidence of venous thromboembolism (Fisher and Redmand, 1992; McDonald *et al.,* 1995). Tamoxifen also increases the occurrence of hot flashes in both pre- and postmenopausal women (Fisher *et al.,* 1998). There also appears to be increased risk (RR 1.14, 95% CI 1.01–1.29) of cataract development with tamoxifen (Fisher *et al.,* 1998); the relation of this finding to the SERM profile is uncertain and may be an unrelated pharmacologic effect of tamoxifen.

TOREMIFENE

Toremifene is another clinically available SERM that has been characterized with respect to its estrogen target tissue pharmacologic profile. Toremifene is a tamoxifen analog (Fig. 1) that has been approved for treatment of breast cancer. Compared to tamoxifen, toremifene is less prone to DNA adduct formation (Hellmann-Blumberg *et al.,* 1998); in clinical use it demonstrates breast cancer efficacy similar to that seen for tamoxifen (Gershanovich *et al.,* 1997). Very limited bone and lipid testing has been published (Saarto *et al.,* 1996; Marttunen *et al.,* 1998), showing that toremifene exhibits expected SERM effects to reduce total and LDL cholesterol and to increase BMD.

Summary and Conclusions

SERMs represent a recently recognized pharmacologic class of compounds that share some of the agonist actions of estrogen but antagonize estrogen in other contexts. SERMs have been shown to be useful alternatives in the treatment of a variety of health conditions, including infertility, osteoporosis, and breast cancer. SERMs that have been introduced into clinical use show some heterogeneity in their SERM profile of action, with the most marked differences noted in the effects on the reproductive tract (Table I). These differences, coupled with insights into SERM action at the mechanistic level, provide assurance that this area will be a fertile field for the development of new compounds with newly targeted profiles of SERM action in the future.

Table I Clinical Safety of Raloxifene and Tamoxifen

	Raloxifene	Tamoxifen
Hot flashes	↑	↑
VTE risk	↑	↑
Endometrial thickness	↔	↑
Endometrial cancer risk	↔	↑
Leg cramps	↑	↑
Cataract risk	0	↑

Comparison of the safety of raloxifene and tamoxifen. Data are summarized from various studies and do not represent direct comparison (see text).

CHAPTER 39

Mechanisms of Estrogen Action in Bone

Roberto Pacifici
Division of Bone and Mineral Diseases, Washington University, St. Louis, Missouri 63110

Introduction

Postmenopausal osteoporosis is a heterogeneous disorder characterized by a progressive loss of bone tissue that begins after natural or surgical menopause and leads to fracture within 15–20 years from the cessation of the ovarian function.

Although suboptimal skeletal development ("low peak bone mass") and age-related bone loss may be contributing factors, a hormone-dependent increase in bone resorption and an accelerated loss of bone mass in the first 5 or 10 years after menopause appear to be the main pathogenetic factors (Riggs and Melton, 1986a,b) of this condition. That estrogen deficiency plays a major role in postmenopausal bone loss is strongly supported by the higher prevalence of osteoporosis in women than in men (Nilas and Christiansen, 1987), the increase in the rate of bone mineral loss detectable by bone densitometry after artificial or natural menopause (Genant *et al.,* 1982; Riggs *et al.,* 1981; Slemenda *et al.,* 1987), the existence of a relationship between estrogen levels and rates of bone loss (Johnston *et al.,* 1985; Ohta *et al.,* 1993; Ohta *et al.,* 1992), and the protective effect of estrogen replacement with respect to both bone mass loss and fracture incidence (Ettinger *et al.,* 1985; Horsman *et al.,* 1983; Lindsay *et al.,* 1980). The potential fracture risk for any postmenopausal female depends on the degree of bone turnover, the rate and extent of bone loss, associated disease processes that induce bone loss, age of menarche and menopause, and bone mass content achieved at maturity. The latter depends on the extent of estrogen exposure, habitual physical activity, quantity of calcium intake, and genetic predisposition. The manner with which the genetic "signal" conditions those biological mechanisms that are essential to achieve peak bone mass in adolescence is still unknown, although evidence shows that low peak bone mass may be linked to a particular vitamin D receptor phenotype (Morrison *et al.,* 1994).

The bone-sparing effect of estrogen is mainly related to its ability to block bone resorption (Manolagas and Jilka, 1995), although stimulation of bone formation is likely to play a contributory role (Bain *et al.,* 1993; Chow *et al.,* 1992). Estrogen-dependent inhibition of bone resorption is, in turn, due to both decreased osteoclastogenesis and diminished resorptive activity of mature osteoclasts. However, inhibition of osteoclast formation is currently regarded as the main mechanisms by which E_2 prevents bone loss (Manolagas and Jilka, 1995; Pacifici, 1996).

Cells and Cytokines That Regulate Osteoclast Formation

Osteoclasts arise by cytokine-driven proliferation and differentiation of hematopoietic precursors of the monocytic lineage. This process is facilitated by bone marrow stromal cells (Fig. 1), a population that provides physical support for nascent osteoclasts (OC) and produces soluble and membrane-associated factors essential for the proliferation and/or the differentiation of osteoclast precursors (Roodman, 1996). Lymphocytes of both T and B-cell lineages also contribute to the regulation of osteoclastogenesis, especially in stimulated conditions. For example, during inflammation, activated T cells assume a key role in stimulating osteoclast formation and do so by producing potent membrane-bound

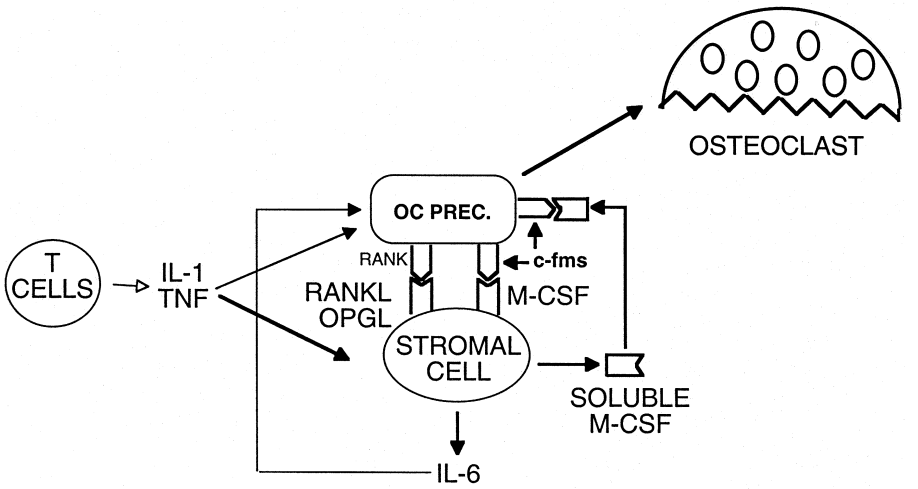

Figure 1 Cells and cytokines critical for osteoclast formation. Estrogen decreases osteoclast formation by downregulating the monocytic production of IL-1 and TNF and the stromal cell production of M-CSF and IL-6.

and soluble cytokines (Kong *et al.,* 1999a). B cells have been reported to have complex and controversial effects on osteoclastogenesis. For example, B-cell-deficient mice have been found to display decreased trabecular area and increased bone resorption, as compared to B-replete mice of the same strain (Dissanayake *et al.,* 1997), suggesting that B cells inhibit bone resorption and osteoclastogenesis. In contrast, other studies have shown that estrogen deficiency upregulates B lymphopoiesis in the bone marrow (Erben *et al.,* 1998; Masuzawa *et al.,* 1994), suggesting that cells of the B lineage may contribute to the increased OC production characteristic of estrogen-deficient animals. In humans, B cells inhibit OC formation, as they are an important source of TGFβ, a factor that inhibits osteoclast formation by inducing apoptosis of early and late osteoclast precursors and mature osteoclasts (Weitzmann *et al.,* 2000).

Among the cytokines involved in the regulation of osteoclast formation are receptor activator NFκB ligand (RANKL) (also known as OPGL, TRANCE, or ODF) and M-CSF (Kong *et al.,* 1999b; Lacey *et al.,* 1998; Macdonald *et al.,* 1986; Suda *et al.,* 1992; Tanaka *et al.,* 1993; Yasuda *et al.,* 1998). These factors are produced primarily by stromal cells, osteoblasts, and activated T cells (Kong *et al.,* 1999a).

RANKL is a member of the TNF family, which exists in a membrane-bound and in a soluble form. RANKL binds to the transmembrane receptor RANK, which is expressed on the surface of osteoclasts and osteoclast precursors of the monocytic lineage (Lacey *et al.,* 1998). RANKL binds also to OPG, a soluble decoy receptor produced by numerous hematopoietic cells. Thus, OPG, by sequestering RANKL and preventing its binding to RANK, functions as a potent antiosteoclastogenic cytokine (Simonet *et al.,* 1997).

In the presence of M-CSF, RANKL induces the differentiation of monocytic cells into osteoclasts (Lacey *et al.,* 1998) by activating the MAP kinase JNK, an enzyme that enhances the production of two essential osteoclastogenic transcription factors: c-*Fos* and c-*Jun* (Hsu *et al.,* 1999). RANKL binding to RANK also activates NF-κB, a family of transcription factors essential for osteoclast formation and survival.

In physiological conditions, M-CSF and RANKL are the only factors produced in the bone marrow in an amount sufficient to induce osteoclast formation. Thus, M-CSF and RANKL are regarded as true essential physiologic osteoclastogenic cytokines. The critical role of each of these cytokines in the osteoclastogenic process is demonstrated by the finding that deletion of either gene prompts osteopetrosis due to the absence of osteoclasts, a circumstance reversed by administration of the relevant cytokine (Felix *et al.,* 1990; Kodama *et al.,* 1991; Kong *et al.,* 1999b).

M-CSF induces the proliferation of early osteoclast precursors, the differentiation of more mature osteoclasts, and the fusion of mononucleated preosteoclasts and increases the survival of mature osteoclasts (Fuller *et al.,* 1993; Sarma and Flanagan, 1996; Suda *et al.,* 1999). RANKL does not induce cell proliferation, but promotes the differentiation of osteoclast precursors from an early stage of maturation to fully mature multinucleated osteoclasts. RANKL is also capable of activating mature osteoclasts, thus rendering these cells capable of resorbing bone.

While consensus exists that RANKL stimulates bone resorption in organ cultures, the effect of M-CSF on bone resorption is controversial, as both inhibitory and stimulatory effects on bone resorption have been reported (Edwards *et al.,* 1998; Fuller *et al.,* 1993; Hattersley *et al.,* 1988; Lees and Heersche, 1999; Sarma and Flanagan, 1996; Suda *et al.,* 1999).

Monocytes, stromal cells, osteoblasts, and lymphocyte produce inflammatory cytokines, which have direct proosteoclastogenic effects. Among these factors are IL-1, IL-6, IL-11, and TNF (Bertolini *et al.,* 1986; Canalis, 1986; Girasole *et al.,* 1992; Gowen *et al.,* 1983, 1985; Jilka *et al.,* 1992; Lorenzo *et al.,* 1987; Passeri *et al.,* 1993; Stashenko

et al., 1987; Thomson *et al.,* 1987). These factors stimulate osteoclast formation by increasing the stromal cell production of RANKL (Hofbauer *et al.,* 1999b; O'Brien *et al.,* 1999; Yasuda *et al.,* 1998) and M-CSF (Fibbe *et al.,* 1988; Thery *et al.,* 1992). Another factor relevant for osteoclastogenesis is TGFβ. This cytokine stimulates OPG production (Takai *et al.,* 1998), thus inhibiting osteoclast formation.

While in physiological conditions, IL-1, IL-6, and TNF are produced in the bone marrow at low concentration and their bone marrow levels increase both during inflammation and in conditions of estrogen deficiency (Manolagas and Jilka, 1995; Pacifici, 1996). Thus, IL-1, IL-6, and TNF play a critical role in enhancing osteoclast production, survival, and activity in pathological conditions.

Kobayasi *et al.* (2000) demonstrated that TNF, in the presence of M-CSF, induces the differentiation of monocytes into mature multinucleated osteoclasts (through NF-κB and JNK activation), which are, however, incapable of resorbing bone. Neither IL-1 nor IL-6 is capable of directly promoting the differentiation of osteoclast precursors into multinucleated osteoclasts. However, the addition of IL-1 to cultures of osteoclasts generated using TNF and M-CSF induces the capacity of resorbing bone and increases their survival.

It has been demonstrated that T cells from ovariectomized animals release increased amounts of TNF and that T cell-produced TNF synergizes with RANKL, thus potentiating osteoclast formation (Cenci *et al.,* 2000b).

Thus, TNF is a true osteoclastogenic cytokine, which can induce osteoclast formation via a direct effect on osteoclast precursors and by synergizing with RANKL. In contrast, IL-1 is incapable of inducing osteoclast formation, although it promotes osteoclast activation and survival.

Because M-CSF and RANKL are present in the bone marrow in physiological conditions, osteopetrosis is not a feature of transgenic mice lacking the capacity of producing and/or responding to IL-1, IL-6, or TNF (Ammann *et al.,* 1997; Lorenzo *et al.,* 1998; Poli *et al.,* 1994). Thus, IL-1, IL-6, and TNF stimulate osteoclastogenesis in pathological conditions, but are not essential for baseline osteoclastogenesis.

In summary, accumulated data demonstrate that RANKL and M-CSF are the only two factors known at the present time that are absolutely critical for osteoclast formation in physiological conditions. In contrast, the inflammatory cytokines IL-1, IL-6, and TNF are not essential for the maintenance of baseline osteoclastogenesis, although they are key for enhancing osteoclast formation and osteoclast activity during inflammation (Isomaki and Punnonen, 1997; Suda *et al.,* 1999) and in conditions of E_2 deficiency (Manolagas and Jilka, 1995; Pacifici, 1996).

Effects of Estrogen on the Production of Osteclastogenic Cytokines

It is now recognized that estrogen downregulates the production of several proosteoclastogenic factors, including IL-1, IL-6, TNF, M-CSF, and PGE_2. In addition, estrogen stimulates the production of important antiosteoclastogenic factors, including IL-1ra (Pacifici *et al.,* 1993), OPG (Hofbauer *et al.,* 1999a), and TGFβ (Oursler *et al.,* 1991).

The cytokines first recognized to be regulated by estrogen were IL-1 and TNF. This observation was prompted by the finding that monocytes of patients with "high turnover" osteoporosis, the histological hallmark of postmenopausal osteoporosis, secrete increased amounts of IL-1 (Pacifici *et al.,* 1987). Cross-sectional and prospective comparisons of pre- and postmenopausal women revealed that monocytic production of IL-1 and TNF increases after natural and surgical menopause and is decreased by treatment with estrogen and progesterone (Pacifici *et al.,* 1989, 1990). Subsequent observations showed that the postmenopausal increase in IL-1 activity results from an effect of estrogen on the production of both IL-1β and IL-1ra (Pacifici *et al.,* 1993). Studies in normal women undergoing ovariectomy (ovx) (Fiore *et al.,* 1993; Pacifici *et al.,* 1991) revealed that estrogen withdrawal is associated not only with an increased production of IL-1 and TNF, but also of GM-CSF. Changes in these cytokine levels occur in a temporal sequence consistent with a causal role of IL-1, TNF, and GM-CSF in the pathogenesis of ovx induced bone loss (Pacifici *et al.,* 1991).

Estrogen and progesterone have been shown to decrease the secretion of IL-1 from peripheral blood and bone marrow monocytes and to decrease the steady-state expression of IL-1 mRNA in monocytes (Polan *et al.,* 1988). However, the exact molecular mechanism by which E_2 decreases IL-1 production remains to be determined. Estrogen has been shown to increase the expression of the decoy type II, IL-1 receptor in bone marrow cells and osteoclasts (Sunyer *et al.,* 1997). Thus, upregulation of cell responsiveness to IL-1 via downregulation of IL-1RII is also likely to be a key mechanism by which estrogen deficiency induces bone loss.

The mechanism by which estrogen represses TNF gene expression has been found to involve ERβ and AP-1 (Fig. 2). ERα and ERβ respond differently to ligands, leading to opposite effects on AP-1-induced gene expression (Paech *et al.,* 1997). Specifically, whereas ERα-mediated effects of E_2 lead to stimulation of AP-1-induced gene expression, E_2 acts as a repressor of AP-1-induced transcription when bound to ERβ (Paech *et al.,* 1997).

Cells of the monocytic lineage are known to express both ERα and ERβ. Estrogen binding to ERβ leads to decreased activation of the Jun terminal kinase (JNK), a phenomenon that leads to decreased production of c-Jun and JunD, two members of the AP-1 family of transcription factors (Srivastava *et al.,* 1999). Decreased AP-1-production results in decreased AP-1-induced TNF gene expression and lower TNF production (An *et al.,* 1999; Srivastava *et al.,* 1999)

Studies conducted to determine if estrogen regulates the production of IL-6 revealed that in murine stromal and osteoblastic cells, IL-6 production is inhibited by the addition of estrogen (Girasole *et al.,* 1992) and is stimulated by estrogen withdrawal (Passeri *et al.,* 1993).

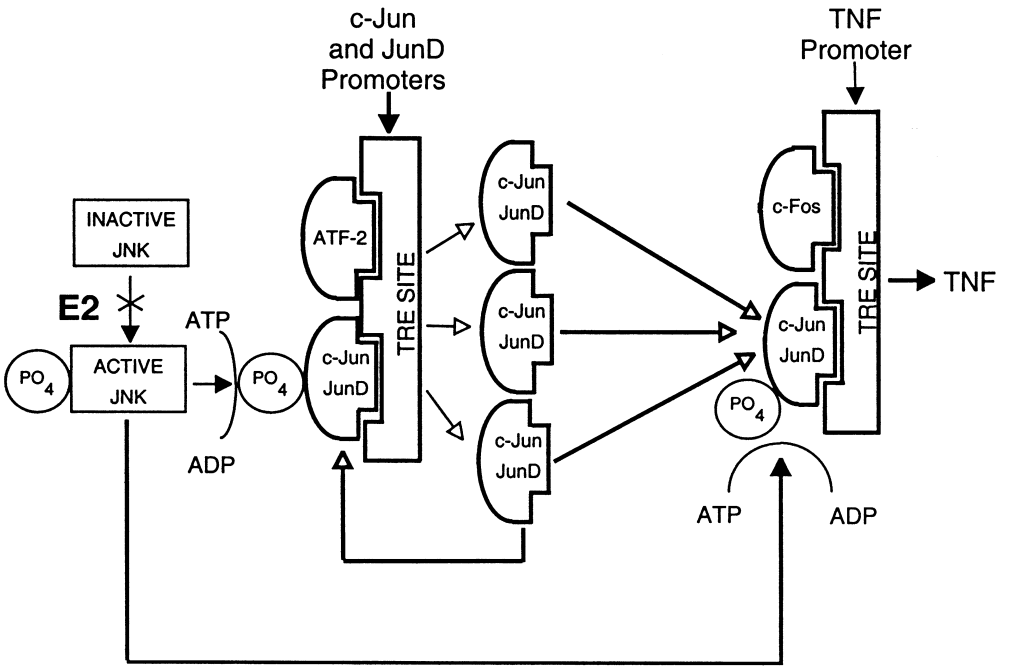

Figure 2 Mechanism by which estrogen represses TNF gene expression. By blocking JNK activation, estrogen blunts the autostimulation of the Jun promoter, thus decreasing the production of Jun. JNK inhibitions also decrease the phosphorylation in the N terminus of Jun bound to the TNF promoter, thus repressing its transcriptional activity.

In vivo studies also revealed that the production of IL-6 is increased in cultures of bone marrow cells from ovx mice (Jilka *et al.,* 1992). This effect is mediated, at least in the mouse, by an indirect effect of estrogen on the transcription activity of the proximal 225-bp sequence of the IL-6 promoter (Pottratz *et al.,* 1994; Ray *et al.,* 1994)

Interestingly, although studies with human cell lines demonstrated inhibitory effects of estrogen on the human IL-6 promoter (Stein and Yang, 1995), three independent groups have failed to demonstrate an inhibitory effect of estrogen on IL-6 production from human bone cells and stromal cells expressing functional estrogen receptors (Chaudhary *et al.,* 1992; Rickard *et al.,* 1992; Rifas *et al.,* 1995). These data raise the possibility that the production of human IL-6 protein does not increase in conditions of estrogen deficiency. This is further supported by a report that surgical menopause in humans is not followed by an increase in IL-6, although it causes an increase in the soluble IL-6 receptor (Girasole *et al.,* 1995).

Studies have unveiled that one of the key mechanism by which estrogen regulates osteoclastogenesis is by modulating the stromal cell production of M-CSF.

In conditions of E_2 deficiency, the high bone marrow levels of IL-1 and TNF lead to the expansion of a stromal cell population that produces larger amounts of soluble M-CSF (Kimble *et al.,* 1996). These high M-CSF-producing stromal cells have an increased capacity to support osteoclastogenesis (Fig. 3). Interestingly, estrogen has no direct regulatory effects on the production of soluble M-CSF as it regulates M-CSF secretion exclusively by conditioning the differentiation of stromal toward a phenotype characterized by a lower production of M-CSF. The high M-CSF-producing stromal cells found in estrogen-deficient mice are characterized by increased phosphorylation of the transcription factor Egr-1.

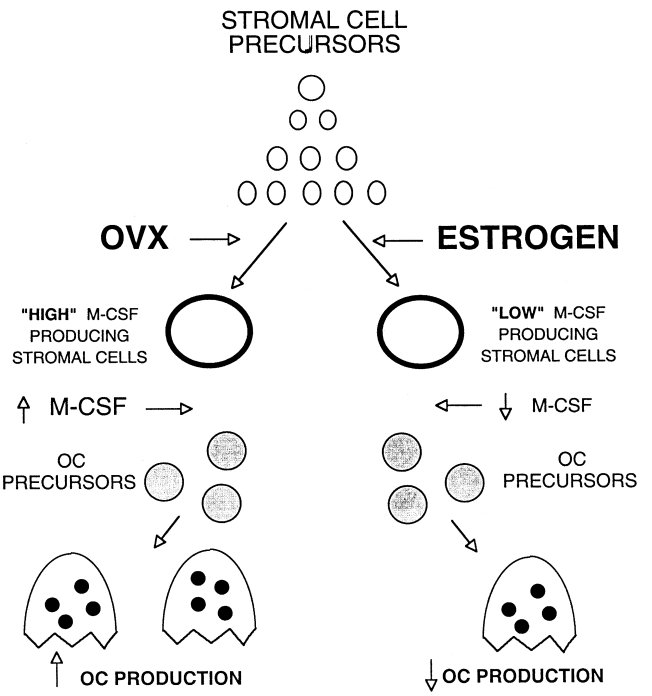

Figure 3 Estrogen regulates the differentiation of stromal cell precursors and leads to the formation of "low" M-CSF-producing stromal cells.

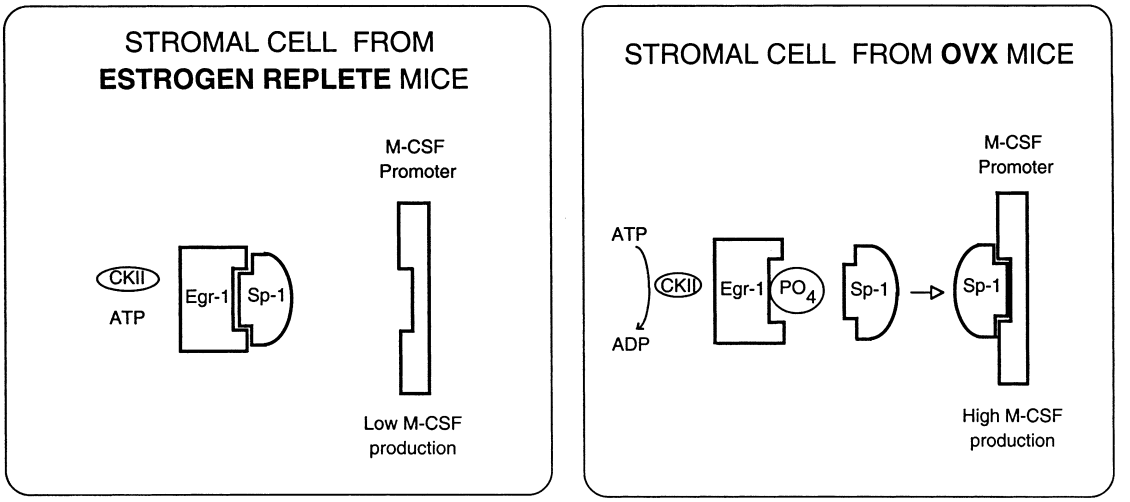

Figure 4 Mechanism by which stromal cells from estrogen-deficient mice produce low levels of M-CSF. Stromal cells from estrogen-deficient mice exhibit increased CKII-dependent phosphorylation of the nuclear protein Egr-1. Phosphorylated Egr-1 binds less avidly to the transcriptional activator Sp-1, and the resulting higher levels of free Sp-1 stimulate M-CSF gene expression.

While Egr-1 binds and sequesters the nuclear protein Sp-1, phosphorylated Egr-1 does not bind to Sp-1. As a result, cells from estrogen-deficient mice are characterized by increased levels of free Sp-1. This protein binds to the M-CSF promoter and stimulates M-CSF gene expression (Srivastava *et al.,* 1998) (Fig. 4).

In addition to an indirect effect on soluble M-CSF, E_2 has been shown to decrease the production of membrane-bound M-CSF via a direct effect on bone marrow cells (Lea *et al.,* 1999; Sarma *et al.,* 1998). However, the source of membrane-bound M-CSF under estrogen regulation remains to be defined. Regardless of the specific cell involved, estrogen regulates this key osteoclastogenic cytokine by at least two distinct mechanisms.

Little information on the effects of menopause on the production of RANKL is currently available. However, the promoter region of the RANKL gene does not contain regions known to be repressed (directly or indirectly) by estrogen (Kitazawa *et al.,* 1999). Therefore it is likely that future studies will confirm the preliminary observation available at the moment, which indicates that estrogen does not regulate RANKL. In contrast, estrogen has been shown to increase the production of OPG in osteoblastic cells (Hofbauer *et al.,* 1999a). Thus, estrogen enhancement of OPG secretion by osteoblastic cells is likely to represent another major mechanism in explaining the antiresorptive action of estrogen on bone.

Another possible intermediary in estrogen action is transforming growth factor β (TGFβ). This growth factor is a multifunctional protein that is produced by many mammalian cells, including osteoblasts, and has a wide range of biological activities. TGFβ is a potent osteoblast mitogen (Oursler, 1994). In specific experimental conditions, TGFβ decreases both osteoclastic resorptive activity and osteoclast recruitment.

Oursler *et al.* (1991) have reported that estrogen increases the steady-state level of TGFβ mRNA and the release of TGFβ protein. This mechanism provides the first example of "positive" effects of estrogen in bone, which may result in decreased bone turnover.

Effects of Menopause on the Production of Bone-Resorbing Cytokines

The abundance of *in vitro* studies that demonstrated the potent effects of IL-1, TNF, and IL-6 on bone prompted a series of investigations on the relationship among bone remodeling, cytokine production, and osteoporosis. These studies were conducted using cultures of peripheral blood monocytes because these cells, when cultured in polystyrene plates with ordinary tissue culture medium (which contains small amounts of LPS), express IL-1 and TNF mRNA and secrete small quantities of IL-1 and TNF protein (Dinarello, 1989; Fuhlbrigge *et al.,* 1987; Kitazawa *et al.,* 1994).

Another reason that prompted investigators to select this model is that the secretion of cytokines from peripheral blood monocytes reflects the secretory activity of bone marrow mononuclear cells (Kitazawa *et al.,* 1994). This is not surprising because the *in vitro* production of cytokines from cultured monocytes is a reflection of phenotypic characteristics acquired in response to local stimuli during their maturation in the bone marrow, and these characteristics are maintained after release into the circulation (Witsell and Schook, 1991). This phenomenon is thought to play an important role in providing the basis for tissue and functional specificity. Consequently, monocyte cytokine secretion is relevant to postmenopausal bone loss, as it mirrors cytokine secretion from marrow resident cells of the

monocytemacrophage lineage or monocytes that have homed to bone (Horowitz, 1993).

It is also important to recognize that monocytes are the major source of IL-1 and TNF in bone marrow (Dinarello, 1989). Moreover, the anatomical proximity of mononuclear cells to remodeling loci, the capacity to secrete numerous products all recognized for their effects in bone remodeling, and the expression of integrin receptors (Hynes, 1992), which make these cells capable of adhering to the bone matrix, make them likely candidates as participants in skeletal remodeling.

Investigations of monocyte production of IL-1 led to the discovery that monocytes of patients with "high turnover" osteoporosis secrete higher IL-1 activity than those from patients with "low turnover" osteoporosis and, indeed, those from normal subjects (Pacifici *et al.,* 1987). Because increased bone turnover is characteristic of the early postmenopausal period, these data suggested the hypothesis that the bone-sparing effect of estrogen is related to its ability to block the production of IL-1 from cells of the monocytic lineage. This hypothesis was first tested on studies designed to investigate the effect of natural menopause and estrogen/progesterone replacement on the monocytic production of IL-1. Results showed that IL-1 activity increases after menopause in both normal and osteoporotic women. However, whereas IL-1 activity in normal women returned spontaneously to premenopausal levels within 7 years after menopause, in osteoporotic subjects the increase in IL-1 activity lasted up to 15 years after menopause (Pacifici *et al.,* 1989). As a result, the finding of increased IL-1 activity 8–15 years after menopause is characteristic of women with postmenopausal osteoporosis. Data also showed that treatment of women in both the early and the late postmenopausal periods with estrogen and progesterone normalizes IL-1 activity within the first month of treatment. Similar effects of menopause have also been documented for TNF and GM-CSF. The latter is a cytokine recognized as a potent stimulator of osteoclastogenesis (Pacifici *et al.,* 1990).

The increased production of cytokines associated with estrogen withdrawal occurs in a time fashion consistent with a direct causal role of these factors in postmenopausal bone loss. This was demonstrated by analyzing the time course of changes in cytokine secretion and markers of bone turnover in normal women undergoing bilateral ovariectomy. Using this strategy, it was demonstrated that the monocytic secretion of GM-CSF increases within 1 week after ovariectomy. This is followed by a marked increase in TNF and IL-1 at 2 weeks post surgery. The increase in the latter two cytokines is associated with a concurrent increase in biochemical indices of bone resorption (Pacifici *et al.,* 1991). Initiation of estrogen replacement therapy at 1 month after ovariectomy results in the rapid normalization of cytokine production (Pacifici *et al.,* 1991). Subsequent studies confirmed that natural and surgical menopause are associated with an increased production of IL-1 and TNF from peripheral blood and bone marrow monocytes (Fiore *et al.,* 1993; Kimble *et al.,* 1994; Matsuda *et al.,* 1991; Pioli *et al.,* 1992). An increased mononuclear cell production of IL-6 has also been reported after ovariectomy (Pioli *et al.,* 1992). Because IL-1 and TNF are powerful stimulators of IL-6 production (Chaudhary *et al.,* 1992; Lacey *et al.,* 1993), the latter is likely to reflect the impact of the higher levels of IL-1 and TNF induced by ovariectomy.

That the increased monocytic production of cytokines plays a direct role in inducing bone resorption was later demonstrated by Cohen-Solal *et al.* (1993), who examined the bone resorption activity of monocyte supernatants obtained from pre- and postmenopausal women. Using this approach, it was found that culture media of monocytes obtained from postmenopausal women have a higher *in vitro* bone resorption activity than that from either premenopausal women or estrogen-treated postmenopausal women. The increased bone resorption activity of media from postmenopausal subjects is blocked by the addition of IL-1ra and anti-TNF antibody.

Studies by Suda and co-workers (1999) of bone marrow supernatants from estrogen-deficient mice have also indicated that IL-1 plays a dominant role in mediating the impact of estrogen withdrawal on bone resorption. Antibodies against IL-1α (the dominant IL-1 species in mice) but not antibodies against many other cytokines completely blocked the bone resorption activity of the monocyte-conditioned medium. Antibodies IL-1β, IL-6, and IL-6 receptor resulted in a partial neutralization of bone resorption activity.

Thus, it is likely that IL-1 and TNF account for most of the resorption activity produced by cultured monocytes. Yet undetermined is whether this effect is direct or mediated by other factors produced in response to IL-1 and TNF.

More direct evidence in favor of a cause–effect relationship between increased production of IL-1 and TNF (and IL-6) and postmenopausal osteoporosis is also provided by findings that IL-1, TNF, and IL-6 mRNAs are expressed more frequently in bone cells from untreated postmenopausal women than in those from women on estrogen replacement.

Effect of Menopause on the Production of IL-1 Receptor Antagonist

IL-1 bioassays are based on the measurement of the proliferation of IL-1-dependent cell lines. Thus, IL-1 bioactivity is stimulated by IL-1 and inhibited by IL-1ra. Therefore, IL-1 bioactivity reflects closely the IL-1/IL-1ra ratio. Because mammalian cells secrete IL-1ra along with IL-1, the regulatory effects of ovarian steroid on IL-1 bioactivity may involve both IL-1 (α or β) and IL-1ra. Studies have addressed this issue and revealed that estrogen and progesterone downregulate the production of both IL-1β and IL-1ra (Pacifici *et al.,* 1993). In contrast, estrogen and progesterone have no inhibitory effects on the secretion of

IL-1α. Interestingly, in normal women, the decrease in IL-1 bioactivity that accompanies the passage of time since menopause is associated with a parallel increase in the secretion of IL-1ra. Thus, in normal women, the increasing production of IL-1ra that accompanies the passage of time since menopause is likely to help restore normal monocytic IL-1 bioactivity after menopause. IL-1 is a powerful autocrine factor. In fact, IL-1 produced by monocytes binds to IL-1 receptors expressed on the monocyte surface and further stimulates IL-1 secretion (Dinarello *et al.,* 1991). Because this process is inhibited by IL-1ra, the progressive postmenopausal increase in IL-1ra secretion observed in nonosteoporotic women may also help explain the parallel decrease in the secretion of IL-1β observed in these subjects as time elapses from menopause.

As discussed earlier, in osteoporotic women the production of IL-1 bioactivity is increased for a length of time twice as long as in normal women. This is associated with an increased secretion of IL-1β, which persists as long as the increase in IL-1 bioactivity. Interestingly, the levels of IL-1ra measured in osteoporotic women are higher than those of normal women, but do not change with the passage of time since menopause (Pacifici *et al.,* 1993). Thus, in osteoporotic women, IL-1 bioactivity appears to be regulated primarily by changes in the production of IL-1β.

Because only a small fraction of the cytokines released into the bone microenvironment escape into the systemic circulation, studies based on the measurement of serum cytokine levels have been, for the most part, unrewarding. However, the development of supersensitive cytokine assays has made it possible to document that the serum IL-1/IL-1ra ratio is significantly higher in women with postmenopausal osteoporosis than in their normal counterparts (Khosla *et al.,* 1994). The use of these sensitive assays has also led to the demonstration that the rate of bone loss in osteoporotic women correlates inversely with serum IL-1ra levels (Hannon *et al.,* 1993). Taken together, these data indicate that a modulatory action of estrogen and progesterone on the secretion of IL-1ra contributes to the events of the menopause and the effects of hormone replacement on IL-1 bioactivity.

The molecular mechanism by which estrogen and menopause regulate the monocytic production of IL-1ra remains to be defined. The local microenvironment is known to condition the production of IL-1ra. For example, alveolar macrophages from patients with interstitial lung disease produce more IL-1ra than those from normal controls (Galve-de Rochemonteix *et al.,* 1992). It is likely, therefore, that the increased bone resorption induced by IL-1 and other cytokines after menopause may lead to the release of factors in the bone microenvironment that, in turn, stimulate the secretion of IL-1ra. One such a factor is TGFβ (Arend, 1991), a constituent of the bone matrix released locally upon activation of osteoclastic bone resorption (Oreffo *et al.,* 1989; Pfeilschifter *et al.,* 1988). Differences in the secretory pattern of IL-1ra observed between normal and osteoporotic women could, indeed, result from the more intense bone resorption and the resulting higher release of TGFβ that characterize the postmenopausal period of women with osteoporosis (Delmas, 1988).

Since an altered T4/T8 lymphocyte ratio (Imai *et al.,* 1990; Rosen *et al.,* 1990) and abnormal mixed leukocyte reactions have been reported in osteoporotic patients (Duke-Cohan *et al.,* 1985), it is conceivable that specific monocyte phenotypes characterized by the ability to produce constitutively high amounts of IL-1ra may be expressed preferentially in osteoporotic patients. Should this be the case, the difference in IL-1ra levels observed between normal and osteoporotic patients could be related to intrinsic differences in the prevailing monocyte population.

Effects of Ovariectomy on the Response of Maturing Osteoclasts to Osteclastogenic Cytokines

Osteoclastic differentiation of monocytic cells is driven by engagement of the receptors c-fms and RANK by M-CSF and RANKL, respectively. Thus one additional mechanism by which estrogen may repress osteoclast formation is by diminishing the responsiveness of maturing osteoclasts to stimulatory cytokines.

While no effects of estrogen have been described on the expression of c-fms or M-CSF signaling, estrogen appears to be capable of decreasing the responsiveness of maturing osteoclasts to RANKL. In fact, in vitro estrogen treatment decreases RANKL-induced osteoclast formation by about 50% (Shevde *et al.,* 2000). This phenomenon is a result of the ability of estrogen to repress RANKL-induced JNK activation and the consequent diminished production of c-Jun and c-Fos. However, it should be emphasized that the contribution of this mechanism to the regulation of osteoclast formation *in vivo* remains to be determined.

Cytokine Inhibitors and Transgenic Mice: Tools for Investigating the Contribution of Candidate Factors to Ovariectomy-Induced Bone Loss

Because several cytokines are under hormonal control and exhibit overlapping biological effects, analysis of cytokine expression and secretion in bone and bone marrow cells is unlikely to provide definite evidence in favor of a cause–effect relationship between increased cytokine production and postmenopausal bone loss. However, direct demonstration that cytokines mediate the impact of estrogen deficiency on bone can be achieved with the use of genetic models and specific cytokine antagonists, such as the IL-1 antagonist, IL-1ra, and the TNF antagonist, TNF-binding protein (TNFbp).

Lorenzo *et al.* have shown that mice insensitive to IL-1 due to the lack of IL-1 receptor type I are protected against ovx-induced bone loss. These findings confirmed earlier studies conducted by treating ovariectomized rats with IL-1ra beginning either at the time of surgery (early

postovariectomy period) or 4 weeks later (late postovariectomy period) (Kimble *et al.,* 1994). These experiments revealed that the functional block of IL-1 has distinct effects in both periods. In fact, in the second month after ovariectomy, treatment with IL-1ra completely blocked bone loss, duplicating the effect of estrogen. In contrast, in the first month after ovariectomy, bone loss was completely prevented by estrogen replacement therapy and decreased IL-1ra treatment by about 40%. These findings indicated that cytokines produced independently of IL-1 contribute to induce bone loss in the early postovariectomy period. Because IL-1 and TNF have powerful additive and synergistic effects in many systems, TNF appeared to be the most likely candidate factor. That TNF contributes to bone loss in the early postovariectomy period was demonstrated by treating ovariectomized rats with IL-1ra, TNFbp, and a combination of the two inhibitors for 2 weeks starting at the time of surgery (Kimble *et al.,* 1995). This critical experiment demonstrated that while treatment with either IL-1ra or TNFbp alone partially prevented ovariectomy-induced bone loss, complete bone sparing was achieved when ovariectomized rats were treated simultaneously with IL-1ra and TNFbp.

Histomorphometric studies also demonstrated important effects of IL-1ra and TNFbp on bone formation (Kimble *et al.,* 1994, 1997). Two weeks after surgery there were no significant differences in trabecular and cortical bone formation rate between ovariectomy and sham-operated rats. Interestingly, however, treatment with either IL-1ra or TNFbp induced a marked increase in bone formation rate in ovariectomized but not in sham-operated rats. This suggests that inhibition of endocortical bone formation resulting from high levels of IL-1 and TNF (characteristic of the early postovariectomy period) counteracts and masks direct stimulatory effects of ovariectomy on bone formation. In contrast, in the late postovariectomy period, bone formation is increased in the trabecular but not in the cortical bone, and in this time period neither IL-1ra nor TNFbp has significant effects on this index.

Thus, when taken together, data support the hypothesis that estrogen deficiency modulates bone resorption via an IL-1/TNF-dependent pathway and bone formation via a complex mechanism that involves an IL-1/TNF-independent stimulatory effect and an IL-1/TNF-mediated inhibitory effect. Early after ovariectomy the dominant phenomena mediated by IL-1 and TNF are the stimulation of osteoclast activity and the inhibition of bone formation. As time progresses from ovariectomy, the IL-1- and TNF-dependent inhibition of bone formation subsides while the most important effect of these factors become the induction of osteoclastogenesis.

These initial observations about the causal role of TNF were confirmed by Ammann *et al.* (1997), who reported that transgenic mice insensitive to TNF due to the overexpression of soluble TNF receptor are also protected against ovx-induced bone loss (Ammann *et al.,* 1997). Finally, an orally active inhibitor of IL-1 and TNF production was also shown to completely prevent bone loss in ovx rats (Bradbeer *et al.,* 1996).

Although the finding that functional block of either IL-1 or TNF is sufficient to prevent ovx-induced bone loss may appear to be difficult to explain, it should be emphasized that in most biological systems, IL-1 and TNF have potent synergistic effects. Thus, the functional block of one of these two cytokines elicits biological effects identical to those induced by the block of both IL-1 and TNF. The long-term stimulation of bone resorption that follows ovx is sustained primarily by an expansion of the osteoclastic pool. Because OC formation is stimulated synergistically by IL-1 and TNF (Kitazawa *et al.,* 1994), it is not surprising that long-term inhibition of either IL-1 or TNF results in complete prevention of ovx-induced bone loss.

Although evidence has accumulated that demonstrates that TNF plays a key role in the pathogenesis of ovx-induced bone loss, cells producing TNF have been scarcely defined. We have found that T cells in ovx mice are the major source of TNF. Ovariectomy enhances the T-cell production of TNF, which, acting through the TNF receptor p55, augments M-CSF and RANKL-induced osteoclastogenesis (Cenci *et al.,* 2000b). Attesting to the relevance of this phenomenon *in vivo*, ovariectomy fails to induce bone loss and stimulate bone resorption (Fig. 5) in T-cell-deficient mice. These data establish T cells as essential mediators of the bone-wasting effects of estrogen deficiency *in vivo* (Cenci *et al.,* 2000b). TNF potentiates the response of maturing osteoclasts to RANKL because TNF and RANKL synergistically activate the NF-κB and JNK pathways (Lam *et al.,* 2000).

While studies with transgenic mice and inhibitors of IL-1 and TNF have consistently demonstrated that IL-1 and TNF are key inducers of bone loss in ovx animals, investigations aimed at assessing the contribution of IL-6 to ovx-induced bone loss have yielded conflicting results. In favor of a causal role for IL-6 in ovx-induced bone loss is the report of Poli *et al.* (1994) indicating that IL-6 knockout mice are protected against the loss of trabecular bone induced by ovx. Against a significant pathogenetic role of IL-6 are studies demonstrating that osteoporosis is not a feature of transgenic mice overexpressing IL-6 (Kitamura *et al.,* 1995). Studies have also been conducted by injecting an antibody-neutralizing IL-6 in ovx mice. Neutralizing IL-6 prevents the increase in OC formation induced by estrogen deficiency (Jilka *et al.,* 1992; Kimble *et al.,* 1997), but does prevent ovx-induced bone loss and does not decrease *in vivo* bone resorption (Kimble *et al.,* 1997). These findings confirm that IL-6 contributes to the expansion of the osteoclastic pool induced by ovx. However, this cytokine does not appear to be the dominant factor in inducing bone loss in estrogen-deficient mice.

Studies have been conducted to elucidate the relevance of M-CSF in the pathogenesis of ovx-induced bone loss *in vivo*. In agreement with the key role of M-CSF in osteoclastogenesis, these studies have demonstrated that the functional block of M-CSF by the anti-M-CSF antibody 5A1

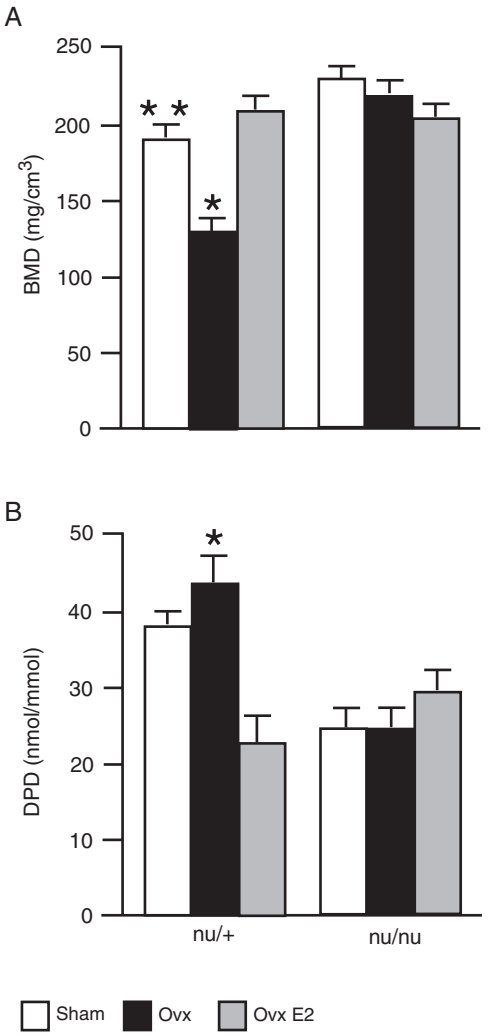

Figure 5 Ovariectomy fails to induce bone loss and upregulate DPD excretion in nude mice ($n = 6$ per group). $^{*}p < 0.05$ compared to all other groups. $^{*}p < 0.05$ compared to sham nu/nu. (A) Trabecular BMD (mean ± SEM) of the tibia was measured 4 weeks after surgery in excised tibiae by pQCT. (B) DPD excretion (mean ± SEM) 4 weeks after surgery.

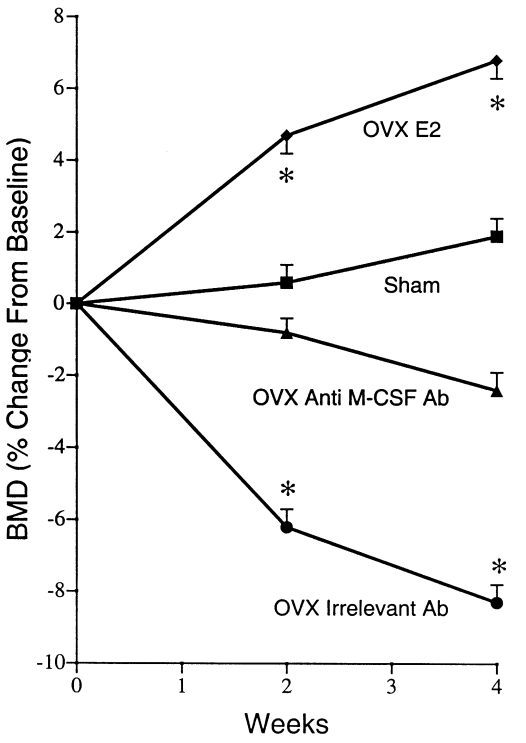

Figure 6 Treatment with anti-M-CSF Ab 5A1 Ab prevents ovx-induced bone loss. Results (mean ± SEM) are expressed as percentage change from baseline. $^{*}p < 0.05$ compared to baseline and to any other group.

completely prevents ovx-induced bone loss in mice (Fig. 6) (Cenci *et al.,* 2000a). That M-CSF is another cytokine that plays a key role in ovx-induced bone loss was further demonstrated by examining mice lacking the transcription factor Egr-1 (Wilson *et al.,* 1992). Egr-1-deficient mice produce maximal amounts of M-CSF both in the presence and in the absence of estrogen (Srivastava *et al.,* 1998). Thus, Egr-1-deficient mice have high M-CSF stromal cell production, increased osteoclastic bone resorption, and low bone density (Cenci *et al.,* 2000a). Furthermore, ovx does not further stimulate osteoclast formation in these mice, as it fails to further enhance M-CSF production. Importantly, Egr-1-deficient mice are completely protected against ovx-induced bone loss, a finding that confirms the relevance of M-CSF (Cenci *et al.,* 2000a).

No studies have been conducted to determine the effects of ovx in mice insensitive to RANKL, although one would predict that these animal will sustain significant bone loss due to the stimulated production of TNF.

The role of IL-1, IL-6, TNF, M-CSF, and RANKL in osteoclastogenesis has been directly investigated using murine bone marrow cultures and RANKL-stimulated monocytes obtained from ovariectomized mice. Ovariectomy not only increases the number of bone marrow cells, but also increases the number of osteoclasts generated by *ex vivo* cultures of bone marrow cells (Kalu, 1990). IL-1ra and TNFbp both completely prevent the increase in osteoclastogenesis induced by ovariectomy (Kimble *et al.,* 1997). *In vivo* treatment of ovx mice with the anti-M-CSF antibody prevents the effects of ovx on *ex vivo* osteoclast formation and bone resorption (Cenci *et al.,* 2000a) in a manner similar to treatment with IL-1 and TNF antagonists. These data are consistent with the notion that estrogen deficiency increases M-CSF production indirectly via an IL-1- and TNF-mediated mechanism (Kimble *et al.,* 1996; Srivastava *et al.,* 1998).

Osteoclast formation is also decreased, in part, by the anti-IL-6 antibody 20F3. However, the anti-IL-6 antibody is less effective than IL-1ra and TNFbp (Kimble *et al.,* 1997). Another important difference between these inhibitors is that *in vivo* treatment with IL-1ra and TNFbp also decreases the urinary excretion of DPD in a manner similar to estrogen, whereas the anti-IL-6 antibody does not. In contrast, when *in vitro* bone resorption is evaluated by examining the effects of the three inhibitors on the formation of resorption

lacunae, it appears that IL-1ra, anti-IL-6 antibody, and TNFbp all inhibit the formation of resorption pits (Kitazawa *et al.,* 1994).

Because the regulatory role of IL-6 is limited to the initial steps of the osteoclast differentiation process (Roodman, 1992), it could be that the block of IL-6 *in vivo* is insufficient to prevent the complete maturation and activation of those cells that are downstream with respect to the IL-6-dependent steps. According to this hypothesis, the lack of change in DPD excretion with anti-IL-6 antibody treatment would reflect the maintenance of an unaltered pool of active, mature osteoclasts. Conversely, the decreased pit formation observed with the IL-6 block is likely to reflect the decreased bone marrow content of osteoclast precursors and the resulting decrease in the number of cells that reach functional maturity *in vitro* (Suda *et al.,* 1992). From these data it appears reasonable to hypothesize that inhibition of IL-1 and TNF blocks bone resorption *in vivo* and *in vitro* because, at least in rodent, these cytokines regulate early and late steps of osteoclast maturation.

Studies have demonstrated that the presence of severe osteopetrosis is due to the complete lack of osteoclasts in mice lacking either RANKL or the RANKL receptor RANK. However, the effects of ovariectomy and/or estrogen deficiency in these animals remain to be investigated.

Summary and Conclusions

The mechanism(s) of the bone-sparing effects of estrogen appears to be particularly complex as it involve the regulated production of cytokines from hematopoietic cells and bone cells (Horowitz, 1993; Turner *et al.,* 1994) and the responsiveness of stromal cells to these cytokines. In addition, the contribution of specific factors to postmenopausal bone loss appears to vary as the system adapts over time to the hormonal withdrawal. Although many details of this process remain to be defined, it is now clearly established that estrogen downregulates the production of proosteoclastogenic and antiosteoclastogenic factors by targeting several bone and bone marrow cells. Estrogen represses the monocytic production of IL-1 and IL-6 and the proliferation of T cells in the bone marrow, thus leading to decreased T-cell TNF production. Sex steroids also regulate the production of IL-6, OPG, and TGFβ by stromal cells and osteoblasts.

At the present time, stromal cell-produced RANKL and M-CSF should be regarded as the factors responsible for osteoclast renewal in unstimulated conditions. The enhanced osteoclastogenesis and the increased osteoclastic bone resorption leading to postmenopausal bone loss result from the stimulated production of inflammatory cytokines. Among them, monocytic IL-1 and T-cell-produced TNF appear to play a particularly important role. First, the increase in bone marrow levels of IL-1 and TNF induced by estrogen deficiency leads to the selection of a population of stromal cells that exhibit increased Egr-1 phosphorylation, decreased binding of Egr-1 to Sp-1, and enhanced free Sp-1 levels. This, in turn, results in increased Sp-1-induced M-CSF production. Second, IL-1 and TNF increase the production of M-CSF and RANKL by stromal cells and osteoblasts. Finally, T-cell-produced TNF augments the capacity of RANKL to stimulate the differentiation of osteoclast precursors into mature osteoclasts.

Uncertainty remains on the exact contribution of IL-6 to the pathogenesis of ovariectomy-induced bone loss because of insufficient data demonstrating that the block of IL-6 decreases bone resorption and bone loss *in vivo*. However, the exact role of IL-6 is likely to be defined in the near future.

Remarkable progress has been accomplished in clarifying the mechanism of the bone-sparing effect of estrogen in animal models. A more challenging task will be to demonstrate the relevance of the mechanisms described earlier in human subjects.
