Consequently, several groups have looked for qualitative differences in the pattern of coactivators recruited or quantitative differences in the strength of RXR heterodimerization or coactivator binding following ligand binding. Liu *et al.,* (2001) used a series of AF-2 domain mutants to reach the conclusion that the conformational changes occurring in the VDR upon hormone or 20-epi-$1\alpha,25\text{-}(OH)_2D_3$ binding have a bigger impact upon RXR-heterodimerization than upon coactivator recruitment. This is in complete contrast to the work of Freedman and coworkers, who have shown repeatedly (Cheskis *et al.,* 1995; Yang and Freedman, 1999) that analog binding (20-epi-$1\alpha,25\text{-}(OH)_2D_3$ or $1\alpha,25\text{-}(OH)_2$-16-ene, 23-yneD_3) to VDR results in no difference in RXR-hetero-dimerization as compared to that of $1\alpha,25\text{-}(OH)_2D_3$. Instead, Freedman's group reports that the ability of a various analogs to transactivate vitamin D-dependent genes or to stimulate differentiation of cells is best correlated to their ability to recruit the coactivator, DRIP-205, one of the many components of the DRIP complex isolated by Freedman's group (Rachez *et al.,* 1999). Among the other coactivators/transcription factors implicated in vitamin D analog action is TIF-2, which has been purported to have a particular propensity to interact with the analog OCT (Takeyama *et al.,* 1999). Thus, it appears that there is a fairly strong basis for the hypothesis that differences in the biopotency advantage of certain vitamin D analogs over $1\alpha,25\text{-}(OH)_2D_3$ is due in part to changes in the recruitment of dimerisation partner and/or coactivators but there is no consensus on which of these proteins is the important one.

Target Cell Catabolic Enzymes

In recent years, much evidence has accumulated to support the hypothesis that $1\alpha,25\text{-}(OH)_2D_3$ is subject to target-cell catabolism and side chain cleavage via a 24-oxidation pathway to calcitroic acid (Makin *et al.,* 1989). The cloning of CYP24, the cytochrome P450 involved, has confirmed that it is vitamin D-inducible since its gene promoter contains a VDRE, carries out multiple steps in side chain modification process, and is present in many (if not all) vitamin D-target cells (Akiyoshi-Shibata *et al.,* 1994). We have postulated that the purpose of this catabolic pathway is to desensitize the target cell to continuing hormonal stimulation by $1\alpha,25\text{-}(OH)_2D_3$ (Lohnes and Jones, 1992). Recently, support for this hypothesis has emerged when St. Arnaud's group engineered a CYP24-knockout mouse which exhibits a 50% lethality by weaning, death resulting from hypercalcemia, and nephrocalcinosis (St. Arnaud, 1999). Surviving mice show an inability to rapidly clear a bolus dose of $1\alpha,25\text{-}(OH)_2D_3$ from the bloodstream and tissues (Jones *et al.,* 2000a) and a metabolic bone disease reminiscent of the excessive osteoid bone pathology observed in rodents given excessive amounts of $1\alpha,25\text{-}(OH)_2D_3$ (Hock *et al.,* 1986). Recent work with this model has shown that the defect is probably due to excessive $1\alpha,25\text{-}(OH)_2D_3$ since crossing the CYP24-knockout mouse with the VDR-knockout mouse produces a phenotype without the bone defect

(St. Arnaud *et al.,* 2000). Given the apparent importance of CYP24 to 1α,25-$(OH)_2D_3$ pharmacokinetics, one must ask the question of whether vitamin D analogs might be subject to the same catabolic processes? If not, what other drug-catabolizing systems are present within vitamin D-target cells to inactivate the vitamin D analog?

Certainly there are vitamin D analogs such as calcipotriol, OCT, EB1089, and KH1060 which are metabolized by vitamin D-target cells to clearly defined and unique metabolites (Masuda *et al.,* 1994, 1996; Shankar *et al.,* 1997; Dilworth *et al.,* 1997), which resemble products of the 24-oxidation pathway for 1α,25-$(OH)_2D_3$or which are unique to the particular analog. Furthermore, some of these metabolites are products only of vitamin D target cells and are D-inducible, implying that CYP24 is involved in their formation but this has not been proven. However, in the case of several analogs blocked at C-24 and subject to metabolism elsewhere on the side chain, the direct involvement of CYP 24 is strongly implicated or proven. These include 23-hydroxylation of 26,27-hexafluro-1α,25-$(OH)_2D_3$ (Sasaki *et al.,* 1995); 26-hydroxylation of 24-difluro-1α, 25-$(OH)_2D_3$ (Miyamoto *et al.,* 1997); 26-hydroxylation of 1α, 25-$(OH)_2$-16ene-23yne-D_3 (Satchell and Norman, 1995); and 26- and 28-hydroxylation of 1α,25-$(OH)_2D_2$ (Rao *et al.,* 1999; Shankar *et al.,* 2001). Since many of these same products are observed *in vitro* and *in vivo* and since pharmacokinetic parameters often parallel target cell metabolic parameters (Kissmeyer *et al.,* 1995; Jones, 1997), one concludes that target cell metabolism of vitamin D analogs must contribute to the pharmacokinetics and biological activity observed *in vitro* and *in vivo.* In fact, there is little doubt that the poor performance of some promising vitamin D analogs during *in vivo* testing is due to their poor metabolic stability. Accordingly, greater attention to the metabolic potential of *in vitro* testing systems and/or greater use of defined target cell (and hepatic) metabolic systems is warranted.

One factor regarding target cell metabolism considered in recent years is the possibility that vitamin D analogs might be *activated* rather than *catabolized* by the same enzymes (Siu-Caldera *et al.,* 1999). While this is potentially more important for prodrugs (Table II), the generation of large numbers of metabolites from such analogs as KH 1060 (Dilworth *et al.,* 1997) or the formation of long-lived metabolites such as 26,27- hexafluro-1α,23,25-$(OH)_3D_3$ from 26,27-hexafluro-1α,25-$(OH)_2D_3$ (Sasaki *et al.,* 1995) complicates the picture. In most cases, however, this issue can be resolved on pharmacokinetic grounds.

Other Factors

Hepatic Clearance of Vitamin D Analogs

The poor DBP binding properties of many side-chain modified calcitriol analogs opens up the possibility of alternative plasma carriers and accelerated degradation. The liver plays a major role in such metabolic clearance and a small number of detailed studies performed to date have included *in vitro* incubation with liver preparations. Calcipotriol (Sorensen *et al.,* 1990), OCT (Masuda *et al.,* 1996), EB1089 (Kissmeyer *et al.,* 1997), and KH1060 (Rastrup-Andersen *et al.,* 1992) are all subject to metabolism by liver enzymes. These give rise to intermediate polarity molecules or truncated metabolites, which can be further glucuronidated and excreted in bile (e.g., OCT; Kobayashi *et al.,* 1991). Few, if any, studies have separately considered the *rate* of such metabolism relative to 1α,25-$(OH)_2D_3$. However, data are available comparing the *in vivo* rate of metabolic clearance of vitamin D analogs to 1α,25-$(OH)_2D_3$, though inevitably this probably measures a few *in vitro* parameters such as the rate of both hepatic and target cell metabolism in addition to the affinity of DBP binding within a single *in vivo* parameter. Thus, in lieu of detailed *in vitro* metabolic analyses, the $t_{1/2}$ of the vitamin D analog is a useful term for indicating the general survival of the vitamin D drug *in vivo.* Data for this parameter have recently been published for some of the most interesting analogs (Kissmeyer *et al.,* 1995).

Nongenomic Actions of Vitamin D Analogs

The nongenomic actions of 1α,25-$(OH)_2D_3$ have been reviewed elsewhere (Norman *et al.,* 1992; Bouillon *et al.,* 1995) and were described in detail in Chapter I.D.31 and will not be repeated here. One analog purported to discriminate between genomic and nongenomic actions is 1β,25-$(OH)_2D_3$, the epimeric form of 1α,25-$(OH)_2D_3$, which is an antagonist of nongenomic but not genomic actions (Bouillon *et al.,* 1995). The membrane VDR initially described by Nemere *et al.* (1994) and now identified as annexin II (Baran *et al.,* 2000) may be involved in mediating putative nongenomic effects. It will be interesting to see if an annexin-II knockout mouse will possess a distinct phenotype which will aid in delineating the nongenomic actions of vitamin D in the same way that the VDR-knockout mouse has aided our understanding of the genomic actions. At this point in time, little work has been performed on the specificity of the vitamin D binding site of this membrane VDR/annexin II and thus the possibility that the nongenomic actions/membrane VDR might explain vitamin D analog actions seems premature.

Proposed Molecular Mechanisms of Action of Vitamin D Compounds

Building upon the data acquired from a variety of *in vitro* tests performed over the past 10–15 years and described briefly in the previous section of this chapter, one is able to identify those criteria that are important to vitamin D analog action. This in turn allows us to put forward a model for how vitamin D analogs may work *in vivo.* This is depicted in Fig. 1. As a general model, it allows for consideration of both prodrugs (those requiring 25-hydroxylation by CYP27A or those requiring 1α-hydroxylation by the kidney or extrarenal 1α-hydroxylase) and 1α,25-$(OH)_2D_3$ analogs. This model features a conventional VDR-RXR heterodimer

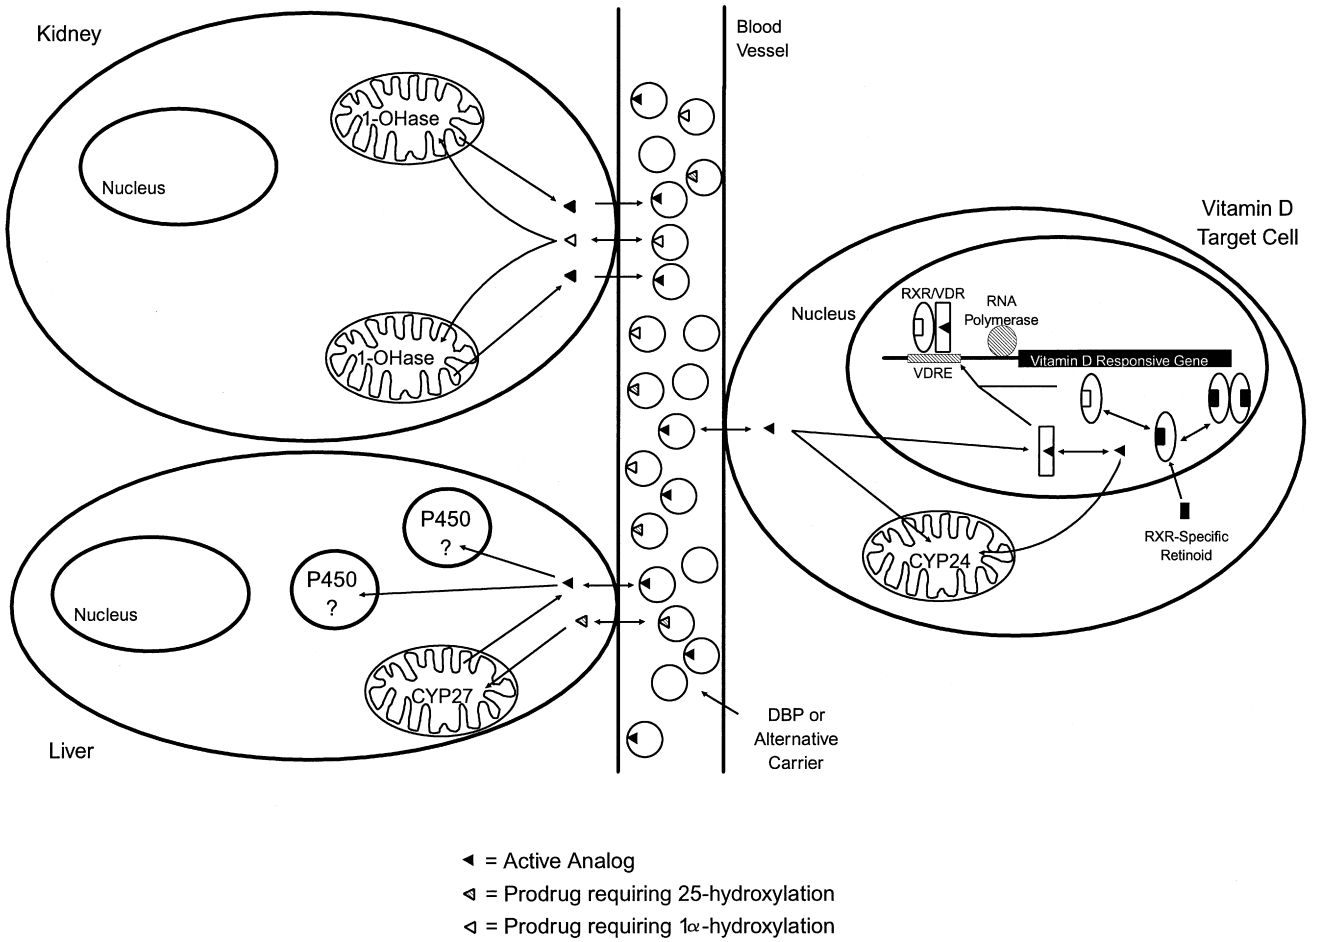

Figure 1 Proposed mechanism of action of vitamin D analogs. For discussion of the ideas contained within this figure please see text. The model incorporates plasma-binding proteins, which act as carriers of analogs; activating enzymes involved in activation of analog; target cell transcriptional machinery involved in biological actions of analogs; and target cell catabolic enzyme systems involved in degradation of the analog.

working through a DR-3 type VDRE in most genes. Crucial characteristics for each new analog (all measurable *in vitro*) are in our opinion:

(1) affinity for DBP,
(2) affinity for VDR,
(3) ability to recruit RXR and coactivators followed by transactivation of genes,
(4) rate of target cell metabolism (reflected partly in pharmacokinetic measurements),
(5) rate of hepatic clearance (reflected partly in pharmacokinetic measurements).

All parameters contribute significantly to the overall biological activity. Target cell distribution differences might be expected for those analogs that do not bind DBP and this model does not incorporate the differences observed at different genes within the same or different cells.

However, it might be useful to predict broad expectations for a new compound. Based upon this model one would predict that those analogs that have good VDR binding affinity but slow rates of target cell metabolism due to side chain blocks, such as strategically placed fluorine atoms or double bonds, might be more active than $1\alpha,25\text{-}(OH)_2D_3$ *in vitro* and perhaps also *in vivo.* Hexa-fluoro-$1\alpha,25\text{-}(OH)_2D_3$ and EB1089 are such compounds; looking alike *in vitro* and differing *in vivo* due to differences in DBP binding. On the other hand, a compound such as calcipotriol binds VDR well and is rapidly metabolized in both the liver and the vitamin D target cell and is moderately active *in vitro* or when applied to the skin topically but is inactive when administered orally and is forced to enter the bloodstream and pass the liver to get to its target site. It remains to be seen if this general model can be applied to all vitamin D analogs (e.g., KH1060, which has a very complex metabolic picture but very high biological activity *in vitro*) or must be adapted.

Future Prospects

A number of researchers remain optimistic that the unraveling of the genomic (or nongenomic) mechanism of action of $1\alpha,25\text{-}(OH)_2D_3$ will reveal new approaches by which the vitamin D signaling cascade can be exploited.

Certainly, the significant progress made in characterizing the coactivator proteins and the rest of the transcriptional apparatus will continue. One is able to predict fairly confidently from success in related steroid hormone fields that a fully functional vitamin D-dependent *in vitro* VDR–RXR transcriptional system will be reconstituted soon. Such a system devoid of the complications of metabolic enzymes will be the perfect model to test the transactivation activity of vitamin D analogs. Perhaps then it will be possible to dissect out the exact step(s) that give certain analogs a transcriptional advantage over $1\alpha,25\text{-}(OH)_2D_3$.

Modeling of the vitamin D binding pockets of VDR, DBP, and the three vitamin D-related cytochrome P450s will continue to be a major goal now that all these specific proteins have been cloned and overexpressed. While the full-length proteins are slightly beyond the current limits of NMR or X-ray crystallography, the ligand-binding domains or substrate binding pockets are not. It is also likely that technical problems with these procedures will be overcome shortly and the full-length proteins can be tackled. The initial work of the Moras group (Rochel *et al.,* 2001) on the ligand-binding domain of the VDR will be extended to new analogs and there will also be a growing focus on the other major proteins in the vitamin D signal transduction pathway.

The growing availability of recombinant cytochromes P450 will allow for modeling studies of the enzymes involved in vitamin D metabolism. The membrane-associated region of cytochromes P450 poses problems but enormous strides have been made based upon models built with X-ray data from soluble prokaryotic isoforms and with truncated mammalian isoforms such as CYP2C5 (Williams *et al.,* 2000). Access to full-length CYP24 and CYP27B will also permit a more efficient search for potential inhibitors. Such specific inhibitors of CYP24 and CYP27B (Schuster *et al.,* 2001; Muralidharan *et al.,* 1997) may be of value in blocking $1\alpha,25\text{-}(OH)_2D_3$ catabolism or synthesis in certain clinical conditions. Modeling of VDR and cytochromes P450 is expected to lead to more rational vitamin D analog design to take advantage of structural idiosyncrasies of all of these key proteins. Meanwhile, the not-so-rational synthesis of new analogs is likely to continue.

The list of applications for vitamin D compounds continues to increase (reviewed in Jones *et al.,* 1998). These applications have been further rationalized with the availability of VDR knockout mice to demonstrate vitamin D-dependent processes (Yoshizawa *et al.,* 1997; Li *et al.,* 1997). Elucidation of the mechanism by which $1\alpha,25\text{-}(OH)_2D_3$ and its analogs regulate the cell cycle and proliferation remains an important priority of the field. Current applications still fall mainly into calcium-related and cell-proliferative/differentiating ones. The goal of developing analogs that can completely separate the "calcemic" and "cell-differentiating" properties of $1\alpha,25\text{-}(OH)_2D_3$ has not yet been realized. However, some promising compounds have been synthesized and interesting idiosyncrasies of their biological actions have surfaced (e.g., tissue, cell, gene, and VDRE differences). It remains to be seen if these differences can be exploited. On the other hand, it must be stated that if vitamin D analogs work *only* through a VDR-mediated genomic mechanism, it is difficult to appreciate how the "calcemic" properties of $1\alpha,25\text{-}(OH)_2D_3$ can ever be fully resolved from the "cell-differentiating" properties given that pharmacokinetic differences have provided only a partial separation. On a more optimistic front, it can be stated that since the first edition of this book was published, several new vitamin D analogs (OCT, $1\alpha,24\text{-}(OH)_2D_3$, $1\alpha\text{-}OH\text{-}D_2$, and 19-nor-$1\alpha,25\text{-}(OH)_2D_2$) have received governmental approval to be used in the treatment of various clinical conditions worldwide. We must remain upbeat that more vitamin D analogs will be developed and important new applications of vitamin D, particularly in the area of bone biology, remain to be uncovered.

Historical Perspectives

Calcitonin was discovered as a hypocalcemic principle that was later confirmed to originate from the C cells of the thyroid gland (Copp and Cheney, 1962; Kumar *et al.,* 1963; Hirsch *et al.,* 1963). Subsequently, human calcitonin was purified and sequenced from extracts of medullary thyroid carcinoma (Neher *et al.,* 1968). It is a 32 amino-acid-long peptide with an N-terminal disulfide bridge and a C-terminal prolineamide residue. Calcitonin was found to be a potent inhibitor of bone resorption. Notably, the peptide was first shown to decrease calcium influx directly from isolated cat tibiae (MacIntyre *et al.,* 1967). Later histological and organ culture studies confirmed an effect of calcitonin on the osteoclast (reviewed in Zaidi *et al.,* 1991). Nevertheless, it remained unclear until the early 1980s whether calcitonin had a direct effect on osteoclastic receptors.

In 1983, Chambers and colleagues showed that osteoclasts were sensitive to femtomolar concentrations of salmon calcitonin (Chambers, 1982). Since then osteoclastic receptors for calcitonin have been cloned and sequenced. Systematic studies using deletion mutagenesis and chimeric receptors have clarified specific regions of the calcitonin receptor that are necessary for ligand binding and intracellular signaling through cyclic AMP and calcium. Because of its potent anti-resorptive effect and powerful analgesic action calcitonin has been used extensively for the treatment of Paget's bone disease, osteoporosis, and hypercalcemia of malignancy.

This chapter focuses on key aspects of the synthesis and structure of calcitonin, its mode of action at the cellular and molecular levels, and its clinical pharmacology.

Gene Structure

The calcitonin gene complex comprises two known genes, the α and β genes (reviewed in Zaidi *et al.,* 1991). In man, both genes are located on chromosome 11 between the catalase and parathyroid hormone genes (Kittur *et al.,* 1985). The α calcitonin gene has six exons; the first three exons are shared between calcitonin and the alternative splice product, calcitonin gene-related peptide (CGRP) (Fig. 1). The organization of the β gene is similar to that of the α gene, although the 3′ and 5′ non coding regions differ considerably (Alevizaki *et al.,* 1986). The β gene gives rise to β-CGRP, but not to a second calcitonin at least in man. The latter molecule was predicted but not proven.

The α gene is either spliced at exon 4 to yield calcitonin or at exon 6 to produce CGRP. The latter is a neuropeptide and potent vasodilator (Emson and Zaidi, 1989). Since the first three exons are spliced in either process, both calcitonin and CGRP have identical 5′-coding and noncoding regions. It is believed that splicing to calcitonin or CGRP involves recognition or nonrecognition, respectively, of exon 4 (Lou *et al.,* 1994; Zandberg *et al.,* 1995). Important regulatory elements in exon 4 have been identified; in cells producing

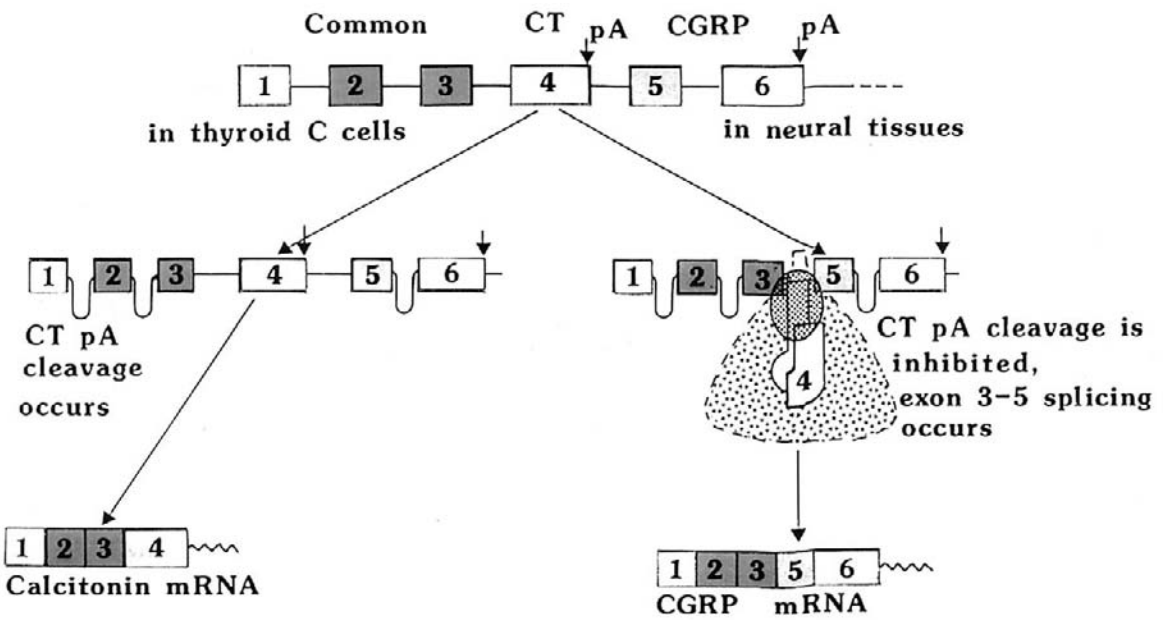

Figure 1 Alternative splicing of the α calcitonin (CT)/calcitonin gene-related peptide (CGRP) gene in a tissue-specific manner. For splicing to CGRP, the splice site in exon 4 is not recognized and transcription proceeds to exon 6 to produce CGRP.

calcitonin, these interact with cellular protein(s) facilitating exon 4 recognition (Cote *et al.,* 1992; van Oers *et al.,* 1994). It has also been shown that 3′ and 5′ coding sequences participate in recognition (Zandberg *et al.,* 1995). There is also an intron element that resides in intron 4 of the calcitonin gene (Lou *et al.,* 1996). The latter functions to enhance polyadenylation of an embedded alternative 3′-terminal exon and is potentially involved in tissue-specific regulation of calcitonin RNA processing (Lou and Gagel, 1998).

The regulation of tissue-specific calcitonin expression is being studied intensively. The cloning and sequencing of the calcitonin promoter has revealed a negative response element to vitamin D, a cAMP-response element (CRE), and a transcriptionally active octomer sequence (CRE-O) (Peleg *et al.,* 1993; Monla *et al.,* 1995). Following splicing to either calcitonin or CGRP mRNA, mature peptides are synthesized initially as large precursors that are cleaved intracellularly to release the active molecule. Post-translational processing also includes amidation at the C-terminus. It is interesting that procalcitonin has been used recently as a marker for severe bacterial infections (Hammer *et al.,* 1999).

Peptide Structure

Biologically active calcitonin comprises 32 amino acids. It has an N-terminal disulfide bridge between residues 1 and 7 in contrast to CGRP, in which the latter is positioned between residues 2 and 7 (Zaidi *et al.,* 1990a). There is also a proline amide at residue 32. The sequences of calcitonins from seven species are shown in Fig. 2. These display considerable variation in primary structure, varying from between a difference of 2 (between rat and human) to 19 (between human and ovine) amino acid substitutions. Eight residues (positions 1, 4, 5, 6, 7, 9, 28, and 32) are common to all species studied. Of these, six are clustered at the N-terminus, suggesting physiological constraints on this region of the molecule. The highly conserved regions at the two ends of the molecule also suggest that the termini are important for biological activity. The variable middle portion is thought to be involved in controlling the potency and duration of action of calcitonin. More recently, sardine calcitonin, currently the most potent calcitonin, has been sequenced (Suzuki *et al.,* 1994).

It has been suggested that the conformational flexibility of a given calcitonin molecule determines its biological potency (reviewed in Breimer *et al.,* 1988). A more flexible calcitonin potentially can attain a larger number of conformations at the receptor membrane complex. Molecular flexibility is dependent on the bulkiness of its side chains, glycine being the least bulky. As three glycine residues are conserved in salmon and eel calcitonin, both peptides possess a remarkably low potential for forming rigid helices. Although it appears that the valine residue at position 29 of eel calcitonin might induce conformational rigidity due to its bulky side chain, the effect is annulled by an alanine at position 29. The substitution of salmon calcitonin with amino acids containing less bulky side chains has been shown to produce more active analogs.

Kapurniotu and Taylor (1995) synthesized lactam bridge-containing derivatives of calcitonin and concluded that the lactam bridges are compatible with biological activity. They also show that the amphiphilic α helix and a type 1 β-turn (involving residues 17 to 20) may play an important role in receptor recognition by calcitonin. It has also been demonstrated through CD spectroscopy that human calcitonin forms a left-handed extended helix in solution (Siligardi

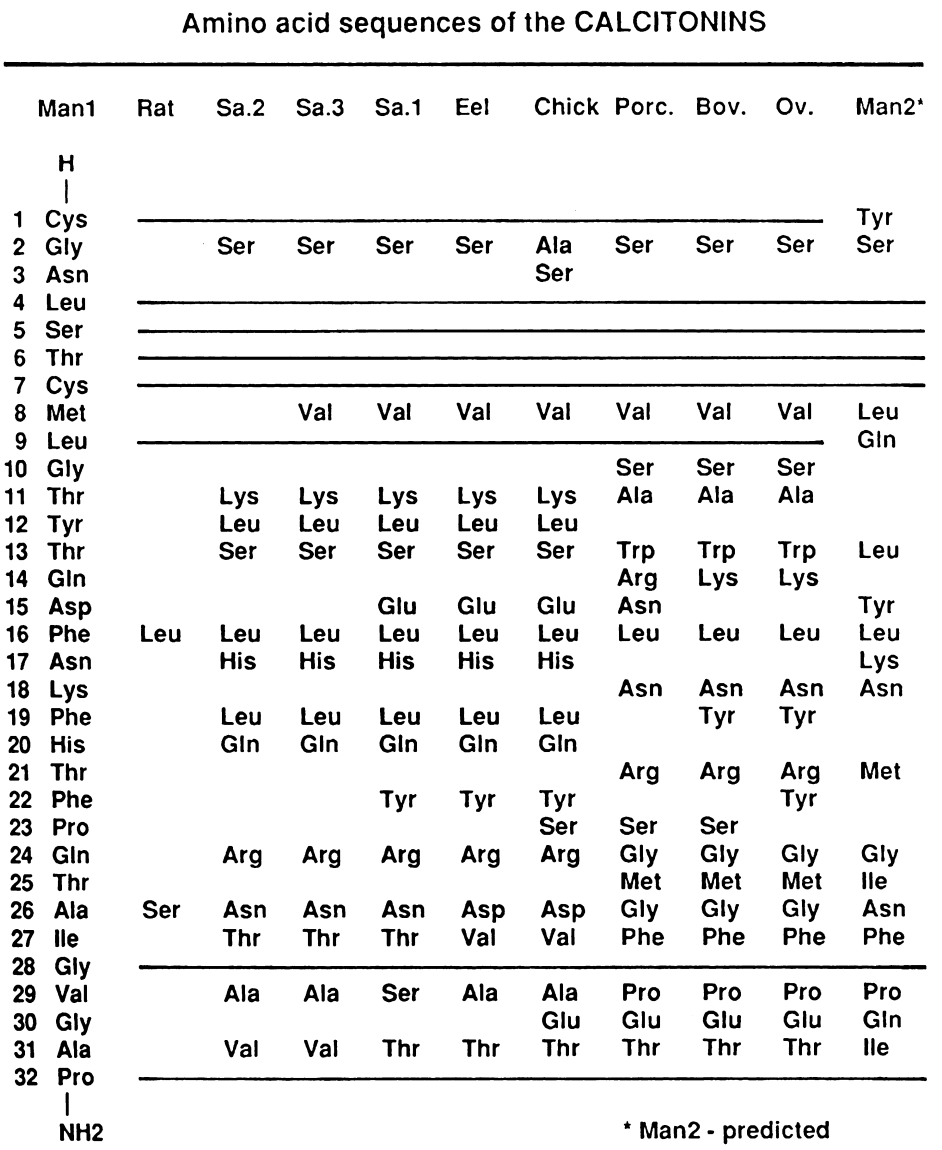

Figure 2 Structure of calcitonins from various species including human (Man1 and the predicted second human calcitonin, Man2), rat, salmon (Sa.1 to Sa. 3), eel, chicken (Chick), porcine (Porc.), bovine (Bov), and ovine (Ov) calcitonin. The lines indicate nonvariant residues.

et al., 1994). Another hypothesis arising from the 3-D structure determination of calcitonin is that human calcitonin has a hydrophobic face composed of one Met and four Leu residues that facilitate interaction with the receptor (Katahira *et al.,* 1995).

Modifications of the primary structure that cause a reduction in biological activity include deletion of the C-terminal proline amide, shortening of the C-terminal end, cleavage of the disulfide bond (except when it is replaced by a carba-type linkage as in asu$^{1-7}$-eel calcitonin), or oxidation of the methionine at position 8 (human calcitonin). Modifications that do not alter biological activity include oxidation of the methionine residue at position 25 in porcine, bovine, and ovine calcitonins. Modifications that tend to increase homology of a given calcitonin with salmon calcitonin generally increase biological activity. One recent revelation has been that human calcitonin fibrillates in solution due to the formation of hydrogen bonds (Kanaori and Nosaka, 1995). When fibrillation is avoided, potency can be enhanced (Cudd *et al.,* 1995). This new knowledge may have implications in the development of new analogs for human use.

There have been recent studies on the binding of calcitonin with its receptor—these highlight the secondary and tertiary structural requirements for binding. For example, with the parathyroid hormone (PTH) receptor, elegant photoaffinity cross-linking studies using benzolphenylalanine derivatives have identified two specific contact sites for ligand receptor interaction (Behar *et al.,* 1999). The entire bimolecular surface of the PTH–PTH1 receptor complex has now been mapped (Pischerio *et al.,* 2000). It

has been shown that there is spatial proximity between Lys^{27} of the hormone's principal binding domain and Leu^{261} of the first extracellular loop of the receptor (Greenberg *et al.,* 2000). Similar studies have also been initiated using a novel biologically active benzophenone-containing calcitonin analog for photolabelling the calcitonin receptor (Suva *et al.,* 1997). Such investigations should help us understand the precise biomolecular interaction between calcitonin and its receptor as a prelude to the future development of novel receptor-specific therapeutics.

Cellular Actions

Calcitonin inhibits basal and stimulated resorption of intact bone in organ culture (reviewed in Breimer *et al.,* 1988). In bone sections, calcitonin acts directly on the osteoclast to cause a rapid loss of the ruffled border (Holtrop *et al.,* 1974; Kallio *et al.,* 1972; Chambers and Magnus, 1982). When applied for a longer term, there is a reduction in the number of osteoclasts in bone.

When applied *in vitro* to isolated osteoclasts, femtomolar concentrations of calcitonin result in an acute cessation

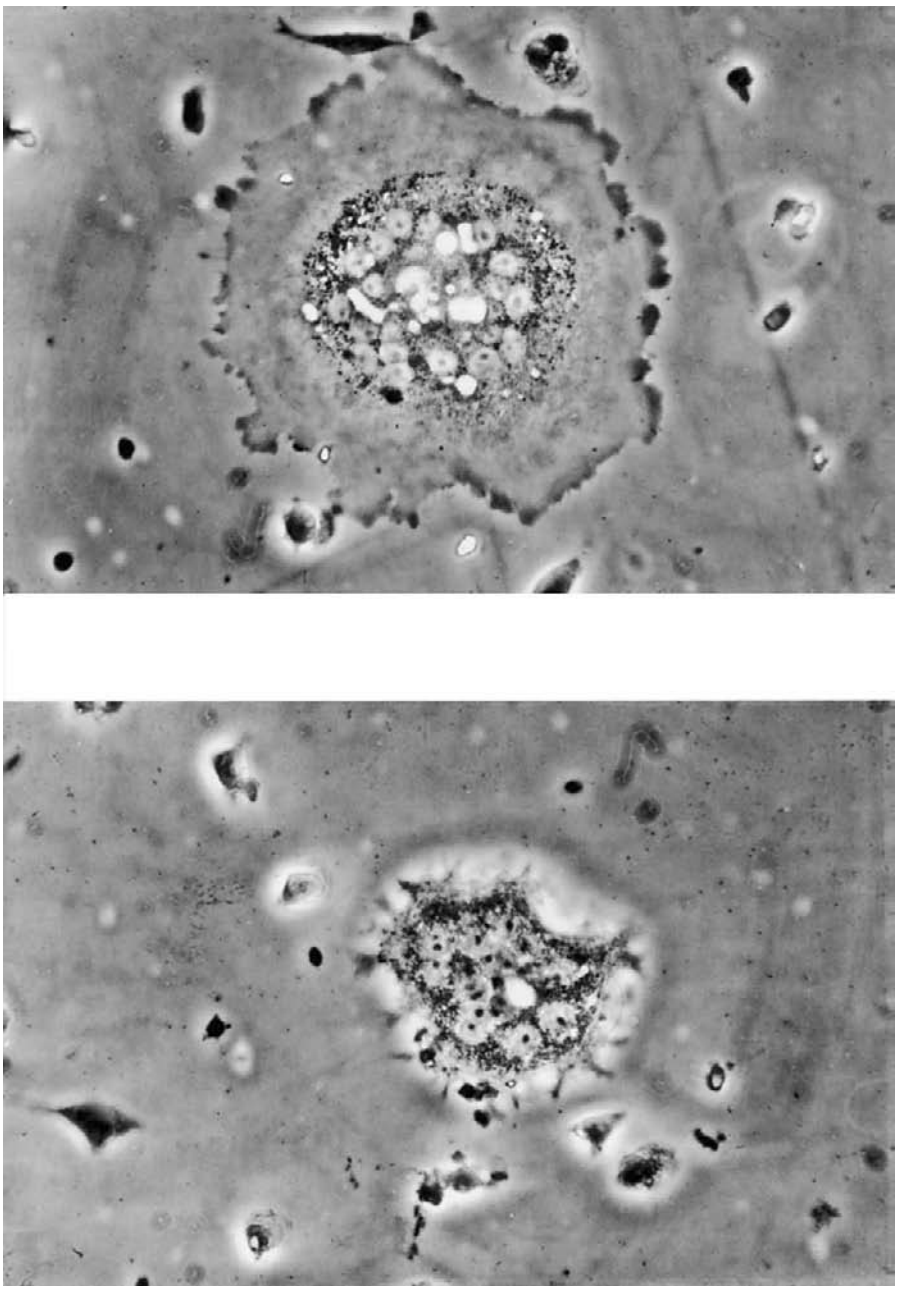

Figure 3 The effect of calcitonin on the morphology of isolated osteoclasts. Disaggregated osteoclasts with (bottom) or without (top) calcitonin treatment. Used with kind permission of Professor T. J. Chambers (London).

of cytoplasmic motility followed by gradual pseudopodial retraction (Chambers, 1982) (Fig. 3). The predictability of the response, its specificity for osteoclasts, and the near-physiological concentrations used clearly suggest that the phenomenon is of physiological significance. We provided the first quantitative estimates for calcitonin action on isolated osteoclasts using a novel method to quantitate osteoclast motility and shape change (Zaidi *et al.,* 1990a, 1992b). Calcitonin action was separable into more a rapid quiescence (Q) component with a $t_{1/2}$ of 15 min that was characterized by cessation of motility. The late retraction (R) component with a $t_{1/2}$ of 27 min was composed mainly of pseudopodial and margin retraction (Fig. 4). The latter, we believe, may reduce resorption by decreasing the area of contact of the osteoclast with the bone surface.

In addition, calcitonin inhibits osteoclast secretion. Notably, it reduces tartrate-resistant acid phosphatase (TRAP) secretion and Na^+-K^+-ATPase activity and alters the localization of carbonic anhydrase and thus acid secretion in osteoclasts (Chambers *et al.,* 1987; Moonga *et al.,* 1990; Akisaka and Gay, 1986). Additionally, calcitonin inhibits TRAP release and synthesis from osteoclasts (Yumita *et al.,* 1991).

These inhibitory effects of calcitonin on the osteoclast are translated into a marked inhibition of resorption that is reproducible in every osteoclast resorption assay studied. For example, calcitonin reduces the formation of osteoclasts in the classical pit forming assay (Chambers *et al.,* 1984; Zaidi *et al.,* 1987; Dempster *et al.,* 1987) (Fig. 5). This assay involves culturing osteoclasts onto devitalized bone or dentine substrate and quantifying either the number, area, or volume of bone resorbed. Calcitonins display a rank order of potency in inhibiting resorption with salmon calcitonin being the most potent and human the least potent (Fig. 5). These potency estimates correlate perfectly with the *in vivo* potency of the respective calcitonins (Zaidi *et al.,* 1988). CGRP and amylin both interact with the calcitonin receptor, but at 100- and 40-fold higher concentrations (Zaidi *et al.,* 1987, 1988, 1994; Datta *et al.,* 1989).

Calcitonin has surprising new actions. It releases osteoclasts from the inhibitory effects of a high extracellular Ca^{2+} (Zaidi *et al.,* 1996). Ca^{2+}-induced Ca^{2+} signaling was found to be markedly attenuated in the presence of femtomolar

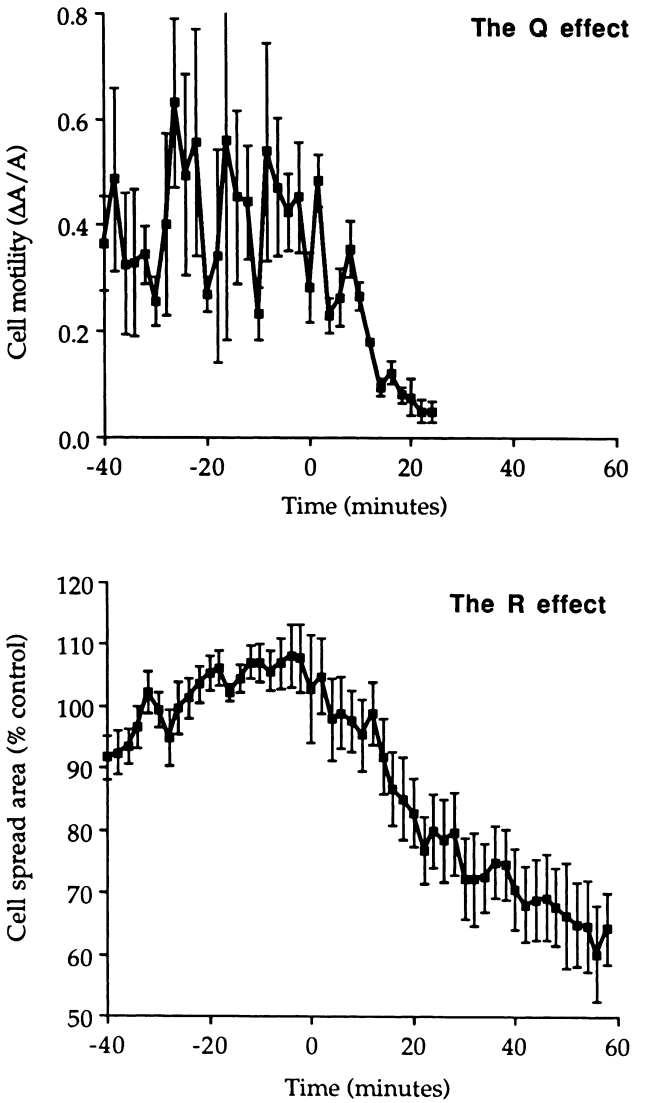

Figure 4 The Q (quiescence) and R (retraction) effects of calcitonin added at time 0. Cell motility was quantitated as the rate of change of shape area ($\triangle A$) per unit cell area. Used with permission from Zaidi *et al.* (1993).

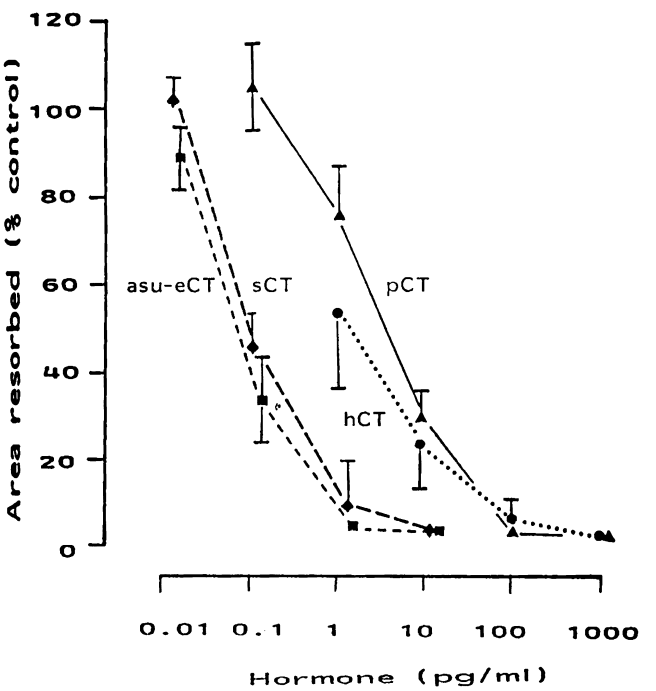

Figure 5 The effect of various therapeutically used calcitonins on bone resorption by isolated rat osteoclasts that were plated on devitalized cortical bone substrate. Area of resorption has been quantitated by scanning electron microscopy. Used with permission from Zaidi *et al.* (1987).

concentrations of the peptide. This apparent paradox to the known potent anti-resorptive action of calcitonin may explain the lack of any bone loss during the absence of calcitonin (such as after thyroidectomy) as well as the absence of osteopetrosis in the presence of high circulating calcitonin (as in medullary thyroid carcinoma). Second, calcitonin has been shown in some systems to interact with osteoblasts, although there is no convincing evidence for calcitonin receptors on any osteoblast-like cells. For example, eel calcitonin has recently been shown to have an anabolic effect on osteoblasts, specifically to enhance osteoinduction by BMP-2 (Furuichi *et al.,* 2000; Wallach *et al.,* 1999; Okubu *et al.,* 2000). It also increases the concentration of insulin-like growth factors in serum-free cultures of human osteoblast-like cells (Farley *et al.,* 2000). Calcitonin has also been shown to prevent osteoblast and osteocyte apoptosis (Plotkin *et al.,* 1999), but this action is controversial.

Another interesting cellular action of calcitonin had been the early demonstration of its effect on the growth of breast cancer cells. Calcitonin can induce growth retardation in calcitonin receptor-transfected HEK cells. New evidence indicates that the cyclin-dependent kinase inhibitor p21/WAF1/CIPI that causes cell cycle arrest in G1 and G2/M phases possesses calcitonin sensitivity (Evdokiou *et al.,* 2000). In fact, calcitonin affects gene transcription through the transcription factor, Sp1. It is also evident that the insert-negative (but not insert-positive) calcitonin receptors (see below) cause downstream activation of Erk1/2-MAP kinase and inhibition of cell growth (Raggatt *et al.,* 2000). More interesting is the observation that calcitonin suppresses expression of the growth factor, PTH-related peptide (PTHrP), in breast cancer cells (Rong *et al.,* 1999). Such emerging evidence for an effect of calcitonin on cell cycling molecules, growth factors, and cell growth itself revives a long forgotten area of calcitonin and cancer biology. Furthermore, calcitonin inhibits the osteoclastogenic effects of osteoprotegerin-ligand, an effect that may be relevant therapeutically (Mancini *et al.,* 2000).

Finally, calcitonin, at pharmacological concentrations, has for some years known to increase renal calcium and phosphate excretion and 1,25-dihydroxycholecalciferol production (Agus *et al.,* 1981). More recently, it has been shown to be a major regulator of the expression of the renal 25-hydroxyvitamin D_3 hydroxylase gene in normocalcemic rats (Shinki *et al.,* 1999).

The Calcitonin Receptor Family

Several calcitonin receptor subtypes have been cloned and sequenced (Goldring *et al.,* 1993). Essentially, these are membrane receptors with seven transmembrane domains and a long extracellular domain (reviewed in Zaidi *et al.,* 1994). They fall within the superfamily of PTH/PTHrP/calcitonin/adrenomedullin/secretin receptors. There is >30% homology between the human and porcine calcitonin and the opposum and rat PTH–PTHrP receptors. The human ovarian receptor and porcine renal receptor sequences are ~80% similar. The deduced peptide sequences exhibit multiple hydrophobic domains flanked by charged residues. There are six Cys residues in the extracellular loops and two N-linked glycosylation sites. Both structures appear well conserved and appear to be important requisites for ligand binding (Ho *et al.,* 1999). There are approximately 1 million calcitonin receptors per osteoclast (Nicholson *et al.,* 1986). All calcitonin receptors bind calcitonin with high affinity, and the alternative ligands, CGRP, amylin, and adrenomedullin, with low affinity. The ligand affinities of different receptors are reviewed in Zaidi *et al.,* 1994. (Fig. 6).

Several calcitonin receptor isoforms have been identified (Egerton *et al.,* 1995). These were demonstrated on the basis of pharmacological studies even prior to their molecular cloning (Alam *et al.,* 1993). Subtypes of the human calcitonin receptor arise from alternative splicing of the primary mRNA transcript of the human calcitonin receptor gene (Nakamura *et al.,* 1995; Moore *et al.,* 1995; Nusenszveig *et al.,* 1995). The gene consists of multiple exons separated by lengthy introns allowing for splicing (Yamin *et al.,* 1994).

The two most common human subtypes isolated from BIN-67 and T47D cells, respectively, differ in the sequence by a 16-amino-acid insert in the first putative intracellular domain (Force *et al.,* 1992; Gorn *et al.,* 1992) (Fig. 7). C1a, or the insert-positive form, is the most prevalent and is capable of transducing intracellular signals at least through G_s and G_q protein-coupled mechanisms (Su *et al.,* 1992; Nussenzveig *et al.,* 1994). The two rat isoforms, C1a and C1b, cloned from the osteoclast differ in the structure of their first extracellular loop (Houssami *et al.,* 1994; Ikegame *et al.,* 1995) (Fig. 7). Two further calcitonin receptors have been cloned from a hypothalamic cDNA library: these consist of 478 and 515 amino acids, respectively (Sexton *et al.,* 1993; Albrandt *et al.,* 1993; Wimalawansa, 1996). The 515-amino-acid-long receptor, has an inframe insert of 37 amino acids.

Little is known about the regulation of calcitonin receptor expression. New and important insights include an effect of calcitonin in inhibiting calcitonin receptor expression through a transcriptional mechanism (Inoue *et al.,* 1999). It is also known that glucocorticoids stimulate calcitonin receptor expression (Wada *et al.,* 1994). Another important observation is that calcitonin receptor expression in osteoclasts is downregulated during osteoclastogenesis (Takahashi *et al.,* 1995). A further more recent demonstration is that M-CSF and NFκB regulate the expression and function of the calcitonin receptor in human osteoclast-like cells (Samura *et al.,* 2000). A further interesting finding, albeit not unexpected, is that calcitonin receptors can be induced to appear in mammary tissue during pregnancy (Tverberg *et al.,* 2000). The physiological significance of this observation is unclear. Finally, the transgenic expression of calcitonin receptor in mice indicates its role in morphogenesis in general, and skeletal development in particular (Jagger *et al.,* 2000).

There are several reports of the cloning of calcitonin receptor-like receptors that bound primarily to CGRP and amylin.

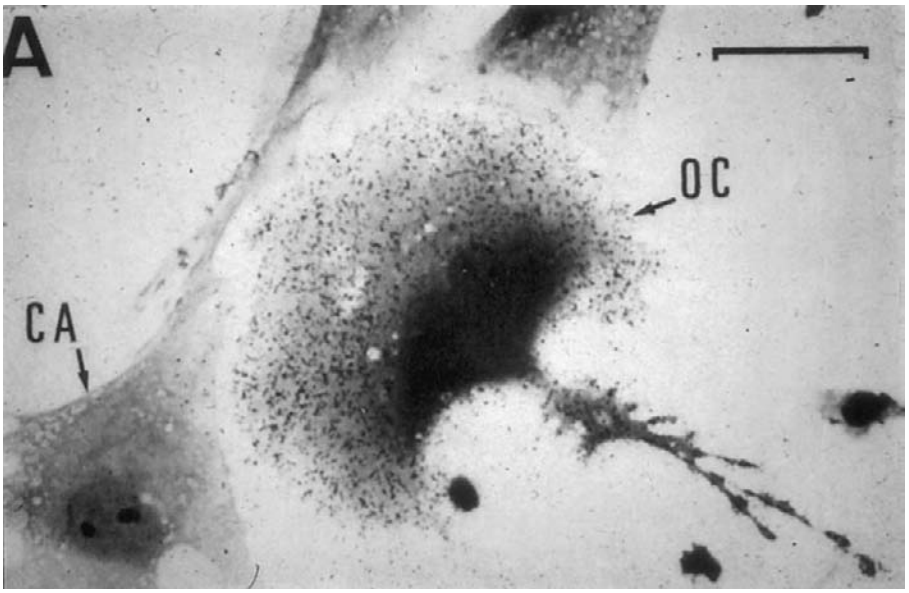

Figure 6 Autoradiograph of an osteoclast incubated with [^{125}I]salmon calcitonin showing a high calcitonin receptor number (1 million per cell). Used with permission from Nicholson *et al.* (1986).

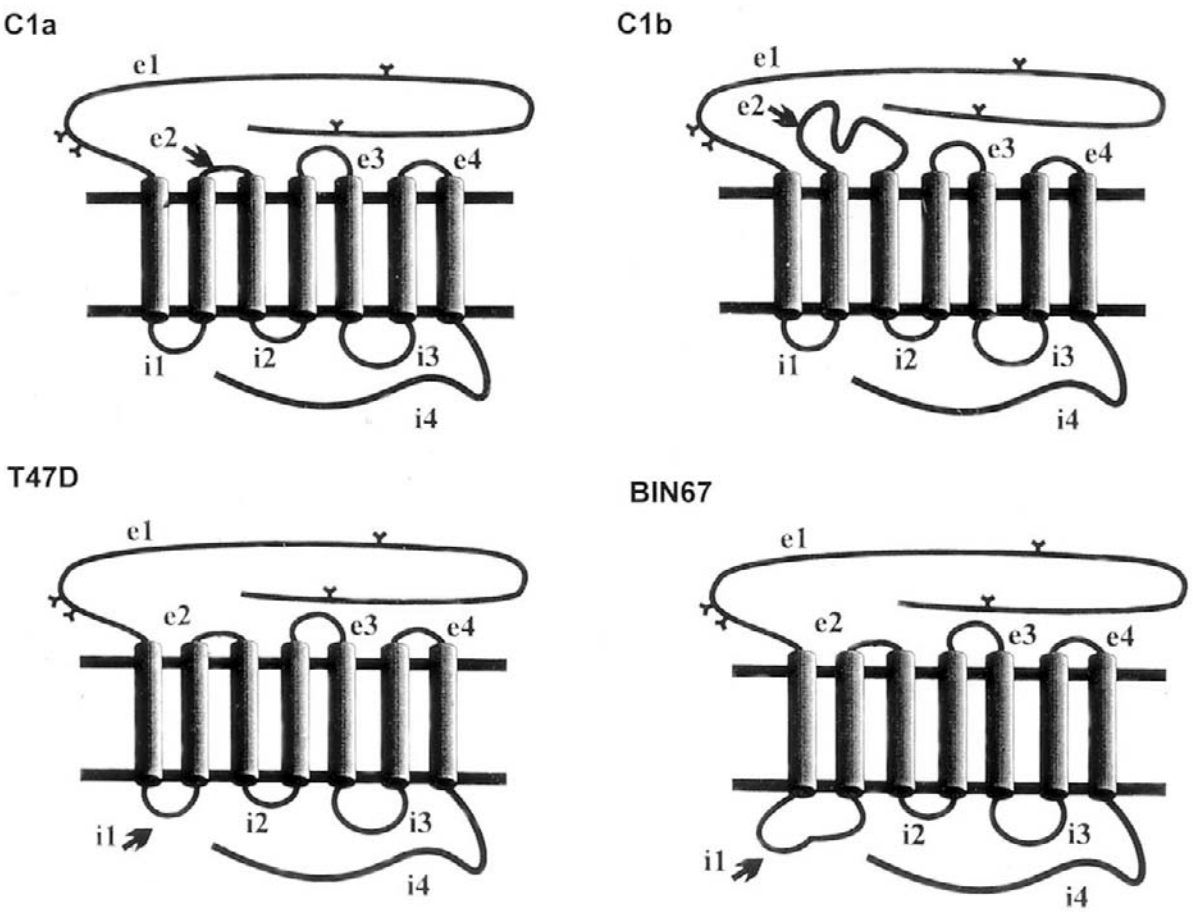

Figure 7 Receptor isoforms of the rat (top) and human (bottom) calcitonin receptors showing the extracellular (e1 to e4) and intracellular (i1 to i4) domains. In C1b, e2 contains an extra 37-amino-acid insert. In the human receptor from BIN-64 cells, i1 contains a 16-amino-acid-long insert that is not present in breast cancer cells, T47D. Used with permission from Martin *et al.* (1994).

The canine orphan receptor gene, RDC-1 gene, was tentatively assigned as being the CGRP-1 receptor (Kapas and Clark, 1995). More recently, Aiyar and coworkers (1996) also cloned and sequenced another CGRP-1 receptor. Like the calcitonin receptors, the CGRP receptors have seven transmembrane domains with up to three N-linked glycosylation sites and several disulfide bridges (reviewed in Wimalawansa, 1996). As with the adrenomedullin receptor, the canine CGRP receptor also has an unusual SIF-FLTCXS sequence, the significance of which is unclear. Finally, a 146-amino-acid linear peptide, the CGRP receptor component peptide, has been predicted from sequence analysis (Luebke *et al.,* 1996). This peptide is thought to bind to and stabilize the CGRP receptor–CGRP complex.

There was an initial suggestion that the osteoclast calcitonin receptor was the Ca^{2+}-sensing receptor on the osteoclast (Stroop *et al.,* 1993). This suggestion was later revoked and it was shown that calcitonin binding was in fact cation-sensitive (Stroop *et al.,* 1993; Stroop and Moore, 1995). It is now becoming clear that osteoclast Ca^{2+} sensing is a function of a uniquely expressed surface ryanodine receptor that is controlled by cyclic ADP-ribose generated from CD38, an ADP-ribosyl cyclase (Zaidi *et al.,* 1995, 1996; Sun *et al.,* 1999). It has also been shown that ryanodine receptors and CD38 are located in the nuclear membrane of bone cells, exemplifying a mechanism through which changes in cytosolic Ca^{2+}, for example triggered through calcitonin receptor activation, are transduced intranuclearly to affect gene transcription (Adebanjo *et al.,* 1999, 2000). Thus, it is likely that the calcitonin and Ca^{2+} receptor systems in the osteoclast interact at several levels of cellular organization. This is, however, by no means proven.

There has been significant new progress on understanding the biology of the calcitonin receptor. This has been pursued through the use of chimeric receptor constructs and site-directed mutagenesis. Orcell *et al.* (2000), by making chimeric receptors between the calcitonin receptor and the insulin-like growth factor receptor, have delineated the regions of the calcitonin receptor that are required for G_s-mediated signal transduction, most notably the third intracellular loop (Fig. 8). Deletion of 14 amino acids in the seventh transmembrane domain has been found not only to abrogate coupling to phospholipase C, but also to alter ligand binding (Shyu *et al.,* 1996). The first intracellular domain and N-terminus also exert a significant impact on both ligand binding and signal transduction (Stroop *et al.,* 1996). Stroop and colleagues have shown, again using a chimeric receptor between the calcitonin and glucagon receptors, that there are two dissociable binding sites for calcitonin (Stroop *et al.,* 1995). Interestingly, chimeric calcitonin-PTH receptors have been shown to be responsive to hybrid calcitonin-PTH ligands that do not activate either wild-type receptor. As indicated above, photoaffinity labeling has been used to understand bimolecular interactions between receptor and ligand. These strategies, taken together, are likely to unravel important tertiary structural prerequisites for the interaction between calcitonin and its receptor.

The possibility that allosteric activation of the calcitonin receptor using a calcitonin receptor mimic that does not occupy the ligand binding site, but instead sensitizes the receptor, is being explored. Preliminary data show that such lead compounds can be synthesized and used *in vivo.* Furthermore, drugs targeting one transmembrane domain over the other may abolish certain receptor functions while sparing others. Finally, because different receptor isoforms may

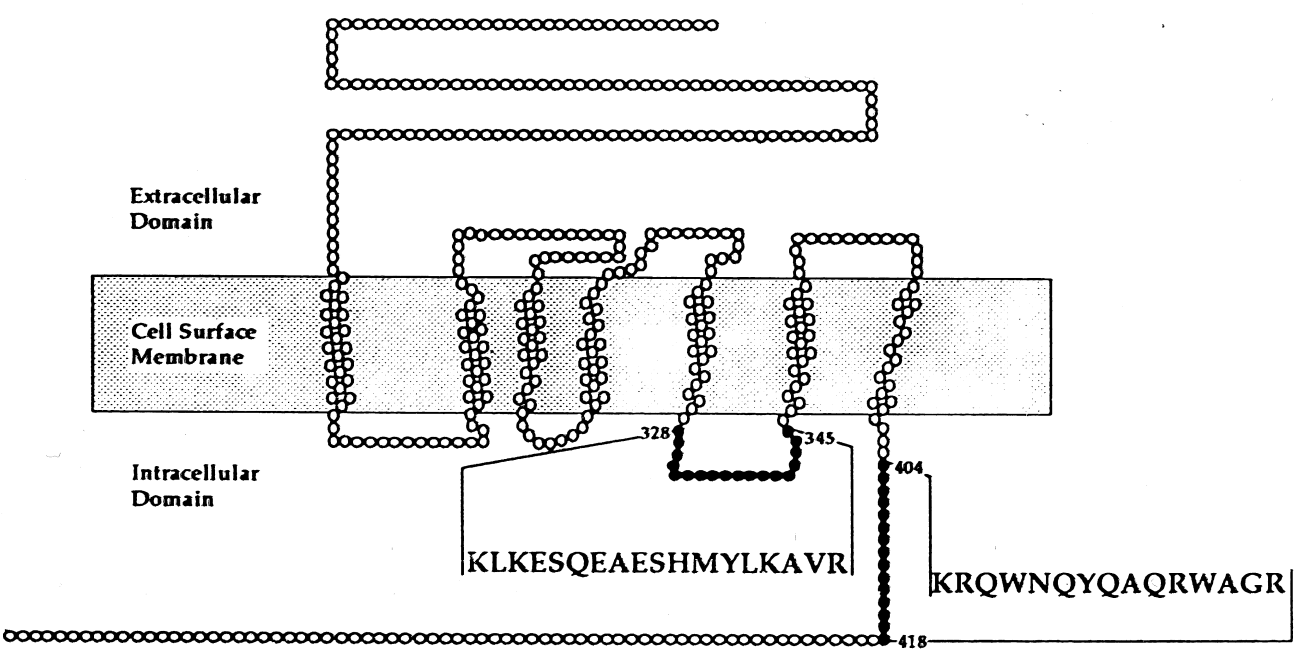

Figure 8 G protein-coupling sequences in the porcine calcitonin receptor. Modified from Orcell *et al.* (2000).

regulate different functions, drugs targeting one isoform over another may reduce side effects or preferentially target forms of osteoporosis that have high or low bone turnover rates. A comprehensive discussion of the structure and molecular biology of the calcitonin receptor is provided by Melson and Goldring in Chapter 34.

Molecular Actions

It has been shown in pharmacological studies with intact osteoclasts that distinct signal transduction pathways, possibly also involving separate calcitonin receptor subtypes, mediate the Q and R effects of calcitonin (Zaidi *et al.,* 1990a). A cholera toxin-sensitive G_s protein mediates the cAMP-dependent Q component (Fig. 9). A pertussis toxin-sensitive G_q protein mediates the R component via a rise in intracellular Ca^{2+}. The Q component is also activated by related peptides, including amylin and CGRP. In contrast, the R effect is highly specific for calcitonin (Alam *et al.,* 1991, 1992, 1993). We and others also provided direct evidence that calcitonin elevates intracellular Ca^{2+} in isolated osteoclasts (Moonga *et al.,* 1992; Teti *et al.,* 1995; Findlay *et al.,* 1995).

Different calcitonin receptor isoforms can couple to G_s, G_q, or G_i (Su *et al.,* 1992; Chabre *et al.,* 1992; Force *et al.,* 1992; Alam *et al.,* 1993; Ransjo *et al.,* 1994). This can also happen in a cell-cycle-dependent manner and may involve divergent structural requirements (Chakraborthy *et al.,* 1991; Houssami *et al.,* 1995). It has also been shown that receptor activity-modifying proteins (RAMPs) can form heterodimers with two G protein-coupled receptors to define ligand-specificity of a given receptor (Derst *et al.,* 2000). Several RAMPs have been cloned (Leuthauser *et al.,* 2000). RAMP-1 can interact with human calcitonin receptor C1b as well as the calcitonin receptor-like receptor. RAMP-3 can interact with the calcitonin receptor and make it amylin receptor-like (Armour *et al.,* 1999).

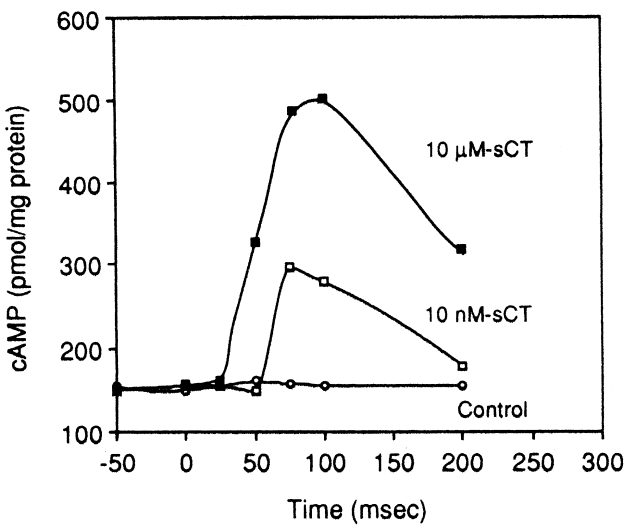

Figure 9 Ultrafast (millisecond) measurements of cyclic AMP in rabbit osteoclasts in response to salmon calcitonin (sCT). Used with permission from Zaidi *et al., Am. J. Physiol.* **271,** F637–F644.

Inhibiting or depleting protein kinase C does not affect the activation of adenylyl cyclase with the G_s-coupled response, indicating that this signal likely occurs through a protein kinase A pathway (Offermanns *et al.,* 1996). This pathway, occurring through the third intracellular loop and C-terminal tail of the calcitonin receptor (Orcell *et al.,* 2000), likely causes the observed cessation of motility or the Q effect. However, calcitonin receptor signaling coupled to G_i that would inactivate adenyl cyclase is suppressed in the presence of activated protein kinase C (Shyu *et al.,* 1999). Thus, protein kinase C activation may act as a positive regulator for signaling through the G_i-coupled pathway. Signaling through G_q activates both phospholipase C and protein kinase C in osteoclasts. This activation with resulting phosphorylation of Shc and ERK1/2 as well as the human enhancer of filamentation (HEF-1 or CasL) likely induces pseudopodial retraction or the R effect (Chen *et al.,* 1998). Finally, it has also been demonstrated that phospholipase D signaling can be triggered by calcitonin receptor activation (Naro *et al.,* 1998). The significance of this pathway is, however, unclear.

As part of the observed pseudopodial retraction, calcitonin also likely regulates adhesion mechanisms in osteoclasts (Fig. 10). Pyk2 is a major adhesion-dependent tyrosine kinase in osteoclasts that associates with c-Src via its SH2 domain (for a review of integrin signaling see Duong *et al.,* 2000). Engagement of the $\alpha_v\beta_3$ integrin, the major integrin present in osteoclasts, increases tyrosine phosphorylation of Pyk2 and leads to the formation of the sealing zone (Duong *et al.,* 2000). Hef-1 or CasL is a focal adhesion-associated, multiple-domain docking protein. It contains an SH3 domain that binds focal adhesion kinase (FAK) and Pyk2. Transduction from the calcitonin receptor that activates Hef-1 but not $p130^{cas}$ is dependent upon protein kinase C (and thus the G_q-coupled calcitonin receptor), but is independent of the G_s/cAMP/protein kinase A pathway (see Fig. 5) (Zhang *et al.,* 1999). Nevertheless, integrin engagement, actin cytoskeletal rearrangement, and c-*src* activation are required for calcitonin-induced tyrosine phosphorylation of paxillin and HEF1, but not for Erk1/2 phosphorylation (Zhang *et al.,* 2000). Activation of HEF-1 by calcitonin may therefore cause interactions with Pyk2 and other molecules that regulate osteoclast adhesion, although this remains to be established.

Calcitonin also has effects in other tissues that relate indirectly to bone remodeling. The enzyme 25-hydroxyvitamin D_3 1α-hydroxylase (CYP27B1) catalyzes the biosynthesis of 1α, 25-dihydroxyvitamin D_3 from 25-hydroxyvitamin D_3 in renal proximal tubules. Calcitonin has been shown to increase the mRNA expression of the CYP27B1 enzyme and thus could help regulate the production of active vitamin D_3 (Yoshida *et al.,* 1999). In addition, Baron's group have clearly demonstrated changes in localization of critical ion exchangers in renal tubular cells by calcitonin (Chakraborty *et al.,* 1994).

Clinical Pharmacology

Calcitonin's utility as a pharmaceutical agent is due to its inhibitory effect on osteoclastic bone resorption (review: Adebanjo *et al.,* 1998). Its efficacy has been demonstrated by the immediate decrease of urinary resorption markers that occurs within few a hours following the administration of pharmacological doses. Subcutaneous injection of 100 IU salmon calcitonin to osteoporotic subjects results in maximal inhibition of bone resorption within 8–16 hr (Gonzalez *et al.,* 1986). The higher the rate of bone turnover, the earlier and the more pronounced are the biochemical changes. Generally calcitonin's duration of action does not exceed 24 hr. For this reason, Paget's disease served as one of the first human models for testing the efficacy of calcitonin. After a subcutaneous or intramuscular injection, the small transient calcium lowering effect of calcitonin is accompanied by a transient rise of PTH which lasts for about 12 hr (Burckhardt *et al.,* 1973; Fournie *et al.,* 1977)

For achieving any drop in plasma calcium in healthy subjects, relatively high calcitonin doses are required (Buclin *et al.,* 1987; Thamsborg *et al.,* 1990). When calculated as area under the curve, the hypocalcemic response shows a significant dose relationship (Overgaard *et al.,* 1991), indicating that even relatively small doses might exert significant effects on bone metabolism.

After each dose of calcitonin, parathyroid hormone increases transiently, for less than 24 hr, in response to the transient fall in plasma calcium (Burckhardt *et al.,* 1973). Basal levels of plasma calcium and PTH are unchanged in the setting of longer periods of exposure. When unchallenged by concomitant oral calcium, this rise in PTH is associated with a nocturnal rise in bone resorption (Burckhardt *et al.,* 1988; Abbiati *et al.,* 1994; Vega *et al.,* 1989).

In addition to the injectable forms, salmon calcitonin has also been used as a nasal spray and rectal suppository (Kollerup *et al.,* 1994; Kraenzlin *et al.,* 1996). The latter two forms exhibit almost identical short-term effects in healthy subjects (Buclin *et al.,* 1987). Eel calcitonin has also been used effectively as a rectal suppository.

For practical clinical reasons, attempts have been made to establish bioequivalence for the nasal and injectable forms of salmon calcitonin. For clinical usage, 200 IU as nasal spray is deemed almost equivalent to 50 IU intramuscular. However, the data supporting its usage is fraught with discrepancies (Overgaard *et al.,* 1991). For example, nasal salmon calcitonin at 400 IU inhibits the increase in bone resorption caused by immobilization only partially, while 100 IU given intramuscularly exerts a total inhibition (Tsakalakos *et al.,* 1999; Van der Wiehl *et al.,* 1993). Furthermore, in Paget's disease, 50 IU subcutaneous salmon calcitonin and 400 IU nasal spray are equally effective as hypocalcemic agents (Vega *et al.,* 1989). Taken together, the data over the past 20 years show that calcitonin when administered subcutaneously is effective, while the nasal formulation is variable. For obtaining the same hypocalcemic effect with nasal calcitonin, up to 30 times higher dosages of salmon calcitonin must therefore be administered intranasally (O'Doherty *et al.,* 1990).

Given as a rectal suppository, salmon calcitonin shows the same acute biologic effects as when given as the nasal spray, although it provoked higher plasma levels of calcitonin (Buclin *et al.,* 1987). When compared with intramuscular administration, the dose equivalence of eel and salmon calcitonin was 50% (Fiore *et al.,* 1992; Pagani *et al.,* 1991). At high doses, rectal eel calcitonin provokes a transient hypocalcemia even in healthy subjects (Buclin *et al.,* 1987; Nuti *et al.,* 1992).

Oral preparations of analogs, such as ASC 710, have been tested in Paget's disease and have had the same effect to salmon calcitonin given by injection, but with an approximate dose equivalence of 100:1 (Devogelaer *et al.,* 1994).

Hypercalcemia

The usefulness of calcitonin as a therapy for acute hypercalcemia is covered elsewhere in this book (see Chapter 60).

Paget's Disease

As the first effective drugs for the treatment of Paget's disease, human and animal calcitonins (salmon, pork, eel) were unchallenged until the bisphosphonates became available. In Paget's disease, salmon calcitonin can be given over long periods at doses of 50–100 IU by subcutaneous or intramuscular injections three to seven times weekly; human calcitonin can be used at 100 IU (0.5 mg) per day. Treatment lowers biochemical markers of bone turnover by about 30–50%, relieves bone pain, and can lead to radiological healing of pagetic lesions (Murphy *et al.,* 1980). Even reversal of neurological deficits has been observed at times (Chen *et al.,* 1979), as has the stabilization of hearing loss, and improvement in abnormalities in cardiac output. However, the efficacy of the treatment is limited. First, bone turnover returns to normal only in mild cases. Second, the short duration of action of the drug leads invariably to a recurrence of disease manifestations after each interruption of therapy, heralded by a rise in markers of bone turnover, reappearance of hyperthermic bones, and hyperactive bones by bone scintigraphy. Unlike the potent bisphosphonates, with which one course of treatment can eliminate a whole generation of osteoclasts, calcitonin inhibits osteoclast function for several hours per day only, and decreases osteoclast number only when given over longer periods. The nasal spray formulation of calcitonin requires relatively high doses, such as 400 IU (Nagant *et al.,* 1987; Reginster *et al.,* 1992).

Treatment with calcitonin is limited further by two other effects. First, a plateau is reached in some patients, where no further improvement can be achieved (Singer *et al.,* 1990). A second limitation is due to the appearance of circulating antibodies against the animal calcitonins (Singer *et al.,* 1972). As explained later, these antibodies will neutralize the pharmacological effect of the drug in those few patients with very high titers. In these cases, switching to human calcitonin can reestablish responsiveness (Rojanasathit *et al.,* 1974). Antibody formation does not explain all cases of calcitonin resistance. Although transient loss of receptor sensitivity after calcitonin is known to occur, persistent lack of responsiveness to the usual therapeutic doses remains unexplained (Singer *et al.,* 1980).

Although largely replaced by the bisphosphonates in the treatment of Paget's disease, calcitonin represents an alternative when long-term safety considerations are raised as in younger populations (Tuysuz *et al.,* 1999).

Osteoporosis

Calcitonin is used widely as an antiresorptive agent in the treatment of osteoporosis. Some studies have demonstrated that it prevents bone loss, or even increases bone mass while lowering the incidence of vertebral fractures. Its effect on cortical bone is inconsistent in the forearm and absent in the femoral neck. Since calcitonin inhibits osteoclast activity transiently, markers of bone turnover are not as much reduced as with bisphosphonates. After cessation of treatment, bone markers return rather quickly to baseline levels (Kraenzlin *et al.,* 1996). The modest and transient effects of calcitonin on bone markers make them clinically impractical to use in the context of therapy.

In situations of accelerated bone turnover and bone loss, such as in acute immobilization, after fracture or after organ transplantation, nasal spray calcitonin was ineffective (Uebelhart *et al.,* 1999; Valimaki *et al.,* 1999), while 100 IU given by intramuscular injection had some benefit (Tsakalakos *et al.,* 1993). Vertebral bone loss due to corticosteroid therapy can be prevented by daily intramuscular injections and also by the nasal spray formulation (Adachi *et al.,* 1997). In perimenopausal or in early menopausal states, as well as later in the menopause, various regimens have been useful (Arnala *et al.,* 1996; Gennari *et al.,* 1992; Ellerington *et al.,* 1996; Overgaard *et al.,* 1994; Reginster *et al.,* 1995). Rectal administration is also effective (Kollerup *et al.,* 1994), but not practical for long-term use because of the frequency of local irritation.

The therapeutic endpoints of the treatment of osteoporosis are in increase in bone mass and a decrease in fracture incidence. 100 IU of injectable salmon calcitonin increases bone density, but only during the first 18 months of therapy. This dosage also increases cortical bone density (Crespo *et al.,* 1997). However, for reasons of compliance, long-term studies have been performed primarily with nasal spray calcitonin. With the nasal form, 100 IU of salmon calcitonin was insufficient (Adami *et al.,* 1995). However, when calcitonin was given together with calcium and vitamin D, the nasal formulation increased vertebral bone mineral density significantly in several studies (Overgaard *et al.,* 1995).

Calcitonin has reduced the incidence of vertebral fractures in several small studies (Rico *et al.,* 1995, Overgaard *et al.,* 1992), but significance could be achieved only when the results of several studies were pooled together (Burckhardt *et al.,* 1993; Kanis *et al.,* 1999). Again, nasal spray calcitonin was required for effectiveness to be demonstrated. The largest prospective clinical trial to determine the efficacy of calcitonin in postmenopausal osteoporosis, the PROOF study, was recently published by Chesnut *et al.,* (2000). The use of nasal calcitonin at only the 200-IU dose, and not at the 100- or 400-IU dose, was associated with a significant reduction in vertebral fracture incidence. There was a minimal change in bone mineral density and only a modest effect to reduce indices of bone resorption. It is not clear how the results of this study are best interpreted. The lack of a substantial effect on bone mass and on bone markers suggest that calcitonin might have reduced vertebral fracture incidence by skeletal effects that are not yet quantifiable by available measurements.

Calcitonin has also been used in other bone diseases, such as multiple myeloma, bone metastases, osteogenesis imperfecta, juvenile osteoporosis, osteopathy in thalassemia, reflex sympathetic osteodystrophy, spinal stenosis, rheumatoid arthritis, osteoporosis of biliary cirrhosis, and other disorders.

The Analgesic Effect of Calcitonin

In patients who have sustained an acute vertebral crush fracture, calcitonin has an apparent analgesic effect. Controlled, double-blinded studies have shown that calcitonin decreases pain and the use of analgesics, accelerates mobilization, and shortens length of hospitalization. This analgesic effect appears as early as the second day of treatment and cannot be readily explained by antiresorptive actions alone. Calcitonin was also efficient in treating pains due to bone metastases (Allan, 1993; Schiraldi *et al.,* 1987). Its effect on Paget's disease is related also to this analgesic property.

Binding sites for calcitonin in several areas of the brain might be related to its antinocioceptic action. Mechanisms include serotoninergic or adrenergic actions, modification of calcium fluxes in neuronal membranes, beta-endorphin production, cyclooxygenase inhibition, and histamine interference (Braga, 1994). The analgesic effects of calcitonin are likely to be multifactorial with evidence for involvement of beta endorphin not yet clear (Laurian *et al.,* 1986; Francescini *et al.,* 1989; Overgaard *et al.,* 1991; Vescovi *et al.,* 1990).

The analgesic effects have been seen via injection (Lyritis *et al.,* 1991), nasal spray (Pun *et al.,* 1989; Lyritis *et al.,* 1997), or rectal suppository (Lyritis *et al.,* 1999). The effectiveness seems to be limited to 2–4 weeks. In oncology, an analgesic effect was reached with very high doses (Schiraldi *et al.,* 1987).

Problems and Adverse Effects

There are several problems with calcitonin administered to humans via the nasal, oral, or rectal routes. Response variation is the main issue and this is shared with other large peptides, such as insulin or parathyroid hormone. Highly charged and folded peptides cannot effectively cross cell membranes (Zaidi *et al.,* 1992a). Another problem is that of rapid compartmentalization of absorbed peptide, particularly when the absorption is slow. It has been speculated that circulating monomeric calcitonin is in direct or indirect communication with several compartments (Zaidi *et al.,* 1991; MacIntyre *et al.,* 1990). The transfer coefficients into these compartments are unknown, although one compartment could possibly be the receptor itself (MacIntyre *et al.,* 1990; Hee *et al.,* 2000). A further complication is that calcitonin in the circulation binds to plasma proteins. This effect may be reversible, but again, the rates of association and dissociation are unknown. Thus, the measurement of plasma calcitonin levels at a certain time point may reflect the amount of biologically active calcitonin in one compartment, but not another.

A further problem with long-term treatment of humans with a nonhuman calcitonin (salmon, porcine, and eel) is the development of antibodies (Haddad and Caldwell, 1972; Plehwe *et al.,* 1977; Tagliaro *et al.,* 1995; Singer *et al.,* 1972, 1980). The incidence of antibody formation is directly proportional to the duration of treatment. Within 6 months of salmon calcitonin treatment, 40% of patients develop antibodies. The incidence increases by 10% with every additional 6 months of treatment (Muff *et al.,* 1991; Reginster *et al.,* 1993).

It has been demonstrated by various groups that low antibody titers do not attenuate the effect of the drug; that is, they do not decrease the reduction in bone turnover in Paget's disease (Plehwe *et al.,* 1977), do not diminish the transient hypocalcaemic response seen after each administration (Muff *et al.,* 1990; Hosking *et al.,* 1979), and do not reduce the efficacy of calcitonin in preventing a decline in bone mineral density (Tagliaro *et al.,* 1995; Reginster *et al.,* 1993). Calcitonin-induced cyclic AMP formation (in a human breast cancer cell line) also remains unaffected (Grauer *et al.,* 1990).

However, there is a linear correlation between antibody titer and the serum dilution required for half-maximal inhibition of cAMP production (Muff *et al.,* 1991). At high titers, therefore, antibodies do reduce the efficacy of the drug. This explains the resistance to salmon calcitonin first observed in Paget's patients (Woodhouse *et al.,* 1977; Singer *et al.,* 1980). Patients who become resistant to salmon calcitonin usually respond well when switched to the human peptide, as shown with patients with Paget's disease (Grauer *et al.,* 1990; Muff *et al.,* 1990; Altman *et al.,* 1987). Antibodies to human calcitonin are rare (Dietrich *et al.,* 1979). Only 1 out of 33 patients with osteoporosis treated with human calcitonin developed neutralizing antibodies, and the neutralizing effect was comparatively mild compared with the effects of antibodies against salmon calcitonin (Grauer *et al.,* 1993).

High antibody titers do not provide an explanation for all cases of calcitonin resistance. In fact, it has been shown that antibodies to eel calcitonin for example, do not impact on efficacy; instead the pharmacokinetics of the drug becomes altered (Tagliaro *et al.,* 1995). Another factor is the loss of responsiveness to calcitonin due to receptor downregulation. Calcitonin inhibits the synthesis of its own receptor (Lee *et al.,* 1995; Rakapoulos *et al.,* 1995; Liu *et al.,* 2000). Notably, calcitonin-dependent downregulation of the C1a osteoclastic receptor has been shown to involve a transcriptional mechanism (Inoue *et al.,* 1999). There is also significant evidence of homologous desensitization of the calcitonin receptor (Schneider *et al.,* 1993). Additionally, it has been shown that postmenopausal women treated with calcitonin had decreased calcitonin receptor mRNA levels compared to placebo-treated counterparts (Beaudreuil *et al.,* 2000). In these women, prevalence of calcitonin receptor-2 was inversely proportional to bone turnover rates (Beaudreuil *et al.,* 2000).

Current and Future Therapeutics

Several prospective controlled trials have also documented stabilization of, and in some cases modest short-term increases in, bone mineral density in osteoporotic patients treated for 5 years or less (Gruber *et al.,* 1984; Mazzuoli *et al.,* 1986; Reginster, 1993). Much of this benefit has been observed in trabecular bone; the benefit of calcitonin in reducing cortical bone loss has not been clearly demonstrated

(Reginster, 1993; Overgaard *et al.,* 1995). Similar effects have been demonstrated utilizing calcitonin as a preventive treatment for menopausal trabecular bone loss (Reginster, 1993; Mc Dermott *et al.,* 1987). Three studies directly evaluating the impact of calcitonin on fracture reduction have all shown significant fracture reduction. This benefit was observed both in postmenopausal and elderly women (Overgaard *et al.,* 1995; Kanis *et al.,* 1992; Rico, 1992). Long-term studies using calcitonin reveal a 1.2% increase in bone mineral density at the spine over 5 years (Chesnut, 2000).

Compromised trabecular microarchitecture is an important and independent causal factor in the pathogenesis of vertebral fractures in both men and women (Legrand *et al.,* 2000). It is now emerging that there is a temporal dissociation between reduction in fracture risk that can occur between 12 and 18 months, bone markers, and long-term effects on bone mineral density. Notably, a benefit in fracture risk occurs before a change in bone mineral density. Recent clinical trials with antiresorptives, such as calcium plus vitamin D, calcitonin, and raloxifene, indicate significant protection from fracture despite only modest increases in bone mineral density. This has led to the belief that anti-resorptives, such as calcitonin, by preventing osteoclastic resorption, conserve bone microarchitecture (Dempster, 2000).

It is not that calcitonin is an inactive drug (MacIntyre and Zaidi, 1990); rather the problem of efficacy arises almost purely from its bioavailability (Lee and Sinko, 2000). Several new approaches are currently being used to enhance calcitonin access to the osteoclast, its target cell. First, there is interest in the development of novel allosteric activators of the calcitonin receptor with a goal of making the receptor more sensitive to changes in circulating calcitonin (see above) (Chen *et al.,* 1999). This strategy has been achieved for the parathyroid cell Ca^{2+}-sensing receptor, another G protein-coupled seven-pass receptor, whereby an oral calcimimetic (or Ca^{2+} receptor agonist) is being evaluated for use in hyperparathyroidism (Silverberg *et al.,* 1997; Collins *et al.,* 1998; Goodman *et al.,* 2000). The latter drug shifts the PTH–serum calcium response curve to the right, and hence, by increasing the sensitivity of the Ca^{2+} sensing receptor to serum Ca^{2+}, decreases PTH secretion.

Second, there is the possibility of modulating the release of endogenous calcitonin itself by a drug that activates the C-cell Ca^{2+} sensing receptor, again through an allosteric mechanism, by making it more sensitive to circulating serum Ca^{2+}. However, this approach is unlikely to succeed, as the calcimimetic is likely also to depress PTH secretion through the parathyroid cell Ca^{2+} receptor.

Third, eminent is the development of an oral calcitonin that is coupled to a molecule that will enable absorption and prevent breakdown, but retain biological activity (Lee *et al.,* 2000; Dogru *et al.,* 2000). These compounds are also likely to be absorbed in a site-specific manner, for example, in the colon (Tozaki *et al.,* 2001). There is the likelihood of a polyethylene glycol-modified salmon calcitonin that has significant biological activity and prolonged plasma half-life (Yoo *et al.,* 2000). Pulmonary and transdermal routes are also under consideration (Chang *et al.,* 2000; Patton, 2000). Finally, there are now gene therapy vectors available that would allow osteoclast precursors to carry the calcitonin gene to specific bone sites of osteolysis. The next few years should therefore see the revival of calcitonin as an important therapeutic agent.

CHAPTER 83

Growth Hormone and Insulin-like Growth Factor-I Treatment for Metabolic Bone Diseases

Clifford J. Rosen

The Jackson Laboratory and the Maine Center for Osteoporosis Research and Education, St. Joseph's Hospital, Bangor, Maine 04401

Introduction

The growth hormone (GH)/insulin-like growth factor-I (IGF-I) regulatory system, which includes endocrine/paracrine/autocrine effects of IGF-I, is involved in determining bone size, length, density and architecture of the mature mammalian skeleton. As noted in an earlier chapter, skeletal IGF-I, in concert with other determinants, regulates osteoblast recruitment and differentiation. Although it is still not clear exactly how the effects of IGF-I partition in respect to skeletal regulation, it is likely that both types of action (i.e., endocrine and autocrine/paracrine) are essential for acquisition and maintenance of peak bone mass (see Fig. 1). Indeed, the importance of the endocrine aspects of IGF-I in respect to bone modeling and remodeling have recently been highlighted. For example, several studies have shown that serum levels of IGF-I correlate with bone mineral density (BMD), cross-sectional area of the femur, risk of future hip fracture, and a polymorphism in the IGF-I gene (Donahue and Rosen, 1998; Boonen *et al.,* 1997; Langlois *et al.,* 1998; Nicholas *et al.,* 1994; Sugimoto *et al.,* 1997; Bauer *et al.,* 1998; Rosen and Pollak, 1999; Garnero *et al.,* 2000; Kurland *et al.,* 1997). In mice, serum IGF-I cosegregates with the BMD phenotype, is directly correlated with femur length, and has been associated with a marked increase in bone formation indices (Rosen *et al.,* 2000). Moreover, changes in skeletal expression and content of IGF-I reflect serum levels of this peptide (Rosen *et al.,* 2000). Hence, circulating and tissue expression of IGF-I are important in maintenance of skeletal homeostasis, and thereby provides a significant rationale for considering the administration of either GH or IGF-I as a potential anabolic agent for the treatment of metabolic bone disorders associated with low bone formation. In this chapter, I will review the evidence for and against the use of these peptides in bone diseases such as osteoporosis.

Growth Hormone Therapy for Osteoporosis

Physiology of GH

Overview of GH Secretion

The regulation of growth hormone secretion from the pituitary is complex and involves the elaboration of discrete neurosecretory peptides from the hypothalamus. These include growth hormone-releasing hormone (GHRH) and other growth hormone-releasing peptides (GRPs). Somatostatin (SMS), a small but ubiquitous polypeptide, inhibits GH synthesis and secretion, thereby tightly controlling GH production. Both neuropeptides (GHRH and SMS) are synthesized in specialized hypothalamic neurons, released from axon terminals in the median eminence, and transported through the hypophyseal portal circulation into the anterior pituitary (Cronin and Thorner, 1989). GH secretion is pulsatile (due to episodic release of GHRH) and circadian, with the highest pulse amplitude occurring between 02:00 and 06:00 (Winer *et al.,* 1990; Ho and Weissberger, 1990). Puberty has a dramatic effect on the amplitude of GH pulses,

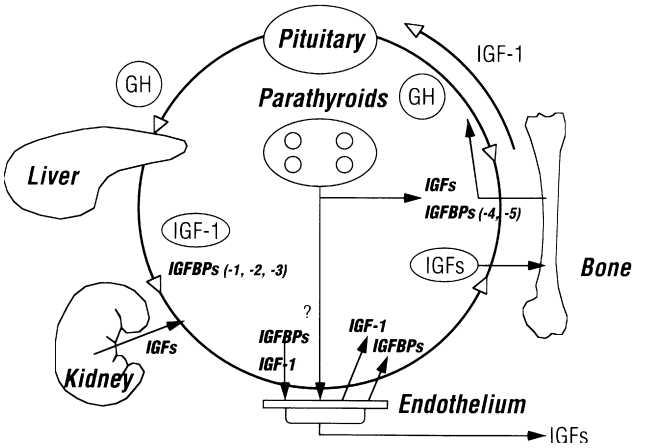

Figure 1 The circulating IGF regulatory system represents the sum of IGFs produced by the liver, kidney, and skeleton, as well as IGFBPs which come from various tissue sources and are regulated by a myriad of autocrine, paracrine, and endocrine factors. The endothelium serves as a site for passage of IGFs and IGFBPs to and from the circulation.

due to changes in the hypothalamic milieu as a result of rising sex steroid concentrations (Jannson *et al.,* 1985). Apart from tight neuroendocrine regulation of GH secretion by SMS and GHRH, there is a negative feedback loop on GHRH and GH by IGF-I.

Effects of Gonadal Status on GH/IGF-I

The pattern of GH secretion in animals and humans depends highly on age and sex (Cronin and Thorner, 1989; Winer *et al.,* 1990; Ho and Weissberger, 1990). Both factors strongly influence the frequency and amplitude of GH pulses, GH basal secretory rates, and the levels of serum IGF-I. Characteristic changes during puberty in rats parallel pubertal changes in humans (Jannson *et al.,* 1985). GH secretion in male and female rats is identical after birth but at puberty, a sexually differentiated pattern of secretion appears, with male rats displaying high-amplitude low-frequency pulses, and female rats displaying pulses of high frequency but low amplitude (Jannson *et al.,* 1985). This sexual dimorphism can be altered by manipulating the gonadal steroid environment, suggesting that sex steroids are important modulators of GH secretion.

In humans, sexual differences in GH secretion during puberty are less pronounced, even though administration of gonadal steroids to prepubertal children increases GH pulses and mimics the pubertal milieu of the hypothalamus. Various sampling techniques (profiles versus stimulatory tests) and assays with different sensitivities, have produced disparate findings. However, spontaneous and stimulated GH peaks in humans are enhanced during puberty. Matched for age and body mass index, young girls were found to have higher integrated GH (IGHC) levels than boys (Ho and Weissberger, 1990; Weissberger *et al.,* 1991). Other secretory characteristics, including pulse amplitude, frequency, and the fraction of GH secreted as pulses (FGHP), were similar in both sexes of the same age. In a preliminary study, black adolescents (males and females) had higher GH secretory rates than age-matched whites (Wright *et al.,* 1994). Higher GH secretion rates in adolescent blacks could lead to greater acquisition of bone mass.

Gonadal steroids affect GH secretion in perimenopausal women. IGHC, mean pulse amplitude of GH and FGHP are lower in older women than premenopausal women (Weissberger *et al.,* 1991). GH secretory indices in postmenopausal women correlate with serum estradiol, but not with total serum androgen levels. During menopause, GH secretion is reduced (Ho and Weissberger, 1990; Weissberger *et al.,* 1991). However, oral administration of estradiol (or conjugated equine estrogens) increases GH secretion as a result of reduced hepatic generation of IGF-I (Ho and Weissberger, 1990; Jannson *et al.,* 1985; Weissberger *et al.,* 1991; Wright *et al.,* 1994; Dawson-Hughes *et al.,* 1986). On the other hand, transdermal administration of 17-β estradiol, increases serum IGF-I concentration, suggesting that suppression of IGF-I by oral estrogens is due to "first-pass" hepatic effects (Weissberger *et al.,* 1991). Impaired IGF-I generation in the liver removes a key component of negative feedback on the hypothalamus, resulting in increased GH release (Bellantoni *et al.,* 1991).

Effects of Age on GH–IGF-I

The GH–IGF-I axis undergoes changes over a life span so that elders have lower spontaneous GH secretion rates and serum IGF-I levels than younger people (Rosen *et al.,* 1990). These age-related differences are a function of an altered hypothalamic–pituitary set point due in part to changes in lifestyle and nutrition (Ghigho *et al.,* 1993). The GH secretory response to common stimuli such as GHRH, clonidine, L-dopa, physostigmine, pyridostigmine, hypoglycemia, and met-enkephalin, but not arginine, are reduced by aging (Carpas *et al.,* 1993). Somatotrope responsiveness to GHRH and arginine does not vary with age, implying that the maximal secretory capacity of somatotropic cells is preserved in elderly people (Carpas *et al.,* 1993; Kelijman, 1991).

There is fairly strong evidence that GH and IGF-I concentrations decline with advanced age although several large cross-sectional studies have either failed to demonstrate an association between diminished serum IGF-I and age-related bone loss or a weak association between serum IGF-I and bone mineral density (Donahue and Rosen, 1998; Boonen *et al.,* 1997; Langlois *et al.,* 1998; Nicholas *et al.,* 1994; Bennett *et al.,* 1994). On the other hand, concentrations of IGF-I, IGF-II, and IGFBP-5 in femoral cortical and trabecular bone decline significantly with age (Donahue and Rosen, 1998; Boonen *et al.,* 1997; Langiois *et al.,* 1998; Nicholas *et al.,* 1994).

Mechanisms of GH Action on Bone

Growth hormone has direct and indirect effects on bone, depending on age and skeletal maturity. Indirectly, GH can enhance BMD through its effects on muscle mass and calcium transport in the gut. In addition, growth hormone can directly

stimulate bone remodeling and increase endochondral growth through its actions on the osteoblast. For example, in orchiectomized rats, GH stimulates bone formation and bone density (Prakasam *et al.,* 1999). Similarly, administration of GH and or IGF-I, without estradiol, can enhance bone formation and trabecular bone volume in ovariectomized rats (Verhaeghe *et al.,* 1996). Overall, GH is considered essential for both the growth and maintenance of skeletal mass. This is especially evident in growth hormone deficiency (GHD) states, whether it be in childhood or adulthood, in which there is reduced BMD. In one of the largest observational trials to date, KIMS, GHD was linked to a marked increase in fracture risk compared to that seen in age-matched normals (Rosen, 1997).

Substantial differences between the direct and indirect effects of GH on the osteoblast partially explain changes in skeletal responsiveness to GH and IGF-I. For example, exogenous GH stimulates longitudinal growth in normal rats, but rhIGF-I does not. Similarly, transgenic mice that overexpress GH grow to twice their normal size while transgenic IGF-I mice are not longer, and exogenous administration of IGF-I is far less efficient in stimulating long bone growth (Guler *et al.,* 1988). Thus, despite the fact that GH induces IGF-I production in the skeleton and elsewhere, treatments with GH and with IGF-I are not equivalent. In general, skeletal responses to GH and IGF-I depend on the species, the GH status of the animal, and the mode of administration. Even the systemic side effects of rhGH and rhIGF-I therapy may differ substantially.

Effects of GH on Bone Mineral Density and Bone Turnover

GH Treatment for GHD Children

Early clinical experiences with rhGH in GHD children provided investigators with a model for studying skeletal responsiveness to somatotropin. Intermittent (daily or three times weekly) injections of rhGH results in a prolonged and sustained GH profile with resultant catch-up growth evident during the first year of treatment (Rappaport and Czernichow, 1993). This increase in skeletal growth is accompanied by a rise in serum levels of type I procollagen peptide (Carey *et al.,* 1985). Although dosage schemes vary between the United States and Europe (0.1 mg/kg/tiw [US] to 0.7 U/kg/week [Europe]), there is a strong dose-related growth response to rhGH (DeMuinck Keizer-Schrama *et al.,* 1992).

The skeletal response to GH depends on several factors including: (i) GH secretory status, (ii) pretreatment IGF-I levels, (iii) pretreatment height velocity, and (iv) GH dosage. The rate of change in serum IGF-I (rather than the absolute level of IGF-I attained by GH treatment) is a relatively nonspecific predictor of growth as are procollagen I and osteocalcin concentrations (DeMuinck Keizer-Schrama *et al.,* 1992). Serum procollagen III levels do correlate with growth rates during GH treatment (Carey *et al.,* 1985).

Linear growth is a measurable response to exogenous GH, but changes in bone mineral density in children are more difficult to quantify. In some studies, bone mineral content is increased during GH treatment to a greater extent than expected for change in bone size (Inzucchi and Robbins, 1994). However, it should be remembered that short stature, which is the central phenotypic component of GHD in children, leads to an underestimation of true bone mineral density. In general, a 20-cm difference in body height is associated with an approximately 1 SD decline in BMD. However, this effect can be taken into account and an areal density corrected for size (BMAD) can be calculated for the femur or vertebrae. Similarly, pQCT and QCT measurements demonstrate that GHD children have low volumetric BMD, which responds to GH treatment. In one of the longest intervention trials to date, 26 GH-deficient children were given rhGH (0.6 IU/kg per week) for 12 months (Saggese *et al.,* 1993). Baseline radial bone mineral content (BMC) *Z* scores (corrected for their chronological, statural, and bone ages) were significantly reduced, as were serum osteocalcin and procollagen peptide levels. Treatment with rhGH six times per week increased BMC and normalized *Z* scores of the radius in nearly 50% of the subjects. Serum levels of procollagen peptide during the first week of treatment were positively related to growth velocity at 6 and 12 months and radial BMC at 12 months. Although there are striking differences between longitudinal growth in children and remodeling in adults, criteria that determine skeletal responsiveness in children may also be relevant for the effects of rhGH on the skeleton in older individuals.

GH Administration to Healthy Adults

The treatment of adult GHD is a relatively new option for patients with low BMD. Yet some of the same principles of treatment hold for adults as for children with GHD. Evidence from several longitudinal controlled trials provides insight into the expected responses of different adult populations to rhGH. These include: (i) healthy adults, (ii) GHD adults, (iii) elderly men and women with/without osteoporosis. Initial studies with rhGH in adults focused primarily on changes in body composition. Short-term treatment with rhGH leads to a decrease in adiposity and an increase in lean body mass (Crist *et al.,* 1991). There is also a marked shift in extracellular water (Holloway *et al.,* 1994). Detailed analysis of skeletal markers during GH treatment was first reported by Brixen *et al.* (1990). Twenty male volunteers (ages 22–31) were given a relatively large dose (0.1 IU/kg) of rhGH twice daily for 7 days. Serum osteocalcin increased after 2 days of treatment and remained elevated for 6 months. Bone alkaline phosphatase decreased initially (during the 7 days of GH treatment) but then increased slightly over 6 months (Brixen *et al.,* 1990). Serum calcium and phosphate increased but only during the 7-day treatment phase. Like bone formation indices, urinary markers of bone resorption (urinary Ca/Cr and hydroxyproline/creatinine) rose during treatment and remained elevated for up to 4 weeks after discontinuation of therapy.

Treatment with rhGH stimulates bone remodeling. More importantly, the anabolic effect on bone may persist well beyond discontinuation of growth hormone. Early (2-day)

and late (2-week) osteocalcin responses imply that GH can stimulate existing osteoblasts and enhance recruitment of new osteoblasts. Very recently, Biller *et al.* (2000) demonstrated that after discontinuation of rhGH in GHD, patients still acquired BMD at a significant rate. Still, it is uncertain if those effects are mediated through IGF-I. For example, Brixen *et al.* (1990) was unable to find a significant correlation between the rise in serum IGF-I and an increase in osteocalcin or bone alkaline phosphatase. The absence of a significant correlation between bone formation markers and serum IGF-I, however, may be due to the low skeletal specificity of serum IGF-I.

Skeletal resistance to GH has been considered a possible cause for postmenopausal osteoporosis. On the basis of one double-blinded rhGH trial in postmenopausal women, this is unlikely. Kassem *et al.* (1994) noted that administration of rhGH (0.2 IU/kg/day) for 3 days increased serum IGF-I, osteocalcin, and procollagen type I C-terminal propeptide (PICP) to the same extent in 15 women with severe postmenopausal osteoporosis as in 15 age-matched control women. Serum and urinary markers of bone resorption also did not differ between the two groups. *In vitro* studies of marrow stromal cells from osteoporotic women demonstrate full GH responsiveness (Kassem *et al.,* 1994). Therefore, it is unlikely that the osteoporotic skeleton is resistant to rhGH treatment.

GH Treatment for Growth Hormone-Deficient Adults

Generalized GH Actions during Treatment in Adult GH Deficiency Growth hormone deficiency can be documented by provocative stimuli (GHRH, insulin, glucagon) and serial GH measurements. The majority of adult patients treated with rhGH have either idiopathic GHD or a history of previous central nervous system (CNS)/pituitary–hypothalamic tumors. Early trials with rhGH replacement therapy examined changes in muscle mass, muscle strength, and body fat. Daily administration of subcutaneous rhGH to GHD patients produced a marked rise in serum IGF-I and an increase in muscle mass and basal metabolic rate (Jorgensen *et al.,* 1991). Some of those anabolic changes were noted soon after the initiation of rhGH. For example, mean nitrogen retention during the first 15 days of rhGH treatment was as much as 2.8 g per day (approximately 20 g of muscle mass) (Valk *et al.,* 1994). GH treatment can also increase the total cross-sectional area of thigh muscles and quadriceps as well as improve hip flexors and limb girdle strength (Jorgensen *et al.,* 1991; Cuneo *et al.,* 1991). At least one group has suggested that rhGH can increase the number of type II muscle fibers. Total fat mass, however, consistently decreases during rhGH treatment (Jorgensen *et al.,* 1989, 1991; Cuneo *et al.,* 1991). Based on these and other studies, the U.S. FDA approved the use of rhGH in patients with established growth hormone deficiency.

GH Effects on Biochemical Markers of Bone Turnover in GHD Several biochemical tests reflect the physiologic action of GH on the skeleton. Serum calcium, osteocalcin, and urinary hydroxyproline all increase, while PTH declines slightly during rhGH treatment (Van der Veen and Netelembos, 1990). Newer and more sensitive markers of bone turnover also reflect changes during rhGH treatment. Urinary deoxypyridinoline, and N-telopeptide increases threefold and the amino-terminal propeptide of type III procollagen doubles during 4 months of daily rhGH (Johansen *et al.,* 1990; Christiansen *et al.,* 1991). After cessation of rhGH treatment, deoxypyridinoline excretion decreases but type III procollagen levels remain higher than controls for several months (Jorgensen *et al.,* 1990). The balance between resorption and formation markers suggest that rhGH would modestly enhance trabecular BMD. It is conceivable that in the post-treatment period, the persistent increase in bone mineral density noted by Biller *et al.* (2000) is a function of enhanced bone formation at a time when bone resorption is declining. Further studies should clarify this potentially important effect on remodeling.

Effects of GH on Bone Density in GHD If prolonged growth hormone deficiency in adults results in profound changes in the musculoskeletal system, then GH replacement would be expected to enhance muscle performance and bone mass. However, skeletal responses to rhGH therapy are very dependent on several factors: (1) GH dose, (2) time of onset of GHD (i.e., childhood [lower BMD] vs adult), (3) age of treatment, (4) timing of response, (5) skeletal site measured, and (6) gender (women tend to have slightly less brisk of a BMD response than men) (Burman *et al.,* 1997). Notwithstanding, it does appear that muscle mass is significantly enhanced by rhGH treatment in GHD patients (Welle *et al.,* 1996). In general, doses of rhGH to adult GHD patients have tended to decrease with longer experience, such that the replacement dose recommended by the U.S. FDA is approximately 0.005 mg/kg/day. For example, in earlier studies with relatively higher daily doses of rhGH, 14 GHD adults given a nightly dose of 0.5 IU/kg/ week showed increases in exercise capacity, maximum oxygen consumption, and alkaline phosphatase even though quadriceps strength and spinal bone density did not change (Whitehead *et al.,* 1992). When 0.25 IU/kg/week of rhGH was administered to 12 GH-deficient adults for 1 year, there was a marked increase in trabecular bone density (measured by single- and dual-energy QCT of the spine) at 6 and 12 months. At 12 months, proximal and distal forearm BMC increased, mid-thigh muscle area was greater, and fat cross-sectional area decreased. Since the rise in spine BMD was noted with both single- and dual-energy CT measurements of the spine, this increase probably resulted from enhancement in bone mass not a reduction in marrow fat.

More recently, several groups have performed longer studies with rhGH for replacement in the GHD syndrome. Although changes in BMD are not significant at 12 months, by 24 and 36 months, BMD can increase by as much as 5–8% in the spine (Janssen *et al.,* 1998; Johannsson *et al.,* 1996; Baum *et al.,* 1996; Papadakis *et al.,* 1996; Rahim *et al.,* 1998). Moreover, some investigators have also reported

a concomitant increase in muscle strength after 2 years of treatment. However, it should be noted that the longer duration trials were not placebo-controlled for more than 18 months; those subjects followed out to 3 years had open label rhGH after either 6, 12, or 18 months of treatment. Notwithstanding that caveat, it appears that those individuals with earlier onset of GHD, as well as those with the lowest BMD, had the greatest likelihood of showing significant changes in bone mass with rhGH. Moreover, in those individuals receiving rhGH as replacement therapy, it appears that any judgement about efficacy in respect to BMD will require a follow-up BMD not earlier than 24 months. A relatively large randomized placebo-controlled trial of rhGH with BMD as a primary end point, and of 2 years duration, is currently entering its final stages and may provide our best indication yet about the magnitude of the anabolic effects of BMD on the skeleton. For now, it is apparent that rhGH treatment to adult GHD patients increases bone turnover, enhances BMD, and increases muscle mass and strength.

GH Administration to Elders

Generalized GH Effects Elderly people have lower GH secretory amplitudes and reduced serum levels of IGF-I and IGFBP-3 compared to younger adults (Finkelstein *et al.,* 1972; Lieberman *et al.,* 1994). Moreover, the pulse frequency for GH is lower in older people. Based on these data, it was assumed that skeletal responsiveness to GH in elders would be identical to that seen in GHD patients. In elderly men one group has reported a blunted serum IGF-I response to 0.1 mg/kg GH (36% lower) compared to that in younger men or adults with GHD (Finkelstein *et al.,* 1972; Lieberman *et al.,* 1994). However, Rosen *et al.* (1999) noted recently that generation of IGF-I after various doses of rhGH to frail elders was not associated with growth hormone resistance. Based on some recent data it appears that GH replacement for adult GHD or for pharmacological treatment of elders results in similar IGF-I responses.

Effects of GH on Bone Density and Bone Remodeling in Elders The most widely publicized growth hormone trial in elders involved 21 men over age 65 randomized to receive 0.03 mg/kg of rhGH three times per week (as a subcutaneous injection) or to no treatment whatsoever. Twelve men received rhGH while 9 men served as observational controls. The men were selected on the basis of a low serum IGF-I (<350 IU/liter) concentration (Rudman *et al.,* 1991). rhGH produced a threefold rise in circulating IGF-I, an increase in lean body mass (as measured by ^{40}K analysis), and a decline in total adipose mass. Bone density of the lumbar vertebrae (L_1–L_4) as measured by dual photon absorptiometry, increased 1.6% after 6 months in the treatment group while no change was noted in controls. Biochemical markers of bone turnover were not examined and no changes in bone density were detected in the mid- or distal radius or three areas of the hip. Furthermore, the spinal BMD changes at 6 months were not sustained at 1 year (Rudman *et al.,* 1991).

Marcus *et al.* (1990) studied the effects of rhGH in 16 men and women over age 60. Daily doses of rhGH (0.03, 0.06, or 0.12 mg/kg BW/day) were randomly assigned to each subject and administered once daily for 7 days. Serum IGF-I, osteocalcin, PTH, and calcitriol concentrations all increased during treatment. In this short-term study, there was also a significant rise in urinary hydroxyproline and urinary calcium excretion with a decline in urinary sodium. Holloway *et al.* (1994) conducted a longer randomized double-blinded placebo-controlled trial of daily rhGH for 1 year in 27 healthy elderly women, 8 of whom took a stable dose of estrogen throughout the study. Thirteen women completed 6 months of treatment and 14 women completed 6 months in the placebo group. Side effects prompted a 50% reduction in the original dose of rhGH (from 0.043 mg/kg BW or approximately 0.3 mg rhGH/kg/week to 0.02 mg/kg/day) and led to several dropouts in the treatment group. Fat mass and percentage body fat declined in the treatment group but there were no changes in bone density at the spine or hip at 6 or 12 months in other groups (Holloway *et al.,* 1994). Although BMD did not change, there were changes in some biochemical parameters. In particular, urinary markers of bone resorption (hydroxyproline and pyridinoline) increased after 6 months of rhGH treatment. The response of bone formation markers was more variable. Osteocalcin increased but type I procollagen peptide levels did not change. For women taking estrogen replacement therapy, indices of bone turnover (both formation and resorption) were blunted.

More recently, Rosen *et al.* (1999) reported that there is a dose-dependent decrease in bone mass after 1 year of rhGH in frail elderly men and women. This occurred despite striking increases in osteocalcin and serum IGF-I with the highest doses of rhGH (0.01 mg/kg/day). In part, the absence of a GH effect on BMD is not surprising since resorption is coupled to formation and GH activates the entire remodeling sequence. Indeed, in the same trial of 132 frail elderly subjects by Rosen and colleagues (1999), urinary N-telopeptide and osteocalcin both rose to the same extent, suggesting that total bone turnover, not just bone formation, was increased by rhGH therapy. Also, 1 year is too short a time to conclude definitively that rhGH would not increase bone mass. This is best exemplified by the rhGH trials in GHD. However, the relatively high incidence of side effects (weight gain, carpal tunnel syndrome, edema, glucose intolerance) in GH trials, especially in the frail elderly, is particularly troublesome. Ongoing rhGH studies in elders will examine factors such as the age of the person, presence of preexisting conditions, and IGF-I levels after GH to determine if these side effects can be predicted.

GH Treatment for Osteoporotic Patients

Short nonrandomized clinical trials with GH in osteoporosis were attempted well before GH replacement therapy was considered. As early as 1975, two patients with osteogenesis imperfecta and one patient with involutional osteoporosis were treated with GH (Kruse and Kuhlencordt, 1975).

Histomorphometric parameters of increased bone formation and resorption were noted. Subsequent studies employed GH with and without anti-resorptive agents. Aloia *et al.* (1976) administered between 2 and 6 U/day of GH for 12 months to eight patients with postmenopausal osteoporosis (the first 6 months of treatment featured low-dose GH; the last 6 months consisted of high-dose GH (6 U/day). Radial bone mineral content dropped slightly and histomorphometric parameters did not change during treatment. However, severity of back pain decreased considerably in several people (Aloia *et al.,* 1976). Daily GH injections (4 U/day) combined with alternating doses of calcitonin produced an increase in total body calcium (measured by neutron activation analysis) but a decline in radial bone mass after 16 months (Aloia *et al.,* 1977). In a separate trial, 14 postmenopausal women were given 2 months of GH and then 3 months of calcitonin in a modified form of coherence therapy (Aloia *et al.,* 1987). Total body calcium increased 2.3%/year and there were few side effects, but there were no changes in bone mineral density or histomorphometric indices. Dambacher *et al.* (1982) administered 16 U of rhGH every other day along with daily sodium fluoride to six women with postmenopausal osteoporosis. On histomorphometric analysis, there was a significant increase in the number of osteoblasts and osteoclasts but bone mass was unchanged.

Johannson *et al.* (1994) conducted a placebo-controlled double-blinded crossover trial of rhGH and IGF-I in 14 men with idiopathic osteoporosis. In this 7-day trial with rhGH (2 IU/m^2), procollagen peptide and osteocalcin levels increased after treatment as did urinary markers of bone resorption. The changes in osteocalcin were relatively small, however, and were not sustained after discontinuation of growth hormone treatment. There are no GH trials (past or present) which have examined spinal fractures as a therapeutic end point. Therefore, it is difficult to judge the potential efficacy of GH in the treatment of osteoporosis. However, GH stimulates bone remodeling activity, thereby leaving open the possibility that GH can be coupled to anti-resorptive agents. Holloway and colleagues (1997) tested this thesis in a 2-year randomized trial. In that study, rhGH and nasal calcitonin increased spine BMD by approximately 2%. This, however, was not much different than the use of CT alone, and certainly less than what has been seen in very large randomized trials with anti-resorptive agents. Once again, there were several side effects that produced limited enthusiasm for rhGH as a primary treatment for osteoporosis. Therefore, it is likely that GH may induce small but significant changes in bone mass which over an extended period could translate into fewer spine fractures. However, there are still no data to support that contention. In the meantime, several very small trials have looked at the effects of GH-releasing analogs on bone turnover and bone mass. Not unlike rhGH, however, these studies have been small, and the results somewhat conflicting. However, in contrast to rhGH, GH-releasing analogs are NOT associated with significant side effects. Hence, further trials are likely to begin with these analogs.

IGF-I for the Treatment of Osteoporosis

Introduction

In the late 1980s clinical trials with recombinant human IGF-I for diabetes mellitus were begun. The availability of this recombinant peptide and the absence of other treatments to stimulate bone formation accelerated animal and human studies of rhIGF-I in metabolic bone diseases. Theoretically, there are potential benefits for rhIGF-I compared to rhGH. These include: (i) more direct stimulation of bone formation, (ii) bypass of skeletal GH resistance, (iii) reduction in GH-induced side effects such as carpal tunnel and diabetes mellitus. There are, however, considerably fewer animal and human studies using rhIGF-I than rhGH. Therefore, these advantages have either yet to be fully realized or have not been validated. More importantly, we are still not certain how autocrine/paracrine/or endocrine IGF-I affects bone modeling and remodeling. For example, IGF-I stimulates bone formation by enhancing collagen biosynthesis in osteoblasts; however, the temporal sequence *in vivo* is not entirely clear. Moreover, there is now ample evidence that IGF-I can enhance recruitment of osteoclast precursors, and that IGF-I suppresses production of OPG, the dummy receptor for RANK ligand. These lines of evidence suggest that IGF-I may be important for both bone resorption and bone formation. Unfortunately, there are no long-term studies with rhIGF-I to confirm this putative role. Some newer studies, as noted below, are provocative and provide a framework for further investigation.

Animal Studies with rhIGF-I

rhIGF-I and Bone Growth

IGF-I is not a potent mitogen in most tissues and bone is no exception. There are high-affinity receptors for IGF-I on osteoblasts and IGF-I can stimulate preosteoblast replication and provoke resting cells to proceed through their growth cycles. IGF-I maintains the differentiated osteoblast phenotype, stimulates collagen synthesis, and prevents collagen degradation. It may also be critical in preventing apoptosis of osteoblasts. As noted above, IGF-I may also play a role in the recruitment of osteoclasts. Theoretically, therefore, despite its relatively weak mitogenic properties, IGF-I could have significant anabolic activity on the skeleton.

In hypophysectomized rats, growth can be fully restored by administration of either GH or IGF-I but not IGF-II (Schoenle *et al.,* 1982, 1985). A similar growth response occurs after rhIGF-I in streptozotocin-diabetics rats but not in sex linked dwarf-mutant chickens (Zapf *et al.,* 1989; Tixier-Bouchard *et al.,* 1990). In normal rats, rhIGF-I administered either systemically or locally (hindlimb infusions), does not stimulate longitudinal bone growth (Zapf *et al.,* 1990). In the spontaneously diabetic BB rat, rhIGF-I treatment does not result in changes in epiphyseal width, osteoblast surfaces, or osteocalcin concentration (Verhaege *et al.,* 1992).

The skeletal response to rhIGF-I is determined by the growth hormone/IGF-I status of the animal. For example, IGF-I does not increase bone formation in normal rats, whereas it stimulates bone growth and normalizes type I procollagen mRNA levels in hypophysectomized rats (Schmid *et al.,* 1989; Spencer *et al.,* 1991; Tobias *et al.,* 1992). Similarly, in the spontaneous mouse mutant (*lit/lit*), absence of GH releasing hormone receptors results in very low levels of IGF-I and skeletal dwarfism. IGF-I treatment restores growth and increases total body water but does not enhance bone mass in these mice (Donahue *et al.,* 1993). These findings are somewhat similar to the effects of GH on the skeleton in GH-deficient animals. However, rhIGF-I and rhGH differ in their actions on the circulatory IGF regulatory system. Growth hormone stimulates hepatic production of both IGF-I and IGFBP-3 while rhIGF-I administration increases the total circulating pool of IGF-I but suppresses hepatic production of IGFBP-3, primarily through feedback inhibition of GH secretion. It is conceivable that variations in IGF-I biological activity (between direct IGF-I administration and endogenously produced IGF-I as a result of GH treatment) may be due to the relative proportion of IGF-I bound to IGFBP-3.

rhIGF-I Effects on Bone Density in Animals with Altered Bone Turnover

Several experimental paradigms have been employed to study the effects of IGF-I on bone turnover in animals. These include: (i) oophorectomy, (ii) diabetes mellitus (spontaneous or induced), (iii) immobilization. In each situation, bone remodeling is markedly altered prior to IGF-I treatment in order to study growth factor actions on bone resorption and formation. These experimental models provide useful clinical information since IGF-I has been considered a potential therapeutic agent under conditions similar to those produced experimentally.

In oophorectomized rats, administration of rhIGF-I has variable effects on bone remodeling, bone mass, and bone strength. Kalu *et al.* (1991) reported partial restoration of trabecular bone volume after oophorectomy in adult rats treated with rhIGF-I. In older oophorectomized rats, rhIGF-I increased mid-shaft tibial BMD and enhanced periosteal bone apposition (Ammann *et al.,* 1993). Six weeks of rhIGF-I (delivery by mini-osmotic pump) to older rats caused a dose-dependent increase in bone density in the lumbar spine and proximal femur although bone strength and stiffness did not change. Mueller *et al.* (1994) reported that subcutaneous administration of rhIGF-I to adult oophorectomized rats stimulated bone formation as evidence by increased osteoid surfaces, osteoblast surfaces, and mineral apposition rates. At high doses of rhIGF-I, osteoclast surface and osteoclast number also increased. In contrast, Tobias *et al.* (1992) found that rhIGF-I (200 mg/kg) administered for 17 days to 15-week-old rats increased longitudinal and periosteal growth but suppressed trabecular bone formation in both oophorectomized and control rats. Bone resorption was also slightly suppressed during rhIGF-I treatment, although not to the extent that bone formation was inhibited.

Type I insulin-dependent diabetes mellitus (IDDM) is associated with decreased cortical bone mineral density (Santiago *et al.,* 1977). Although the pathophysiology of diabetic osteopenia remains unknown, it appears that the duration of diabetes, the extent of diabetic control, and the timing of disease onset are each associated with higher risks of low density (McNair, 1988; Heath *et al.,* 1980). Serum markers of bone formation are reduced in type I diabetics, suggesting a possible defect in osteolastic activity (Mazess, 1981). Serum IGF-I levels are either normal or low in type I diabetes mellitus, but often are reduced in patients with poor diabetic control. In these same people, serum IGFBP-1 levels are quite high. This has led investigators to believe that changes in the IGF regulatory system during poor metabolic control contribute to impaired growth.

Spontaneously diabetic BB rats exhibit osteopenia and therefore provide a useful model for studying the effects of IGF-I on bone remodeling. Even though bone formation is lower in BB than control rats (as measured by serum markers), administration of rhIGF-I does not increase bone epiphyseal width, osteoblast surfaces or serum osteocalcin (Heath *et al.,* 1980). Thus, despite evidence that circulating levels of IGF-I are reduced in some patients with type I IDDM, preliminary animal studies have failed to show that IGF-I administration can correct any inherent defect in bone formation.

Chronic immobilization inhibits bone formation and leads to significant bone loss. The pathophysiology of immobilization caused by bed rest, hindquarter elevation, or spaceflight is unknown, but the bone remodeling unit is uncoupled due to a transient decrease in bone formation and a marked rise in bone resorption (Tuukkanene *et al.,* 1991; Heaney, 1962). Some investigators have proposed that reduced bone formation during immobilization results from resistance to skeletal IGF-I. Immobilization in rats by the hindlimb elevation method causes cessation of bone growth (Bikle *et al.,* 1994). Paradoxically, mRNA levels for IGF-I and the type I IGF-I receptor are substantially increased in the proximal tibia and distal femur of hindlimb elevated rats (Bikle *et al.,* 1994). Infusion of rhIGF-I (200 mg/day) during hindlimb elevation does not reverse the cessation in linear growth induced by immobilization, even though growth and bone formation resume relatively soon after immobilization is stopped (Bikle *et al.,* 1994). This would suggest that there may be, at least transiently, resistance to IGF-I bioactivity.

Other investigators have reported contrasting results during hindlimb elevation. Machwater *et al.* (1994) continuously infused rhIGF-I (1.3–2.0 mg/kg/day) for 14 days to 5-week-old hindlimb elevated rats. The decline in bone mineral density of the proximal femur with unloading was blunted by infusions of IGF-I. At the tibial metaphysis of IGF-infused animals, bone formation rate and trabecular number were markedly increased. Marrow stromal cells from unloaded rats exhibit decreased proliferative characteristics, but addition

of IGF-I greatly increased alkaline phosphatase positive cell proliferation. rhIGF-I also enhanced serum alkaline phosphatase activity and osteocalcin levels in immobilized rats.

Alternate ways of exploiting the anabolic properties of IGF-I in bone have been proposed. IGF-I has been administered by intraarterial infusion or coupled to IGFBP-3. Infusion of rhIGF-I continuously into the arterial supply of the right hindlimb of ambulatory rats for 14 days leads to a 22% increase in cortical and trabecular bone formation in the infused limb (Spencer *et al.,* 1991). By histomorphometry, the number of osteoblasts (but not osteoclasts) increases. Using an alternative model, Bagi *et al.* (1994) administered rhIGF-I or a complex of IGF-I–IGFBP-3 to 16-week-old oophorectomized rats. The IGF-I/IGFBP-3 complex (7.5 mg/kg/day) increased bone formation more than did IGF-I alone, even though both treatments increased longitudinal bone growth. The highest doses of rhIGF-I and rhIGF-I-/IGFBP-3 enhanced trabecular thickness in the lumbar vertebrae and femoral epiphyses and increased bone resorption but only in the femoral metaphysis. A similar study contrasting IGF-I with IGF-I–GFBP-3 was performed in 22-week-old oophorectomized rats (Bromage *et al.,* 1993). Bone mineral density increased in both groups but fewer than 10% of the rats treated with IGF-I–IGFBP-3 complex developed hypoglycemia, compared to nearly 50% with rhIGF-I alone.

Human Studies with IGF-I

The potential utility of insulin-like growth factors in several disorders has led to trials with IGF-I in humans (see Table I). To understand how IGF-I affects bone remodeling, three groups of adults have been studied before and after rhIGF-I: normal postmenopausal women, GH-resistant children and adults, patients with age-related, idiopathic osteoporosis and anorexia.

IGF-I Administration to Normal Postmenopausal Women

There is one published study of bone markers that employed rhIGF-I to healthy young postmenopausal women. Doses of rhIGF-I from 30 to 180 mg/kg/day were administered daily by subcutaneous injection for 6 days to older postmenopausal women without fractures and normal bone density (Eberling *et al.,* 1993). Very significant dose-dependent increases in serum type I procollagen carboxyl-terminal propeptide (PICP), osteocalcin, and urinary deoxypyridinoline were reported. Although the rise in PICP was greater than the increase in collagen breakdown (measured by deoxypyridinoline), it is uncertain whether this meant that formation was stimulated more than resorption. For the two highest doses of rhIGF-I (120 and 180 mg/kg/day), orthostasis, weight gain, edema, tachycardia, and parotid discomfort were noted. At lower doses (30 and 60 mg/kg/day) fewer side effects were reported, but less discrete changes in PICP were noted. As noted below, high- and low-dose rhIGF-I was also administered for 28 days to elderly postmenopausal women and the results are somewhat different in that bone formation was stimulated by lower doses of rhIGF-I.

Table I Studies Reporting on Effects of Recombinant Human IGF-I on Bone Metabolism in Adult Humans

Study	Patients	Age (yrs)	Dose (μg/kg/d)	Duration	Formation	Resorption	Comment
Johansson *et al.,* 1992	1 man; idiopathic osteoporosis	59	80 × 2	7 d	↑	↑	Sustained increase in markers of bone formation four weeks post-treatment.
Ebeling *et al.,* 1993	18 women; healthy & postmenopausal	66 ± 7	30, 60, 120, 180	6 d	↑	↑	The lowest dose enhanced bone formation alone.
Rubin *et al.,* 1994	1 woman; postmenopausal & Werner syndrome	43	30–75	6 months	↑	↑	BMD increased by 3% in the lumbar spine. The patient was also treated with estrogen.
Grinspoon *et al.,* 1995	14 women; young & healthy	22 ± 4	100 × 2	6 d	↑	↔	Treatment during fasting and after 4 d of fasting.
Johansson *et al.,* 1995	24 men; idiopathic osteoporosis	46 ± 10	20, 40, 80	6 weeks	↑	↑	The lowest dose enhanced bone formation alone.
Johansson *et al.,* 1996	12 men; idiopathic osteoporosis	44 ± 8	80	7 d	↑	↑	Comparison to effects of GH; qualitatively no difference.

Note. Arrows denote changes in bone formation and bone resorption, estimated by biochemical markers of bone metabolism in serum and urine. BMD = bone mineral density, GH = growth hormone.

IGF-I ADMINISTRATION TO GH-RESISTANT SHORT STATURE

One potential indication for IGF-I might be in the GH-resistant short stature syndrome (Laron dwarf). By the end of the past century, Sweden and several other European countries had approved rhIGF-I for that purpose. Patients with the Laron dwarf syndrome lack functional growth hormone receptors and thus do not respond to GH; their IGF-I levels are very low, growth is slow, and circulating GH levels are high (due to lack of negative feedback on GH by IGF-I) (Bondy, 1994). Underwood treated one such boy (age 9) with 2 weeks of continuous intravenous rhIGF-I (Bondy, 1994). Urinary calcium excretion increased while urinary phosphate and sodium decreased. After a 2-week continuous infusion of rhIGF-I, the patient was treated with twice daily sc rhIGF-I (120 mg/kg) for 2 years. Growth occurred at a rate of 10 cm/year, compared to 5 cm for the 3 years prior to treatment. Subsequently, Underwood and colleagues have treated eight patients in this manner without hypoglycemia while Laron and his group have treated five children (Bondy, 1994; Laron and Kupper-Auerbach, 1992). More recently, a child with an IGF-I deletion mutation in exon 5 has been reported. This patient had very short stature, mental retardation and other abnormalities along with very low levels of circulating IGF-I (Woods *et al.,* 1996). RhIGF-I treatment led to a marked increase in linear growth and a huge increase in spinal bone mass. However, when corrected for changes in size of the bone, the incremental changes in volumetric bone mass were much less impressive (Camacho-Hubner *et al.,* 1999). Hypoglycemia is avoided in many cases by having children eat 3 to 4 hr after their IGF-I injection, although several children had selective growth of adenoidal tissue.

Two unique aspects about these IGF-I data challenge previous concepts about the role of GH in skeletal homeostatsis. First, IGF-I can act as a classical endocrine hormone stimulating longitudinal growth independent of GH; second, GH may not be absolutely essential for statural growth; i.e., the stimulatory effect of GH on chondrocytes which permits skeletal responsiveness to IGF-I may not be as critical as once perceived. However, caution must be undertaken in examining the effects of rhIGF-I on bone mass in children since most of the changes in the skeleton relate to linear growth and periosteal enhancement, both of which can contribute to two-dimensional changes in BMD as measured by DXA, but lesser changes when corrected for size (Bachrach *et al.,* 1998).

IGF-I ADMINISTRATION IN IDIOPATHIC AND AGE-RELATED OSTEOPOROSIS

Idiopathic osteoporosis in men in an ill defined syndrome of low bone mass and spinal fractures without associated hypogonadism. By histomorphometry, these men often have low bone turnover, suggesting a possible defect in bone formation. Several groups of investigators has suggested that this syndrome is related to low serum IGF-I levels (Ljunghall *et al.,* 1992). Since the therapeutic options in males with osteoporosis are somewhat limited and treatment for low bone turnover states, in general, is frustrating, the therapeutic potential for anabolic agents like IGF-I in this condition should be quite high. In one male with idiopathic osteoporosis and low serum IGF-I, Johansson *et al.* (1992) administered subcutaneous rhIGF-I (160 mg/kg/day) for 7 days. Bone alkaline phosphatase, osteocalcin, and the carboxyterminal peptide of procollagen type I all increased more than 40% over baseline. However, urinary calcium/creatinine and hydroxyproline excretion rose during treatment. In a recent trial rhIGF-I (at doses of 80 mg/kg/day) and rhGH (2 IU/m^2/day) in 12 men, serum osteocalcin, serum procollagen peptide, and urinary deoxypyridinoline excretion all increased following 7 days of rhIGF-I treatment (Ljunghall *et al.,* 1992). Although there were slight differences in the response of certain biochemical markers to IGF-I and GH, both forms of therapy produced significant increases in bone resorption.

Clinical trials provide evidence that IGF-I acts by increasing the birth rate of remodeling osteons, thereby promoting bone resorption and formation. Yet, it is conceivable that low doses of rhIGF-I ($<$30 mg/kg/day) may differentially stimulate bone formation. In one trial of 16 healthy elderly women, 60 μg/kg/day (high dose) and 15 mg/kg/day (low dose) of rhIGF-I were tested for 28 days (Ghiron *et al.,* 1995). The high-dose rhIGF-I increased markers of bone resorption and formation. However, low doses of rhIGF-I caused increases in serum osteocalcin and type I procollagen carboxyterminal peptide, but had no effect on total pyridinoline excretion (Ghiron *et al.,* 1995). These data would support the thesis that low doses of rhIGF-I may directly increase osteoblastic function with only a minimal increase in bone resorption. However, further studies will be needed to assess the future therapeutic role of low doses rhIGF-I in osteoporosis.

Recently novel approaches to enhancing IGF-I action in bone have been proposed. One strategy is to administer a bone-specific agent which stimulates bone mass such as parathyroid hormone (PTH). Intermittent hPTH increases trabecular bone by stimulating osteoblasts to synthesize IGF-I and other growth factors (Donahue and Rosen, 1998). Another strategy is to administer IGF-I along with an IGF binding protein. Bagi *et al.* (1994) previously reported that IGF-I/IGFBP-3 complex could enhance bone mass in the metaphysis and epiphysis of rats (see Fig. 2). One very small randomized trial utilized subcutaneous infusions of IGF-I/IGFBP-3 in 24 older women with hip fractures. Bone loss in the contralateral hip was reduced considerably after 6 months (i.e. from 6 to 1.5%) in those subjects who were given the complex vs those receiving saline (Geusens *et al.,* 1998). Accompanying that change in BMD, there was also an increase in grip strength in those that received the active agent, while no significant side effects were reported. Larger clinical trials are likely to commence utilizing this or other combinations linking IGF-I to one or more IGFBPs, especially if bone is considered the principle target.

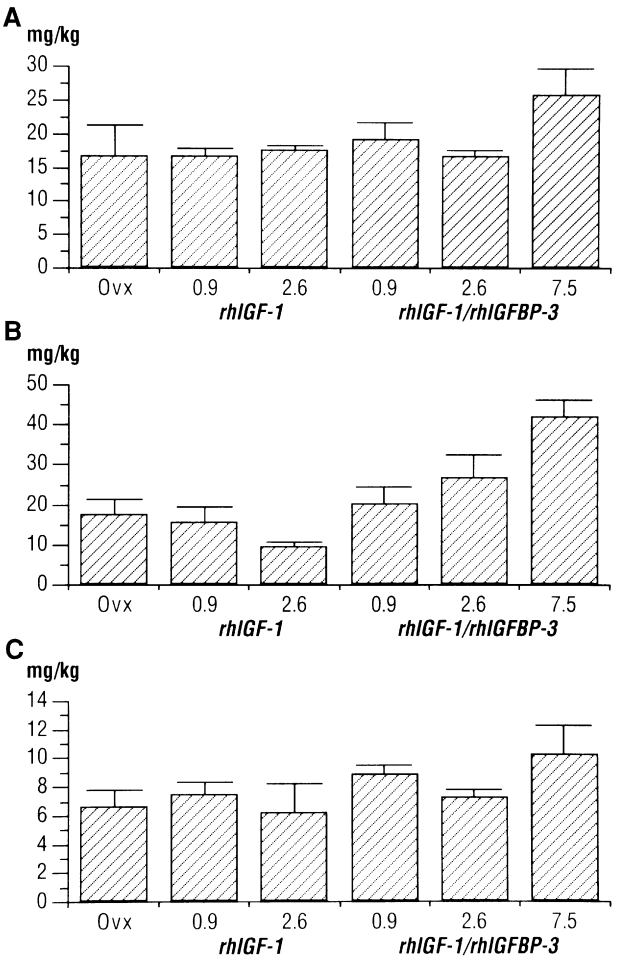

Figure 2 Dose-related effects of rhIGF-I and rhIGF-I/IGFBP-3 complex on bone formation rate in metaphyses (A), epiphyses (B), and lumbar vertebral bodies (C) after 8 weeks of treatment. Each column shows the mean ± SEM. The 7.5 mg/kg/day dose was significantly greater than OVX at $p < 0.05$ for the metaphysis and epiphysis. [Reproduced by permission of the publisher.]

IGF-I IN ANOREXIA NERVOSA

Osteopenia frequently accompanies anorexia nervosa (AN). The reduced bone mass in AN is characterized by reduced bone formation (Soyka *et al.,* 1999). Serum IGF-I levels are reduced by 50% despite a marked increase in the frequency of GH pulsatility. Recently, Soyka and colleagues (1999) reported that serum IGF-I concentrations accounted for nearly 70% of the variance in both osteocalcin and bone-specific alkaline phosphatase and, that bone resorption indices were comparable in both AN and age-matched controls. Grinspoon *et al.* (1996) administered 100 μg/kg, 30 μg/kg, or placebo of rhIGF-I to 23 women with AN and low spine BMD. After 6 days, one marker of bone formation increased without any change in bone resorption. These data were used to support a much larger, currently ongoing trial of 30 μg/kg of rhIGF-I in more than 70 AN patients. Results from that RPCT will help to determine whether this treatment is feasible on a larger scale. Clinical and pharmacological interest in IGF-I has been tempered by the fact that high normal levels of serum IGF-I have been linked to a greater risk of certain malignancies (Rosen and Pollak, 1999). If IGF-1 is ultimately to become a useful therapeutic agent, such concerns will have to be carefully addressed and critically evaluated.

Summary

Several lines of evidence suggest that administration of recombinant growth factors, such as IGF-I or GH, may be anabolic for the skeletal remodeling unit. First, both GH and IGF-I stimulate osteoblastic differentiation. Second, in animal models, GH and IGF-I enhance longitudinal growth, bone formation, and bone mineral density. Third, in GHD children and adults with an impaired GH-IGF-I axis, rhGH and rhIGF-I both increase trabecular and cortical BMD. However, evidence from randomized placebo-controlled trials that rhGH or rhIGF-I can differentially stimulate bone formation for a sustained period in older non-growth-hormone-deficient adults is lacking, in part because previous studies have been of short duration, and with small numbers of subjects. Therefore, favorable skeletal responses in properly controlled clinical trials will be required before rhGH or rhIGF-I can be recommended for the treatment of postmenopausal osteoporosis. In the meantime, in selected catabolic conditions such as anorexia nervosa , the use of these growth factors in trials will continue, with an eye toward the future application of these agents in metabolic bone diseases.

CHAPTER 84

Anabolic Steroid Effects on Bone in Women

Azriel Schmidt, Shun-ichi Harada, and Gideon A. Rodan
Department of Bone Biology and Osteoporosis Research, Merck Research Laboratories, West Point, Pennsylvania 19486

Introduction

Anabolic steroids are androgenic compounds that produce both anabolic effects and promote virilization in men and women. Anabolic steroids modulate a variety of body functions, e.g., muscle mass and strength, and have been used to treat many conditions, including anemia, protein deficiency, psychiatric disorders, reproductive dysfunctions, and others (Caltin, 1995; Ehrmann *et al.,* 1995; Hiipakka and Liao, 1995; Parker, 1995). Their beneficial effect in anemia results from stimulation of erythropoiesis via increased erythropoietin production in the kidney and hemoglobin synthesis in erythroblasts. Their marked effect on muscle mass and strength has led to abuse of these compounds in athletes. Their diverse physiological effects makes it hard to separate between primary and secondary actions. For example, the proposed beneficial effects of anabolic steroids on bone may result either from direct effects on bone cells, or from effects on muscle or on calcium metabolism, via reduction in calcium excretion in the kidney and increased calcium absorption in the gastrointestinal tract (Caltin, 1995; Ehrmann *et al.,* 1995; Hiipakka and Liao, 1995; Parker, 1995). Since testosterone is rapidly metabolized, some of its effects could be due to aromatase-mediated conversion to estrogen or to other metabolites. Various anabolic steroids with improved resistance to metabolism have also been developed (Rasmusson and Tonney, 1994). Androgenic compounds rendered resistant to gastrointestinal and liver metabolism by containing an alkyl group at the C17α position, such as stanozolol, are orally active (see Table I), whereas anabolic steroids with increased lipophilicity due to esterification at the C17β position, such as nandrolone decanoate or testosterone esters such as testosterone enanthate, are given parenterally (Caltin, 1995; Melchert and Welder, 1995). Recently, transdermal delivery of androgens via skin patches was developed. The mode of administration of various anabolic steroids is shown in Table I.

This chapter deals specifically with effects of androgenic compounds on bone in women, in the context of osteoporosis. A separate chapter by Wiren and Orwoll (Chapter 43) covers the role of androgens in skeletal development and in shaping and maintaining the skeleton and the effect of androgens on bone cells. Questions that are addressed in this chapter, not all of which have been satisfactorily answered at this time, include: (1) In females, do androgens play a role primarily during bone development or do they play a role in mature bones as well? (2) Do androgens, like estrogens, mainly prevent bone resorption or do they stimulate bone formation? (3) Do they play a role in the pathophysiology of postmenopausal osteoporosis? (4) Do they act directly on bone tissue or indirectly via other organs? (5) What is their target cell and mechanism of action? This review will attempt to summarize the current literature on the subject and point to areas that are under investigation.

Androgen Levels in Women

Androgenic steroids are produced in women by the ovaries, the adrenal glands, and the adipose tissue. The natural androgens produced in the ovary are testosterone and 5α-dehydrotestosterone (DHT). Both have high affinity for the androgen receptor (AR), although DHT has a slower

Table I Androgenic Anabolic Steroids and Their Route of Administration

Parenteral administration	Oral administration
Nandrolone decanoate	Methyltestosterone
Testosterone cypionate	Methanadrostenlonone
Testosterone enanthate	Stanozolol
Testosterone propionate	Fluoxymesterone
Boldenone	Oxandrolone
	Norethandrolone
	Danazol

dissociation rate. The average normal plasma testosterone level in women is 1.3 n*M* (normal range 0.69–2.6 n*M;* Ehrmann *et al.,* 1995; Parker, 1995). The serum testosterone concentration falls after menopause to an average level of 0.7 n*M* (normal range 0.53–1.06 n*M,* Ehrmann *et al.,* 1995; Jassal *et al.,* 1995; Morales *et al.,* 1994; Ohta *et al.,* 1993; Parker, 1995). The serum DHT level in postmenopausal women is slightly lower, around 0.32 n*M* (Morales *et al.,* 1994). Androgens produced by the adrenal gland are androstenedione, dehydroepiandrosterone (DHEA), and its metabolite DHEA-sulfate (DHEAS). These androgens, which are present in young women at a concentration of 1.9 to 6.9 n*M,* 1.52 to 15.2 n*M,* and 1.28 to 5.2 μM, respectively, decrease significantly with age to an average concentration of 1.3 n*M* for androstenedione, 7.19 n*M* for DHEA, and 1.78 μM for DHEA-S (Morales *et al.,* 1994; Ehrmann *et al.,* 1995; Parker, 1995). In the circulation, androgens are bound to albumin, a high-capacity, low-affinity carrier, and to the more specific steroid hormone binding β-globulin (SHBG), a high-affinity, low-capacity carrier. Binding to serum proteins serves as a reservoir for steroid hormones and influences the availability of free (active) steroid hormones (Ehrmann *et al.,* 1995; Moore and Bulbrook, 1988; Parker, 1995). Sex steroids were reported to modulate the level of SHBG—estrogen and progesterone increasing it, and androgens decreasing it (Darney, 1995), thus regulating free steroid levels in that manner, as illustrated by the observation that bone mineral density (BMD) correlates better with free rather than with total androgen levels (Longcope *et al.,* 1984, 1986; Acar *et al.,* 1998).

Postmenopausal women maintain significant androgen levels (Moore and Bulbrook, 1988; Parker, 1995), derived from androgens produced by the adrenals and fat tissue, which serve as precursors for the synthesis of testosterone, as well as estrogen. Natural androgens can be converted to estrogens by the enzyme aromatase, also shown to be present in osteoblast-like cells, which could explain some of the effects of androgens on bone (Bruch *et al.,* 1992; Nawata *et al.,* 1995; Roapena *et al.,* 1994; Schwelikert *et al.,* 1995; Tanaka *et al.,* 1993). Other metabolic pathways for androgens include the convergence of androstenedione and testosterone to more potent androgens by 5α-reductase and 17β-hydroxysteroid dehydrogenase, which have also been found in bone cells (Bruch *et al.,* 1992).

The Role of Androgens in the Female Skeleton

It is well established that androgens play an important role in bone metabolism in men, which parallels the role of estrogens in women (Seeman, 1995, and Chapter 43). Elderly men experience a decline in bone density that parallels the decline in serum bioavailable testosterone with aging. Castration or treatment with AR antagonists for prostate cancer causes osteoporosis in men similar to that produced by estrogen deficiency in women. Part of the mechanism also appears similar in that androgen treatment reduces bone turnover and bone resorption (Chapter 43). The role of androgens and anabolic steroids in bone metabolism in women is less clear.

Overall, most of the evidence suggests that androgens and anabolic steroids have beneficial effects on bone in women, although reports vary regarding the extent of these effects. Following are some of the observations that support this conclusion.

The androgen insensitivity syndrome is caused by mutations in the AR, resulting in a partial or complete female phenotype in individuals who are genetically males. The external genitalia are usually female, but there is no uterus and instead of ovaries there are internal testes (Hiipakka and Liao, 1995). Testosterone is aromatized to estrogen, and the body build and bone types are female. It was recently reported that a 17-year-old individual with this phenotype had very low BMD (about 4 SD below the age-matched female average), and BMD did not increase during 4 years of treatment with estrogen and progestin, suggesting that androgens may play a role in reaching peak bone mass (Munoz- Torres *et al.,* 1995).

Genetic support for the role of AR on bone mass was demonstrated in women with androgen insensitivity syndrome (AIS) caused by androgen receptor abnormalities, rendering them partially or completely refractory to androgen. A study of 22 women with complete AIS shows that the average lumbar spine BMD *z* score of women with complete AIS was significantly reduced at -1.08 ($P = 0.0003$). Furthermore, 6 of these women had sustained cortical bone fractures, of whom three reported multiple (>3) fractures (Marcus *et al.,* 2000). The human AR is polymorphic at the polyglutamine (poly Q) expansion of the N-terminal domain. The length of this poly Q repeat correlates with the expression and activity of AR (short poly Q, higher AR expression/activity). A recent study in eugonadal men showed that longer AR poly Q tracts (i.e., lower AR activity) were significantly more common in osteoporotic men than in controls. In addition, in the Michigan Women's Health Study, women possessing AR alleles with longer poly Q tracts concomitantly had BMDs in the lowest quintile for the population studied (Sowers *et al.,* 1999). These results point to an important role for AR in the regulation of bone mass.

Further support for the role of androgens in determining BMD in the premenopausal period comes from the fact that women with hyperandrogenic amenorrhea have relatively high BMD, and BMD decreases following treatment with the antiandrogens spironolactone and lynestrenal (Prezelj and Kocijancic, 1993, 1994). In peri- and postmenopausal women, BMD was shown to correlate positively with androgen levels (Longcope *et al.,* 1984, 1986). A role for androgens in postmenopausal skeletal health was also strongly suggested by the fact that in a 16-year prospective follow-up study of postmenopausal women, low testosterone, rather than estrogen levels, showed a correlation with height loss, a measure of osteoporotic vertebral fractures (Fig. 1) (Jassal *et al.,* 1995). SHBG, mentioned above as an important determinant of bioavailable testosterone, was also found to have a negative correlation with vertebral fractures in elderly women (Longcope *et al.,* 1984, 1986; Moore and Bulbrook, 1988; Moore *et al.,* 1991).

Furthermore, DHEA-S levels were shown to correlate with BMD in the lumbar region, the femoral neck, and the radius midshaft (Deutsch *et al.,* 1987; Rozenberg *et al.,* 1990; Szathmari *et al.,* 1994). DHEA and DHEA-S levels decrease markedly with age, and their decrease parallels reduction both in lean body mass and in bone mass (Buchanan *et al.,* 1988a,b; Davidson *et al.,* 1983; Haffner and Bauer, 1992; Nordin *et al.,* 1985; Ohta *et al.,* 1993). These declines also correlate with the decline in growth hormone and insulin-like growth factor (IGF)-I, which play a role in bone metabolism, but it is not known if these correlations point to any causal relationships. Administration of adrenal androgens to elderly patients improves their physical and psychological well-being, but effects on BMD were not measured in that study (Morales *et al.,* 1994).

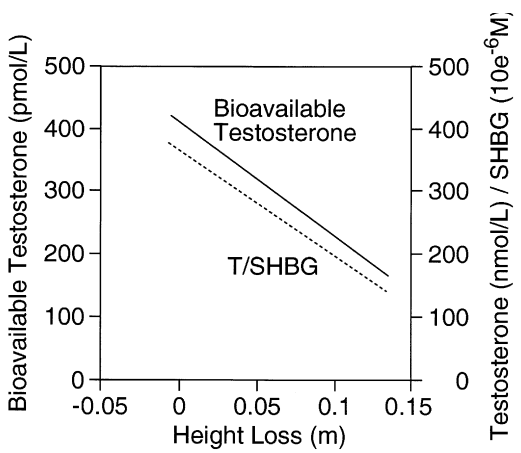

Figure 1 The multiply adjusted association of bioavailable testosterone and testosterone/SHBG with height loss. Height and plasma for sex hormone assays of 170 postmenopausal women with a mean age of 64.5 years were taken, and 16 years later, at a mean age of 80.7 years, height was remeasured. [Reprinted from *Journal of Bone and Mineral Research* 10 (4), Jassal, S. K., Barrett, C. E., and Edelstein, S. L. (1995) Low bioavailable testosterone levels predict future height loss in postmenopausal women, pp. 650–454, with kind permission from Blackwell Science Inc., Cambridge, MA]

Treatment Effects

Anabolic steroids have been used for many years in the treatment of osteoporosis. However, their use is limited due to virilization and adverse effects on serum lipids. Anabolic steroids such as methandrostenolone or stanozolol were shown to increase bone mass in postmenopausal women (Chesnut *et al.,* 1977, 1983). The largest treatment experience to date is with nandrolone decanoate, which was reported to increase BMD and bone mineral content (BMC) in several studies (Need *et al.,* 1986, 1987a,b). In one study, BMC fell after cessation of therapy, further supporting a role for nandrolone decanoate in increasing BMC, but in another study, BMC was maintained (Hassager *et al.,* 1989; Need *et al.,* 1989a,b). Another anabolic steroid, stanozolol, was shown by histomorphometric analysis of transiliac bone biopsies to increase bone formation rates significantly without changing the osteoclast surface. The major bone-forming activity was observed on endocortical surfaces (Beneton *et al.,* 1991).

Positive effects of androgens in the treatment of postmenopausal osteoporosis were also demonstrated in studies with combined testosterone and estrogen treatment (Davis *et al.,* 1995; Raisz *et al.,* 1996; Watts *et al.,* 1995). In a 2-year study (Davis *et al.,* 1995), combined treatment increased significantly the rate and extent of a rise in lumbar and hip BMD relative to treatment with estrogen alone (Fig. 2). Similar observations were made in a separate study in which post-surgical menopause patients, average age 45 years old, were treated for 2 years with either esterified estrogen alone or in combination with methyltestosterone. In this study, combined treatment increased lumbar BMD by 3.4% relative to baseline, whereas estrogen alone increased it only by about 0.5%. No significant changes in radius, femoral neck, Ward's triangle, or greater trochanter BMD were observed in either group (Watts *et al.,* 1995). Furthermore, methyltestosterone did not counter the positive effects of estrogen on lipids in that study.

Similarly, it was reported in a 2-year study in surgically menopausal women that the combined treatment of esterified estrogen plus methyltestorone increased lumbar spine and hip BMD significantly more than estrogen alone (Barrett-Connor *et al.,* 1999). Interestingly, estrogen in combination with the androgenic progestin norethisterone increased bone density more than with medroxyprogesterone (Hosking *et al.,* 1998).

Another agent with androgenic activity reported to produce beneficial effects on bone is danazol, which also has anti- estrogenic activity and is used in the treatment of endometriosis (Bergquist, 1990; Dawood *et al.,* 1995; Fukushima *et al.,* 1993; Rock *et al.,* 1993). This condition, which affects about 14% of women, is caused by excessive estrogen and is usually treated by suppressing ovarian function with GnRH agonists, which cause estrogen deficiency and bone loss. Danazol, which in addition to being an anti-estrogen has progesterone and androgenic activity, increased in 12 months thoracic and lumbar BMD by up to

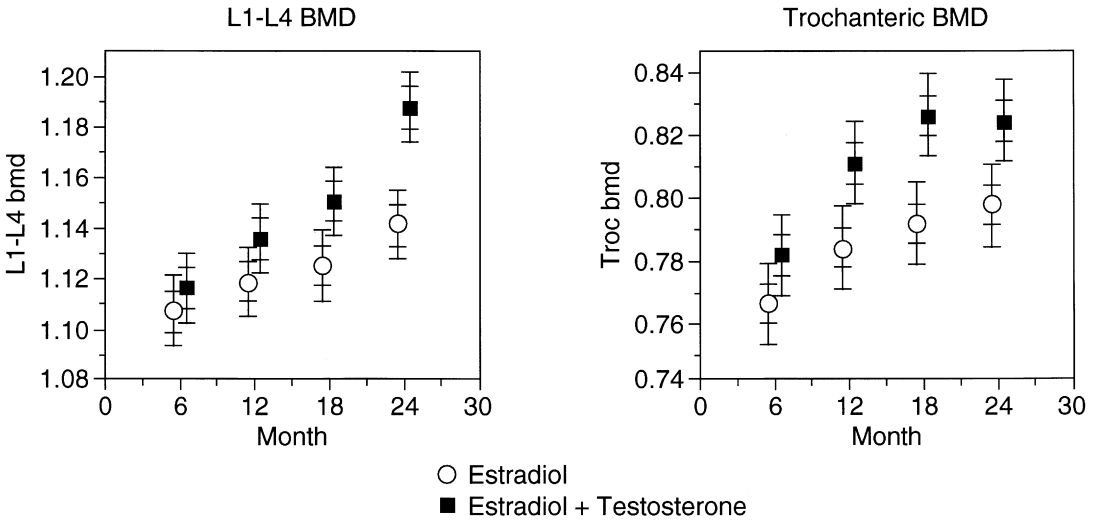

Figure 2 The effects of hormonal implants on BMD (g/cm^2): lumbar spine (L1 – L4) and femoral trochanter (Troc), estradiol, and estradiol plus testosterone. Error bars represent SEM. Inner error bars are used to compare means between times for the same treatment. The comparison between the groups is made with outer error bars. The means are significantly different by a P value of at least 0.05. [Reprinted from *Maturitas,* **21**(3), Davis, S. R., McCloud, P., Strauss, B. J., and Burger, H. (1995) Testosterone enhances estradiol's effects on postmenopausal bone density and sexuality, pp. 227 – 236, with kind permission from Elsevier Science Ireland Ltd., County Clare, Ireland.]

8%, suggesting stimulation of bone formation. Similar observations were made in a number of other recent studies. Measurement of biochemical markers in patients treated with danazol or the GnRH agonist nafarelin showed a 50% increase in hydroxyproline excretion, consistent with higher bone resorption caused by estrogen suppression. However, serum osteocalcin and alkaline phosphatase, biochemical indicators of bone formation, increased by 88–120 and 34–40%, respectively, consistent with increased bone formation. Both markers remained elevated 3 months after treatment with nafarelin, and osteocalcin levels remained elevated in patients treated with danazol (Dawood, 1994; Dawood *et al.,* 1995; Ylikorkala *et al.,* 1990).

To summarize this section, the data available so far suggest that androgens may play a positive role in determining the bone mass in women, both before and after menopause. The limited information available on the effects of androgen treatment suggests that it increases bone mass, in excess of the effects of estrogen alone, possibly via stimulation of bone formation.

Effects of Androgens on Bone in Animal Studies

In male animals, orchiectomy causes changes similar to those produced by ovariectomy in females—increased bone turnover and bone loss, which are reversed by androgen administration. In this section, we shall focus specifically on a small number of studies that examined the effects of androgens on female animals.

The role of endogenous androgens in the control of bone mass in female rats was suggested by the use of the nonsteroidal, anti-androgen flutamide, which antagonizes the action of androgens produced by the gonads and adrenal glands. In 3-month-old female Wistar rats, 4-week treatment with flutamide at 10 mg/kg/day decreased total body calcium and had little effect on urinary hydroxyproline or urinary ^{45}Ca excretion, suggesting suppression of bone formation rather than increased resorption (Goulding and Gold, 1993). In another study, it was shown that suppression of trabecular bone formation and reduction in trabecular thickness caused by flutamide in normal rats was not observed in OVX rats, suggesting that flutamide acted as an antagonist to androgens produced by the ovaries (Gallagher *et al.,* 1995). This study showed that the reduction in testosterone levels following OVX was associated with a decrease in bone formation rates and in trabecular thickness in the proximal tibia, even when bone resorption was inhibited by 3-amino-1-hydroxypropylidene-1-bisphosphonate, consistent with androgen effects on bone formation.

In another study rats were ovariectomized (OVX) at 13 weeks and DHT was administered starting at 90 days, when bone turnover had reached a steady state. Treatment with 0.01, 0.1, or 1.0 mg/kg/day for 60 days partially restored cancellous bone volume and trabecular thickness (Tobias *et al.,* 1994). DHT also increased cortical bone volume and endocortical and periosteal bone formation rates. Bone resorption parameters were not altered, suggesting a stimulatory effect of DHT on bone formation. These observations are consistent with those in another study in which DHT was administered to 12-month-old SD rats. Six months of treatment with 5 mg/kg/day restored the cortical (femur) and trabecular (vertebrae) bone mineral density measured by DXA (Vanin *et al.,* 1995).

The synthetic anabolic steroid nandrolone decanoate was also shown to increase bone volume and bone strength in the

cortical bone of rats, along with an increase in the bone formation marker osteocalcin (Aerssens *et al.,* 1993). Another synthetic steroid anti-androgen, TZP-4238, which acts as an antagonist in the gonad (Murakoshi *et al.,* 1993), was reported to increase BMC, bone volume, and strength in ovariectomized and neurectomized rats (Fuse *et al.,* 1997), raising the possibility of tissue-specific androgen action.

The stimulatory effect of androgens on bone density and mechanical strength of long bones was also demonstrated recently in a long-term study on nonhuman female primates (Kasra and Grynpas, 1995). Adult, 4 – 11-year-old female cynomologus monkeys, dosed for 2 years with testosterone, had an increase in bone density, torsional rigidity, and bending stiffness of the tibia, as well as increased density and strength of the trabecular bone in the femoral head (see Table II).

To summarize this section, the small number of studies conducted in animal models suggest that androgens act on the female skeleton independently of estrogens to increase bone mass and strength, possibly via stimulation of bone formation.

Nuclear Receptors

Androgen action is mediated by the AR, a member of the nuclear receptor (NR) superfamily (Evans, 1988). NRs mediate the action of a large number of hormones that control bone metabolism, including estrogens, glucocorticoids, retinoids, thyroid hormones, and vitamin D. Recent progress in this field has identified several new ligands of NRs as putative regulatory molecules, which participate in the physiological regulation of important metabolic processes. These include prostaglandin J_2 as the ligand for peroxisome proliferator activator receptor (PPAR)γ, fatty acids for PPARα, oxysteroles for liver X receptor (LXR), bile acids for farnesoid X receptor/bile acid receptor (FXR/BAR), steroids and xenochemicals for steroid and xenobiotic receptor/pregnenolone X receptor (SXR/ PXR), and androstane for the constitutive androstane receptor (CAR) (Blumberg and Evans, 1998). PPARγ stimulation promotes the differentiation of adipocytes, which share the same precursor cells as osteoblasts (Forman *et al.,* 1995; Kliewer *et al.,* 1995). Eicosapentanoic acid (EPA), a potent activator of PPARs, was recently reported to prevent the reduction in bone density and bone strength caused by a low calcium diet in ovariectomized rats (Sakaguchi *et al.,* 1994). Recent reports suggest a role for other NRs in bone development or metabolism, e.g., the orphan nuclear receptors RAR-related orphan receptor (ROR)α (Meyer *et al.,* 2000) and the estrogen-related receptor α 1 (ERR1).

The classical model for activation of NR receptors, illustrated by the glucocorticoid receptor (GR), involves the following steps. Upon binding of the cognate hormone, the receptor undergoes a conformational change, dissociates from heat shock proteins to which it was initially bound in the cytoplasm, and translocates to the nucleus, where it interacts with target genes via specific steroid response elements (SRE) and activates transcription (Evans, 1988; Tsai and O'Malley, 1994). This initial relatively simple model has evolved since initially proposed. For example, many NRs were shown to be localized in the nucleus in the absence of hormone, bound to DNA in an active state. Thus, the ligands would have to enter the nucleus and activate the NRs. In addition, some receptors,

such as COUP-TF, are constitutively active in the nucleus in the absence of ligand, while ligand mediated inactivation/transcriptional repression was observed in other cases, such as for CARβ (Forman *et al.,* 1998). The NRs were shown to bind to DNA as dimers, either homodimers for the progesterone receptor (PR), AR, estrogen receptors (ER), and GR or as heterodimers with the retinoid X receptor (RXR) for the thyroid receptor, retinoid A receptors (RAR), vitamin D receptor (VDR), PPARs, LXR, FXR, PXR/SXR and CAR (Mangelsdorf and Evans, 1995; Repa and Mangelsdorf, 1999). There are three RXR receptors, which increases the combinatorial receptor–receptor interaction possibilities and thus the possible outcome of hormone action. ER was also reported to bind to DNA as a monomer, and NRs can not only stimulate but also suppress transcription.

All NRs have two conserved domains: a carboxy terminal region responsible for ligand binding, and a centrally located and highly conserved DNA binding domain. In addition, there are two nonconserved domains, the highly variable amino terminal region and the region that links the DNA binding to the ligand binding domain. Additional regions responsible for important receptor functions include two domains involved in cell-type-specific transcriptional transactivation, one in the variable amino terminal region, activation function-1 (AF-1), and one in the ligand binding region, AF-2, which acts as a ligand-dependent transactivation domain (Beato and Klug, 2000; Mangelsdorf, 1995).

In addition, transactivation is also influenced by regions in the carboxyl end of the ligand and in the DNA binding domains, that interact with nuclear receptor corepressor proteins (Chen and Evans, 1995; Horlein *et al.,* 1995; Kurokawa *et al.,* 1995). Sequences important for nuclear translocation are adjacent to and within the DNA binding domain. The ligand binding domain also contains the region important for the binding of heat shock proteins. Both the DNA and the ligand binding domains contain the amino acid residues important for receptor dimerization (Evans, 1988; Tsai and O'Malley, 1994).

Many NRs are expressed as proteins with variable amino terminal regions as a result of cell-type-specific alternative splicing or multiple promoter usage. The different isoforms can exhibit cell- and promoter-dependent transactivation. For example, the progesterone receptor has two isoforms, PR-A and PR-B, PR-A being 164 amino acids shorter than PR-B, which exhibits different effects on transcription.

Nuclear receptors (NRs) can either stimulate or suppress the transcription of genes depending on their cellular background and promoter context (Klinge, 2000; Xu *et al.,* 1999). In the case in which these NRs directly interact with their response elements upon ligand binding, stimulation of transcription occurs via a cooperative interaction of these NRs with coactivators, namely p160 coactivators (SRC-1/NCoA1, GRIP1/TIF2/SRC-2/NcoA-2, AIB1/ACTR/RAC3/ SRC-3), via LxxLL motifs (NR boxes) present in these coactivators. These coactivators recruit a large enzymatic complex involving CBP/p300 and P/CAF that leads to chromatin remodeling via histone acetyl transferase (HAT) activity present in these molecules. Ligand-bound NRs also interact with TRAP220/DRIP205 in a NR box dependent manner and recruit a TRAP/DRIP coactivator complex that interacts with the basal transcriptional machinery and stimulate transcription via a chromatin-dependent manner (Freedman, 1999). Conversely, in the absence of ligands, these NRs interact with corepressors such as N-CoR and SMART and recruit corepressor complexes resulting in transcriptional repression via histone deacetylase (HDAC) activity (Klinge, 2000). Similar negative or positive regulation occurs when NRs control transcription via protein–protein interaction with other transcription factor complexes such as Fos/Jun, NF-κB, and other transcription factor families.

Another level of complexity for NR action was revealed by studies with the ligand RU486. Normally, RU486 is a potent antagonist of both the PR and the GR. However, given together with 8BrcAMP to cells transfected with a progesterone-responsive promoter, RU486 behaves as an agonist and stimulates the transcription mediated by PR (Beck *et al.,* 1993a,b).

Tissue-specific effects of a ligand for NR are illustrated by raloxifene. Raloxifene is an anti-estrogen that has partial agonistic activity. In the uterus, it is an anti-estrogen and does not exhibit uterotrophic activity, whereas in bone it acts as an agonist and like estrogen, prevents ovariectomy-induced bone loss (Beck *et al.,* 1993a,b). Tissue-selective effects of AR ligands are illustrated by the fact that DHT produces gene activation in all androgen-responsive tissues, while testosterone cannot substitute for DHT in specific genital tissues (Hiipakka and Liao, 1995).

The complexity of steroid hormone action is further amplified by crosstalk between signaling pathways. For example, growth factors, such as EGF, and neurotransmitters, e.g., dopamine, can activate NRs by a ligand-independent mechanism (Power *et al.,* 1992). A pathway for receptor activation in the absence of cognate ligand was demonstrated for COUP-TF, PR, and ER. In this pathway, activation of G protein-coupled D1 dopamine receptor by dopamine initiates the signal transduction pathway that leads to NR activation, presumably by induction of a cascade of protein kinase activities that results in receptor phosphorylation and nuclear translocation of the activated receptor (Power *et al.,* 1991, 1992).

Furthermore, steroid hormones can produce effects via nongenomic signaling. For example, androgens can increase cellular calcium through activation of G-proteins, and progesterone metabolites can influence the activity of the brain GABA receptor (Callachan *et al.,* 1987; Lieberherr and Grosse, 1994; Maggi and Perez, 1984). Moreover, the metabolic interconversion of hormones mentioned above, testosterone to DHT, *trans*-retinoic acid to retinoic acid, T4 to T3, further increases the complexity of hormone action via NRs. This complexity can generate a diversity of responses that can be tissue-, promoter-, and ligand-specific and could depend on other signals impinging on the cell at the time.

The Androgen Receptor

The human AR is a protein that contains 918–919 amino acids and is transcribed from a major 10-kb and a minor 7-kb mRNA transcript (Chang *et al.,* 1988; Lubahn *et al.,* 1988; Tilley *et al.,* 1989; Trapman *et al.,* 1988). In mammals, only one AR has been identified, located on the X chromosome, while a second AR that binds to 11-keto testosterone as its preferred ligand has recently been identified in fish (Ikeuchi *et al.,* 1999). The amino terminal region contains a stretch of about 20 glutamine residues, which in humans exhibit polymorphism, ranging between 17 and 26 glutamine residues. Longer stretches were found to be associated with X- linked spinal and bulbar muscular atrophy (La-Spada *et al.,* 1991). The single AR gene identified so far implies that the AR protein should mediate the genomic actions of testosterone, DHT, and possibly the adrenal androgens, either directly or after conversion to testosterone. Both testosterone and DHT bind tightly to AR with K_ds of 1 and 0.1 nM, respectively (Rasmusson and Tonney, 1994). Naturally occurring mutations have been identified, both in the DNA and in the ligand binding domains of AR. These mutations cause androgen insensitivity resulting in different degrees of abnormality in male sexual development (Yarbrough *et al.,* 1990; Quigley *et al.,* 1995). An XY genotype with a complete lack of androgen responsiveness will develop as a female phenotype with female-type bones, as mentioned above. Aberrations in male sex organ development are also found in individuals with mutations in the 5α-reductase gene, who exhibit partial development of some male organs, such as epididymis and vas deferens, but not of the urogenital tract, the prostate, and the external genitalia, indicating that T cannot substitute for DHT as an activator of AR in genital development (Hiipakka and Liao, 1995). This ligand specificity for certain tissues raises the possibility that androgenic compounds with AR agonistic activity could have specificity for certain tissues, such as bone, while lacking activity in other tissues, such as those responsible for virilization.

The ligand-bound AR recognizes a palindromic androgen response element (ARE) as a homodimer and, like other NRs, activates transcription by recruiting large coactivator complexes. The prototypical androgen response element (ARE) was identified functionally in the promoter regions of androgen-responsive genes present in prostate, such as probasin or prostate-specific antigen (Rennie *et al.,* 1993; Brinkman *et al.,* 1999). The optimal ARE was later characterized by gel shift assays using random oligonucleotides as "RGAWCA NNN TGTTCT" (Schoenmakers *et al.,* 2000). Transcriptional activities of AR have been mapped to both N-terminal (NTD)and C-terminal (LBD) domains as AF1 and AF2. A unique feature of transactivation by AR is the functional interaction between NTD (AF1) and LBD (AF2) that is essential for transcriptional activity (Ikonen *et al.,* 1997). Unlike other NRs where AF2 activity is predominant, AR possesses a potent AF1 activity and weak intrinsic AF2 activity. The ligand-dependent activation of AF2 activity, evaluated in the context of Gal4DBD-AR-LBD fusion protein, depends on the recruitment of the NTD which is further potentiated by p160 coactivators and CBP/p300 (Brinkman *et al.,* 1999). In contrast to TR or RAR that interact with p160 coactivators via the AF2 domain alone, in a NR box dependent manner, AR also interacts with the C-terminal domain of p160 coactivators via the AF1 domain that interacts with the C-terminal domain of p160 coactivators via the AF1 domain. Mutational analysis of p160 coactivators documented the predominant role of AF1 interaction with p160 coactivators in AR-mediated transcriptional activation. Upon association with AR, activation domain 1 (AD1) of p160 coactivators interacts with CBP/p300 that remodel histones (Ma *et al.,* 1999). In addition to HAT activity present in CBP/p300 and P/CAF, a recent report documented the role of arginine methyl-transferases, CARM1 (coactivator-associated arginine methyltransferase) and PRMT1 (protein arginine N methyltransferase), that interact with AD2 of p160 coactivators to potentiate AR-mediated transcription by methylating histones (Chen *et al.,* 1999; Koh *et al.,* 2001).

The biological relevance of the interaction of AR NTD/LBD domains has been documented in mutations that disrupt the NTD/LBD interaction, causing marked reduction in transcriptional activity and androgen insensitivity syndrome (He *et al.,* 1999). Interestingly, a recent report documented the role of FXXLF and WXXLF motifs present in NTD for its association with LBD, suggesting that NTD interacts with the hydrophobic surface of LBD in a manner analogous to the interaction of AF2 with p160 coactovators (He *et al.,* 1999).

In addition to p160 coactivators, a number of coactivators are found to interact with AR. The LBD (AF2) of AR interacts with ARA54, a RING finger B box family protein (Kang *et al.,* 1999), ARA55/Hic-5 with a LIM motif ARA70, RIP140 (Ikonen *et al.,* 1997), and Tip60 (Brady *et al.,* 1999). The AR-NTD(AF1) interacts with ARA24/RAN (Hsiao *et al.,* 1999), a nuclear small G-protein, Cyclin E (Yamamoto *et al.,* 2000), and TFIIF (McEwan and Gustafsson *et al.,* 1997) and also with ANPK, a nuclear protein kinase (Moilanen *et al.,* 1998); ARIP3, a STAT binding protein (Moilanen *et al.,* 1999); PDEF, an ETS transcription factor (Oettgen *et al.,* 2000); SNURF, a ring finger protein (Poukka *et al.,* 2000); and ARIP4, a nuclear ATPase (Janne *et al.,* 2000). Like p160 coactivators, ARA160 (Hsiao and Chang, 2000) and FHL2, a LIM only protein (Muller *et al.,* 2000), were shown to interact with multiple regions of AR.

Negative transcriptional control by AR was reported for the expression of the maspin gene in prostate cells (Zhang *et al.,* 1997). It was shown that the maspin promoter contains an HRE (hormone response element) site that mediates the negative regulation of the maspin gene by AR. Transcriptional regulation, negative or positive by NRs can also occur via protein–protein interaction with other components of the transcription machinery, including AP-1, SP1, C/EBP, or Nf-KB, which in turn act on their respective DNA binding sites (Diamond *et al.,* 1990; Jonat *et al.,*

1990; Mukaida *et al.,* 1994; Perkins *et al.,* 1993; Ray and Prefontaine, 1994; Ray *et al.,* 1995; Stein and Baldwin, 1993; Stein *et al.,* 1993a,b). Such interactions can explain, for example, the effects of GR on the action of interleukins IL-6 and IL-8 (Diamond *et al.,* 1990; Jonat *et al.,* 1990; Mukaida *et al.,* 1994; Perkins *et al.,* 1993; Ray and Prefontaine, 1994; Ray *et al.,* 1995; Stein and Baldwin, 1993; Stein *et al.,* 1993a,b). Glucocorticoids were also shown to induce the expression of inhibitory protein-κB (I-κB), a nuclear factor that antagonizes the activity of the nuclear transcription factor NF-κB (Auphan *et al.,* 1995; Scheinman *et al.,* 1995).

The participation of AR in negative control of transcription via protein–protein interaction was demonstrated for the transcriptional repression of the matrix metaloproteinase-1 gene (MMP-1) in prostate cells (Schneikert *et al.,* 1996). In this case, the inhibition of transcription by AR was dependent on the presence of the Ets transcription factor binding site and the interaction of the Ets protein with the amino terminus region of AR. Above examples of negative and positive regulation of transcription by AR indicate that the role of AR in the control of bone metabolism may be the result of transactivation, transrepression or a combination of both activities on different target genes.

AR was also shown to modulate transcription from the promoter of the low affinity neurotropin receptor gene without directly interacting with a specific DNA element (Kalio *et al.,* 1994). This type of receptor transcription factor interaction could be responsible for AR or ER suppression of transcription from the promoter of the IL-6 gene, that lacks a typical ER or AR SRE (Bellido *et al.,* 1995).

Androgen Mode of Action on the Skeleton

The actual mechanism for androgen effects on bone is still under investigation. Improved methodology for the detection of AR led to the demonstration of both AR mRNA and protein expression in osteoblasts, supporting the hypothesis that androgens act directly on bone cells. AR mRNA was found in normal human osteoblasts as well as in human osteosarcoma TE85 cells (Benz *et al.,* 1991; Colvard *et al.,* 1989a,b; Liesegang *et al.,* 1994). Specific binding of androgens to nuclear proteins was documented in human osteoblasts in human osteosarcoma SaOS, US02, and TE85 cells, as well as in rat UMR106 cells and in mouse MC3T3-E1 osteoblastic cells (Benz *et al.,* 1991; Colvard *et al.,* 1989a,b; Orwoll *et al.,* 1991). The affinity of DHT to AR in human osteoblasts, isolated from both men and women was similar to that in classical androgen-responsive tissues (kDa between 0.43 to 1 nM). The number of AR per cell in human osteoblasts varied between 514 and 2800, sufficient for producing a physiological response. ARs were also visualized by immunocytochemistry in mouse osteoclast-like cells generated in culture, suggesting potential androgen effects on osteoclasts (Mizuno *et al.,* 1994). Other recent studies, however, failed to detect estrogen, testosterone, and their respective receptors in bone, although endogenous 1α,25-dihydroxyvitamin D_3 and progesterone and their receptors were localized at the ultrastructural level (Boivin *et al.,* 1994). Thus, the presence, abundance, and activity of ARs in bone cells and the type of bone cells that contain ARs require further investigation.

The addition of androgen to osteoblast cultures has generated various physiological responses. It was observed that androgens stimulate the proliferation of various osteoblast-like cells in culture and upregulate the expression of several mRNAs or proteins (Kasperk *et al.,* 1989, 1990; Gay *et al.,* 1992; Masuyama *et al.,* 1992; Takeuchi *et al.,* 1994). Testosterone increases production of type I collagen. TGFβ1, c-*fos,* and c-*jun* in HOS, TE85, and SAOS-2 human osteosarcoma cells (Takeuchi *et al.,* 1994). DHT upregulated the expression of alkaline phosphatase and TGFβ2 in TE89 and SAOS-2 human osteosarcoma cells (Takeuchi *et al.,* 1994). DHT upregulated the expression of alkaline phosphatase and TGFβ2 in TE89 and SAOS-2 human osteosarcoma cells (Kasperk *et al.,* 1989, 1990). Moreover, it was shown that DHT treatment increases the steady-state level of the AR mRNA in the human osteosarcoma TE85 cells, in contrast to reducing AR mRNA levels in prostate cancer cells (Takeuchi *et al.,* 1994). This modulation of AR mRNA levels by DHT treatment may contribute to the inconsistent observations on androgen effects in osteoblastic cells. The adrenal androgens DHEA and DHEA-S were shown to suppress c-*fos* expression at physiological concentrations in normal human osteoblasts and to increase TGFβ activity without altering the steady-state level of TGFβ_1 mRNA (Kasperk *et al.,* 1989, 1990). It was shown in human osteosarcoma TE85 cells that norethindrone pretreatment synergistically potentiates the effects of fluoride, an anabolic agent that stimulates bone formation in osteoporotic women (Takada *et al.,* 1995). In this context, similar pretreatment with either progesterone or DHT did not produce similar synergistic effects, suggesting a potentially unique property of this anabolic steroid. Some of the androgen effects observed in the various studies of osteoblasts in culture may be mediated by nontranscriptional effects. It was shown that osteoblast treatment with nanomolar concentrations of testosterone induces a rapid increase in intracellular calcium concentration, inositol 1,4,5-triphosphate, and diacylglycerol formation via G-protein-coupled pathways, consistent with so-called nongenomic effects of testosterone (Lieberherr and Grosse, 1994). The molecular basis of these effects require further study.

To summarize this section, androgens act via the AR, a nuclear receptor that has not been as extensively studied as the estrogen and progesterone receptors. AR is expressed in osteoblastic cells, and androgens at physiological concentrations produce effects on these cells in culture. However, further studies are needed to establish the target cells of androgens *in vivo* and relate the *in vitro* effects to their anabolic action on bone.

Conclusions

The evidence available to date suggests that androgens have a beneficial effect on the female skeleton and may increase bone mass both before and after menopause. The therapeutic use of anabolic steroids, most frequently in older women and reported mostly in uncontrolled studies, supports these conclusions. The use of anabolic steroids in postmenopausal osteoporosis is limited by side effects such as virilization and elevation of plasma lipids. Most studies were conducted with compounds developed for use in males, chosen on the basis of androgenic or anti-androgenic activities in rats. The human receptor was cloned later than that of other steroid hormones (1988) and the mode of action of androgens and anabolic steroids on the skeleton is still under investigation. Only one AR gene has been identified, and there are at least two isoforms produced from this gene. AR expression was documented in human and rodent osteoblastic cells, however, the mode of androgen action on bone *in vivo* remains to be elucidated. The tools are currently available to develop selective androgenic and anti-androgenic compounds and to study their effects in bone and their mode of action.

CHAPTER 85

Estrogen Effects on Bone in the Male Skeleton

John P. Bilezikian,[*] Sundeep Khosla,[†] and B. Lawrence Riggs[†]

[*]Departments of Medicine and Pharmacology, College of Physicians and Surgeons, Columbia University, New York, New York 10032; and [†]Department of Endocrinology, Metabolism, and Nutrition, Mayo Clinic and Foundation, Rochester, Minnesota 55905

Over the past decade, we have seen fundamental changes in the landscape that used to describe osteoporosis as a rather exclusive disease of postmenopausal women. We now appreciate the fact that osteoporosis affects men as well as women (Orwoll, 1998; Bilezikian, 1999). Moreover, osteoporosis is being recognized increasingly among elderly men as a medical, social, and economic burden (Orwoll, 1995a). As much as 20% of the total incidence of osteoporosis in the United States may be in men, with proportionate costs attributed to this incidence figure in the male (Looker *et al.,* 1997). These observations have led, in turn, to efforts to understand better the physiology of the male skeleton, in terms of both protective factors and factors that place the male skeleton at risk. The purpose of this chapter is to review this information in the context of the developing and adult male skeleton and the role of estrogens.

Cartoons that describe the change in bone mass with time have tended to emphasize the role of aging per se because it is associated with a rather constant rate of decline in bone density from the middle years onward (Fig. 1). The downslope of this curve is more telling in women because they are exposed to an additional insult, besides age, namely the abrupt cessation of ovarian estrogen production at the time of the menopause. The accelerated bone loss characteristic of the early postmenopausal period is believed to place women at greater risk for osteoporosis than men are because men, under normal circumstances, do not experience a menopause-equivalent during their middle years.

Such observations help to explain differences between men and women in their differential susceptibility to osteoporosis. However, equally important is the upswing in the curve describing acquisition of bone mass during the youthful years of skeletal accrual. Factors responsible for the establishment of peak bone mass are also key aspects to any discussion of the osteoporotic process. For example, the attainment of peak bone mass helps to define the reserve that is called upon during the period of age-related bone loss. Someone who has achieved optimal peak bone mass is likely to be relatively more protected from losing so much bone mass that places him/her at risk for osteoporotic fracture. In contrast, someone whose peak bone mass is suboptimal may show evidence for fracture risk earlier in the aging process. While a number of factors help to account for the degree to which an individual achieves optimal peak bone mass (e.g., genetics, nutrition, environmental, exercise, calcium intake), this discussion will deal only with the role of the sex steroids, with particular emphasis on estrogens.

Estrogen deficiency states such as delayed puberty, amenorrhea of any cause, and, perhaps, the use of progestational agents for contraception, can lead to suboptimal acquisition of peak bone mass. In the male, similarly, androgens are thought to be critical to the establishment of peak bone mass. Finkelstein has shown, for example, that delayed puberty in otherwise normal boys, is associated with reduced bone density for as long as 10 years thereafter as compared to boys who entered puberty "on time" (Finkelstein *et al.,* 1992, 1996). Although these results have been disputed by Bertelloni *et al.* (1998), who argue that volumetric bone density is not reduced among boys with delayed puberty, the point is made, nevertheless, that areal density might suffer in growing boys who are not exposed to androgens at a critical time in their skeletal development.

In sex steroid-sufficient, growing boys and girls, a 7–10% difference in the achievement of peak bone mass is believed

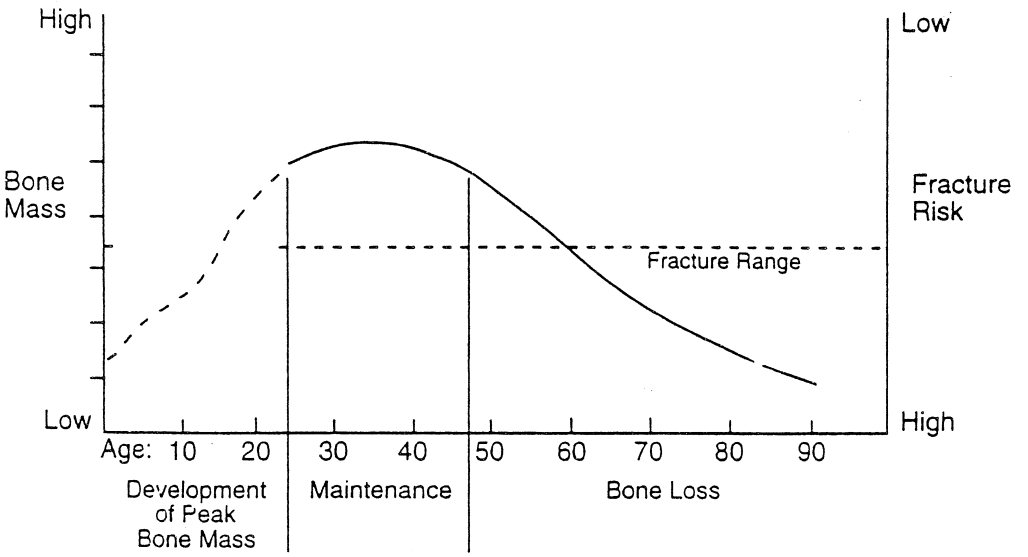

Figure 1 The change in bone mass as a function of the aging process. This schema illustrates the importance of establishing optimal peak bone mass in the chronology of events that take place thereafter. Adapted from Wasnich *et al.* (1991).

to be a key protective factor in the male. Thus, not only do men not normally experience an abrupt cessation of androgen production in their middle years, but they also achieve a greater reservoir of bone due to the attainment of greater peak bone mass in youth. Recent observations have helped to clarify these differences in the achievement of peak bone mass as a function of androgens and estrogens. When true bone density is measured, there is relatively little difference between the growing male and female skeleton throughout childhood (Gilsanz *et al.,* 1994). The difference appears to be bone size, a parameter that is compatible with a specific androgen effect (Beck *et al.,* 1992).

Seeman has emphasized the point that androgens have region-specific actions on bone growth and remodeling so as to lead to larger bones (Orwoll, 1995b; Duan *et al.,* 1999; E. Seeman, personal communication). Bones that are exposed to androgen display greater periosteal apposition, which, in turn, leads to larger cross-sectional diameter. Under the influence of androgens, therefore, bones are bigger, but not necessarily more "dense." In the aging male skeleton, similarly, the male demonstrates greater periosteal apposition than the aging female skeleton. For a given reduction in cortical bone mass, occurring presumably to the same extent among the genders when due only to aging, the male is conferred a relative mechanical advantage by increased bone diameter. This effect may well be a specific feature of androgens.

While it may have seemed clear that differences between the growing female and male skeleton as well as the skeleton in decline could be attributable satisfactorily, if not completely, to the sex-specific steroids (estrogens in women; androgens in men), recent observations have shattered this simple concept. It is no longer straightforward. The new observations underscore the normal biosynthetic pathway by which estrogens are made. C-18 estrogens are derived from androgens via the activity of aromatase, a cytochrome P450 product of the CYP 19 gene (Bulun *et al.,* 1993). The obligate precursors are the C-19 androgenic steroids. The human P450 aromatase enzyme is found in many tissues such as placenta, ovary, testis, brain, and adipocyte. Regulation of aromatase activity occurs through tissue-specific promoters and alternative splicing mechanisms (Simpson *et al.,* 1997). The translated gene product, however, is the same among all tissues that harbor an active aromatase gene.

With this background, one can quite reasonably revisit the classical observation assigning differences among male and female skeletal growth to androgens or estrogens, respectively. It is possible that the growing male skeleton is also dependent upon estrogens and that some skeletal events previously noted to be androgenic may actually be due, at least in part, to estrogens. Such thinking, which seemed rather heretical a short 5–7 years ago, has received seminal support by two fundamental experiments of nature. In two rare syndromes, the estrogen receptor or the aromatase gene has been "knocked out" by a point mutation, rendering subjects either estrogen resistant (receptor defect; Smith *et al.,* 1994) or estrogen deficient (aromatase defect; Morishima *et al.,* 1995; Carani *et al.,* 1997). A key role of estrogens in male skeletal development has emerged from insights gleaned from the study of these unusual subjects.

Alpha-Estrogen Receptor Deficiency in the Male

In 1994, Smith *et al.* described a 28-year-old man with a disruptive homozygous mutation in exon 2 of the alpha-estrogen receptor gene. The gene defect was inherited as an autosomal recessive from his consanguineous parents who were heterozygotes for the gene defect. A cytosine to

thymidine transition at codon 157 resulted in a stop codon and an alpha estrogen receptor that is severely truncated and cannot bind estrogen. He had no detectable response to administration of large doses of exogenous estrogen (transdermal ethinyl estradiol), achieving serum concentrations of estradiol 10-fold higher than the typical male, 270 pg/ml (nl, 10–50). His own baseline estradiol (119 pg/ml) and estrone (145 pg/ml) levels were markedly above normal. Although bound and free testosterone as well as dihydrotestosterone concentrations were normal, LH (37 mIU/ml) and FSH (33 mIU/ml) levels were in the mildy castrate range. He was extremely tall (204 cm) without acromegalic features and still growing with open epiphyses (bone age, 15 years) and genu valgum. The growth curve did not show a pubertal growth spurt although his puberty in all other respects was normal. His body proportions were eunuchoid. Bone density of the lumbar spine as measured by dual energy X-ray densitometry was 0.745 g/cm^2, corresponding to 2 standard deviations below average for a 15-year-old boy.

Aromatase Deficiency in the Male

In three male subjects, each products of consanguineous marriages, aromatase deficiency has been described (Morishima *et al.,* 1995; Carani *et al.,* 1997; Deladoey *et al.,* 1999). In each case a point mutation in the aromatase gene at exon IX (Morishima *et al.,* 1995; Carani *et al.,* 1997) or at exon V (Deladoey *et al.,* 1999) was associated with a completely inactive gene product. The report of Morishima *et al.* (1995) describes a 24-year-old man with a single base change at base pair 1123 (C to T) with an amino acid substitution at R375, adjacent to the heme binding site. Similarly, the report of Carani *et al.* (1997) describes a 31-year-old man with a single base pair change at position 1094 (G to A) with the amino acid substitution at R365. In the report of Deladoey *et al.* (1999) of a newborn male, the defect was discovered to be in exon V, causing a frame shift mutation with an ensuing premature stop codon. The truncated gene product is completely devoid of aromatase activity.

The two adult men were very tall and still growing with unfused epiphyses, a bone age of 15, eunuchoid features (upper segment/lower segment = 0.85–0.88), and genu valgum. The patient of Morishima *et al.* had markedly elevated androgen levels with the complete biochemical profile shown in Tables I and II. The growth curve of that patient, similar to that of the man with the alpha-estrogen receptor defect, did not give evidence for a pubertal growth spurt although in all other respects puberty was not delayed (Fig. 2). Both patients had reduced bone mass. The bone mineral density of the

Table I Biochemical Parameters in a Man with Aromatase Deficiency

Calcium	9.9	8.7–10.7 (mg/dl)
Phosphorus	3.3	2.5–4.5 (mg/dl)
PTH	26	10–65 (pg/ml)
25-Hydroxyvitamin D	36	9–52 (ng/ml)
1,25-Dihydroxyvitamin D	55	15–60 (pg/ml)
Alkaline Phosphatase	241	39–117 (IU/L)
Urinary calcium	185	150–300 (mg/24 hr)
Deoxypyridinoline	25.3	4–19 nmol/nmol Cr

Note. Adapted from Morishima *et al.* (1995).

Table II Sex Steroids and Gonadotropin Concentrations in a Man with Aromatase Deficiency

Estradiol	<7	10–50 pg/ml
Estrone	<7	10–50 pg/ml
Testosterone	2015	200–1200 ng/dl
5-α dihydrotestosterone	125	30–85 ng/dl
FSH	28.3	5–9.9 mIU/ml
LH	26.1	2.0–9.9 mIU/ml

Note. Adapted from Simpson *et al.* (1997).

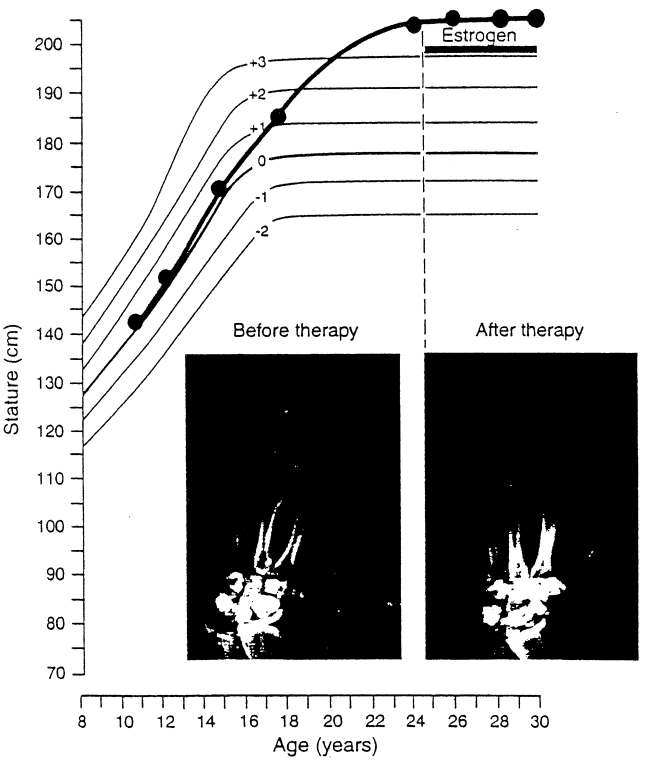

Figure 2 Growth curve and bone age before and after 5 years of estrogen therapy in a man with aromatase deficiency. After conjugated estrogen therapy was begun (bar), linear growth ceased immediately. Height has remained at 204 cm since therapy whereas previously it was showing continued increases. All epiphyses were closed within 6 months (insets). The curves with + and − numbers represent the mean and standard deviations for normal young men.

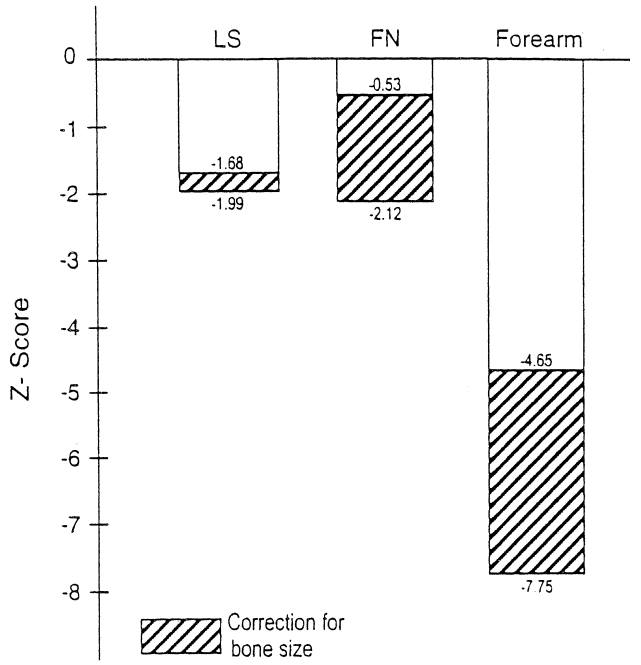

Figure 3 Bone mineral density at baseline in a man with aromatase deficiency. For each site, the bone mass is shown as the two-dimensional value (g/cm^2) and as bone mineral apparent density using correction factors for body size (Morishima *et al.,* 1995). For each site, estimated true bone density is substantially lower than the direct measurement, as shown in the shaded area of each site.

patient described by Morishima *et al.* is shown in Fig. 3. When these values were corrected because of his large bone size, bone mineral density was even more impressively reduced with *T* scores of −1.99 (spine), −2.12 (femoral neck), and −7.75 (forearm). Thus, the apparent bone density was even more evidently osteoporotic than the direct two-dimensional area density measurement.

Both men with aromatase deficiency responded to the administration of estrogen (Carani *et al.,* 1997; Deladoey *et al.,* 1999; Bilezikian *et al.,* 1998). Data are now available with a 5-year follow-up in the patient described by Morishima, Bilezikian, and their colleagues. Starting on low-dose conjugated estrogen, 0.3 mg, he was quickly raised to 0.75 mg daily, the dosage that he has consistently taken for most of the period of observation. Estradiol levels rose from undetectable into the normal range for men. Androgen levels fell from markedly elevated levels to normal. The rising estrogen levels and falling androgen levels occurred over the same period of time. The concomitant return of the gonadotropins, luteinizing hormone (LH) and follicle-stimulating hormone (FSH), to normal illustrates well the role of estrogens in controlling gonadotropin production in the male (Fig. 4). He immediately stopped growing with closure of all open epiphyses within 6 months of starting estrogen therapy (Fig. 2). Bone markers that were elevated at baseline returned slowly to normal (Fig. 5). Most impressively, this man has experienced a dramatic increase in bone density with estrogen therapy. During the first 3 years, increases in the lumbar spine, femoral neck, and

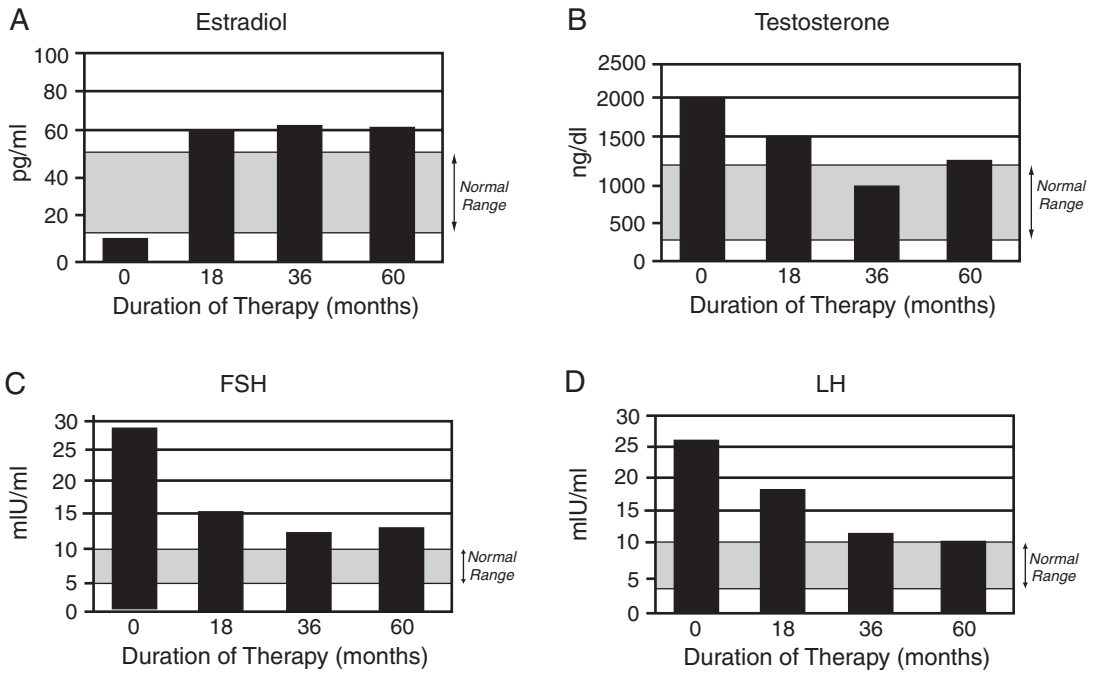

Figure 4 Changes in sex steroids and in gonadotropins with estrogen therapy in a man with aromatase deficiency. The data are shown for estradiol (A), testosterone (B), FSH (C), and LH (D). Over 5 years, estradiol levels initially rose and then were maintained at levels in the normal range for males when administered at 0.75 mg per day. Testosterone levels fell into the normal range, as did FSH and LH levels.

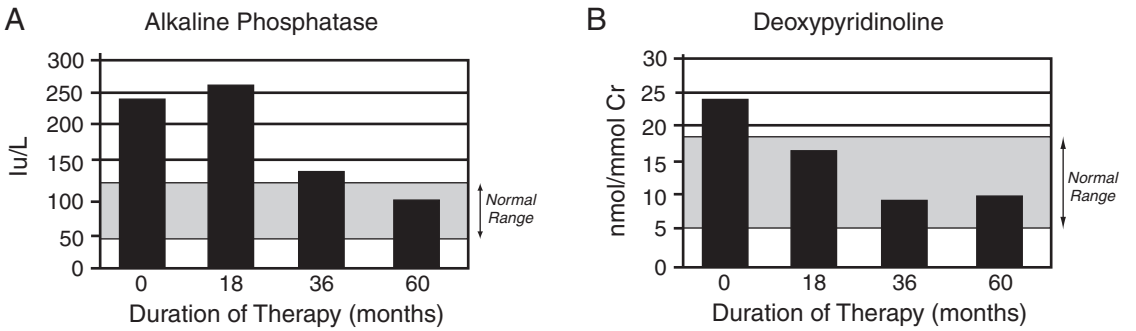

Figure 5 Changes in bone markers with estrogen therapy in a man with aromatase deficiency. The data are shown for alkaline phosphatase (A) and for deoxypyridinoline (B). The resorption markers, deoxypyridinoline, appear to fall faster over time than did the formation marker, alkaline phosphatase.

forearm were 20.7, 15.7, and 12.9%, respectively. Over the next 2 years of estrogen therapy, the gains in the lumbar spine and femoral neck were maintained with further marked increases in the forearm bone density, now totaling 26% (Fig. 6). The improvement in bone mass is seen also by the change in *T* score with normal values at the lumbar spine and femoral neck and from markedly osteoporotic levels in the forearm to mildy osteopenic levels ($T = -4.65$ to -1.84). The effect of estrogen to improve bone mass is best described as anabolic because of the magnitude of the change and also because further bone growth did not occur. Without further bone growth, the change in bone mineral density is more likely to reflect improved mineralization per unit area. It should be noted that this action of estrogen to stimulate the acquisition of bone mass through an anabolic effect is quite different from its effects in the postmenopausal woman, in whom the estrogen effect is more accurately described as antiresorptive. A summary of the skeletal aspects of aromatase deficiency is shown in Table III. A comparison between the syndromes of estrogen resistance and estrogen deficiency in the male is shown in Tables IV and V.

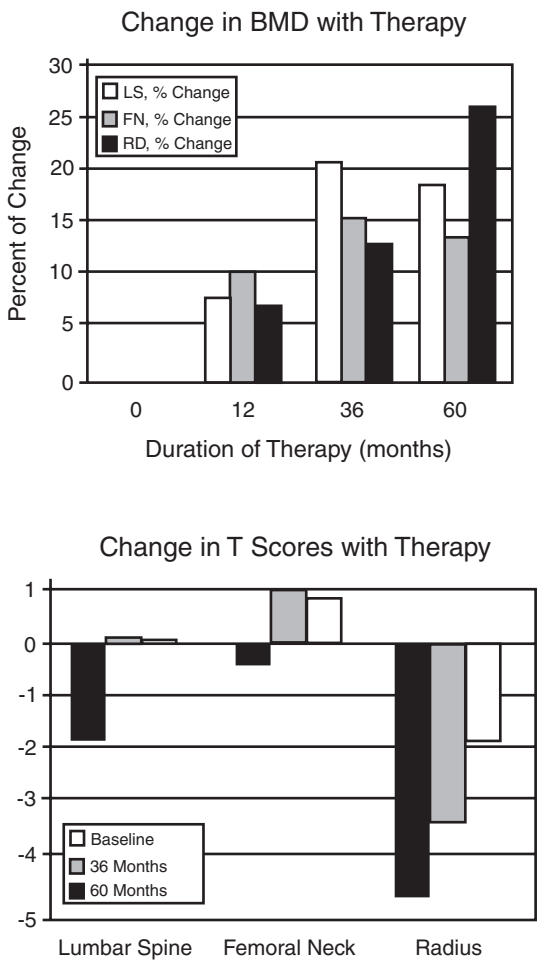

Figure 6 Changes in bone mineral density with estrogen therapy in man with aromatase deficiency. Percentage (A) and *T* score (B) changes are shown for lumbar spine, femoral neck, and distal radius. The data are shown not corrected for bone size.

Of special note is the relationship between the pubertal growth spurt and estrogen. In the syndromes of estrogen deficiency or resistance, the tallness and continued growth well into adulthood was not associated with a pubertal growth spurt. If estrogens are important in this regard, syndromes of estrogen excess would be expected to be associated with premature or early growth spurt. In the example of aromatase excess, due to an activating mutation of the aromatase gene, with elevated estrogen levels, puberty occurs early and is accompanied by skeletal maturation. This occurs despite normal testosterone levels (Hemsell *et al.,* 1977; Bulun *et al.,* 1999; Stratakis *et al.,* 1998; Shozu *et al.,* 1998). Additional evidence for an important role of estrogens in the pubertal growth spurt is the testicular feminization syndrome in which

Table III Importance of Estrogens in Male Skeletal Development

Linear bone growth
Pubertal growth spurt
Epiphyseal maturation
Optimal peak bone mass

Table IV Skeletal Aspects of Aromatase Deficiency in the Male

Constant linear growth
Lack of pubertal growth spurt
Delayed skeletal maturation
Markedly reduced bone mass

XY males do not respond to androgens because of a mutation in the androgen receptor. Responsiveness to estrogens is normal. In this syndrome, the pubertal growth spurt is seen (Grumbach and Auchus, 1999; Zachmann *et al.,* 1986). Finally, in estrogen-secreting tumors, similar observations of premature skeletal maturation have been made (Coen *et al.,* 1991; Simpson *et al.,* 1994; Grumbach and Styne 1998). These observations, therefore, argue rather persuasively that in the male, as in the female, the pubertal growth spurt is a function of estrogens, not androgens.

It is interesting to speculate that the difference in height among women and men may reflect the difference in the time of onset of puberty. Boys gain a few more years of linear growth because their puberty occurs later. The notion, namely, that the additional stature in the male is due to estrogen, not androgens, is particularly intriguing.

From these human experiments of nature, it seems reasonable to conclude that in the male, estrogens are important in the control of linear growth, in the pubertal growth spurt, in epiphyseal maturation, and in the achievement of optimal peak bone mass (Table VI). Such conclusions, obviously, must be tempered by an appreciation that androgens are also important in the acquisition of peak bone mass. In the testicular feminization syndrome, for example, the peak bone mass achieved is consistent with expectations for an estrogenic influence only since these XY boys have bone density most consistent with expectations for an XX girl (Kelch *et al.,* 1972). In either event, the failure to achieve peak bone mass may be a risk factor for the development of osteoporosis later in life. While one does not expect to "find" many examples of complete estrogen deficiency or resistant syndromes, there are possible more subtle abnormalities in those genes that would render men at risk for osteoporosis on this basis.

Table V Comparison of α-Estrogen Receptor and Aromatase Deficiency Syndromes

	α-Estrogen receptor	Aromatase deficiency
Testosterone	Normal	High
Estrogen	High	Low
Gonadotropins	High	High
Calciotropics	Normal	Normal
Bone turnover	High	High

Table VI Comparison of α-Estrogen Receptor and Aromatase Deficiency Syndromes

	α-Estrogen receptor	Aromatase deficiency
Tallness	+	+
Eunuchoid	+	+
Masculinized	+	+
Testicular size	Normal	Large
Bone age	Reduced	Reduced
Bone mass	Reduced	Reduced
Response to E	No	Yes

Animal "Knockouts" of the Estrogen Receptor and Aromatase Genes

Animal models that reflect the human gene defects in the alpha-estrogen receptor and in the aromatase enzyme are now available. The alpha-estrogen receptor knockout mouse displays a 20–25% reduction in bone density (Lubahn *et al.,* 1993; Korach *et al.,* 1996; Couse and Korach, 1999), consistent with the human patient described by Smith *et al.* (1994). In contrast, the beta-estrogen receptor knockout male mouse shows no skeletal abnormalities (Windahl *et al.,* 1999). It is of interest that the same beta-estrogen receptor defect in the adult female mouse, however, does show changes with an increase in bone mineral content due to an increase in cross-sectional cortical area.

Oz *et al.* (2000) have recently characterized the skeletal features of the aromatase knock out mouse (first reported by Fisher *et al.,* 1998). The male mice show radiographic evidence for reduced bone mineral density. Histologically, the mice show significant reductions in trabecular bone volume and in trabecular thickness. By histomorphometry, male knockout (but not female counterparts) show reductions in both osteoblastic and osteoclastic surfaces. Female mice showed a picture more consistent with high bone turnover. This sexual dimorphism with respect to these histomorphometric features has no ready explanation at this time. Nevertheless, these animal knockout experiments provide general confirmation of the human gene knockout disorders, documenting further the important role of estrogens in male skeletal development.

Studies in Humans—Observational Data

The data noted above from the human "experiments of nature" clearly indicate that estrogen plays a significant role in the male skeleton. In particular, they demonstrate that estrogen is required for epiphyseal closure, that it has significant effects on skeletal modeling during growth, and that it is necessary for optimal acquisition of bone mass during puberty in

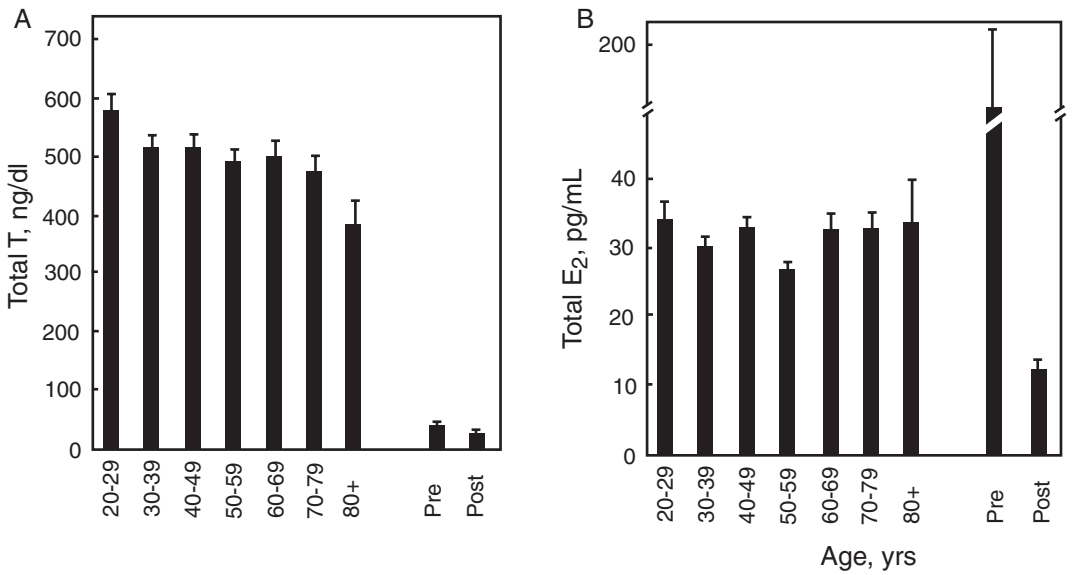

Figure 7 Serum total testosterone (A) and estradiol (B) levels as a function of age in a population-based sample of men. Data are adapted from Khosla *et al.* (1998), with permission.

boys. These observations, however, leave several major questions unresolved. In particular, they leave open the issues of what, if any, are the roles of estrogen in regulating bone remodeling in adult men with mature skeletons, whether estrogen is necessary for the maintenance of bone mass in adult men, and what, if any, is the role of estrogen (or estrogen deficiency) in mediating age-related bone loss in men.

Before addressing these issues, it is useful to review the available data on age-related changes in serum sex steroid levels in normal men. As shown in Fig. 7A, serum total testosterone levels do not change significantly in otherwise healthy men until the ninth decade. Similarly, there is little or no change in serum total estradiol levels in men over life (Fig. 7B). By contrast, serum bioavailable (or non-sex hormone binding globulin (SHBG) bound) testosterone levels decrease by approximately 70% (Fig. 8A) and serum bioavailable estradiol levels decrease by approximately 50% (Fig. 8B) over life. To the extent that the non-SHBG bound sex steroid fraction is the one that has access to target tissues (Manni *et al.,* 1985; Giorgi and Moses, 1975), these data indicate that while men do not have the equivalent of the menopause, they clearly have significant (but gradual) age-related decreases in bioavailable testosterone and estradiol levels

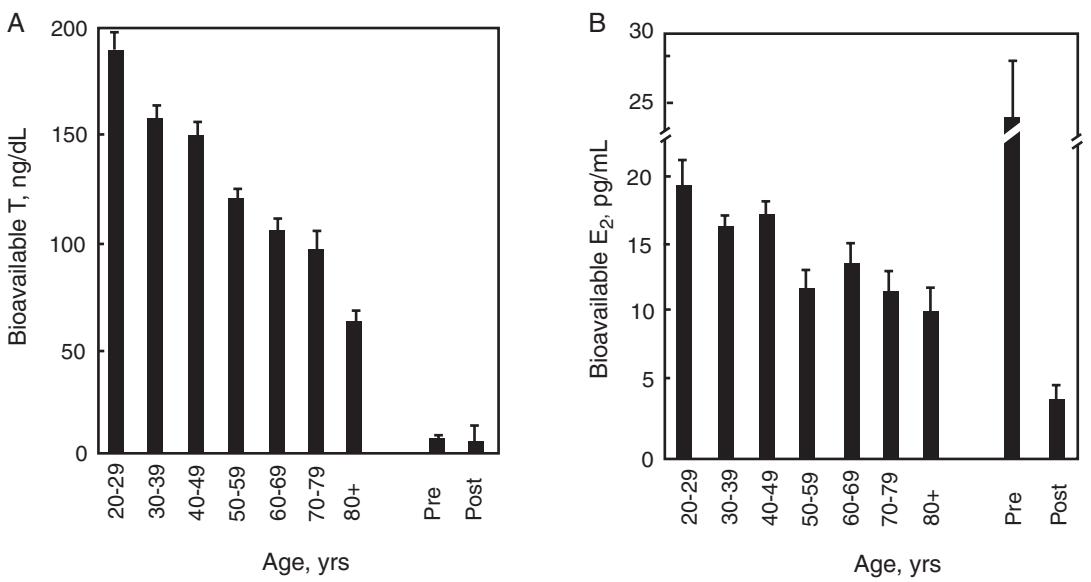

Figure 8 Serum bioavailable testosterone (A) and estradiol (B) levels as a function of age in a population-based sample of men. Data are adapted from Khosla *et al.* (1998), with permission.

over life. These changes are due primarily to a large increase (of approximately 125%) in serum SHBG levels over life in men (Khosla *et al.,* 1998). While the reason(s) for this increase in SHBG levels are unclear, it is apparent that the age-related increase in SHBG serves to limit the availability of testosterone and estradiol to target tissues in elderly men.

One approach to assessing the relative roles of estrogen versus testosterone in the male skeleton has been to measure sex steroid levels in adult men and to relate them in cross-sectional studies to bone mineral density (BMD) at various sites. Using this approach, Slemenda *et al.* (1997) found that in men over the age of 65 years, BMD was significantly positively associated with serum estradiol levels at all skeletal sites (correlation coefficients of 0.21 to 0.35). Serum testosterone levels were actually negatively associated with BMD in this study (correlation coefficients −0.20 to −0.28). Similar findings were noted by Greendale *et al.* (1997) in a study of 534 community-dwelling men ages 50–89 years. In this study, serum bioavailable estradiol and testosterone were directly measured, and serum bioavailable estradiol levels were most strongly associated with BMD at all sites, even after adjusting for age, body mass index, and other possible confounders. In a subsequent study, Khosla *et al.* (1998) also found that serum bioavailable estrogen levels were the most consistent independent predictors of BMD in both young (less than 50 years) and older (over 50 years) men. These and several other cross-sectional studies (Ongphiphadhanakul *et al.,* 1998; Center *et al.,* 1999) thus clearly indicate that, at least using this approach, BMD is more closely associated with serum estrogen levels than with serum testosterone levels in adult men.

While these findings add to the evidence from the ER-alpha and the aromatase-deficient males in building the case for an important role for estrogen in the male skeleton, there are clear limitations to cross-sectional observational data. Thus, since BMD in adult men is a function both of peak bone mass and bone loss with aging, these studies cannot dissociate the effects of estrogen on the acquisition of peak bone mass in early adulthood from its effects on continued bone loss later in life.

To address this limitation in the cross-sectional data, Khosla *et al.* (2000) recently assessed longitudinal rates of change in BMD in young (age less than 40 years) and elderly (greater than 60 years) men and related these to serum sex steroid levels. They found that the rate of increase in mid-radius and ulna BMD in the young men as well as the rate of decrease in BMD at these sites in the elderly men were more strongly associated with serum bioavailable estradiol levels than with serum testosterone levels. Together with the cross-sectional data, these longitudinal data thus provide additional support for a role for estrogen both in the acquisition of peak bone mass in young men and in bone loss in elderly men. However, these associations were found only at the forearm sites and not at the spine or hip, perhaps due to the greater precision of the forearm BMD measurements. Moreover, even the longitudinal findings are limited by the fact that correlation does not prove causality, and direct interventional studies are necessary to dissect out the relative contributions of estrogen versus testosterone toward bone metabolism in adult men.

Studies in Humans — Interventional Data

In order to definitively dissect out estrogen versus testosterone effects on the adult male skeleton, Falahati-Nini *et al.* (2000) studied 59 elderly men (mean age 68 years) in whom they eliminated endogenous testosterone and estrogen production using a GnRH agonist (leuprolide acetate) and an aromatase inhibitor (letrozole). Physiologic testosterone and estrogen levels were maintained by concurrently placing the men on testosterone and estradiol patches. Following baseline studies in which markers of bone resorption (urinary deoxypyridinoline, Dpd, and N-telopeptide of type I collagen, NTx) and formation (serum osteocalcin and amino-terminal propeptide of type I procollagen, PINP) were measured, the men were randomized into one of four groups: group A had

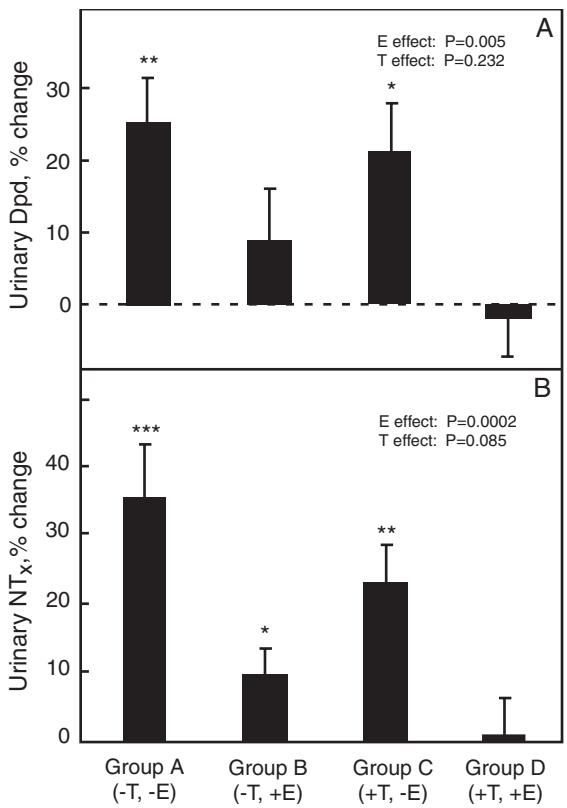

Figure 9 Changes in urinary Dpd (A) and NTx (B) excretion between the baseline and final visits in the four groups as described in the text. $^{***}P < 0.001$, $^{**}P < 0.005$, and $^{*}P < 0.05$ for change from baseline. The overall estrogen (E) and testosterone (T) effect on the bone markers was analyzed using a two-factor ANOVA model. Adapted from Falahati-Nini *et al.* (2000), with permission.

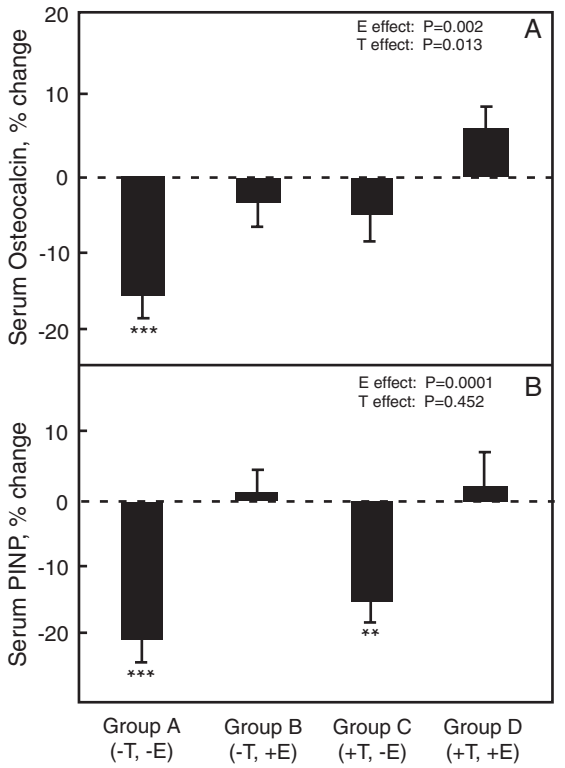

Figure 10 Changes in serum osteocalcin (A) and PINP (B) levels between the baseline and final visits in the four groups as described in the text. $^{***}P < 0.001$ and $^{**}P < 0.005$ for change from baseline. both patches withdrawn, group B continued the estradiol patch but had the testosterone patch withdrawn, group C continued the testosterone patch but had the estradiol patch withdrawn, and group D continued both patches. After 3 weeks, the baseline studies were repeated. As shown in Fig. 3, estrogen had the dominant effect in preventing the increase in both urinary Dpd (Fig. 9A) and NTx (Fig. 9B) excretion that was observed in group A. These studies thus definitively established that estrogen was the major sex steroid regulating bone resorption in normal elderly men, although the data could not completely exclude a small effect of testosterone on bone resorption.

As shown in Fig. 10A, serum osteocalcin levels decreased following acute sex steroid withdrawal in these men, and either estrogen or testosterone was able to prevent the decrease in serum osteocalcin levels. By contrast, estrogen, but not testosterone, was effective in preventing the decrease in serum PINP levels (Fig. 10B). Since osteocalcin is produced primarily by mature osteoblastic cells and osteocytes (Lian *et al.,* 1999), these findings are consistent with an important role for both estrogen and testosterone in maintaining the functional integrity of these cells, perhaps by preventing apoptosis (Manolagas, 2000). Type I collagen, by contrast, is produced by cells of the entire osteoblastic lineage (Orwoll, 1995b), and these data would suggest that it is primarily estrogen that regulates this process.

Consistent with these findings, several other interventional studies have found significant effects of estrogen on the adult male skeleton. Thus, in a preliminary study, Taxel and Raisz *et al.* (1997) treated 9 elderly men with either 0.5 mg or 2.0 mg daily of micronized 17β-estradiol and found significant reductions in bone resorption markers. In addition, Anderson *et al.* (1997) treated 21 eugonadal men with osteoporosis with intramuscular testosterone and found a significant increase in lumbar spine BMD, which was correlated with changes in serum estradiol, but not testosterone levels.

Collectively, then, the observational and direct interventional data now provide conclusive evidence for an important and indeed, dominant role for estrogen in the male skeleton. Moreover, given the data noted earlier on age-related decreases in serum bioavailable estradiol levels over life in men, a plausible hypothesis is that this decline is primarily responsible for age-related bone loss in men. Clearly, further studies are needed to address this issue.

CHAPTER 86

Mechanisms of Exercise Effects on Bone

Robert Marcus

Aging Study Unit, Geriatrics Research, Education, and Clinical Center, Veterans Affairs Medical Center, Stanford University, Palo Alto, California 94304

"The law of bone remodelling is the law according to which alterations of the internal architecture . . . as well as secondary alterations of the external form of the bones . . . occur as a consequence of primary changes in the shape . . . or in the stressing of the bones".

Julius Wolff, *The Law of Bone Remodelling (1892)*

Introduction

The skeleton is a multifunctional organ. It enables locomotion, neutralizes metabolic acid, surrounds and protects brain and viscera, and most importantly, permits organisms to withstand gravitational and other forms of mechanical stress. To accomplish the latter in a manner that optimizes bone strength while at the same time not unduly increasing its weight, bones accommodate the loads that are imposed on them by undergoing alterations in mass, in external geometry, and in internal microarchitecture. The first enunciation of this adaptive principle is generally credited to the German scientist Julius Wolff, whose paraphrased statement appears at the top of this page (Wolff, 1892). In recent years, considerable energy has been directed toward elucidating the biological and molecular mechanisms by which perturbations in mechanical loading are recognized and transformed into changes in skeletal architecture and mass. Skeletal adaptation has been reviewed by many authors (Currey, 1984; Frost, 1987; Fyhrie and Carter, 1986; Lanyon, 1984; Rubin, 1984; Turner, 1991), and a variety of models to explain it have been proposed. Frost (1987) offered the term *mechanostat* to indicate the mechanism(s) that sense and respond to mechanical signals in bone. Although this term has helped to focus the attention of clinicians and exercise physiologists on mechanical loading, it must be pointed out that the mechanostat model was preceded by other more rigorously quantitative and formal models of functional adaptation, such as those of Firoozbakhsh and Cowin (1981) and Fyhrie and Carter (1986).

A general, albeit imprecise, recognition of skeletal adaptation, combined with repeated observations of relatively high bone mass in athletes, has engendered the view that physical exercise is beneficial to bone, a view that has achieved axiomatic stature. However, as formal tests of this concept, controlled exercise trials to date have produced relatively disappointing improvements in bone mass. To understand why this is so, it is necessary to achieve better understanding of the fundamental mechanisms by which bone responds to mechanical stimulation. In this chapter, I discuss current views regarding the skeletal response to mechanical loading, summarize recent experience with exercise as a means of promoting bone mass, and suggest approaches for future work. Comprehensive analysis of quantitative adaptive models lies beyond the scope of this chapter, and discussion of them will be given in general and qualitative terms.

Relationship of Bone Mass to Habitual Loading

If, as stated in Wolff's law, bone accommodates the loads imposed on it, steady-state bone mass should reflect habitual loading history, a principle that is applicable when comparing bone mass among individuals, different bones within an individual, and even different regions within a single bone. A substantial body of published work has addressed this prediction. These studies are of two general types: comparisons of bone mass of athletes to that of sedentary controls and descriptions of associations between level of physical activity or fitness and bone mass within a general population. The first type of study generally considers only very active or sedentary subjects, hence extreme differences in activity are represented. In the latter case, a broader range of physical activity levels is examined.

Exercisers vs Sedentary Controls

Considerable evidence indicates that elite athletes and chronic exercisers have higher bone mineral density (BMD) than age-matched, nonexercising subjects, a finding, not surprisingly, that applies primarily to sites that undergo loading during the exercise. Compared to sedentary individuals, chronic long-distance runners have increased total body calcium (Aloia *et al.,* 1978), calcaneal BMD (Daléan and Olsson, 1974), and vertebral trabecular bone density (Lane *et al.,* 1986; Marcus *et al.,* 1985). Even competitive runners in the sixth decade and beyond have been reported to show ~40% higher vertebral trabecular BMD than nonexercising matched controls (Lane *et al.,* 1986). By contrast, more casual recreational running may have only a limited effect on bone mineral, especially in older women (Kirk *et al.,* 1989; Nelson *et al.,* 1988).

Activities associated with high load intensity at low number of cycles are associated with substantial increases in bone mass. World-class and recreational weight lifters have 10–35% greater lumbar spine BMD (Block *et al.,* 1986, 1989; Colletti *et al.,* 1989; Granhed *et al.,* 1987; Heinrich *et al.,* 1990) than sedentary age-matched controls. It is not certain whether weight lifting is also associated with increased hip BMD, as indicated by some (Colletti *et al.,* 1989; Heinrich *et al.,* 1990) but not all (Block *et al.,* 1989) reports.

Athletes whose activity involves loads at relatively high impact may gain particular skeletal benefit. The BMD values of collegiate gymnasts significantly exceeded those of equivalently trained runners or of age-based normative predictions, even though the former showed a high prevalence of oligo- and amenorrhea, conditions known to result in bone loss (Robinson *et al.,* 1995). The high impact associated with gymnastics training may have provided an adequate stimulus to overcome hormonal disruption. Other cross-sectional studies also support a skeletally beneficial effect of high-impact activities (Pettersson *et al.,* 2000).

Bassey and colleagues (1998) directly assessed the role of high-impact loading in a prospective study of a jumping program in healthy women. The exercise consisted of 50 8.5-cm vertical jumps each day, with loads equivalent to 3–4 body weights per jump as estimated by measurement of ground reaction forces. Five months into the trial, premenopausal women showed an increase in femoral neck and trochanteric BMD of 2–3%. By contrast, postmenopausal women, irrespective of HRT status, showed no change in BMD, even among those who completed a full year of training. Thus, jumping exercise improved BMD in young, but not older women and the failure of the latter to respond to impact loading seemed not to be determined by estrogen deficiency.

On the other hand, it appears that swimming, a trivial-impact activity, does not increase BMD (Heinrich *et al.,* 1990; Jacobson *et al.,* 1984; Taaffe *et al.,* 1995). In one study of elite university athletes (Taaffe *et al.,* 1995), swimmers actually had a lower bone mass than gymnasts or nonathletic controls, despite increased muscle bulk and regular weight training. Young athletes who spend >20 hr each week in a buoyant environment for many years may simply not experience sufficient gravitational stress to promote fully the expected degree of bone acquisition. Whether swimming activity provides effective muscular loading for skeletal maintenance in adults remains unclear, since Orwoll *et al.* (1989) showed that middle-aged long-term male, but not female, swimmers have higher vertebral trabecular bone density than sedentary, age-matched subjects.

A special case of cross-sectional study is represented by comparing dominant to non-dominant limbs in athletes whose sport involves unilateral loading. Jones *et al.* (1977) reported ~30% greater thickness of the humeral cortex in the playing arm than in the nonplaying arm of tennis players, a finding that has been repeatedly confirmed (Daleán *et al.,* 1985; Heinonen *et al.,* 1995; Huddleston *et al.,* 1980; Pirnay *et al.,* 1987).

The durability of training-related increases in BMD remains to be established. Taaffe *et al.* (1997) observed female collegiate gymnasts to show substantial BMD plasticity even during the course of a single year. When training diminished during summer months bone was lost, but with reinitiation of training BMD was regained. In a study of retired elite gymnasts (~25 years of age), the BMD at multiple sites was 0.5–1.5 SD higher than the predicted means for controls and no attenuation of this advantage was observed across the years since retirement despite the lower frequency and intensity of exercise (Bass *et al.,* 1998). Similar retention of BMD advantage into retirement and old age has also been reported for different types of athletes, although results have not been uniformly positive (Karlsson *et al.,* 1999).

This discussion has focused on the relationship of exercise to bone mineral density, but recent studies have brought attention to the possibility that early childhood exercise might lead to permanent biomechanically advantageous changes in bone geometry. Haapsalo *et al.* (1996)

compared the mineral density and geometry of the humerus in Finnish adult long-term tennis players. As expected, the athletes showed exaggerations of normal dominant–nondominant differences in bone mineral content and density. However, tennis players who had commenced training in their sport as children (age 9–10 ± 2 years) also showed significantly greater humeral width. As overall humeral dimensions would not be expected to change with age, and as the bending strength of a bone is related to its cross-sectional area, this geometrical advantage could provide a permanent degree of protection against fracture in later years.

Habitual Physical Activity and Bone Mass of Nonathletes

Evidence from several laboratories points to a significant skeletal effect of physical activity in children and on acquisition of peak bone mass in the third decade (Kroger *et al.,* 1992; Recker *et al.,* 1992; Ruiz *et al.,* 1995; Slemenda *et al.,* 1991). Slemenda *et al.* (1991) described stepwise increments in BMD at multiple sites in children stratified according to activity tertile, and Ruiz *et al.* (1995) reported that time devoted to recreational exercise became a significant predictor of bone mass when children reached the Tanner stage II phase of pubertal maturation. Bailey *et al.* (1998) conducted a longitudinal study of adolescent boys and girls. Participants were stratified into quartiles depending on a standardized gender-specific physical activity score. The authors estimated that an average of 26% of adult total body bone mineral was accrued during the 2-year period at which bone accrual velocity was highest. At that time, when maturational and size differences between groups were controlled for, they observed a 9 and 17% greater total body BMC for active boys and girls, respectively, over their inactive peers. Recker *et al.* (1992) showed that physical activity independently predicted the terminal phase of bone acquisition in healthy women over the age span of 18 to 28 years. In that regard, a recent longitudinal study of Caucasian teenaged girls showed a significant relationship of physical activity history, but not calcium intake, to proximal femur BMD at age 18 (Lloyd *et al.,* 2000).

The situation is less clear for moderately active adults, however, in whom no consistent relationship between *current* activity level and bone mass has been established. Many laboratories exploring this question have reported positive relationships for some age groups at some skeletal regions, but not at others (Aloia *et al.,* 1988; Buchanan *et al.,* 1988; Fraúndin *et al.,* 1991; Greendale *et al.,* 1995; Mazess and Barden, 1991; McCulloch *et al.,* 1990; Metz *et al.,* 1993; Sentipal *et al.,* 1991; Snow- Harter *et al.,* 1992; Sowers *et al.,* 1991; Stillman *et al.,* 1986; Suominen and Rahkila, 1991; White *et al.,* 1992). Mazess and Barden (1991) carefully studied a large group of healthy young women in whom daily activity was quantified by motion sensors. No difference was observed in BMD or in change in BMD over time at any site according to activity quartile. In young women, Kanders *et al.* (1988) described a positive correlation between lumbar spine BMD and total daily energy expenditure. However, the authors did not normalize energy expenditure for body weight, an established independent predictor of bone mass. In our own work (Bouxsein, Snow-Harter, Marcus, unpublished data), strong relationships between estimates of daily energy expenditure and BMD at the spine and hip were completely negated by normalizing the data for body weight or lean mass.

Several reports document positive relationships between *lifelong* physical activity patterns and bone status (Astroúm *et al.,* 1987; Greendale *et al.,* 1995; Kriska *et al.,* 1988; McCulloch *et al.,* 1990; Tylavsky *et al.,* 1992). Astroúm *et al.* (1987) reported that postmenopausal women with hip fracture had undertaken a lower level of occupational and leisure time physical activity between ages 15–45 years, and Greendale *et al.* (1995) observed highly significant associations between BMD at the hip and early-life exercise in a large group of older men and women.

Thus, cross-sectional studies generally support the notion that elite athletes and chronic exercisers have increased bone density relative to age-matched, sedentary individuals. The magnitude of this difference likely depends on the type and intensity of exercise; the age, sex, and hormonal status of the individual; and the number of years spent in training. Bone sites that undergo mechanical loading during exercise show the greatest advantage in bone density. However, data concerning the skeletal effects of *moderate* physical activity remain uncertain, particularly with regard to the role of *current* activity levels.

Cross-sectional comparisons of athletes and control subjects must be interpreted with caution. Since no measurements of bone mass are made prior to initiation of the exercise program, a *causal* relationship between exercise and bone cannot be established. It may be that individuals with higher bone density are more apt to succeed in athletic endeavors; therefore, they become the athletes and chronic exercisers. Conversely, elite swimmers may have excelled in buoyant activity because of a lighter skeleton. In many studies, important characteristics of the matched controls have been neglected. Factors such as menstrual status, nutrient intake, and use of tobacco or alcohol may confound the results. Finally, skeletal status is most frequently expressed as the areal bone mineral density (BMD, g/cm^2), a term that overestimates BMD in persons with large bones and underestimates it in smaller people (Carter *et al.,* 1992). Thus, if exercisers and controls are not well-matched for bone size or factors affecting it (gender, race, age, height, and weight), conclusions based on BMD measurements may be spurious.

Estimating Habitual Skeletal Loads

Studies relating activity level to bone mass pose interpretive difficulties. The instruments used to assess physical activity vary widely and few data establish their validity or reliability. Many instruments currently in use, designed

originally to assess aerobic work or energy expenditure, may simply fail to reflect the loads actually experienced by the skeleton. Even devices that quantify the number of steps taken in a 24-hr period do not distinguish the intensity of impact, and therefore do not fully describe skeletal loading.

Estimating habitual skeletal loads from activity records is not a trivial undertaking. Early attempts to provide such estimates assumed typical conditions to which a bone is regularly exposed, for example, the single limb stance phase during walking. These studies proved useful in understanding relationships between form and function in trabecular bone. However, a more complete understanding required consideration of the fact that bone is loaded under many different conditions and with great variation in the number of cycles during daily activity. Carter *et al.* (1987) introduced a general method of defining loading history as a series of discrete loading events. As a first approximation, they assumed that each loading condition can be best expressed by its load magnitude [s] and number of cycles [n] and that the daily loading experience can be decomposed into histograms of load histories that consist of i discreet loading conditions ($i = 1,2,3 \ldots$), each associated with n_i applications of load. For example, $i = 1$ may represent the activity of single-limb stance during walking with $n_1 = 5000$ cycles. Getting out of a chair 37 times may be expressed by $i = 2$, $n_2 = 37$ cycles. Thus, the steady-state loading history may be expressed as a constant daily stimulus [STIM], representing a summation of all loading events over a 24-hr period, each defined by its load intensity and by its number of cycles (Eqs. [1] and [2]):

$$[\text{STIM}] \propto (s_1n_1 + s_2n_2 + s_3n_3 + \ldots s_nn_n)$$

or

$$[\text{STIM}] \propto \Sigma(s_in_i).$$

Assuming that an individual is at equilibrium, that is, the skeleton is neither gaining nor losing bone, the loading history for each bone, or indeed for each region of a bone, will indicate the stress stimulus necessary for bone maintenance, and quantitative differences in bone density between bones and regions of a bone would be predicted from differences in stress stimulus.

Skeletal Adaptation

Various models have been proposed to explain the responsiveness of bone to loading. Most of these are predicated on the view that adaptive responses lead to optimization of some objective function. Such a function could be the ratio of peak stresses to a bone's maximum tolerable stress (ultimate breaking stress) or, as proposed by Fyhrie and Carter (1986), strain energy density, defined as the concentration of mechanical energy stored in a material. Optimization of strain (the deformation induced by a load or stress) seems particularly attractive (see also Chapter 3), in view of the remarkable uniformity characterizing the magnitude of bone strains experienced by diverse animals undergoing their usual activities. Whether it is measured in galloping horses, flying geese, swimming fish, or chewing macaques, peak strains consistently approximate 2000–3500 microstrain (μE), where 1 E represents a 1% deformation (Rubin and Lanyon, 1984) (Table I). Such *dynamic strain similarity* suggests that skeletal morphology and loading patterns together elicit a specific and beneficial habitual level of strain. By a strain-dependent model, bone would regulate its trabecular orientation and mass as a means for preventing habitual strains at any one site from exceeding an optimal range, above which fracture is more likely.

Table I Peak Functional Strains (PE_q in Microstrain) Measured from Bone-Bonded Strain Gauges in Animals Undergoing Customary Activity

Bone	Activity	PE_q
Horse		
Radius	Trotting	−2800
Tibia	Galloping	−3200
Metacarpal	Accelerating	−3000
Dog		
Radius	Trotting	−2600
Tibia	Galloping	−2100
Goose		
Humerus	Flying	−2800
Cockerel		
Ulna	Flapping	−2100
Sheep		
Femur	Trotting	−2200
Humerus	Trotting	−2200
Radius	Galloping	−2300
Tibia	Trotting	−2100
Pig		
Radius	Trotting	−2400
Fish		
Hypural	Swimming	−3200
Macaca		
Mandible	Biting	−2200
Turkey		
Tibia	Running	−2350

Note. While the primary role of all these bones is load-bearing rather than protection or display, it appears that, regardless of location or origin of loading, maximum peak strains induced during functional activity are similar. Adapted from Rubin and Lanyon, (1984).

Frost (1988) called attention to the very large difference between the loads in cortical bone that induce fracture (~25,000 μE) and those that are typically encountered, and proposed the existence of a minimum effective strain (MES), above which the system would be overloaded and adaptive mechanisms would be called into play. He suggested a range for MES, based on published strain measurements, of ~1500–3000 μE. When loads are within that range, no adaptive response is evoked, even if applied repeatedly and in a sustained manner. By contrast, using an elegant model of skeletal immobilization, Rubin and Lanyon, (1985) defined a strong inverse relationship between strain magnitude and number of cycles needed to induce adaptive remodeling, and showed that prolonged stimulation clearly initiates adaptive

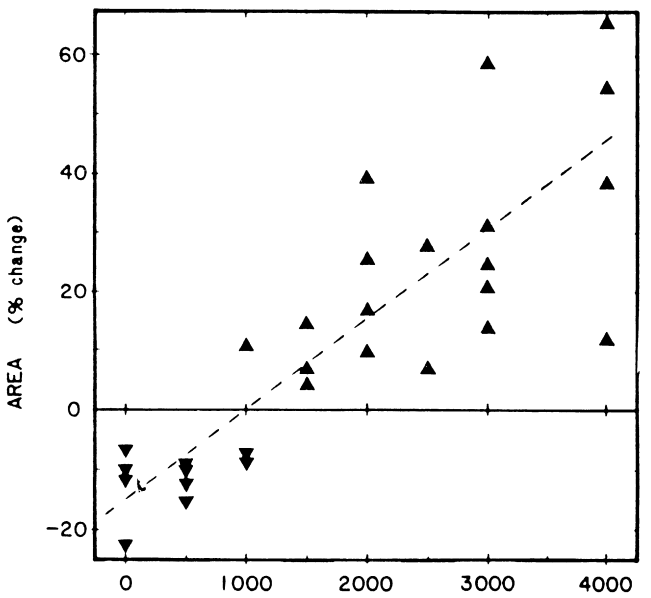

Figure 1 Changes in cross-sectional area of experimental turkey ulnae, loaded for 100 load reversals/day, to peak strains up to 4000 μE. These areal changes reflect comparisons of the left (experimental) to right (intact control) ulnae following an 8-week experimental period. Reproduced with permission from Rubin and Lanyon (1985).

remodeling, even at very low strain magnitudes. By this model, turkey ulnae are surgically isolated from their metaphyseal ends while retaining normal neurovascular connections. The immobilized segments are then placed into a loading device that delivers bending loads under highly defined conditions. Following 8 weeks of immobilization, ulnar cross-sectional area (CSA) decreased by ~20%. Application of 100 load cycles each day led to maintenance of CSA when peak magnitudes were 1000–2500 μE, and actually increased CSA by ~40% when peak strains of 4000 μE were employed (Fig. 1).

Characteristics of Effective Mechanical Loading

Mechanical loads may be characterized by several independent parameters, including load magnitude, number of cycles, and the rate at which strain is induced. To be an effective initiator of remodeling, mechanical stimulation must be dynamic. Using the immobilized turkey ulna model described above, Lanyon and Rubin (1984) showed that simple application of a static load produced no adaptive remodeling and did not protect the bone from atrophy, whereas application of 100 cycles per day of the same load induced bone deposition and increased ulnar cross-sectional area.

Load Intensity versus Cycle Number

Whalen and Carter (1988) introduced a model for comparing the relative effects of load intensity and cycle number on bone mass. Progressing from Eq. [2] (above), they derived an expression to approximate bone apparent density (ρ) from the load history (Eq. [3]):

$$\rho \propto [\Sigma n_i s_{mi}]^{1/2m}$$

By this formulation, the superscript [m] represents a weighting factor that reflects the relative importance of load magnitude to number of cycles. Assume that a 70-kg man walks 1 hr each day. If $m = 1$, magnitude and number of loads have an equal effect on stress stimulus, so walking 2 hr each day would be equivalent to walking 1 hr with a 70-kg backpack. If $m < 1$, cycle number would be more effective than increasing the load, but if $m > 1$, load magnitude would provide a more effective stimulus. Based on a careful analysis of two published human studies in which running exercise was imposed, they predicted values for m that ranged from 2 to 6. Thus, Whalen and Carter concluded that load intensity would be far more important than cycle number.

This conclusion is certainly in line with indications from clinical literature, in which highest bone density values have been observed in athletes whose activities include lifting of heavy loads and application of high-impact forces (Block *et al.,* 1989; Heinonen *et al.,* 1995; Robinson *et al.,* 1995; Snow-Harter *et al.,* 1992). It is also consonant with animal data indicating that the number of loading cycles necessary to maintain bone mass is relatively small (Lanyon and Rubin, 1984), that although modest running activity is associated with higher bone mass in rats, running 3 or 18 km/day has the same effect on bone mineral content (Newhall *et al.,* 1991), and that increasing the magnitude of loads with weighted backpacks is a more effective stimulus for increasing bone mass than increasing the duration of treadmill running (van der Wiel *et al.,* 1995).

Rate of Strain

Peak load magnitude does not itself describe the intensity of loading nor does it determine skeletal response. *Rate of strain* is a term used to describe the time over which strain develops following load application, and is roughly comparable to what is meant by "impact." In several experimental models, rate of strain has been shown to be of critical importance to skeletal response, a principle that applies even at large peak strains (O'Connor *et al.,* 1982; Turner *et al.,* 1993). Turner *et al.* (1995) applied loads of 54 N[1] at 2 cycles per second for 18 sec each day to rat tibias and measured the effect of varying the rate of strain on bone formation and mineral apposition. Results showed a marked linear rise in both variables as rate of strain increased.

The Curvilinear Nature of Skeletal Response

Complete immobilization, as seen with high level spinal cord injury, leads rapidly to devastating bone loss, with deficits that approach 30–40% over several months. By contrast, imposition of even substantial training regimens on normally ambulatory people or animals increases bone mass by only a few percent over a similar period. This is illustrated in Fig. 2, where the effect of walking on bone mass is schematized. As an individual goes from immobility to full ambulation, duration of time spent walking becomes a progressively less efficient stimulus for increasing bone

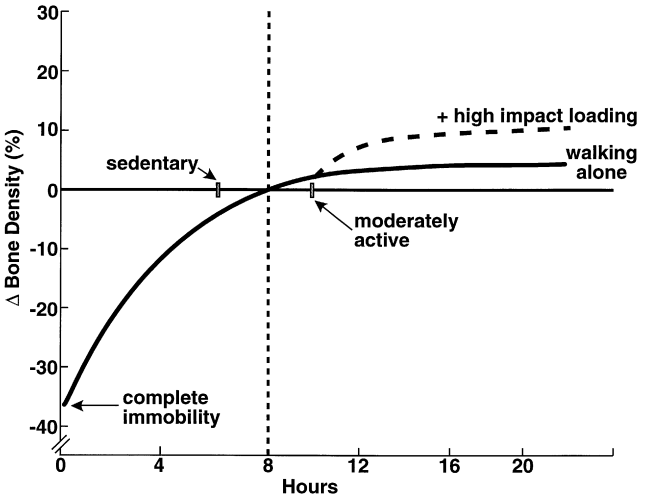

Figure 2 The curvilinear nature of skeletal response. The effect on bone mass of immobility is far greater than that of adding additional walking to an already ambulatory subject. It is more effective to provide a higher intensity stimulus than simply to extend the duration of ordinary loading activity. Ordinary activity, as shown by the region between "sedentary" and "moderately active," defines most individuals, and is characterized by a relatively modest dose–response slope.

mass. A person who habitually walks 6 hr each day might require another 4–6 hr just to add a few more percent BMD. On the other hand, adding a more rigorous stimulus, such as high-impact loading, for even a few cycles would increase the response slope.

The Cellular Basis of Skeletal Adaptation

Since the demonstration in 1975 by Rodan *et al.* (1975) that compressive forces of physiological magnitude lowered the tissue concentration of cyclic 3′5′-adenosine and -guanosine monophosphates (cAMP and cGMP) in incubated avian bone, considerable work has been done to elucidate the biochemical basis for this mechanical transduction. These studies have involved incubation of osteoblast-like cells and bone explants, as well as analysis of bones removed from mechanically loaded animals.

STUDIES IN INCUBATED CELLS

Mechanical loads can be delivered to incubated cells by several techniques, including application of hydrostatic and shear pressures, osmotic swelling, and stretch. Cells can be cultured on specially designed dishes fitted with a flexible bottom. When these are subjected to vacuum or other mechanical stimulation, the entire cell layer is stretched. Stretch can be applied cyclically under highly controlled conditions of magnitude, duration, and frequency. One potential difficulty with this approach is that strain magnitudes are not uniform across the bottom of each well. In one study, for example, strains varied from 0 μE at the edge to 120,000 μE at the center of the well (Harter *et al.,* 1995). In this circumstance, it is necessary to assume the validity of averaging strains over the entire well.

Results of cellular loading experiments have not been consistent. Some perturbations have increased cellular proliferation, whereas others have suppressed proliferative activity while promoting differentiated functions. After examining the available data, Burger and Veldhuijzen (1993) concluded that proliferative activity results from high applied strains, while lower strains promote differentiated activities, such as production of bone matrix proteins. Further consideration of these results led to the suggestion that selective activation of proliferative versus differentiated responses could determine a bone's mechanical characteristics. If an osteoblast is subjected to strains within a favorable range, no requirement for increased mass or change in trabecular orientation would be present, and maintenance of differentiated function would occur. For example, Harter *et al.* (1995) incubated human osteoblastic cells under sustained low-frequency strain, and showed a coordinated upregulation in production of type I collagen, osteopontin, and osteocalcin. On the other hand, if strain magnitude or orientation change substantially, a proliferative response leads to a change in trabecular orientation and density until the magnitude and distribution of strain per osteon returns to the former state.

STUDIES WITH INTACT BONE

A brief period of load application initiates a complex series of biochemical events in bone, resulting several days later in a substantial rise in bone-forming activity (Pead *et al.,* 1988). In cortical bone, mechanical loading stimulates increased bone formation on the periosteal surface, apparently without stimulating an initial resorption phase. Several reports document changes in cellular total mRNA content from 6 to 24 hr following mechanical loading of bones in organ culture (Dallas *et al.,* 1993; Haj *et al.,* 1990). Raab-Cullen *et al.* (1994) examined RNA blots for specific sequences shortly after applying external loads to rat tibias. A rapid but transient increase in mRNA for the oncogene c-*fos* was evident by 2 hr, with increases in message for TGF-β and IGF-I by 4 hr. At the same time, there was a decline in mRNAs for specific differentiated bone matrix proteins, alkaline phosphatase, osteopontin, and osteocalcin. The authors concluded that mechanical loading had induced periosteal cell proliferation.

Turner *et al.* (1995) outlined a cascade of four steps through which mechanical loads couple to skeletal response: mechanical sensing, biochemical coupling, cellular communication, and effector response. There is broad agreement that perception of strain must be a cellular phenomenon and that the cells in bone most likely involved are osteocytes, osteoblasts, and bone surface-lining cells. However, the identity of the mechanosensor itself has not been elucidated. The cells responsible for transducing mechanical signals into chemical mediators may not themselves experience the applied strains, but may receive the signal through strain-induced alterations in canalicular fluid flow (Reich

et al., 1990; Weinbaum *et al.,* 1994) or by generation of electrical potentials (Bassett and Becker, 1962).

The sequence of molecular events in biochemical coupling is not defined, but appears to involve the generation of classical messenger molecules, such as cyclic nucleotides or prostaglandins, by load sensing cells. Lanyon (1992) summarized evidence that stimulation of glucose 6-phosphate dehydrogenase (G6PD), a marker of overall cellular metabolism, occurs in osteocytes and lining cells within a few minutes of load application. This increase appears to be mediated by prostaglandins, since PGE_2 is rapidly and transiently released by mechanically loaded bone (Rawlinson *et al.,* 1991), and the activation of G6PD is blocked by coadministration of indomethacin. In addition, Binderman *et al.* (1984) showed that direct application of physical strain stimulated rapid synthesis of PGE_2 in cultured osteoblast-like cells and also found that electric stimulation of these cells may circumvent the requirement for PGE_2 and directly trigger the adenylate cyclase system.

Cellular communication is required for signal-sensing cells to direct osteoprogenitor and other effector cells to proliferate or to alter their production of bone matrix constituents. Such communication may occur through release of growth factors or other mediators into the canalicular fluid system, as well as by direct cellular contacts. Vander Molen *et al.* (2000) addressed the latter issue in studies of a gap-junction (connexin 43) deficient osteoblastic cell line. Cells were exposed to a 30-Hz, 1.8-mT magnetic flux sufficient to induce a 2 mV/m electric field. Treatment of control cells inhibited cell growth and induced alkaline phosphatase activity. The connexin-deficient cells showed significant treatment-dependent growth inhibition, but alkaline phosphatase induction was impaired. The authors concluded that induction of alkaline phosphatase by electrical fields requires the presence of functional gap junctions.

Effector responses involve activation of a broad range of molecules, including genes for cellular proliferation, genes for such differentiated functions as type I collagen, osteocalcin, or osteopontin, or upregulation of mechano-sensitive ion channels that have recently been characterized in osteoblast-like cells (Davidson *et al.,* 1990; Duncan and Hruska, 1994).

Finally, it should be mentioned that although the focus of most work has been on loading-induced bone *formation,* Klein-Nulend *et al.* (1990) presented evidence that application of mechanical loads to incubated murine long bones also resulted in decreased bone *resorbing* activity. In an elegant *in vivo* demonstration of this phenomenon, Hillam and Skerry (1995) applied 2400 loading cycles/day for 4 days to young rat ulnae. The 7-N peak force was estimated to provide cyclic strains of about 400 μE. In control bones, the medial periosteal surfaces showed resorptive activity, with no fluorochrome incorporation (a measure of bone formation) and with high expression of the resorption marker, tartrate-resistant acid phosphatase (TRAP). In the loaded bones, substantial fluorochrome labeling was observed, representing an 18-fold increase in formation surfaces, and was accompanied by virtual disappearance of TRAP. Rubin *et al.* (1999) assessed the production of osteoclasts in marrow cultures plated on flexible membranes. Application of 5% strain for 10 cycles/min, for 24 hr per day resulted in 40% suppression of osteoclast formation compared to control cultures. By contrast, conditioned media from strained cultures did not inhibit osteoclast formation in unstrained cultures; suggesting that the inhibitory effect of strain requires direct application of strain to the cell rather than the intermediacy of humoral factors.

The Role of Electric Fields in Mechanical Signal Transduction

Induction of both piezoelectric and kinetic currents in bone by mechanical strain gave rise more than 30 years ago to the concept that skeletal adaptation is mediated by cellular responses to electric fields (Bassett and Becker, 1962). Induction of electrical current in bone was shown to prevent bone loss due to denervation (Brighton *et al.,* 1985) and to plaster cast immobilization (Martin and Gutman, 1978), and Rubin *et al.* (1989) demonstrated that pulsed electromagnetic fields not only prevent the bone loss of functional disuse, but also induce new bone formation. Moreover, this work suggested the existence of a distinct frequency range, ~10–30 Hz, at which skeletal response is optimal (McLeod and Rubin, 1992). Indeed, even at peak strains well below those typical of habitual physiological loading, application of 30-Hz signals were shown to be osteogenic, supporting the concept that inducing even very low strains, i.e., <500 μE, may generate an effective osteogenic stimulus, provided that they are induced at optimal frequencies, 15–40 Hz. Surprisingly, a more detailed analysis of these studies indicates that the induced electric field intensities at sites where bone tissue is responding to the stimulus must be very low, indeed, perhaps 1–2 μV/cm. Thus, bone appears to respond with great selectivity and sensitivity to the frequency and amplitude of electrical stimulation. McLeod and Rubin have proposed that strains arising from the ground reaction forces and muscle fiber resonance associated with normal functional activity could themselves provide the signal characteristics to which bone cells respond optimally (McLeod and Rubin, 1990).

Host Factors in Skeletal Adaptation Age

Using the isolated turkey ulna model, Rubin *et al.* (1992) showed impressive deficits with age in the skeletal response to mechanical loading, a finding that was confirmed in a rat model by Turner *et al.* (1995). In view of the complex nature of signal transduction, these deficits could reflect impairments at multiple loci. Adequacy of skeletal response reflects cell numbers and vigor as well as hormonal and cytokine milieu. Since cell populations, circulating growth factors, and production of bone matrix proteins all decline with age (Benedict *et al.,* 1994; Termine, 1990), age-related deficits in skeletal response should ultimately prove to be multifactorial.

The ability of strains at very low magnitude to contribute to skeletal maintenance so long as their cycle number is sufficiently great was alluded to above (McLeod and Rubin, 1990). Huang and colleagues (1999) considered the possibility that an age-related decrease in skeletal exposure to strains induced by normal muscle tone might contribute to bone loss. Histologic studies clearly document age-related decreases in number and cross-sectional areas of both type I and type II muscle fibers. These changes are accompanied by declines in muscle strength and functional capacity. To test whether changes in postural muscle dynamics in the frequency range of 0.1–50 Hz were also associated with age, the authors recorded vibro-myographic output from the soleus muscles of healthy adults, age 20–82 years. They found that muscle vibration frequencies below 15 Hz did not change with age, but frequency components from 30 to 50 Hz decreased substantially with advancing age in both men and women. As 30- to 50-Hz stimuli appear to be those that provide the greatest degree of skeletal response, the authors hypothesize that age-related loss of bone may to some degree reflect the loss of stimulation by postural muscles.

The above considerations notwithstanding, it remains unclear in humans whether or to what degree the BMD response to exercise is constrained by age. Exercise trials in women ranging from the third to the fifth decades have shown increases in bone mass of only a few percent (Friedlander *et al.,* 1995; Gleeson *et al.,* 1990; Lohman *et al.,* 1995; Snow-Harter *et al.,* 1992) or even a loss of BMD (Rockwell *et al.,* 1990), whereas some (Dalsky *et al.,* 1988; Notelovitz *et al.,* 1991) but not all (Prince *et al.,* 1995; Pruitt *et al.,* 1992) studies involving women in the sixth through eighth decades have been associated with increases in spine BMD of 5–8%. One must remember that the overall physical activity of older men and women is lower than that of younger people, so the exercise protocols may have imposed substantially greater incremental loading in the studies of older groups.

The adaptive response of growing bones includes expansion of bone size as well as increases in mass. Once linear growth ceases, plasticity of bone geometry is severely limited. Some ability does persist, even at later decades, for long bones to counteract the weakening effect of endosteal resorption by undergoing compensatory expansion at the periosteal surface, thereby increasing the cross-sectional moments of inertia (Bouxsein *et al.,* 1994; Martin and Atkinson, 1977). The basis for this increase in bone cross-sectional geometry remains obscure, although the hypothesis seems plausible that habitual loads per remaining osteon are increased when bone is lost from the endosteal surface, and that this increase in osteonal loading leads to compensatory periosteal bone apposition. Nonetheless, it seems likely that the greatest opportunity to increase bone dimensions as well as mass through increased physical activity would be during times of growth. It is therefore of interest that not only bone mass, but also the diameters of tennis players' dominant arms are increased if training commenced at an early age (Vuori *et al.,* 1994).

Reproductive Hormonal Milieu

The extent to which endogenous hormone adequacy limits the skeletal response to mechanical loading is not clear, although models of skeletal adaptation suggest that responsiveness may be modulated by hormonal milieu. By Frost's mechanostat model (Frost, 1987), interactions among various elements, including hormonal adequacy, alter a bone's perception of loading, thereby affecting its sensitivity and magnitude of adaptive response. Experimental approaches to this question have largely focused on the effects of estrogen. Estrogen-deficient animals retain the ability to respond to exercise (Barengolts *et al.,* 1994; Hagino *et al.,* 1993; Lin *et al.,* 1994; Yeh *et al.,* 1994). In a well-defined model of external tibial loading, Hagino *et al.,* (1993) subjected rats to a schedule of 36 cycles/day of physiologic strain (~1300 μE) for 3 weeks. Periosteal bone formation increased equally, whether rats had been oophorectomized or sham-operated. Although these results appear to conflict with the notion that loading is perceived differently when hormonal milieu is disrupted, the authors cautioned that since the rat tibial cortex under ordinary circumstances neither responds to changes in reproductive hormone status nor undergoes significant Haversian remodeling, the tibia may not provide an ideal model for testing this issue.

Human studies confirm the ability of estrogen-depleted women to respond to exercise. Although young endurance athletes who lose spontaneous menstrual function show decreased BMD at multiple sites (Drinkwater *et al.,* 1984; Marcus *et al.,* 1985; Myburgh *et al.,* 1993), trabecular bone mass is still higher than that of amenorrheic sedentary women (Marcus *et al.,* 1985). One question of great interest is whether exercise alone will suffice to maintain bone for women who are recently menopausal but who are not taking estrogen. In a controlled trial of resistance exercise, Pruitt *et al.* (1992) found that such women maintained bone mass at the lumbar spine, but did not achieve benefit at the forearm or proximal femur. For older postmenopausal women, estrogen replacement appeared to have no impact on the skeletal response observed by Dalsky *et al.* (1988). However, Khort *et al.* (1995) demonstrated additive effects of estrogen replacement and vigorous weight-bearing exercise in older women, and in another study (Notelovitz *et al.,* 1991), resistance training of postmenopausal estrogen-replete women led to substantial and unprecedented rises in vertebral BMD that have not been otherwise observed in women of similar age.

Constraints on Skeletal Response to Exercise in Humans

As suggested at the beginning of this chapter, improvements in bone mass achieved in well-designed exercise trials have been, with few exceptions, relatively meager. The multiple reasons for this can be considered in light of the principles described above. For an imposed load to effect

a change in bone mass, it must materially alter the daily stress stimulus from its baseline equilibrium state. The most effective way of doing that is to start with very sedentary subjects. When active young people initiate a new activity, it is important to establish that the imposed loads are truly incremental, and are not simply countered by a reduction in other types of activity. Although one cannot be certain in the absence of data, a possible explanation for the 4% *loss* of lumbar spine BMD observed in the resistance-trained subjects of one study (Rockwell *et al.,* 1990) may be that the women, most of whom ran recreationally prior to starting the study, cut back sufficiently on their previous activity to decrease their total loading history, even when the training regimen was taken into account.

A second factor concerns rate of strain. For good reason, resistance training studies have relied on machines that provide safe, highly quantifiable loading to isolated muscle groups. However, this strategy may be counterproductive with regard to generating adequate rate of strain, or impact, to the loaded bones. Several findings are of interest in this regard. The BMD of collegiate gymnasts was significantly higher than that of equivalently trained runners or than age-based normative predictions, even though these women showed a high prevalence of oligo- and amenorrhea, conditions known to result in bone loss (Robinson *et al.,* 1995). It may be that the high impact associated with gymnastics training provided an adequate stimulus to overcome hormonal disruption. In addition, Bassey and Ramsdale (1994) demonstrated a 3.4% increase in trochanteric hip BMD in young women following several months of jumping activity that produced high-impact calcaneal loading. Unfortunately, the safety of such a regimen for older people or for people with skeletal fragility is uncertain. Nonetheless, it seems reasonable to design future trials to include some activities with higher impact than have been applied heretofore. Such activities might include jumping rope or stepping briskly from modest elevation.

A third issue concerns duration of training studies. For logistical regions, and because of high attrition, most published exercise trials have been conducted for 1 year or less. The criticism has been raised that, as opposed to muscle strength acquisition, where gains are maximal within the first few months, skeletal adaptation may evolve more slowly, so longer duration studies would be required to see more impressive skeletal gains. Two studies provide little support for this criticism (Friedlander *et al.,* 1995; Lohman *et al.,* 1995). In one report, lumbar spine, femoral neck, and trochanteric BMD increased by only 1.3, 0.5, and 2.6% after 2 years of supervised training (Friedlander *et al.,* 1995). In the other, BMD gains seen by 5 months either remained stable or actually decreased over the next year, despite continued and fairly dramatic increases in muscle strength through 18 months of training (Lohman *et al.,* 1995).

A final issue concerns the fate of BMD gains when exercise training is stopped or decreased. The paper by Dalsky *et al.* (1988), which is frequently cited to show gains in BMD when exercise is undertaken, also shows clearly that this effect degrades within a few months after the training program terminates, by which time BMD has returned to its baseline values.

Conclusions

In this chapter, I have reviewed the conceptual basis for understanding the relationship between mechanical loading and skeletal adaptation. Complete understanding of this relationship in humans must await development and validation of accurate, quantitative estimates of mechanical loading history. Although this has not yet been accomplished, sufficient information is available to permit general conclusions, as well as speculation about the kinds of exercises that are likely to prove most osteogenic. The adage remains true that the greatest damage occurs when the skeleton is put to rest. The curvilinear nature of skeletal response shows that addition of even modest activity to an immobilized subject will increase BMD to a much greater extent than will a substantial increase in training for a highly active person. Therefore, one might best consider physical activity for most people to be a hedge against bone *loss,* rather than a means of achieving major increases in bone mass. However, should one wish to impose an exercise regimen for the purpose of increasing bone mass and strength, it would be most effectively initiated during years of growth, and include activities that apply loads in an unusual manner or direction, with higher than customary impact. Naturally, one's embrace of this strategy is limited by the subject's ability to undertake such activity with safety.

There is a range of activity in healthy, ambulatory populations in which considerable variation in habitual loading leads to little, if any, change in bone mass. This extremely useful feature assures that adaptive remodeling occurs when changes in *habitual* loading occur, rather than responding to day-to-day alterations in activity. It is this "lazy zone," as designated by Carter, that makes it difficult to show unambiguous relationships between activity level and bone mass in healthy, ambulatory, albeit nonathletic populations.

In medieval times, itinerant priests sold indulgences to counteract future sins. Unfortunately, the skeleton does not allow present good works to be applied against future sloth, but adapts to the demands that are currently made upon it. The experience with astronauts, spinal cord injury, and exercise detraining shows that highly active individuals rapidly lose bone when the loading environment changes.

Modern postindustrial society is becoming increasingly sedentary. In the United States, the President's Council on Fitness estimates that only one of five adults engages in a single episode of recreational exercise each week. More alarming, fitness scores of children are declining. The challenge to the scientific community for developing practical and acceptable exercise programs for the great majority of the population remains formidable. It seems highly unlikely that most people will ever be motivated to participate in multiple exercise

programs, one for aerobic fitness, others for muscle strength and flexibility, and yet another for bone health. Thus, a comprehensive approach is required to develop a single program that offers some, if not optimal, benefit for all these needs.

Finally, the fact that mechanical loads are transduced into electrical and chemical signals in bone suggests that specific pharmacologic or bioelectrical interventions might obviate the need for the initial mechanical stimulus. Such interventions might produce changes in bone mass that exceed what can be accomplished through exercise itself, and might also offer effective strategies for frail individuals in whom rigorous exercise constitutes an unacceptable risk.

CHAPTER 87

Application of Transgenic Mice to Problems of Skeletal Biology

Stephen Clark and David Rowe

Department of Genetics and Developmental Biology, University of Connecticut Health Center, Farmington, Connecticut 06030

Introduction

Transgenic mice provide an excellent setting for studying complex regulatory systems that cannot be modeled or fully appreciated in isolated experimental systems *in vitro* or *in cellulo.* This potential is particularly important in the analysis of the cells that synthesize the extracellular matrix because their response to regulatory signals from the external environment is dependent on their state of cellular differentiation. Because these variables cannot be reliably modeled in isolated systems, the challenge is to develop assay systems within an intact animal that can still ask a focused molecular question. This chapter is designed to illustrate examples where transgenic animals have answered subtle questions about protein structure and gene regulation affecting bone structure or bone cell differentiation that could not have been performed in any other experimental system. In addition, newly developed transgenic approaches will be discussed that have not yet been applied to bone but have great potential in this research arena.

Analysis of Structural Macromolecules in Bone

Type I collagen is the major structural protein of bone, while type II is the primary collagen of cartilage. Mutations affecting the structural integrity of these two molecules result in osteogenesis imperfecta (OI) and chondrodysplasias, respectively. Both of these classes of diseases are inherited as a dominant negative trait, indicating that it is the presence of a mutant gene product that causes the disease. While molecular genetic studies of humans affected with these disorders have illustrated that the spectrum of disease severity can be correlated to specific mutations (Prockop *et al.,* 1993, 1994) a clearer understanding of how these mutations affect protein function can be obtained from transgenic mice.

The concept of the dominant-negative effect of a mutant collagen gene was dramatically demonstrated in transgenic mice carrying an OI producing (glycine substitution) collagen transgene (Stacey *et al.,* 1988). These mice displayed perinatal lethal OI. Molecular analyses showed that lethality was associated with the expression of the transgene to levels as little as 10% of the endogenous normal collagen production. This illustrated that the formation of an extracellular matrix with even a small proportion of mutant molecules has a dramatic destabilizing effect on the entire skeleton. In contrast, another series of transgenic mice were evaluated in which a large internal deletion of the collagen molecule was expressed (Khillan *et al.,* 1991; Pereira *et al.,* 1993). In this case the severity was more variable, predominantly less severe, and correlated with the degree of expression. In the affected yet viable mice, transgene expression was approximately equivalent to the endogenous gene (Pereira *et al.,* 1994). These observations suggest that when the mutant collagen molecule is severely deformed, as in the case of the internal deletion, few of the mutant molecules accumulate in the matrix. Mutations which have a moderate effect on molecular assembly lead to greater accumulation of altered collagen molecules in the extracellular matrix and thus present a more severe phenotype. Comprehension of disease severity based on mutation analysis requires an understanding of how the molecule is assembled, secreted, and incorporated into the extracellular matrix. While these steps may be defined in *in vitro* systems (Bateman and Golub, 1994; Lamande *et al.,* 1995), the functional significance requires a transgenic approach.

Similar observations have been made for type II collagen. Glycine point mutations within this gene produce the phenotype of chondrodysplasia in mice (Garofalo *et al.,* 1991; Maddox *et al.,* 1997) and abnormal craniofacial morphology (Rintala *et al.,* 1993). Transgenic mice with a small deletion in the Col2a1 gene display retarded skeletal development (Savontaus *et al.,* 1996), abnormal craniofacial (Rintala *et al.,* 1997) growth, as well as disruptions in spinal development (Savontaus *et al.,* 1997). However, a large internal deletion has a more variable phenotype which may serve as a model for osteoarthritic changes in older animals (Vandenberg, 1991; Helminen *et al.,* 1993). Mice homozgyous for a knockout of the type II collagen gene die shortly after birth. These mice develop a skeleton with membranous and periosteal bone but no endochondral bone (Li *et al.,* 1995a). Also these null mice do not develop intervertebral discs due to an inability to dismantle the notochord (Aszodi *et al.,* 1998). Furthermore, excessive expression of a normal type II collagen gene can have an equally disorganizing effect on cartilage formation (Garofalo *et al.,* 1993). This important observation underscores a requirement in the design of any gene therapy approach for bone disease. A correcting collagen gene will require a tissue-specific and normally regulated promoter since constitutive high expression or tissue missexpression of a normal extracellular matrix gene can be as deleterious as a low level of expression of a mutant collagen gene.

In addition to illustrating the importance of mutations which disrupt the collagen helix and lead to defective extracellular matrix formation, mutations at other sites within the molecule can demonstrate biological properties of type I collagen (Kivirikko, 1993). The first step in the enzymatic turnover of collagen from the extracellular matrix is cleavage at a specific site within the helix by mammalian collagenase. Collagen molecules containing a mutation at the site of cleavage are more resistant to degradation (Wu *et al.,* 1990b). Embryonic lethality was observed in mice bearing collagen transgenes with this mutation although not as a result of accumulating uncleaved heterotrimers but possibly due to the presence of α1(I) homotrimers. When this mutation was placed within the endogenous gene by homologous recombination, a fibrotic phenotype similar to human scleroderma and increased bone density was observed (Liu *et al.,* 1995a). This model was also used to examine the role of collagenase in the parathyroid hormone (PTH)-stimulated resportion of bone. Interestingly, in mice homozygous for the targeted collagenase resistant allele, the PTH-induced bone resportion responses were blunted. This observation suggests that collagenase degradation of type I collagen is necessary for PTH induction of osteoclastic bone resportion (Zhao *et al.,* 1999). Most recently it has been demonstrated that the altered skeletal remodeling seen in these mutant mice is associated with elevated ostocyte and osteoblast apoptosis, suggesting that matrix degradation may be involved in modulating osteocyte and osteoblast survival (Zhao *et al.,* 2000b).

Chance inactivation of an endogenous gene by insertional mutagenesis has been another important tool for studying the importance of a macromolecule in organ and tissue development. The Mov-13 mouse was discovered as an embryonic lethal in homozygous mice derived from a heterozygous breeding pair containing an experimentally introduced retroviral insertion (Lohler *et al.,* 1984). Further studies revealed that the retroviral insertion had disrupted the Col1a1 locus. Homozygous inactivation of type I collagen resulted in embryonic lethality due to arterial rupture well before bone formation. These mice have had many useful applications in studying collagen regulation and bone biology (Kratochwil *et al.,* 1989). The potential of gene therapy for a collagen mutation was demonstrated by the introduction of a normal collagen transgene which facilitated full embryonic development of the homozygous Mov-13 embryo (Wu *et al.,* 1990a). Initially, the heterozygous Mov-13 mouse was not appreciated as being abnormal. However, sensitive imaging and mechanical testing did demonstrate that mild weakening of the bone was present which spontaneously improved as the bone remodeled in early adulthood. These mice appear to be an excellent murine model of human type I OI (Bonadio *et al.,* 1990).

Cells derived from homozygous Mov-13 mice are valuable tools to study *in vitro* interactions of transfected collagen genes with endogenous macromolecules. For example, the binding of collagen to fibronectin was directly demonstrated by the ability of normal transfected collagen genes to form fibronectin collagen aggregates, in contrast to the failure of these aggregates to form when transfected collagen genes were mutated at sites important to fibronectin binding (Dzamba *et al.,* 1993). From human studies it was apparent that there is specificity of the N-terminal propeptide cleavage site because mutations which inactivated the cleavage region produced altered collagen molecules resulting in Ehlers–Danlos type VII (Weil *et al.,* 1990). However, no human examples of mutations affecting the C-terminal propeptide have been observed. *In vitro* studies in Mov-13-transfected cells suggest that mutations affecting C-terminal cleavage may not have a deleterious effect because secondary sites of cleavage are utilized (Bateman *et al.,* 1990). However, until these studies are performed by mutagenesis of the endogenous gene in a mouse model, the true importance of this region will not be appreciated.

In addition to the major contribution of types I and II collagen in numerous tissues, minor collagens and noncollagenous proteins interact with the major collagens to modify their structural role in tissues of similar composition. This modifying function is best appreciated in transgenic mice or naturally arising mutations in a minor collagen gene. An internal deletion within the type X collagen gene, which normally is expressed in hypertrophic chondrocytes, results in a spondylometaphyseal dysplasia (Jacenko *et al.,* 1993) as opposed to mutations in type II collagen which cause an epiphyseal dysplasia. Further examination of these transgenic mice bearing this dominant interference mutation in type X collagen showed moderate craniofacial skeletal abnormalities (Chung *et al.,* 1997). A somewhat surprising outcome was that a type X null mutation introduced by homologous recombination did not have a detectable phenotype in mice

either heterozygous or homozygous for the null mutation (Rosati *et al.,* 1994). Although a milder phenotype from a heterozygous null mutation would be predicted from studies of type I and type II collagen, lack of any phenotype was unexpected. Recently another group generated type X collagen-deficient mice (Kwan *et al.,* 1997). In these mice abnormalities were observed including a reduction in growth plate thickness in the resting zone and articular cartilage as well as abnormal trabecular bone. Most recently a study reexamined the original knockout mice and has documented a variable skeleto-hematopoietic phenotype that included growth plate compressions primarily within the proliferative zone (Gress and Jacenko, 2000). Type IX collagen is known to bind to type II collagen and promote its interaction with noncollagenous proteins of cartilage. Expression of a helix disrupting mutation within the type IX collagen cDNA in transgenic mice results in a mild form of chondrodysplasia that predisposes to degenerative osteoarthritis (Nakata *et al.,* 1993). A null mutation of the same gene results in an even milder degenerative joint disease (Fassler *et al.,* 1994). The analogous human disease appears to be a form of multiple epiphyseal dysplasia (Briggs *et al.,* 1995). The importance of type XI collagen to cartilage structure and subsequent bone formation has been demonstrated in the cho/cho mouse which harbors a null mutation in the α1(XI) gene and results in a perinatal lethal phenotype with severe bone deformity and shortening (Li *et al.,* 1995b).

Type V collagen is associated with type I in skin and tendon and may regulate type I fiber formation in the same way that type IX affects type II collagen fiber formation. The expression of an α2(V) chain with an N-terminal globular deletion in transgenic mice appears to result in an Ehlers–Danlos type I like phenotype (Andrikopoulos *et al.,* 1995). Bone formation appears to be normal although severe kyphoscoliosis results from ligamentous laxity. As other minor collagens are discovered, their role in the structure of the extracellular matrix will be revealed by mutagenesis in a manner similar to the examples given above.

The noncollagenous proteins of connective tissue are also likely to have a modifying role on type I and type II collagen function. In some cases, the gene knockout approach has not revealed dramatic phenotypes even though the genes are highly expressed in bone. For example, tensacin is strongly expressed in bone (Mackie and Tucker, 1992), and yet the tenacin knockout mouse does not have a connective tissue phenotype (Saga *et al.,* 1992; Forsberg *et al.,* 1996). Similarly, matrilin 1, or cartilage matrix protein, does not have a phenotypic affect when deleted. Homozgygous matrilin 1 knockout mice develop normally with no apparent anatomical or histological abnormalities. This observation suggests a redundancy of function of other matrilin family members (Aszodi *et al.,* 1999). Osteocalcin knockouts have also been generated and do not have a dramatic phenotype, although recent studies suggest there may be a problem in bone remodeling (Ducy *et al.,* 1996) as well as alterations in mineralization in older animals (Boskey *et al.,* 1998). The initial evaluation of osteonectin-deficient mice did not reveal any obvious skeletal changes (Gilmour *et al.,* 1998), however, a more recent study revealed an osteopenia associated with a decrease in bone formation (Delany *et al.,* 2000). Based on the experience of the major and minor collagens that a expressed mutation is more severe than a null mutation, the importance of the noncollagenous proteins may be more dramatically demonstrated by expressing mutations in regions thought to participate in interactions between the noncollagenous proteins and other matrix components. Further, it is clear that often minor but important changes in phenotype are sometimes not detected on first evaluation. It is only when more sophisticated examinations are made or older age groups are studied that differences between wild-type and mutant mice are detected.

Cis Regulation of Structural Macromolecules in Bone and Cartilage

Production of major structural macromolecules constitutes the major synthetic activity of a bone or cartilage cell and can be used to define a particular stage of differentiation. While transient and stable transfection studies can provide insight into the biochemical and molecular interaction, it is only within the intact tissue that the true biological importance of the promoter and transcriptional environment can be appreciated. This is the rationale for the extensive and expensive effort required to carry out a promoter analysis in intact mice. However, when a promoter fragment is identified that controls expression of a transgene in defined subpopulation of cells, it has great value for studies in which tissue directed expression is required as discussed in the following sections.

The Col1a1 and Col1a2 promoters have received the greatest attention. Sequences extending a minimum of 2.3–3.6 kb upstream of the minimal promoter are required for high expression in most type I collagen-producing cells (Krebsbach *et al.,* 1993; Rossert *et al.,* 1995), while sequence as distant as 17 kb are required for strong Col1a2 activity (Antoniv *et al.,* 2001). The role of the first intron is subtle but does direct expression to a subset of type I collagen producing cells. Specifically, knockout of most of the intron produces a subtle reduction on type I collagen synthesis in skin and lung which was insufficient to have a physical phenotype (Hormuzdi *et al.,* 1998). However, when these transgenic mice are challenged with a stimulus for pulmonary fibrosis, an exaggerated transciptional response from the mutant allele was observed (Hormuzdi *et al.,* 1999). While the interpretation of this result is not fully understood, this experimental approach reveals regulatory subtleties that would not be appreciated in cell culture experiments.

A similar type of analysis has demonstrated that there are distinctly separate DNA elements that are important for high expression in different type I collagen-producing cells. The complex nature of the promoter appears to allow a single gene to be differentially regulated in different type I collagen–producing cells such as bone, tendon, and skin (Bogdanovic *et al.,* 1994). The best defined element is the one required to

regulate type I expression in bone. This "bone" element has been delineated to a 6-bp-segment homeobox binding domain located 1.7 kb from the transcription start site (Dodig *et al.,* 1996; Rossert *et al.,* 1996). Mutations within this 6-bp segment inactivates the transgene in bone while transgene activity persists in tendon. The Col1a1 promoter contains another domain upstream of the bone element that is essential for high expression in skin and tendon. An element that is essential for high expression in vascular smooth muscle cells is not located within the 5′ region of the gene (Bedalov *et al.,* 1994). Mapping these elements and defining the transcription factors that interact with them will be an essential step in understanding developmental pathways and signals used by cells that express the same collagen gene to varying levels in different tissues.

The osteocalcin (OC) promoter has received major attention in transient transfection studies to map transcription factor binding domains. A more complex regulatory structure becomes apparent in trangenic studies. A broader spectrum of tissue expression is seen in versions of the transgene than occurs in the endogenous gene and it has been difficult to ensure that all osteocalcin producing cells express the OC promoter transgene (Kesterson *et al.,* 1993; Clemens *et al.,* 1997; Frenkel *et al.,* 1997). A similar complexity is seen for the bone sialoprotein promoter (Chen *et al.,* 1996, 1999; Benson *et al.,* 2000).

The analysis of the type II collagen gene first drew attention to large fragments necessary for activity followed by identifying specific transcription factor binding domains. The importance of the first intron became fully appreciated in transgenic mice (Metsaranta *et al.,* 1995; Seghatoleslami *et al.,* 1995; Zhou *et al.,* 1995). Specific transciptional domans that bind Sox 9 and the SRY-related high-mobility group (HMG) have now been identified (Zhou *et al.,* 1998). Analysis of the type XI promoter (Li *et al.,* 1998; Tsumaki *et al.,* 1998; Liu *et al.,* 2000) in chondrocytes and the type X (Beier *et al.,* 1996) in hypertrophic chondrocytes has also been performed.

Use of Tissue Directed Transgenes to Assess Function of Genes Affecting Skeletal Development and Maintenance of Bone Mass

While targeted inactivation of genes by homologous recombination has contributed greatly to understanding the role of genes to embryonic development, the importance of these genes to bone and cartilage development is often obscured by the fact that other developmental systems are more severely affected and thus preclude analysis of the gene in bone. Examples include knockouts of the wnt and notch pathways, the bHLH family of transcription factors including twist and id and extracellular modifying factors such as noggin all have skeletal components to their embryonic phenotype, indicating an essential role in skeletal biology. This section will review transgenic approaches that had been used to overcome problems associated with global knockouts. In addition the section will review approaches for directing expression of growth factors to the bone environment.

The fundamental tool that is used in this experimental approach is a promoter that has tissue-restricted activity. This strategy creates a biological situation that rarely occurs in nature and can be considered a targeted gain of function mutation. The outcome of transgenic expression can be dramatic, but the interpretation of the biological meaning of the experiment can be complex. Uncertainties include the spectrum of cells that express the transgene. For example, the OC and bone sialoprotein (BSP) expression is specific to bones and thrombocytes, but many versions of the OC and BSP promoter have ectopic expression that includes brain. Within the lineage of bone and cartilage cells, the type I and type II collagen promoter can be designed to have preferential expression at specific stages of differentiation. However, low level expression at other stages of differentiation or for that matter in other cell types may exist and even the low level of activity may be sufficient to disrupt cells in an unintended manner. The other uncertainty is the manner in which the expressed transgene acts, i.e, either within the cell of synthesis (cell autonomous) or on neighboring cells (cell nonautonomous). For example OC-driven production of transforming growth factor (TGF)-β will influence the entire bone cell and osteoclasts lineage (Serra *et al.,* 1997) while OC-driven expression on a dominant negative TGF-β receptor construct will limit its biological affect to the cells that express osteocalcin (Filvaroff *et al.,* 1999). Experimental strategies that achieve inappropriate expression of a growth or transcription factor may produce levels of the product that are never found in a normal cell and affect pathways that normally would never be utilized. This concern always arises when constructs that act in the dominant negative manner on an endogenous transcription complex or signaling pathway in which multimeric interaction exert subtle changes in gene regulation. It cannot be assumed, particularly when the dominant negative protein is highly expressed within its cell, that only the targeted partner will be affected by the interaction.

Despite these reservations, valuable insights into the role of growth and transcription factors and signaling molecules have been achieved using targeted expression techniques. For example, the global knockouts a cbfa1 dramatically demonstrated its central role for bone cell differentiation because mice deficient in this transcription factor fail to develop a mineralized skeleton. Unclear from that work was the effect of cbfa1 on the development of the hypertrophic zone of the growth plate and the role of this structure on endochondral bone formation. When cbfa1 is expressed under control of type II collagen promoter in the background of the cbfa1 knockout mouse, the hypertrophic zone does develop accompanied by vascular invasion and osteoclasts. However, osteoblasts still do not differentiate (Takeda *et al.,* 2001). This experiment is strong evidence against transdifferentiation of the hypertrophic chondrocyte to osteoblasts. In contrast, when a dominant negative cbfa1 is targeted to the chondrocyte with a different Col2a1 promoter, the cartilage remains in a

proliferative stage without development of hypertrophic chondrocytes and osteoblasts fail to differentiate in a pattern very similar to that of the global cbfa1 knockout (Ueta *et al.,* 2001). These observations suggest that the formation of the hypertrophic zone is essential for endochondral bone, but that cbfa1 expression within the osteoblast lineage is required for differentiation in the presence of an intact growth plate.

To assess the role that cbfa1 has in maintaining the osteoblastic phenotype, a dominant negative cbfa1 was expressed under control of the OC promoter. This ingenious design allows the mice to complete embryogenesis normally because OC is not expressed during prenatal life. Osteoblasts do differentiate and the dominant negative is only expressed in late osteoblast differentiation. Mice have an osteopenic phenotype with normal osteoblastic cell number, and primary osteoblastic cultures derived from these mice fail to form mature bone nodules. While this work supports the role of cbfa1 for maintenance of osteoblast lineage even in adult life, it is likely that the dominant negative can act on other members of the family of cbfa1 transcription factors all of which can influence osteoblast differentiation (Harada *et al.,* 1999).

The role that other transcription cofactors have within the osteoblast lineage have been studied by expressing them with promoters that are more broadly expressed but which include the osteoblast lineage. The most surprising result is the role that the fos subfamily (fra-1 and fos B) of the AP-1 helix–loop–helix transcription family have in the osteoblast lineage. Even though these factors are widely expressed and their knockout either has no bone phenotype (c-*fos* knockouts have osteopetrosis, while c-*fos*-overexpressing mice get osteosarcomas and chondrosarcomas), their overexpression produce osteosclerotic bones by stimulating bone formation without enhancing bone resorption (Jochum *et al.,* 2000). A supporting observation is the reciprocal increase in bone mass and reduction of fat tissue in mice transgenic for FosB overexpression (Sabatakos *et al.,* 2000). While the observations are important because this is a biological effect that has great appeal as a therapeutic agent for diminished bone mass, their interpretation of the molecular mechanism is extremely difficult. Because the factors act by forming either homodimers or heteodimers with other members of the AP-1 family and are very dosage sensitive, it is difficult to know if they work directly by partnering with another factor to stimulate an osteogenic molecular pathway or titrate out another factor that is inhibitory to an osteogenic pathway (Aubin, 2001).

Overexpression studies point to the complexities that can influence the differentiation pathway of the osteoblast. While the role of PTHrP has received the greatest attention in the growth plate (see below), it clearly has an equally important effect on the osteoblast lineage. Targeted expression of the constitutively active form of the PTHrP receptor to the osteoblast with a Col1a1 promoter results in a profound increase in trabecular and endochondral bone formation but loss in cortical bone (Calvi *et al.,* 2001). In addition osteoclastic activity was increased in the marrow compartment. Because of the cell autonomous effect of the transgene within the osteoblast lineage, the primary effect of PTHrP in this experimental model is at the level of the osteoblast and the osteoclast response is a consequence of the activated osteoblast lineage. Although the physiological implication of the model will require further evaluation, this well understood pathway in cartilage will have important implication for manipulation of the bone lineage.

Targeting expression of a factor secreted by osteoblast cells affect the regulation of the entire osteoblast and osteoclast lineage making interpretation of the biological role of factor difficult. The first example was the expression of TGF-β under control of OC promoter producing the paradoxical outcome of high bone turnover osteoporosis with an additional component of impaired matrix mineralization. When the effect of TGF-β was limited to the osteoblasts lineage either by addition of bisphosphonates or expression of the transgene in a c-*fos* $-/-$ background, enhanced differentiation of cells into mature osteoblasts was observed. When the deficiency of TGF-β was limited to mature osteoblasts by expression of a dominant negative form of the TGFß receptor driven by OC promoter, osteoclastic activity was diminished and resulted in an increase in trabecular bone mass even though the number of mature osteoblasts was reduced (Erlebacher *et al.,* 1998; Filvaroff *et al.,* 1999). While this experimental approach further underlines the complex interrelationship between bone formation and resorption, it does not adequately discriminate the opposing cellular regulators of bone mass. Although expression of a dominant negative or constituitively active receptor can limit the growth factor effect to a particular lineage, the subpopulation of cells within the lineage, the manner (intermittent vs continuous) in which the stimulus is applied and age/growth rate of the mouse when the analysis is performed can all impact on the phenotype observed. The same type of experiments have now been performed with IGF1 driven either with the OC (Zhao *et al.,* 2000a) or the Col1a1 promoter. Both enhance bone formation and increase bone turnover leading to a similar problem of interpretation as TGF-β forced expression. Targeted expression of noggin (producing bone loss) and the calcitonin gene-related peptide (increase bone mass) (Ballica *et al.,* 1999) are other examples of targeted secretion of a factor affecting the coupling of bone formation and resorption. Even over expression of the tartate-resistant acid phosphatase (TRAP) enzyme results in a phenotype of high bone turnover osteoporosis (Angel *et al.,* 2000). The model utilized the SV40 enhancer and TRAP transgene and resulted in high TRAP activity in osteoclasts of bone and macrophages in nonosseous sites. While defining the cellular control mechanisms for bone remodeling can be fully appreciated only in the integrated system of intact mouse bone, the experimental design has to be improved so as to limit the effect of the probing transgene to a defined subset of cells before an unambiguous interpretation of the experimental data can be made.

Because structural organization of the growth plate provides definition of the stage of differentiation of cells within the cartilage lineage, overexpression studies are more easily understood. The global knockout of PTHrP and

its receptor leads to premature differentiation of hypertrophic chondrocytes while expression of a constitutive active from of the PTHrP receptor causes delayed maturation of hypertrophic chondrocytes. This fundamental observation has lead to a series of experiments in which targeted expression of the constitutive active PTHrP receptor in an ihh −/− or PTHrP receptor −/− background can separate to contribution of ihh and PTHrP to chondrocyte proliferation and hypertrophic differentiation (Schipani *et al.,* 1997; Karp *et al.,* 2000). A similar approach has been used to define the role of cbfa1 in the chondrocyte lineage beyond its role in supporting endochondral bone formation. Overexpression of cbfa1 via the Col2a1 promoter in an otherwise normal background is disruptive to normal joint formation and induces hypertrophic chondrocyte differentiation and vascular invasion at a site that normally never supports bone formation. Of particular interest is a disruption of the pattern of tenacin expression characteristic of the chondrocytes lining an articular cartilage with the reaction of the surrounding tissues suggestive of a degenerative joint. In contrast, targeting the dominant negative form of cbfa1 to chrondrocytes leads to failure of hyperchondrocyte differentiation and expression of tenacin throughout the articular cartilage (Ueta *et al.,* 2001). This work suggests that more subtle levels of chondrocyte differentiation can be controlled by cbfa1 and the possibility that it might play role in the development of degenerative joint disease (Liu *et al.,* 1995b; Ma *et al.,* 1996). TGF-β may also play a role in maintaining the articular cartilage in its appropriate state of differentiation. When same dominant negative TGF-β receptor transgene that was used to remove TGF-β signaling to the osteoblast is targeted to the chondrocyte a state of degenerative joint disease is observed with hypertrophic chondrocytes and synovial thickening (Serra *et al.,* 1997).

Thus ability to assess the state of differentiation by their position or morphology adds to the interpretation of the transgenic experiments. In regards to the osteoblastic lineage, the level of differentiation is probably best appreciated in the sutures of the calvaria. Murine phenocopies of human forms of craniodystosis caused by either overexpression of the normal gene or an activated form of the transcrition factor Msx2 lead to early fusion. These studies suggest that Msx2 acts to keep the cells of the osteogenic front in a proliferative and nondifferentiated state (Dodig *et al.,* 1999; Liu *et al.,* 1999). This conclusion is supported by studies of Msx2 −/− mice that fail to close their suture and demonstrate a diminished number of osteoprogenitor of the osteogenic front (Satokata *et al.,* 2000). The generalized reduction in bone mass seen in the calvaria and axial skeleton is likely to result from a similar cellular mechanism but would not have been appreciated without the analysis of the lineage within the calvarial suture. It would not be surprising that misexpression of other molecular pathways affecting calvarial suture development such as FGF2, twist, and id are likely to act by regulating proliferation and differentiation of the osteogenic front (Rice *et al.,* 2000).

Use of the GFP Transgene Family to Assess Osteoblast Lineage

The previous section stressed the value of recognizing the level of cellular differentiation with the osteoblast and chondrocyte lineage for interpreting the effect of transgenic animal models that alter the biology of bone or cartilage by affecting the regulation of lineage progression. When position or cell morphology is not available to assist in assessing the state of differentiation with a cell population, *in situ* hybridization, immunohistochemistry, or lac Z staining for activity of stage-specific promoter-β-gal transgene can be employed (Rossert *et al.,* 1995; Antoniv *et al.,* 2001). *In situ* hybridization can localize a signal to a specific population of cells and immunohistology is best suited for extracellular molecules, but both procedures are laborious and technically demanding. β-galactosidase has been the traditional enzymatic marker for assessing transgene expression and has been most useful in development studies. However, its use for marking cells an adult tissue is limited because of background endogenous activity and variation of staining intensity due to uncertainties in the diffusion of the substrate into mature tissue. The same techniques can be used to assess lineage in primary culture, but the culture has to be terminated so that progression of a specific cell to later stages of differentiation cannot be recorded.

The green fluorescent protein (GFP) family autofluorescent proteins may provide an approach to overcoming limitations of β-galactosidase in both intact bone and primary cultures derived from transgenic mice. Despite some reports that GFP can have toxic effects in transgenic mice, there are sufficient numbers of examples where viable lines have been produced and have been useful for studying cell lineage and transplantation experiments. Currently there are fluorescent colors that can be distinguished using appropriate filter cubes. Three are isomers of GFP (topaz or yellow, sapphire, cyan) and the fourth is from another species (DS red). The most widely used form of GFP is enhanced GFP (eGFP) because its autofluorescent properties are very similar to fluoroscein-conjugated probes commonly used in most immunohistological studies. However, its emission spectrum spills into GFP sapphire and GFP topaz limiting its use in multicolor experiments.

Sample preparation appears to be important for preserving GFP fluorescence in a histological section. eGFP does not appear to tolerate standard paraffin embedding and instead requires frozen sections to be prepared from histological studies. However, GFP topaz, sapphire, and emerald do maintain a strong fluorescent signal in paraformaldehyde-fixed, EDTA-decalcified, and paraffin-embedded sections of bone. This allows regions of fluorescence within the histological section to be examined under optimal tissue preserving conditions. Once the fluorescent image is recorded, standard histological staining is performed for optimal interpretation of the section. Bone has the additional problem of a high autofluorescent background in the bone marrow and to a lesser

degree in the bone matrix. Use of a dual filter cube optimized for GFP and in the Texas red or rhodamine spectrum allows the green GFP signal to be separated from an orange to yellow autofluorescent color. The section can be examined by either laser confocal microscopy or standard mercury bulb illumination.

The power of the GFP transgenes in primary culture is the detection of the fluorescent signal in the same plate as it progresses from initiation of the culture to full osteoblast differentiation. In this setting the time that the cells activate the transgene can be accurately determined and the transcription profile of that subpopulation of cells can be determined by FAC sorting for the GFP positive cells. For example, a pOBCol3.6 promoter fragment activates GFP concomitant with the expression of alkaline phosphatase and type I collagen synthesis, which is at the stage of preosteoblast differentiation. Once bone nodules form and begin to mineralize the pOBCol2.3, promoter fragments become active along with osteocalcin expression, marking the stage of mature osteoblast/osteocyte differentiation. The two promoter GFP constructs have a different pattern of cellular fluoresence in sections of bone. The pOBCol3.6GFP transgenic mice show expression in the periosteal fibroblasts and lining osteoblast but with little expression in osteocytes. The pOBCol2.3GFP is not expressed in the periosteum but is found on lining osteoblasts and throughout the bone matrix. We envision building a series of promoter-GFP transgenic mice in which different stages of cellular differentiation are marked by a different color of GFP. These mice will provide the ability to recognize stages of differentiation within a complex tissue much like the cell surface markers that are used to identify precursor sells within a hematopoetic lineage. If these reagents become widely disseminated, they can provide a way of standardizing the analysis of factors affecting bone biology at the level of lineage control whether in intact animals or in primary culture derived from the mice.

The availability of a GFP transgene marking stages of cell differentiation will have a wide variety of uses. In primary cell culture, the activation of GFP transgenes can be used to assess the tempo of differentiation and the proportion of clusters of preosteoblasts that form nodules with full bone cell differentiation. Transgenes marking differentiation of adipocytes, smooth muscle cells, chondrocytes (Grant *et al.,* 2000), and vascular and endothelial cells (Kishimoto *et al.,* 2000) are available and need to be modified to a GFP that will function in paraffin-embedded tissues. These markers will allow the investigator to appreciate the complexity of primary marrow stromal cultures and factors that can modulate the culture to various lineages. Possibly its most useful application will be in microarray analysis of the osteoblast lineage. Interpretation of a complex array pattern is extremely difficult in a heterogeneous cell population. Is the change in an expression pattern a consequence of the change that occurred in a subpopulation that only represents 25% of the entire cell population? Are important patterns lost because of an increase in one subpopulation and a fall in another? The GFP also allows the isolation of a specific cell population from a heterogeneous population. The cells can be analyzed by FACS and even collected by cell sorting for biochemical or cellular analysis. This isolation may be an essential requirement for interpreting a microarray experiment.

In intact bone, direct visualizing of the cells that express the transgene, which in turn reflect a level of attained differentiation during development, in a knockout model or in response to a drug intervention will assist in the interpretation of experimental data. Building mosaic mice in which the identity of donor cells are distinguished by transgene expression can reveal cell–cell interactions that could not be appreciated in any other way. For example mosaic mice created with β-Gal marked chondrocytes obtained from the PTHrP receptor $-/-$ mouse produce islands of β-gal-positive hypertrophic chondrocytes within an elongated zone of proliferating and β-gal-negative chondrocytes. This outcome affirmed the model molecular pathway that coordinates lineage maturation within the growth plate. Loss of the PTHrP pathway induced early differentiation and these hypertrophic cells secrete ihh, which stimulates the surrounding PTHrP intact cartilage and color osteoblastic cells into a proliferative and nondifferentiating state (Chung *et al.,* 2001). A third application is in transplantation studies of marrow stromal cells for somatic gene therapy for diseases of bone. Most of these studies to date have used nonspecific marker genes, which did not reflect differentiation into the bone lineage. Recently, engraftment of cells expressing the OC CAT transgene has been demonstrated by *in situ* hybridization, providing the most convincing data that osteoblastic precursor cells can engraft bone and participate in endogenous bone formation (Hou *et al.,* 1999). In the future, GFP will be a more robust and versatile marker for quantitative studies of cellular engraftment and demonstration of transplanted stem cells by direct marrow stromal cells culture of the transplanted mice.

Transgenes as Tools to Ablate a Specific Population of Cells Affecting Bone Biology

The interaction of cells from different lineages is central to organogenesis and bone is no exception. The advent of transgenic technology has led to the development of experimental systems designed to eliminate or destroy specific cell types. The basic concept to direct the synthesis of a gene product that is lethal (the A chains of diphtheria toxin) (Breitman *et al.,* 1990; Breitman and Bernstein, 1992) or conditionally lethal (herpes thymidine kinase, htk transgenic mice) (Borrelli *et al.,* 1989; Heyman *et al.,* 1989) have been the two most widely used strategies. In the case of the viral tk, the viral enzyme can be expressed in mammalian cells without deleterious affects and conditional lethality is achieved by the addition of nucleoside analogs that are phosphorylated only by the viral enzyme. Cell killing occurs when these analogs are incorporated into DNA, thus limiting the lethality to dividing cells. The problem of male sterility in mice transgenic with

the htk gene can be overcome by using a truncated version of the gene in which intrinsic promoter elements within the coding region of the gene are removed without affecting enzymatic activity (Salomon *et al.,* 1995).

The first application of this approach to bone utilized the OC promoter driving an the unmodified form of htk (Corral *et al.,* 1998). After a 4-week treatment protocol with ganciclovir, an osteoporotic phenotype developed in which osteoblasts were destroyed and osteoclasts persisted. Upon removal of the drug, bone mass recovered. The authors interpreted their finding to indicate that the coupled process of bone formation and bone resorption can be dissociated in their model system. Subsequently another model using the truncated form of tk was developed in which a Col1a1 promoter fragment with restricted activity to early osteoblasts was used (Visnjic *et al.,* 2001). In this case a 2-week exposure to ganciclovir resulted in complete loss of osteoblasts and preservation of osteocytes. Osteoclasts were absent and a major disruption in the hemopoietic cell compartment developed. Upon removal of the drug, an osteosclerotic reaction developed in the endochondral and trabecular bone. The remarkable difference in the two models probably relates to level of differentiation within the osteoblast lineage at which the htk was expressed. Late lineage osteoblasts/osteocytes do not contribute the synthesis of new osteoid and probably do not influence the activity of osteoclasts. Osteoblasts actively making osteoid and probably undergoing a limited degree of cell division are more susceptible to ganciclovir toxicity. In addition their cellular activity is either directly or indirectly linked to the activity of osteoclasts and the maintainence of the bone marrow elements. Interpretation of these two models will be helped when GFP lineage markers are incorporated to assess which cells within the lineage survive and continue to influence bone microenvironment.

Probing Skeletal Biology with Strategies that Disrupt the Endogenous Genes

The complete sequencing of the human genome is near completion and will be followed shortly by the sequencing of the entire mouse genome. These achievements have changed the landscape of mammalian genetics. Attention is now focused away from genome structure to the challenge of completely understanding genome function. An obvious area that will be exploited is gene targeting. Systems have been developed and are being further refined as tools to permit the temporal and spatial modulation of a given genetic unit. The Cre/loxP recombinase system developed from the P1 bacteriophage is one such tool. The Cre (causes recombination) recombinase specifically directs recombination at loxP (locus of X-ing-over) recombination recognition sites not only in bacteria but also in eukaryotic cells. A segment of DNA flanked by two directly oriented loxP sites can be excised by the Cre recombinase. When applied to transgenic models, one transgenic line bears the Cre recombinase gene driven by an inducible or tissue-specific promoter. A second transgenic line carries a target transgene. One type of target transgene is an endogenous gene that has been engineered by homologous recombination to contain loxP sites in a desired location so as to produce a predetermined modification of the endogenous allele in the presence of the Cre recombinase. Often the target transgene is "silent" in the absence of the Cre recombinase. By breeding the Cre recombinase-bearing line to the target line, F1 progeny are produced that now contain a modified target transgene. Depending on the nature of the design of the target allele, Cre recombination can either activate or inactivate the targeted locus. This system has been recently employed to develop the first knock-in mouse model for osteogenesis imperfecta (Forlino *et al.,* 1999). Other systems are being developed to control spatial expression of targeted loci by directing of Cre expression to defined cellular components of the skeleton. A Col2a1–Cre fusion transgene has been developed with expression restricted to the chondrocytes (Sakai *et al.,* 2001). Important in the development of these systems is the evaluation of the Cre recombinase expression when driven by a specific promoter. Specialized lines of mice have been developed to serve as indicators of Cre recombinase expression. Information relative to these lines as well as others under development can be obtained from a web site maintained by Andras Nagy (*http:// www.mshri.on.ca/nagy/cre.htm*). While spatial control of Cre expression is a powerful paradigm for studying gene function, systems that allow both spatial and temporal modulation of Cre expression permit more elegant analyses. Several experimental paradigms have been developed to permit the temporal regulation of Cre recombinase expression, including two systems that involve the linking of Cre recombinase to a ligand-binding domain. One model utilizes human estrogen receptor fused to Cre (Cre–ERT). In this system Cre expression is activated by tamoxifen but not by natural hormone, estradiol (Brocard *et al.,* 1997). Recently a modified version of the Cre–ERT has been developed (Cre–ERT2) that is approximately 10-fold more sensitive to tamoxifen induction than Cre–ERT (Indra *et al.,* 1999). The Cre-ERT2 may be particular useful in studies where the impact of the inducing agent is a possible concern since much lower concentrations of tamoxifen are required for recombinase expression. A similar system fuses Cre recombinase to a truncated ligand-binding domain of the progestrone receptor. Like the Cre–ERT system, the Cre recombinase is activated by a synthetic steriod RU486 but not the endogeneous hormone progesterone (Kellendonk *et al.,* 1996). While these systems both permit the temporal and spatial regulation of Cre recombinase expression their value to bone biology may be of potentially limited because of unwanted affects of the tamoxifen or RU486 on bone cell metabolism. Careful experimental design is required to be certain that the synthetic steriods are not impacting on the biological process being evaluated.

While gene targeting is a compelling tool for studying gene function, this gene-driven method requires that the genetic units to be studied have been cloned. Recently, a

second avenue, the phenotype-driven approach, has received a great deal of attention. This research paradigm involves large-scale mutagenesis programs using the chemical mutagen *N*-ethly-*N*-nitrosourea (ENU) and the development of gene trap strategies. While very expensive and labor intense, ENU mutagenesis is important for evaluating a broad spectrum of gene function. Functions associated with a locus may be discovered in an ENU mutagenesis screen that would not be revealed in a gene-targeting experiment. Several major ENU screening programs are underway worldwide and a list of the web site addresses has been published (Justice *et al.,* 1999). Of particular interest to the bone biologist is the program being conducted at the GSF-National Research Center for Environment and Health in Neuherberg, Germany. A component of their screen focuses on dysmorphology which will include alterations in skeletal structure (Hrabe de Angelis *et al.,* 2000). Finally, gene trap methodologies utilizing embryonic stem cells and various targeting vectors are being developed. Trapping vectors are designed to detect *cis*-regulatory elements, splice sites, or poly(A) addition signals. The objective of these programs is to create large libraries of genetically altered ES cells for the generation and analysis of mouse mutations. As with the ENU mutagenesis program, large-scale programs are being initiated worldwide (Cecconi and Meyer, 2000).

CHAPTER 88

Use of Cultured Osteoblastic Cells to Identify and Characterize Transcriptional Regulatory Complexes

Dwight A. Towler* **and Rene St. Arnaud†**

**Department of Medicine, Washington University, St. Louis, Missouri 63110; and*
†Genetics Unit, Shriner's Hospital for Children, Montreal, Quebec, Canada H3G IA6

Introduction

The molecular details of transcription and its regulation in osteoblasts have become the subject of intense interest for researchers in developmental biology, endocrinology, cellular physiology, clinical pharmacology, and biomechanics. Since the original version of this chapter, great strides have been made in our understanding of osteoblast transcriptional regulation. The gene encoding the runt domain factor, Runx2—a.k.a. type II Cbfa1/ Osf2, til-1, PEPB2αA, or AML3—has now been unambiguously identified as necessary for robust expression of the osteoblast phenotype (Ducy *et al.,* 1997, 2000; Komori and Kishimoto, 1998; Komori *et al.,* 1997). In the absence of this crucial transcriptional regulator, ossification programs cannot be elaborated that propagate orthotopic mineral deposition during development. Intriguingly, other transcriptional regulatory circuits—e.g., those modulated by Msx2 (Newberry *et al.,* 1998; Satokata *et al.,* 2000), Dlx5 (Acampora *et al.,* 1999; Benson *et al.,* 2000; Erceg *et al.,* 2000; Ryoo *et al.,* 1997), and Fra1 (Jochum *et al.,* 2000; Newberry *et al.,* 1997c)—that determine the level and temporospatial timing and global extent of osteoblastogenesis, osteoblast gene expression, and matrix synthesis have also emerged. Additionally, members of the Msx gene family may participate in the initiation and propagation of certain heterotopic mineralization programs associated with macrovascular arterial calcification (Towler *et al.,* 1998). Nevertheless, even though the rudimentary components of the osteoblast transcriptional machinery have now been revealed, the cellular physiology of transcriptional regulation in the osteoblast remains poorly understood. As highlighted previously, morphogenetic, metabolic, and mechanical (matricrine) signaling cues all contribute to the control of bone formation, and the molecular pathways modulating gene expression in response to these physiological stimuli remain to be detailed. Moreover, as is increasingly apparent, transcription factors such as Runx2, Msx2, and the AP1 family function not as single entities but as modular components of large nuclear macromolecular transcriptional complexes. While several coregulatory molecules have been identified for these factors, the native "holoprotein" complexes that assemble in osteoblasts and regulate Col1A1, Col1A2, alkaline phosphatase, osteopontin, bone sialoprotein (BSP), osteocalcin (OC), etc., remain undefined.

This chapter will build from the foundation established in the first edition that emphasizes studies immediately relevant to osteoblast gene expression. However, two new methodological approaches will be discussed that are only now receiving attention in the field of bone biology transcriptional regulation. The recent technological advances in protein mass spectrometry and data base analyses tools (Neubauer *et al.,* 1998) will be highlighted, since these approaches will

permit characterization of the nuclear holoprotein complexes and posttranslational modifications that regulate osteoblast gene regulation. Additionally, the application of chromatin immunoprecipitation (ChIP) assays (Kuo and Allis, 1999) to detail holoprotein complexes assembled by specific promoters in native chromatin contexts will be discussed. Dissection of the molecular details of gene expression in the osteoblast holds tremendous promise for development of novel therapeutic strategies for management of the prevalent musculoskeletal diseases, heterotopic ossification syndromes, skeletal neoplasms, and craniofacial dysmorphias that afflict the human population throughout life.

Osteoblast Cell Culture Models

Model systems developed using osteoblastic cell type-specific promoters have provided important general insights into transcription control by steroid hormones, retinoids, cytokines, growth factors, oncogenic proteins, and homeodomain transcription factors (Table I). For example, our understanding of how calcitriol regulates gene expression has been gleaned largely from studies of the osteocalcin and osteopontin promoters, two genes characteristically expressed in osteoblasts. Similarly, important insights into the influence of chromatin structure on gene expression during cell cycle progression have been elucidated using cultured osteoblastic cells (Drissi *et al.,* 2000; Stein and Lian, 1993; Stein *et al.,* 1994). However, much work remains to be done before an accurate and detailed working model of osteoblast-specific transcription control can be drawn.

A variety of cultured cell systems have been successfully used to study the role and regulation of osteoblast-specific elements in transfection assays (Table II). Three general classes of culture systems have been employed: osteoblastic osteosarcoma cell lines, spontaneously transformed and Papova virus antigen transformed cell lines, and primary cultures of osteoblastic cells derived from fetal rat calvaria or subperiosteal bovine fetal long bones. Each system has its advantages and disadvantages; osteoblastic osteosarcomas, MC3T3E1 cells, and primary calvarial cell cultures will be discussed below. The reader is referred to cited references and the earlier edition of this book for full discussion of other, less utilized culture models.

Osteoblastic Osteosarcomas

The most widely used system for studying transcription control in osteoblastic cells has been the ROS 17/2.8 osteoblastic osteosarcoma (Majeska *et al.,* 1980). This mineralizing subclone obtained from a rat osteosarcoma constitutively expresses a number of mature osteoblastic phenotypic markers, including alkaline phosphatase, PTH receptor, vitamin D receptor, osteopontin, BSP, OC, and lower levels of type I collagen (Majeska *et al.,* 1980; Rodan and Noda, 1991). Importantly, these cells are phenotypically very stable, respond to major osteotropic hormones (Rodan and Noda, 1991), and are readily transfected (Table II). Studies of transforming growth factor (TGF)-β regulation of the COL1A2 gene, calcitriol regulation of the osteopontin and osteocalcin genes, and retinoid, tumor necrosis factor (TNF)-α, and glucocorticoid regulation of the osteocalcin promoter have all used ROS 17/2.8 cells (Table I). Moreover, a number of nonmineralizing, nonosseous sarcomatous subclones from the same tumor provide convenient cellular backgrounds for comparison for identifying cell type specific elements. For example, the ROS 25/1 clone, which does not mineralize and does not express osteocalcin (Majeska *et al.,* 1980), has been successfully used in concert with ROS 17/2.8 cells to define the osteoblast cell type-specific transcriptional regulation and DNA protein interactions controlling the rat (Towler *et al.,* 1994a) and mouse (Ducy and Karsenty, 1995) osteocalcin promoters. Of note, comparison of basal OC promoter regulation in these two cellular backgrounds guided the search that ultimately identified Cbfa1/Osf2/Runx2 (Ducy *et al.,* 1997, 2000) and Msx2 (Newberry *et al.,* 1998; Towler *et al.,* 1994b) gene family members as important osteoblast transcription factors.

Transfection of ROS 17/2.8 cells by calcium phosphate and DEAE dextran techniques is straightforward (section III). Electroporation has also been used successfully with ROS 17/2.8 cells for transient transfection analyses (Terpening *et al.,* 1991). However, when performing multiple independent transfections with a large number of systematically altered promoter constructs, DEAE–dextran is preferred because of ease of performance and reproducibility (Keown *et al.,* 1990; Lopata *et al.,* 1984) and low cost.

Similar to ROS 17/2.8 cells, the UMR-106 series of osteosarcomas expresses many aspects of the phenotypic characteristics of osteoblasts, including PTH responsiveness (Rajakumar and Quinn, 1996; Selvamurugan *et al.,* 2000), BSP expression (Lecanda *et al.,* 1998; Ogata *et al.,* 1995), and mineralization (Stanford *et al.,* 1995). However, the lack of significant osteocalcin expression in certain subclones suggests that UMR clones express a distinct, restricted spectrum of the osteoblast differentiation program continuum (Rodan and Noda, 1991). Transfection has been successfully achieved by electroporation (Davis *et al.,* 1994) and calcium phosphate transfection (Ernst *et al.,* 1991). A useful variant of UMR cells has been engineered by stably expressing a cyclic AMP (cAMP)-resistant form of the type I regulatory subunit of cAMP-dependent protein kinase (Bringhurst *et al.,* 1989), which specifically usurps this important signaling pathway in the osteosarcoma background. Such engineered cell culture systems may prove useful in the examination of the positive (Boudreaux and Towler, 1996) and negative (Tintut *et al.,* 1999) effects of cAMP signaling on osteoblast-specific transcription factor complexes.

Much less detailed information exists on transcriptional regulation in human osteosarcoma lines. Similar to the ROS 17/2.8 cell line, MG63 human osteosarcomas express alkaline

Table II A Selected List of Useful Cell Culture Models for Transcription Control in Osteoblasts

Cell culture systems	Phenotypic makers expressed	Transfection modalities	References
ROS 17/2.8 (rat)	COL I, AP, OP ON, BSP, OC	Ca PO_4/Gro shock DEAE dextran/DMSO shock Electroporation Polybrene	Ernst *et al.,* 1991 Yoon *et al.,* 1988 Terpening *et al.,* 1991 Kerner *et al.,* 1989
UMR (rat)	COLI, AP, OP ON, BSP, MMP13	Ca PO_4/Gro shock Electroporation	Ernst *et al.,* 1991 Davis *et al.,* 1994
RCT1 (rat)	COL I, AP, OP (RA dependent)	DEAE–dextran/DMSO shock with chloroquine	Ernst *et al.,* 1991
RCT3 (rat)	COL I, AP, OP	Ca PO_4/Gro shock	Ernst *et al.,* 1991
MG63 (human)	COL I, AP, OP BSP, OC (OC calcitriol dependent)	Liposomes Retrovirus	Cervella *et al.,* 1993 Thacker *et al.,* 1994
MC3T3-E1 (mouse)	COL I, AP, OP ON, BSP, OC, MMP1	Ca PO_4, Gro shock DEAE–dextran/DMSO shock	Hurley *et al.,* 1993 Towler *et al.,* 19994b
Primary calvarial Osteoblasts (rat)	COL I, AP, OP ON, BSP, OC, MMP1, MMP13	Ca PO_4, Gro shock Liposomes	Pash *et al.,* 1995 McCarthy *et al.,* 1995 Newberry *et al.,* 1998
Primary cortical Osteoblasts (bovine)	COL I, AP, OP ON, BSP, OC	Ca PO_4, Gro shock	Ibaraki *et al.,* 1992, 1993

Note. COL I, type I collagen; AP, alkaline phosphatase; Op, osteopontin; ON, osteonectin; BSP, bone sialoprotein; OC, osteocalcin; Ca PO_4, calcium phosphate; Gro, glycerol, DEAE, diethylaminoethyl; DMSO, dimethylsulfoxide; RA, retinoic acid.

phosphatase, bone sialoprotein, MMP1, and osteocalcin (Bonewald *et al.,* 1992; Lajeunesse *et al.,* 1991; Riikonen *et al.,* 1995). However, these cells are much more difficult to transfect; DEAE–dextran and calcium phosphate techniques are generally not useful. Cationic liposome-mediated transfection (Cervella *et al.,* 1993; Riikonen *et al.,* 1995) and retroviral vectors (Thacker *et al.,* 1994) have been successfully used for transfection of MG63 cells. MG63 cells have been widely used in the study of integrin-mediated cell–matrix interactions and regulation by cytokines and hormones (Broberg and Heino, 1996; Riikonen *et al.,* 1995). Studies of β-1 integrin expression in MG63 cells introduced the notion that osteoblastic cell-type specificity exists for one of the two known β-1 integrin gene promoters (Cervella *et al.,* 1993). Moreover, the MG63 line has been used as a convenient source for purification and identification of known and novel osteoblast transcription factor complexes (Newberry *et al.,* 1997a). However, very little published information exists on osteoblast-specific promoter regulation and transcription factor biochemistry in this human osteosaroma line. The MG63 osteosarcoma has yet to reach its full potential as one model cell culture system for studying osteoblast-specific gene expression. Future studies in this cellular background promise to be rewarding.

Another human osteosarcoma, Saos-2 (lacks endogenous tumor suppressor p53), can be transfected by the calcium phosphate technique. The Saos-2 line has been widely used in the studies of p53-activated (Morris *et al.,* 1996; Tang *et al.,* 1998; Thornborrow and Manfredi, 1999) and repressed (Sun *et al.,* 2000) genes that control cell growth, apoptosis, and extracellular matrix turnover. Additionally, estrogen receptor signaling has been examined in this cellular background (Ernst *et al.,* 1991). However, the Saos-2 line expresses a more limited subset of osteoblast phenotypic markers when compared with MG63 cells.

MC3T3-E1 Calvarial Osteoblasts

For a variety of reasons, the MC3T3-E1 cell line provides one of the most convenient and physiologically relevant culture systems for studies of transcription control in calvarial osteoblasts. The MC3T3-E1 cell line is a spontaneously immortalized (not transformed) cell line selected by the 3T3 passaging protocol (Sudo *et al.,* 1983). MC3T3-E1 cells behave as immature, committed osteoblast cells, which go on to differentiate in response to intracellular and extracellular cues. Upon reaching confluence, this clonal cell line differentiates along the osteoblast lineage, sequentially expressing characteristic osteoblast phenotypic markers (including bone sialoprotein and osteocalcin) in a manner closely mimicking that of primary cultures of fractions 3–5 calvarial osteoblasts (Franceschi and Iyer, 1992; Franceschi *et al.,* 1994; Vary *et al.,* 2000). Moreover, postconfluent cultures of MC3T3-E1 cells will mineralize—accumulating hydroxyapatite—when cultured in the presence of ascorbic acid and β-glycerol-phosphate (Sudo *et al.,* 1983). MC3T3-E1 cells respond to osteotropic hormones, prostaglandins, cytokines, and numerous growth factors, including FGF, IGF, and BMP family members. The phenotype of this cell line is very stable as long as stocks are rigorously maintained (in fetal calf serum) by passaging before confluency. Finally, MC3T3-E1 cells

are readily transfected by DEAE–dextran (at higher cell densities) and calcium phosphate modalities (Newberry *et al.,* 1997b; Towler *et al.,* 1994a). With regard to detailed analyses of transcription control, MC3T3-E1 cells have been used most widely in the study of the osteocalcin (Boudreaux and Towler, 1996; Newberry *et al.,* 1999; Towler *et al.,* 1994a; Xiao *et al.,* 2000), type I collagen (Hurley *et al.,* 1993), interstitial collagenase (Bidder *et al.,* 2000; Hurley *et al.,* 1995; Newberry *et al.,* 1997c), bone sialoprotein (Benson *et al.,* 2000), and prostaglandin G/H synthase-2/Cox-2 (Kawaguchi *et al.,* 1995) promoters. This cell line holds tremendous promise as a physiologically relevant model for future studies outlining growth factor-activated signal transduction cascades and their interactions with the calvarial osteoblast transcriptional machinery.

Cultures of Primary Osteoblasts

The most widely used source of primary osteoblasts are proteolytically released cells derived from fetal and neonatal rat calvaria. Cells released at later times of digestion have great osteogenic potential, sequentially expressing osteoblast phenotypic markers and forming mineralizing nodules with time in culture (Kawaguchi *et al.,* 1995). These cells in early passage are neither immortalized nor transformed. The population of cells released from calvarial tissue is inherently heterogenous; however, enrichment of cultures for committed osteoblasts can be obtained by passage and treatment with 0.1 μM dexamethasone (Aronow *et al.,* 1990). Cultures of primary calvarial osteoblasts are readily transfected by calcium phosphate (Newberry *et al.,* 1998; Pash *et al.,* 1995) or lipofection (McCarthy *et al.,* 1995) techniques. The regulation of the insulin-like growth factor (IGF)-I promoter by cyclic AMP in primary calvarial osteoblasts identified the unique role for C/EBP-δ in this signaling cascade, and proved the utility of this culture model for studies of promoter regulation and signal transduction in osteoblasts (Umayahara *et al.,* 1999). More recently, AP1 complex protein/DNA interactions mediating FGF2 regulation of the MMP13/collagenase-3 promoter have been studied in this culture model (Varghese *et al.,* 2000), confirming the important role of the Fos and Fra family members in FGF2-dependent control of osteoblast matrix metalloproteinases (Bidder *et al.,* 2000; Newberry *et al.,* 1997c).

In a similar fashion, cultured primary bovine osteoblasts have been used in studies of the human osteonectin promoter (Dominguez *et al.,* 1991). Subperiosteal bovine osteoblasts express phenotypic markers and mineralize in culture (Ibaraki *et al.,* 1992). Young and coworkers used this system for identifying and characterizing an element consisting of repetitive GGA motifs, which were recognized by a nuclear factor present in primary osteoblasts but not in kidney cell lines; the identity of this factor is unknown (Ibaraki *et al.,* 1993) and cell-type specificity conveyed by the element may be species-specific (Hafner *et al.,* 1995). Finally, chick calvarial osteoblast cultures have also been used for detailed studies of Msx2 actions on osteoblast differentiation programs (Dodig *et al.,* 1999); generally, retroviral transfection is required for efficient use of this system (*vide infra*).

Transcriptional Analysis

A wide variety of techniques exist to allow monitoring of steady-state mRNA levels in bone cells. These include Northern blot assays, S1 nuclease mapping, RNAse protection assays, reverse transcription–polymerase chain reaction (RT-PCR) assays quantified by traditional competitive template analysis or real-time fluorescence signals, differential display-PCR, or the powerful new method of gene arrays and DNA microarrays. A description of all these techniques is beyond the scope of this chapter; however, it should be mentioned that their use and the results that they generate represent the initial step in the study of the control of the expression of any given gene. They have been used extensively to obtain a profile of gene expression in bone cells during cellular differentiation, and in response to a wide variety of signals as diverse as extracellular matrix attachment, cytokine and hormone treatment, drug treatment, and even microgravity during space flight (Bidwell *et al.,* 1998; Carmeliet and Bouillon, 1999; Carulli *et al.,* 1998; Damsky, 1999). Once a condition has been identified that modulates the steady-state mRNA levels of the gene of interest, the real task of determining which mechanisms contribute to the regulation of the expression of the gene can begin.

Transcriptional Control vs mRNA Stability

Detecting increased levels of steady-state mRNA does not necessarily mean that gene transcription is increased. Indeed, bone cells can control the abundance of any given mRNA through a variety of means: transcription initiation, transcription elongation, mRNA stability, pre-mRNA splicing, mRNA transport, and polyadenylation. Translation and posttranslational modifications represent other means available to the cell to ultimately regulate the expression of a given gene product. Changes in splicing efficiency, transport rates, and polyadenylation are not easy to evaluate, and these mechanisms are usually invoked when direct measurements of mRNA stability and transcription initiation have yielded negative results. They still represent bona fide control mechanisms, however, as exemplified by the differential expression of the liver/bone/kidney isozyme of alkaline phosphatase in osteoblasts that is controlled via a posttranscriptional mechanism not involving increased cytoplasmic mRNA stability (Kiledjian and Kadesch, 1991; Manji *et al.,* 1995). Similarly, the major stimulation of bone sialoprotein expression following glucocorticoid treatment of bone cells involves a nuclear posttranscriptional mechanism (Ogata *et al.,* 1995).

Measuring the stability of a given mRNA represents a valid starting point for any study of the mechanisms regulating the expression of a gene in response to a particular

signal. The easiest method for measuring the half-life of an mRNA is to block transcription with an inhibitor such as actinomycin D, 5,6-dichloro-1-β-D-ribofuranosylbenzimidazole (DRB), or α-amanitin. The abundance of the mRNA of interest is measured as a function of time after inhibitor treatment using Northern blotting, S1 nuclease, or RNAse protection assays. The amount of time required for 50% of the mRNA to degrade represents an approximate half-life for the mRNA. The technique can be used if the steady-state abundance of the mRNA is readily detectable and yields useful results when the half-life to be measured is relatively short ($<$2 hr). Longer half-lives are difficult to measure using this approach due to the toxicity of the inhibitors that induce cell death after a few hours of treatment.

This approach has been successfully used to establish that stabilization of the mRNA mediates the induction of Indian hedgehog (Ihh) following TGF-β treatment of primary calvarial osteoblastic cells (Murakami *et al.,* 1997) and cAMP regulation of OC mRNA accumulation (Noda *et al.,* 1988). Suppression of gene expression can also be mediated post-transcriptionally as exemplified by the destabilization of osteonectin mRNA in osteoblasts observed after treatment of the bone cells with basic fibroblast growth factor (Delany and Canalis, 1998).

Evaluation of Transcription Initiation by Nuclear Run-on Assays

If the modulation of steady-state mRNA abundance following treatment is not due to a change in mRNA stability, one likely regulatory step is the control of transcription initiation. This can be measured using the nuclear run-on transcription assay. The nuclear run-on assay was developed to determine if transcription initiation is involved in the regulated expression of mammalian genes (Derman *et al.,* 1981; Greenberg and Ziff, 1984). The method provides a measure of the frequency of transcription initiation and is largely independent of the effects of RNA stability. Isolated nuclei from samples of cells that contain different steady-state amounts of the mRNA of interest (following cytokine or hormone treatment, induction of differentiation, etc.) are incubated with radiolabeled UTP and cold NTPs to allow elongation and labeling of the transcripts that were being synthesized when the nuclei were harvested. It is generally assumed that new transcripts are not initiated during this incubation. The labeled RNA is purified and hybridized to a membrane on which DNA from the gene of interest has been spotted. The strength of the hybridization signal is proportional to the number of nascent transcripts.

Several variations of the nuclear run-on protocol have been developed (Celano *et al.,* 1989; Nepveu *et al.,* 1987; Schibler *et al.,* 1983). A critical parameter is the quality of the isolated nuclei. Intact nuclei must be obtained free of cell membrane and cytoplasmic material, as these contaminants result in poor incorporation of labeled UTP. Isolated nuclei can be snap-frozen as Tris-buffered/40% glycerol stock aliquots at -70°C for up to 1 year. Usually, 5 to 50 $\times$ 10^6 nuclei are used per assay and it is useful to aliquot the proper number of nuclei in the volume recommended by the chosen protocol (which can vary from 20 to 500 μl depending on the protocol selected). Upon thawing, the isolated nuclei are incubated with [α-^{32}P]UTP in reaction buffer (composition varies between protocols but basic constituents include about 1 mM each of cold ATP, GTP, and CTP). The nascent transcripts are labeled by allowing elongation for a short time; here again, conditions vary, but successful run-on reactions using nuclei isolated from osteoblasts have been reported using incubation at room temperature (Elango *et al.,* 1997; Tetradis *et al.,* 1997) or 30°C (Blanquaert *et al.,* 1999). Following elongation, the DNA template is digested with RNAse-free DNAse I, the proteins extracted with phenol/chloroform, and the labeled nascent RNAs purified either by trichloroacetic acid (TCA) precipitation (Nepveu *et al.,* 1987) or modifications of the acid phenol guanidinium isothiocyanate method (Celano *et al.,* 1989; Elango *et al.,* 1997). The radiolabeled RNA is hybridized to appropriate filter strips containing a slot or dot with the cDNA of interest. Genomic DNA fragments can also be used for slot blotting. The filter strips should include a suitable positive control ("housekeeping" gene such as glyceraldehyde-3-phosphate-dehydrogenase or 18S ribosomal RNA) and an appropriate negative control (empty plasmid vector). It is preferable to blot single-stranded DNA fragments (obtained by inserting the desired probe into M13 or phagemid vectors) complementary to the mRNAs to be detected rather than using double-stranded fragments. This is because anti-sense transcription, which is surprisingly common in mammalian cells (Nepveu *et al.,* 1987), can generate non-specific signals.

When suitable probes from various regions of the gene of interest are used, the nuclear run-on assay can assess the contribution of Pol II processivity (Uptain *et al.,* 1997) to postinitiation control of gene expression. This has been described for the vitamin D-induced expression of the c-*fos* proto-oncogene in osteoblasts (Candeliere *et al.,* 1991).

RT-PCR Analysis of Nascent Transcript Levels in hnRNA as an Alternative to Nuclear Run-on Assays

An alternative to the use of the nuclear run-on assay in determining the putative contribution of transcriptional regulation in the control of gene expression has been developed. In this method, RT-PCR is used to amplify the unspliced heterogeneous nuclear RNA (hnRNA) using at least one primer derived from intronic sequences. The method is not a direct measure of RNA transcription but increases in hnRNA are thought to reflect increases in nascent transcript synthesis, although stabilization of unspliced RNA species cannot be ruled out. Various modifications of this method have been used to study gene expression in osteoblasts (Dong and Canalis, 1995; Pash *et al.,* 1995), and the conclusions have been validated using nuclear run-on assays (Franchimont *et al.,* 2000).

Promoter Analysis

An important aspect of the analysis of a gene's transcriptional regulatory mechanisms is the identification of an assay for measuring the activity of putative *cis*-acting regulatory regions. The appropriate functional assay will mimic accurately the expression pattern of the endogenous gene. Mutations can then be introduced in the control region to identify important control elements and, eventually, relevant transcription factors.

Several types of functional assays have been developed to study transcriptional regulation. These include the transient transfection assay, the stable transfection assay, the transgenic assay, or the *in vitro* transcription assay. For the transient and stable transfection assays, plasmids containing the control region of interest are introduced into cultured cells using one of several transfection procedures (see below). When a promoter region is studied, it is usually subcloned upstream of a reporter gene whose mRNA or protein level can be readily measured. When an enhancer or other control region is being analyzed, a well-characterized minimal promoter (initiator region, TATA box, +/−CCAAT box) is placed upstream of the reporter gene, and the enhancer inserter upstream of the promoter or downstream of the reporter gene. A number of useful web-based tools are available to help identify potential regulatory regions by sequence analysis (Table III); however, functional analysis is absolutely required to unambiguously assign functional DNA–protein interactions to putative elements. To lighten up the text, the examples discussed here will be restricted to functional promoter analysis.

Assay Selection

TRANSIENT TRANSFECTION

The transient assay is rapid and simple to perform. Plasmid DNA containing the promoter of interest placed upstream of a convenient reporter gene (see below) is introduced into cells in culture. At a specific time point following transfection, the activity of the promoter is assessed by measuring the mRNA or protein synthesis from the reporter gene (Alam and Cook, 1990; Kricka, 2000; Schenborn and Groskreutz, 1999). The assay is considered to be transient because the plasmids do not integrate into the host genome and thus remain episomal.

The main limitation of the transient assay concerns the artificial configuration and copy number of the transfected plasmids that may lead to aberrant activity of the promoter region under study (Smith and Hager, 1997). This is a major disadvantage when studying regulatory regions that depend on a specific chromatin structure. Since the activity of the reporter gene must be measured within a short time period ranging from 2 to 5 days, the transient transfection assay is not useful for monitoring the activity of a promoter during an extended differentiation period.

STABLE TRANSFECTION

In this assay, the plasmid containing the reporter gene under the control of the promoter of interest becomes stably incorporated into the genome of the host cell (Smith and Hager, 1997). A selectable gene marker (e.g., antibiotic resistance—neomycin, hygromycin) is also required. This can be contained on the same plasmid as the reporter gene or within a separate plasmid. The plasmid or plasmids containing the reporter and selection genes are transfected into cultured cells. The cells that have stably integrated the plasmid into a chromosome are selected by adding a drug to the culture media to kill the cells that do not express the drug-resistance gene. The activity of the promoter region under study can then be assessed in pools of stably transfected cells or in several individual cell clones.

The primary advantage of this assay is that the promoter region being analyzed is usually in a more natural chromatin configuration and at a more natural copy number than when studied by transient transfection (Smith and Hager, 1997). The main disadvantage of the stable transfection assay is that it is more difficult and time-consuming than the transient assay. The second limitation is that the transcriptional activity of the promoter under study can be strongly

influenced by the integration site. It is thus necessary to characterize multiple clones derived from each stable transfection experiment and to interpret the results obtained with caution.

Transfection Methods

Calcium Phosphate

This method has been widely used for both transient and stable transfection experiments in osteoblasts (most examples in Table I). Plasmid DNA is mixed with calcium chloride in a phosphate buffer; this leads to the formation of a DNA–calcium phosphate coprecipitate, which is deposited on the cells, and subsequently taken up by endocytosis (Keown *et al.,* 1990). Briefly, the DNA is dissolved in a 0.25 M $CaCl_2$ solution, the added dropwise with bubbling agitation to a pH 7.05 Hepes (pH is critical) and phosphate-buffered solution to form a fine calcium phosphate precipitate. The precipitate is layered onto the cells, and cultures incubated for 4–20 hr. At the end of the incubation period, the media is aspirated and the cells are subjected to a 1- 2- to min osmotic shock in 15% glycerin/Hepes phosphate-buffered saline. Typically, cellular extracts are prepared for analysis of reporter gene activity 48-72 hr after the glycerol shock.

Diethylaminoethyl (DEAE)–Dextran

The negative charges of the plasmid DNA allows it to bind to the cationic DEAE–dextran. The soluble complex is endocytosed by the cells after it has been deposited on the culture. While this protocol is widely used for transient transfection, it is rarely utilized for stable transfection experiments due to toxicity that affects long-term culture of the transfected cells. The DEAE–dextran method has been succesfully used to introduce DNA into ROS 17/2.8 or MC3T3–E1 osteoblastic cells (Boudreaux and Towler, 1996; Towler *et al.,* 1994a). Typically, the cells are shocked with 10% DMSO in phosphate-buffered saline for 1.5 min, rinsed twice with media, and then refed with complete media. Reporter gene activity can be monitored 36–72 hr after DMSO shock.

Lipofection

In this method, the negatively charged DNA binds the positive charges of cationic lipid compounds and the liposomes, associating with the cell membrane, are readily taken up by the target cells (Felgner *et al.,* 1987; Mannino and Gould-Fogerite, 1988). Usually, the DNA is diluted in serum-free medium in one half of the transfection volume (dictated by the size of the tissue culture dish used). The lipofection reagent is diluted with the other half of the transfection volume, mixed with the DNA, incubated for 10–45 min, and then layered on the cells. Transfection is usually achieved within a short time span (3–5 hr), after which the cells are refed complete media. Expression assays can be performed within 24–72 hr following transfection. For some difficult to transfect osteoblast-like cell lines, such as the MG63 human osteosarcoma line, lipofection has been the only reliable technique for efficient transfection (Cervella *et al.,* 1993; Lin *et al.,* 1993). Proprietary lipid compounds are marketed by several different companies and new compounds keep arriving on the market, providing a wide range of reagents to test for transfection of cells that have typically been hard to transfect. The main drawback of the lipofection technique is its relatively high cost relative to inexpensive methods such as calcium phosphate precipitation and DEAE–dextran.

Electroporation

In this method, the plasmid DNA and the trypsinized cells are mixed in an appropriate buffer. This mixture is then subjected to a high-voltage electrical field that induces or stabilizes pores in the plasma membrane through which the DNA enters the cell (Chu *et al.,* 1987; Neumann *et al.,* 1982). The voltage, affecting the magnitude of the pulse, and the capacitance, affecting the duration of the pulse, need to be optimized for each cell line. The procedure can be conducted at room temperature (Chu *et al.,* 1987), although most protocols call for brief chilling of the cells before and after electroshocking. Electroporation has been used with osteosarcoma cell lines (Davis *et al.,* 1994) and cultured primary bone cells (Feng *et al.,* 1995). One drawback of this method is that successful transfection is often associated with significant cell death (Neumann *et al.,* 1982).

Viral Vectors

Amphotropic retrovirus, vaccinia virus, and adenovirus factors have found a wide range of applications for introduction of genes both *in vitro* and *in vivo* (Stone *et al.,* 2000). These vectors yield very high efficiency of transfection. So far, application of this technique to bone cells in culture has largely been limited to the generation of T-antigen-immortalized osteoblastic cell lines (Heath *et al.,* 1989; Keeting *et al.,* 1992; Harris *et al.,* 1995; Hicok *et al.,* 1998; Hofbauer *et al.,* 1997) and to infection of a few established lines of osteoblastic cells (O'Brien *et al.,* 1999; Thacker *et al.,* 1994). Retroviral vector preparation involves transfection of plasmid expression constructs (containing viral packaging signals) into packaging cell lines followed by preparation of infectious, replication defective virus particles from culture supernates. The maintenance of packaging lines and the necessity to generate infectious virus for each promoter construct limits its general use. Moreover, the virus only inefficiently infects nonavian cell types; however, this latter feature has been used to permit tissue-specific transfection *in vivo* by expression of the avian leukosis virus receptor (tv-a) from a muscle-specific promoter (Federspiel *et al.,* 1994). Of note, Lichtler and coworkers have use a novel transgenic tv-a transgenic line, bAKE, to express transvect Dlx5 in murine bone marrow stromal cells and primary cultures of murine calvarial osteoblasts (Erceg *et al.,* 2000).

Recently, a novel amphotrophic retroviruses have been described by Zheng and Hughes (1999), engineered by

replacing the avian env gene with the murine leukemia virus env gene. This novel virus, RCASBP-M2C, is now able to efficiently infect mammalian cells; however, it is replication competent only in avian cells—a feature that obviates the need for specialized packaging cell lines—and does not require the generation of a transgenic mouse expressing the ALV receptor.

MICROPROJECTILE PARTICLE BOMBARDMENT (BIOLISTIC) TRANSFECTION

Micrometer-sized gold or tungsten particles traveling at high velocity (ca. 500 m/sec) can penetrate cellular membranes (Heiser, 1994). When coated with DNA, microprojectiles can act as a transfection modality. This technology has been successfully used to transfect a number of cell types, both *in vitro* (Becker and MacDougald, 1999; Heiser, 1994), organ culture (Nakayama *et al.,* 2000), and *in vivo* (Sato *et al.,* 2000). Transient and stable transfectants can be obtained. Recently, gold microprojectile particle bombardment has proven useful for introducing DNA into cells that are less efficiently transfected by DEAE–dextran or lipofection techniques (Heiser, 1994). As with viral vectors, particle bombardment holds tremendous promise for introduction of DNA into primary cultures of stromal cells and osteoblasts populations that are difficult to transfect by other modalities. The cost of the microprojectile apparatus is significant (about $15,000).

Reporter Genes

Following introduction into the osteoblasts of the chimeric DNA placing the reporter gene under the control of the promoter region of interest, measurement of the reporter gene product (Alam and Cook, 1990; Schenborn and Groskreutz, 1999) provides an indirect estimate of the induction of gene transcription directed by the regulatory sequence. The reporter gene product assayed should be absent from the transfected cells. The assay itself should be simple and rapid, with a broad linear range to allow the analysis of large or small changes in transcriptional activity. These criteria are met by the reporter genes listed below, which have all been used to study gene expression in osteoblasts.

LUCIFERASE

A commonly used reporter gene is the luciferase gene from the firefly *Photinus pyralis* (de Wet *et al.,* 1987). The luciferase enzyme oxidizes D-luciferin in the presence of ATP, oxygen, and Mg^{2+}, yielding a fluorescent product that can be detected using a luminometer—or a liquid scintillation counter with coincidence circuitry inactivated to detect all photons. Convenient luciferase assay kits are commercially available but the required solutions can also be prepared inhouse.

The transfected cells are lysed either with a nonionic detergent (e.g., Triton X-100) containing lysis buffer or by repeated cycles of freeze–thawing in a phosphate buffer. The lysed cells are microcentrifuged and the supernatant containing the cell extract is collected. A volume of cell extract ranging from 20 to 100 μl is mixed with glycylglycine-buffered luciferase assay buffer containing dithiothreitol (DTT), luciferin, and ATP. The light output is measured at room temperature in a luminometer. Signal decay is rapid with ATP as substrate; adding coenzyme A to the reaction mixture produces a more durable light signal and increases the sensitivity of the assay.

An interesting improvement of the luciferase technology was provided by vectors that utilize the gene from the sea pansy *Renilla reniformis* (Liu *et al.,* 1997), forming the basis for Promega's dual-luciferase reporter assay system. The system utilizes the *Renilla* luciferase gene as an internal control for the efficiency of transfection. Transfected cells are harvested in Promega's passive lysis buffer (a buffer optimized to provide optimum performance and stability of both *Photinus* and *Renilla* luciferase reporter enzymes) and the activity of the reporter enzymes is measured sequentially with a luminometer. Normalizing the activity of the experimental firefly reporter to the activity of the internal control *Renilla* reporter minimizes experimental variability. Additionally, modifications have been made to the *Photinus* luciferase reporter vectors that preclude peroxisomal targeting of the luciferase, thus yielding better expression levels and thus sensitivity.

CHLORAMPHENICOL ACETYL TRANSFERASE (CAT)

A second commonly used reporter gene is the *Escherichia coli* CAT gene (Gorman *et al.,* 1982). The CAT enzyme catalyzes the transfer of acyl groups from acetyl- or *n*-butyryl-coenzyme A to chloramphenicol. There is minimal background activity in eukaryotic cells since CAT is a bacterial enzyme. The most common CAT assay uses cell lysates from transfected cells incubated with ^{14}C-labeled chloramphenicol. The acetylation is monitored by autoradiography after thin-layer chromatography to separate the acetylated from the unacetylated forms of the substrate (Gorman *et al.,* 1982). The assay can be quantified either by using a phosphorimager, by excising the radioactive spots and counting in a scintillation counter, or by analyzing the autoradiograph by densitometry. An alternative assay has been developed using [^{3}H]acetyl-coenzyme A and differential extraction of chloramphenicol from the acetylated derivatives, eliminating the need for chromatography (Seed and Sheen, 1988). Two nonisotopic detection methods for quantifying CAT activity have been developed. A CAT enzyme-linked immunosorbent assay (ELISA) is commercially available and a fluorescent derivative of chloramphenicol can be used (Alam and Cook, 1990; Schenborn and Groskreutz, 1999). Laboratories studying gene expression in osteoblasts have made extensive use of the CAT reporter gene. Thin-layer chromatography has been commonly used as well as alternative detection methods. The CAT reporter has also been used to assess promoter activity in bone from transgenic animals (Dodig *et al.,* 1996; Harrison *et al.,* 1998; Kesterson *et al.,* 1993).

β-GALACTOSIDASE/LACZ

The *lacZ* gene from *E. coli* is a versatile genetic reporter since both *in vivo* and *in vitro* assays are available to detect its gene product, the enzyme β-galactosidase. *In vivo* levels in fixed transfected cells or tissue sections from transgenic animals can be measured using the X-GAL (5-bromo-4-chloro-3-indolyl-β-D-galactoside) or Bluo-GAL (halogenated indolyl-β-galactoside) substrates. These are often used in transgenic assays to compare the pattern of expression of the reporter under the control of the reporter of interest to the endogenous expression pattern (Rossert *et al.,* 1996; Tsumaki *et al.,* 1996). The development of chemiluminescent 1,2-dioxetane substrates for β-galactosidase has greatly improved the utility of *lacZ* as a transcriptional reporter by increasing the sensitivity and extending the linear range of the assay (Bronstein *et al.,* 1996). Activity of the test *lacZ* reporter gene can be measured using the chemiluminescent Galacton substrate following the instructions provided with the Galacto-Light assay kit (Tropix). A light-emission accelerator (Emerald luminescence amplifier), supplied with the kit, is added and photon emission measured with a luminometer.

Recently, Tsien and coworkers described the development of a novel cell-permeant fluorescent lactamase substrate, CCF2, that undergoes intramolecular fluorescence resonance energy transfer (FRET) prior to cleavage by lactamase (Zlokarnik *et al.,* 1998). Following cleavage, intramolecular FRET is relieved, and the higher energy photons emitted following excitation are quantified as an index of promoter activity — assayable in real time in living cells. Since FRET-dependent lower energy photons released by excited uncleaved CCF2 substrate are in large excess, ratioing of the fluorescence signal arising from cleaved substrate to uncleaved substrate generates a normalized value that corrects for cellular uptake and cell number — valuable for high throughput screening analyses necessary for drug discovery efforts that seek to manipulate transcription factor signaling cascades. This technology has been applied to studies of *in vivo* gene expression in living teleost embryos (Raz *et al.,* 1998).

GROWTH HORMONE (GH)

Because the endogenous expression of growth hormone is restricted to the somatotropic cells of the anterior pituitary gland, the growth hormone protein was seen as an attractive choice as a genetic reporter for all other types of mammalian cells. Convenient vectors using human growth hormone (hGH) as reporter have been engineered (Selden *et al.,* 1986). Growth hormone is secreted into the culture medium from the transfected cells; this precludes the preparation of cell lysates. Additional advantages include the possibility of studying kinetics of gene expression by repeated sampling of medium from the same cultures, and low background levels. However, the hGH needs to be detected using a radioimmunoassay that has a relatively low sensitivity and a narrow linear range. The hGH reporter has been used to study the vitamin D-induced transcription of the osteocalcin gene in osteoblasts (Terpening *et al.,* 1991).

SECRETED ALKALINE PHOSPHATASE (SEAP)

A truncated form of the human placental alkaline phosphatase gene lacking the membrane-anchoring domain has served to engineer a series of vectors that can be used to express secreted alkaline phosphatase (SEAP) (Berger *et al.,* 1988). Levels of SEAP activity detected in culture medium parallel changes in SEAP reporter gene transcription. The SEAP reporter gene assays have the same advantages as hGH but sensitivity and linear range are significantly increased when chemiluminescent alkaline phosphatase substrates are used (Bronstein *et al.,* 1996). Because both SEAP and hGH are secreted and measured in culture medium, constructs using one of these reporters can be used as internal control to normalize transfection efficiency when the other gene is used as experimental reporter.

GREEN FLUORESCENT PROTEIN (GFP)

The 28-kDa green fluorescent protein from the jellyfish *Aequorea victoria* represents a recent addition to the selection of reporter genes (Chalfie *et al.,* 1994). GFP expressed in eukaryotic cells emits a bright green fluorescence when the cells are excited by UV light; conditions used for visualizing fluorescein are also suitable for GFP. The major utilization of GFP-based vectors has concerned the subcellular localization of fusion proteins; however, the ability to monitor GFP in real time has led to its use in the study of transcriptional changes (Chalfie *et al.,* 1994) and ligand-dependent protein–protein interactions directed by nuclear receptors (Day *et al.,* 1999; Schaufele *et al.,* 2000). Investigators in the bone field have used GFP to monitor gene expression in osteoclasts from transgenic mice (Luchin *et al.,* 2000).

Assays of DNA–Protein Interactions *in Vitro* and *in Vivo*

Transcription regulation is either directly or indirectly dependent upon sequence-specific DNA–protein interactions assembling on promoter elements. These DNA–protein contacts can be readily detected and easily assayed gel shift assay and DNAseI footprinting. However, although highly predictive when coupled with functional mapping studies using transfected promoter–reporter constructs, such biochemical studies to not unambiguously establish the nature of regulation in the physiological context of cellular chromatin. The application of ligation-mediated PCR to chemical or photo footprinting of DNA and ChIP assays directly assess protein–DNA contacts and complex identity at specific transcriptional regulatory elements *in situ.* This section is meant only to provide a didactic overview; the reader is referred elsewhere for a more all-inclusive treatise of DNA–protein interaction assays.

PREPARATION OF NUCLEAR EXTRACTS

To assess sequence specific DNA–protein interactions by gel shift or by footprinting analysis, extracts of intact nuclear protein must be prepared. The most widely used and reproducible protocol for preparation of nuclear extracts is that described by Dignam *et al.* (1983). Confluent monolayers of cells from 2 to 20 150-mm diameter dishes are harvested by scraping into isotonic buffered saline. Dounce homogenization of cells in hypotonic buffer and collection of nuclei by centrifugation is followed by 0.45 M KCl salt extraction of nuclear proteins off of chromatin. These extracts are then dialyzed against a Hepes-buffered 0.1 M KCl/25% glycerol solution for storage and gel shift analysis. This protocol precludes disruption of the nuclear membrane and subsequent release of nuclear DNA, which hinders detection of protein interactions with radiolabeled probes. Alternatively, whole cell extracts for gel shift can be made by lysis of cell pellets with nonionic detergents in high-ionic-strength extraction buffers. This permits reduction in the total number of cells required for gel shift analysis (e.g., from 35-mm-diameter dishes). Such modified gel shift protocols have been used to characterize the time course of FGF2-regulated DNA binding activities in MC3T3E1 cells (Newberry *et al.,* 1997c). However, for DNAse I footprinting studies or for detection of low-abundance DNA binding activities, nuclear extracts prepared by the standard protocol (Dignam *et al.,* 1983) followed by 55% saturation ammonium sulfate precipation/concentration and dialysis provide the best results (Towler and Rodan, 1995). Note, however, that modifications of standard nuclear extraction techniques are required to efficiently extract some proteins tightly associated with the nuclear matrix, which contains a number of sequence-specific DNA binding activities (Bidwell *et al.,* 1993; Newberry *et al.,* 1999; Thunyakitpisal *et al.,* 2001).

ELECTROPHORETIC MOBILITY GEL SHIFT ASSAYS (EMSA)

The gel shift assay is very sensitive technique for detecting sequence specific DNA–protein interactions (Ceglarek and Revzin, 1989; Fried, 1989; Revzin *et al.,* 1986). A ^{32}P-radiolabeled duplex oligonucleotide (typically 20,000 cpm/0.1 pmol per 20 μl reaction) containing the potential binding site for a transcription factor is mixed with nuclear extracts (5–50 μg of protein) prepared from the appropriate cellular background. Oligonucleotide bound by nuclear factors (migrates slowly) is separated from unbound/free oligonucleotide (migrates rapidly) by nondenaturing polyacrylamide gel electrophoresis and visualized by autoradiography. Several parameters can alter the binding of transcriptional regulators to protein (Fried, 1989). The two most common modifying factors are lowering ionic strength and decreasing temperature of electrophoretic separation to 4°C; these favor detection of DNA–protein interactions. This assay can be used to quantify the affinity of recombinant DNA binding proteins for altered DNA binding sites to developing consensus sequences for recognition. Moreover, the effects of coregulatory molecules on DNA–protein interaction are also readily assayed by this technique (Bidder *et al.,* 2000; Carlberg *et al.,* 1993; Newberry *et al.,* 1998).

Not infrequently, because of the information dense character of promoter elements, multiple DNA–protein interactions are observed. Specificity of the DNA–protein interactions is demonstrated by examining the capacity of unlabeled unrelated or mutated duplex oligonucleotides to compete for factor binding to the radiolabeled oligonucleotide. The inclusion of polymeric duplex poly deoxyinosine-deoxycytosine or sheared calf thymus DNA (0.2–1.5 μg per reaction) decreases nonspecific background DNA–protein interactions. Comparisons between transcriptionally active and nonactive cellular backgrounds can reveal functionally important, cell-type-specific DNA–protein interactions, as have been described for the rat and mouse osteocalcin promoters (Ducy and Karsenty, 1995; Towler *et al.,* 1994a). Because of the sensitivity of the gel shift assay, it is important to functionally assess the importance of any specific DNA–protein interaction by fine 5′-deletion analysis or point mutations, which selectively disrupt factor binding.

DNASEI FOOTPRINTING ASSAYS

DNAseI is a ca. 40-Å-diameter protein possessing nuclease activity that cleaves both strands of the 20-Å duplex B DNA with minimal sequence specificity. Stoichiometric occupancy of a DNA cognate by a transcription factor participating in sequence-specific DNA–protein interactions typically encompasses a 10- to 15-bp (ca. 34- to 51-Å) linear stretch of DNA, and thus sterically inhibits DNA cleavage by DNAseI. When an end-labeled duplex DNA template is factor-bound and digested with DNAseI, the radiolabled DNA fragments electophoretically resolved, and the subsequent autoradiogram compared to one arising from the naked DNA template similarly digested, regions of decreased DNAseI cleavage ("footprints") reflect sites of specific DNA–protein interactions. Segments as large as several hundred base pairs can be assessed for multiple simultaneous protein–DNA interactions that demarcate multiple promoter regulatory elements. Moreover, weak DNA–protein interactions poorly visualized and quantified by EMSA can be readily characterized by DNaseI footprinting. The technique is well established as previously detailed (Augereau and Chambon, 1986), and has been applied to analysis of either expressed recombinant proteins or crude biological admixtures. In brief, concentrated nuclear extracts are prepared as described above and then mixed (25–100 μg protein) in a typical binding reaction (see above) with ^{32}P end-labeled radioactive probe of ~0.3–0.5 kb length (20,000 cpm in $<$0.01 pmol of DNA fragment). Increasing amounts of DNAse I are then added to partially digest the probe and titrated to cleave ~50% of the intact probe, which gives rise to approximately one nick per molecule. Similarly, nuclear extract is added at increasing concentrations to titrate to saturation the binding sites on the probe. A control lane is run in which DNAse I is added to probe in the absence of nuclear extract. After termination of DNAse I digestion, cleaved DNA is subsequently analyzed by denaturing urea

polyacrylamide gel electrophoresis and autoradiography. Regions of the probe involved in sequence-specific DNA–protein interactions are sterically protected from DNAseI digestion indicated upon comparison with the control, unprotected probe. In general, the best footprints are obtained when the DNA–protein interaction is within 50–150 bp of the radiolabeled end of the footprinted fragment. Since some DNA–protein interactions preferentially occur along one strand of duplex DNA, separate footprinting reactions should be carried out using duplex DNA labeled on "sense" and "antisense" strands (Augereau and Chambon, 1986).

In Vivo Footprinting by Ligation Mediated PCR (LM-PCR)

Although EMSA and DNAseI footprinting identify, characterize, and quantify changes in DNA binding protein complexes that regulate transcription, these techniques do not directly assess occupancy of transcription factor binding sites in the native context of the cell nucleus. *In vivo* sequence-specific DNA–protein interactions can be identified in cultured cells by treatment with conditions that predispose DNA to "nicks" that are modified by bound proteins. Dimethylsulfate (DMS) methylates the N7 of guanine bases in the major groove of DNA when not sterically occupied by bound transcription factors; subsequent treatment of extracted DNA with piperidine (cleaves DNA at N7–methyl guanine nucleotides). Similarly, ultraviolet (UV) light induces pyrimidine dimer formation and DNA cleavage, altered by bound proteins that orient adjacent pyrimidine residues that either enhance or limit the quantum yield energy absorbed. Mueller and Wold initiated the widespread use of ligation-mediated PCR to identify with base-specific resolution the DNA–protein interactions sterically footprinted by either DMS or UV treatment (Mueller *et al.,* 1988; Mueller and Wold, 1989). The technique has been well-reviewed. Briefly (for DMS footprinting), a confluent cell culture (150-mm-diameter tissue culture dish) is typically treated for 2 min with 0.1% DMS freshly prepared in phosphate-buffered physiological saline solution. After rinsing thrice with phosphate-buffered saline (PBS), cells are lysed in a Tris-buffered saline/EDTA/sodium dodecyl sulfate (SDS)/proteinase K solution, genomic DNA is isolated by phenol extraction, spooling, and precipitation and finally cleaved as N7-methylated G residues by treatment with 1 M piperidine for 0.5 hr at 90°C. Following removal of the piperidine, the cleaved DNA is utilized as a template for primer extension with a gene-specific primer. The resulting termini—blunt end DNA fragments representing the sites of DMS + piperidine cleavage—are blunt-end ligated to an asymmetric (5′-overhang one end, blunt-end other end) synthetic adapter. Subsequent PCR using an adapter primer with a nested gene-specific primer amplifies the DNA fragments, and tertiary analysis with a radiolabeled, third-nested gene-specific primer results in generation of the DNA ladder that reveals the footprint following autoradiography of electrophoretically resolved fragments. Hererra and coworkers have used this methodology to demonstrate that at the c-*fos* serum response element, the serum-responsive promoter element is constitutively occupied by serum-inducible DNA binding activities of the Ets factor p62TCF and the MADS factor SRF (Herrera *et al.,* 1989). Similarly, while noting delayed (24-hr) increased occupancy of the bipartite Ets-AP1 element of the heparin-binding epidermal growth factor gene in response to raf-1 activation, McCarthy *et al.* (1997) observed kinetically more rapid (2-hr) increases in promoter accessibility at sites adjacent to the Ets and AP1 cognates subsequently occupied. These latter observations add to the accumulating data set that indicates that rapid activation and/or disruption of preformed protein–DNA complexes extant *in situ*—in addition to subsequent upregulation of novel DNA binding activities—contribute to many early transactivation events elicited by growth factor stimuli. Of note, similar footprinting technologies using $KMnO_4$ footprinting (10 mM in PBS for 2 min; modifies unpaired thymine bases, enhances subsequent cleavage by piperidine) have been successfully applied to identify unmelted regions of ssDNA stabilized by ssDNA binding proteins during transcriptional regulation of the vascular smooth muscle actin gene in fibroblasts (Becker *et al.,* 2000); the reader is referred to this excellent example of the application of this conceptually similar *in vivo* footprinting technique. To our knowledge, *in vivo* DMS, UV, or $KMnO_4$ LM-PCR footprinting techniques have not been applied to analysis of DNA–protein interactions in osteoblasts.

Chromatin Immunoprecipitation Assays (ChIP Assays)

A major challenge for the molecular biologist is to unambiguously identify and characterize the macromolecular complexes that regulate transcription in the native nuclear chromatin context. Recently, ChIP assays have become routinely applied to answer such questions (Fig. 1)—particularly in response to hormonal cues (Nissen and Yamamoto, 2000; Shang *et al.,* 2000). Briefly, cultured cells are rinsed, and then treated for 10 min at 37°C with 1% formaldehyde in phosphate-buffered saline to cross-link chromatin-bound macromolecular transcription factor complexes to DNA. Subsequently, the cross-linking reaction is quenched with ethanolamine and cells disrupted and DNA sheared to ca. 300–3000 nucleotide-length fragments by probe sonication. After adjustment of the sonicated cell lysate to the appropriate immunoprecipation conditions (typically 0.3 M NaCl in 10 mM Tris, pH 7.5, 1% Triton X-100, 0.2 mM EDTA, 1 mM DTT with protease inhibitors), specific endogenous DNA binding proteins identified as potential regulators in assays lacking the chromatin context (e.g., transient cotransfection, gel shift) are immunoprecipated. The immunoprecipitated DNA–protein chromatin complexes are washed, heated for 6 to 18 hr at 65°C to reverse the formaldehyde cross-links, extracted with phenol:chloroform to remove protein, and the remaining DNA ethanol precipitated. Using gene-specific primers directed toward a specific regulatory region of interest, the polymerase chain reaction is applied to provide a semiquantitative index of the amount of the

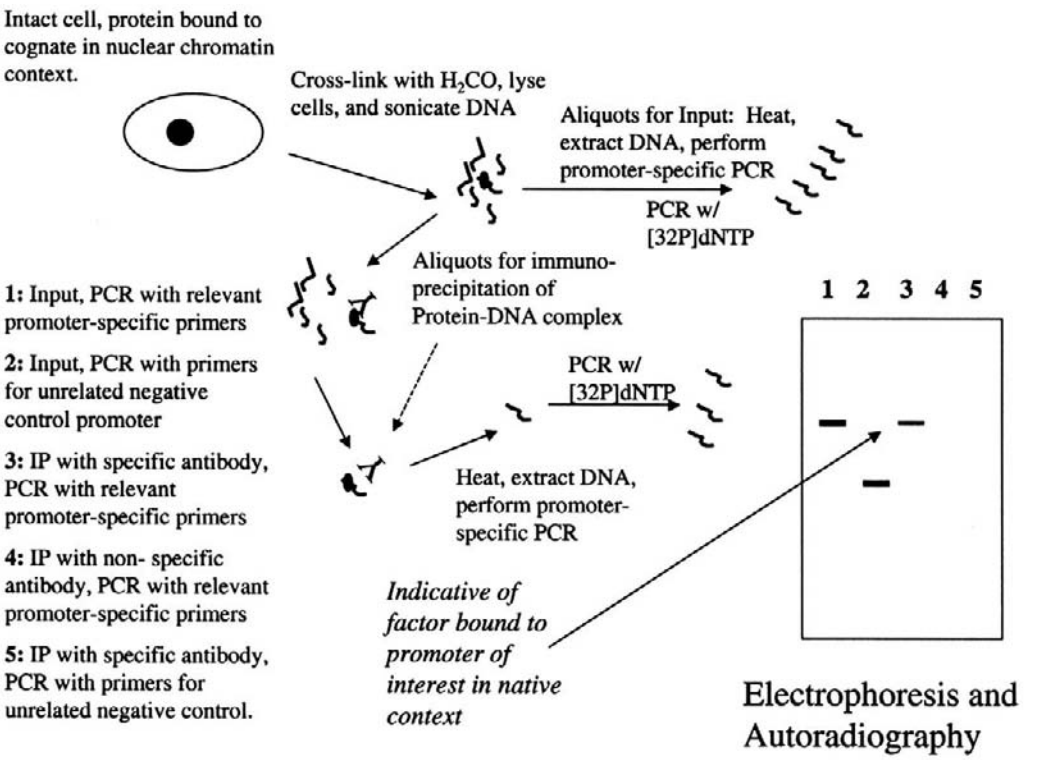

Figure 1 The chromatin immunoprecipitation (ChIP) Assay.

protein–DNA complex assembled. At a minimum, comparisons are made (1) between PCR results obtained using complexes immunoprecipitated from treated and untreated cell cultures; (2) with PCR results obtained from aliquots of extracts processed in parallel without precipitation to control for DNA input; and (3) with PCR results obtained after precipitation with a negative control, i.e., a transcription factor that does not recognize or regulate the promoter of interest (Fig. 1). In one application of this technique, multiple transcription factors are queried by immunoprecipitations performed in parallel to profile the complexes assembled after a stimulus (Shang *et al.,* 2000). For robustly activated promoters, chromatin immunoprecipitation can be performed sequentially with antibodies of differing specificity for establishing these profiles.

As an example of one of the best studies published to date, the protein complexes assembled by the pS2 promoter in MCF7 breast cancer cells were profiled in response to estrogen receptor ligands. In this detailed study by Lazar, Brown, and coworkers (Shang *et al.,* 2000), the estradiol-dependent recruitment of ER-α and a cadre of transcriptional coactivators and corepressors to the pS2 promoter was characterized. In the absence of ligand, the ER-α complex was not associated with the pS2 promoter. In the presence of the agonist estradiol, a sequential, time-dependent recruitment of coactivator complexes was elicited. Impressively, a two-phase transcriptional activation cycle was observed. The first phase waxed and waned within 1 hr, with both p300 and CBP platform protein HAT activities recruited subsequent to the appearance of the p160 coregulators. Of note, however, in the second phase, p300 was excluded from the complex while CBP was again recruited. Most importantly, in the presence of the SERM tamoxifen—an ER-α AF2 antagonist—corepressor complexes consisting of NCoR, SMRT, and HDACs (histone deacetylases) were recruited to the pS2 promoter. Thus, by application of the ChIP technology, this study unambiguously established for the first time that the anti-estrogen tamoxifen—rather that only passively inhibiting promoter activation by sterically preventing agonist binding to ER-α—additionally promotes the assembly of an active repression complex on estrogen-activated genes such as pS2.

Cloning of Transcriptional Regulatory Molecules

Several strategies have been designed to permit the cloning of genes encoding transcriptional regulatory factors. Each method has distinct advantages and drawbacks. This section presents an overview of each technique and reviews the pros and cons of each method.

Screening of an Expression Library with a Binding Site DNA Probe or Southwestern Blot

This strategy is based on the recognition of binding sequences by fusion proteins encoded by recombinant phages from a cDNA library constructed in expression vectors such

as λgt-11. Nitrocellulose lifts of the plated phages are blocked with protein, and then incubated with the binding site DNA probe in the presence of an excess of nonspecific competitor DNA. Washed filters are then exposed to film and further rounds of plaque purification enrich potentially positive clones. The method was simultaenously developed in 1988 in the laboratories of Phil Sharp and Steve McKnight (Singh *et al.,* 1988; Vinson *et al.,* 1988) and represented an important advance in gene cloning technology.

This approach has proved successful in the cloning of a number of diverse transcription factors. Its success relies on the ability of the transcription factor of interest to still be able to bind its recognition site as part of a fusion protein with a bacterial gene. Of course, the genes encoding transcription factors that bind DNA as heterodimers cannot be cloned by this strategy. Moreover, the factor must not require any post-translational modifications, such as tyrosine phosphorylation, in order to be able to bind DNA. Finally, the factor must be capable of binding its target site while immobilized on a nitrocellulose support. Biochemical assays, such as the so-called "Southwestern" assay (Miskimins *et al.,* 1985) can be used to test some of the specific requirements before attempting to use this method.

The expression library screening method presents an additional advantage. The fusion proteins can be crudely purified from lysogenized bacterial cells infected by the positive recombinant phages. This enables the easy characterization of the functional binding activity of the fusion protein and permits to ascertain that the recombinant clone really encodes the factor of interest. While it has been used successfully to clone several transcription factors, we are not aware of any bone transcriptional regulatory molecules that have been cloned using this "Southwestern" expression cloning strategy.

Farwestern Blot or Interaction Cloning Strategies

Recently, a similar expression cloning strategy has been used to clone MINT, novel nuclear matrix protein expressed in bone, brain, and testis that binds the osteoblast homeoproteins Msx2 and Dlx5 (Newberry *et al.,* 1999). The application of the Farwestern blot to transcription factor cloning was initially popularized by Blanar and Rutter (1992) to identify Fos interacting proteins. This strategy relies upon the identification of the interactions between a radiolabeled probe protein and phage-expressed fusion proteins — interactions stabilized by the summed energies of hydrophobic interactions, ion pairing, and hydrogen bond formation. The Towler laboratory utilized a ^{32}P-radiolabeled recombinant GST–Msx2 fusion protein to screen a λgt11 library to identify cDNAs encoding novel Msx2-interacting proteins (Newberry *et al.,* 1999). In this study, clonal phages plaque proteins were transferred to nitrocellulose membranes, denatured in buffered 6 M urea, and renatured in Hepes — buffered per the Blanar and Rutter protocol (Blanar and Rutter, 1992), and probed with [^{32}P]GST-Msx2[55–208] encoding the minimal Msx2 repressor domain. Well-characterized, random hexamer-primed λgt11 library from embryonic brain was utilized for the initial cloning stategy since no adequate calvarial osteoblast libraries existed. Following isolation of 20 clones at the level of secondary screens, a variation was incorporated to identify true positives from false positive clones; in proper orientation, subcloned inserts that initially had been expressed as β-galactosidase fusion protein from lamdba phage were now expressed from the pET23a T7 promoter as an N-terminally tagged T7 polymerase fusion protein. After expression and induction in BL21(DE3) *E. coli,* T7–fusion proteins from all unique subclones were immunoisolated with anti-T7 agarose resin, immunopurified fusion proteins eluted and resolved by SDS–PAGE, and electrotransferred to nitrocellulose for subsequent evaluation by Farwestern blot with [^{32}P]GST-Msx2[55–208]. The addition of this intermediate step permitted relatively rapid yet unambiguous identification of clones that were true positives — i.e., encoded protein domains that interacted with Msx2 — among the 20 or so clones isolated in primary and secondary screens. Standard library and PCR-based cloning techniques were then applied to obtain the full-length cDNA sequence (Newberry *et al.,* 1999). Given the role of Fra1 in augmentation of bone mass (Jochum *et al.,* 2000), and the original utilization of this Farwestern strategy to identify Fos interacting proteins (Blanar and Rutter, 1992), studies applying similar Farwestern strategies to identify Fra1 interacting proteins in the osteoblast promise to be very enlightening.

Purification and Sequencing of Muliprotein Transcription Factor Complexes

Tissue-specific gene expression is regulated by multiprotein complexes — a combination of sequence-specific DNA-binding transcriptional activators, general or basal transcription initiation factors, and associated cofactors. While the general initiation factors are sufficient for basal-level transcription, enhancement of transcription by activator proteins bound to DNA requires the presence of additional mediator proteins, known as transcriptional coactivators (Kingston and Narlikar, 1999; McKenna *et al.,* 1999). Although difficult, biochemical approaches permit the identification and characterization of both DNA binding constituents and the collaborative coregulators that functionally define the transcription factor complex. To identify complexes necessary for vitamin D receptor (VDR)-dependent transactivation, the Freedman laboratory applied an affinity column approach, immobilizing the ligand-binding domain (LBD) of the VDR (Rachez *et al.,* 1998, 1999, 2000). Since the LBD of nuclear receptors contains a transcriptional activation domain that interacts with auxiliary proteins that are required for activated transcription, this generated a VDR-specific cofactor affinity resin. When nuclear extracts from cells that support $1,25(OH)_2D_3$-enhanced transactivation were passed on the ligand-bound affinity resin, 13 proteins of molecular weights ranging from

33 to 250 kDa were selectively retained in the column (Rachez *et al.,* 1998, 1999, 2000). Sequences were obtained from proteolytic peptides using Edman degradation or mass spectrometry, and cDNAs identified either from the translated database or cloning using classical molecular biology techniques. This group went on to identify and clone all components of this DRIP (vitamin D receptor interacting proteins) complex using a combination of peptide sequencing/RT-PCR and antibody generation (Rachez *et al.,* 1998, 1999, 2000). Interestingly, the DRIP complex is almost indistinguishable from the ARC (activator-recruited cofactor) complex, which is recruited by other types of transcription activators to mediate transactivation on chromatin-assembled templates (Naar *et al.,* 1999). This remarkable finding indicates that ARC/DRIP is a multisubunit composite cofactor important for chromatin-dependent transcriptional stimulation by a variety of activators and suggests that selectivity of transcriptional control may reside in subtle changes in the composition of these large, multiprotein complexes.

Classical protein purification techniques have only recently been applied to the characterization of osteoblast transcription factor complexes; a novel heterotrimeric nuclear complex has been purified that participates in the regulation of the FGF response of the osteoblast-specific osteocalcin gene (Willis *et al.,* 2000). In immature osteoblasts, signals elaborated by FGF receptor-1 and -2 activation synergize with A-kinase-dependent pathways to upregulate OC gene expression via a bipartite motif, dependent upon DNA–protein interactions at −144 to −138 (GCAGTCA motif; osteocalcin FGF response element OCFRE) in the rat OC promoter (Boudreaux and Towler, 1996). The OCFRE binding complex is estimated to be ca. 150–200 kDa in size based upon size-exclusion chromatography. Using DNA binding to the GCAGTCA in EMSA to follow activity and classical protein purification techniques, 4 μg of the protein complex binding to the OCFRE was purified to homogeneity from MG63 human osteosarcoma cells (Newberry *et al.,* 1997a). Three protein constituents of 100, 80, and 70 kDa were identified and denoted OCFREB100, OCFREB80, and OCFREB70. The 80- and 70-kDa subunits were identified by LC-MS/MS sequencing of tryptic peptides as Ku70 and Ku80, DNA-binding proteins previously known to regulate DNA repair, transcription, and immunoglobulin gene rearrangement (Willis *et al.,* 2000). FGF regulates the phosphorylation of Ku70 in calvarial osteoblasts in a stage-specific manner. Importantly, skeletal growth and ossification defects are noted in both Ku80 (aka Ku86) (Vogel *et al.,* 1999) and Ku70 (Willis *et al.,* 2000) knockout mice; thus, biochemical and genetic analyses have converged upon Ku70 and K80 as nuclear factors mediating responses to growth factor-regulated signaling cascades that control skeletal growth, tissue-specific gene expression, and orthotopic mineralization. The final subunit, OCFREB100, was a completely novel protein (Willis *et al.,* 2000). Six peptide sequences were unambiguously obtained by LC-MS/MS sequencing (see Fig. 2 and Section 7.0 for overview of technique). After querying the translated EST database, two of the peptides were immediately identified and the EST sequences used in iterative BLAST screening of the database to assemble a novel contig of ca. 1 kb, encoding a contiguous open reading frame (ORF), with two peptides and a perfect nuclear localization signal motif. RT-PCR analysis of cDNA confirmed the contiguous protein ORF. By 5′- and 3′- RACE, the remainder of the coding region was obtained, sequenced, and a total of 23 tryptic peptide sequence tags identified, establishing the contiguity of the peptides sequenced in a single protein (Willis *et al.,* 2000). OCFREB100 is distantly related to a yeast *N*-acetyltransferase that is required for cell growth (Park and Szostak, 1992). Importantly, coexpression of OCFREB100 augments FGF-dependent transactivation of the OC promoter in osteoblasts. The identification of a NAT-related protein as constituent of this MG63 osteoblast transcriptional complex introduces the notion that, like HATs, NATs may play an important role in gene regulation. The powerful combination of classical protein biochemistry, mass spectrometry, and bioinformatics promises to dramatically accelerate the functional characterization of macromolecular transcriptional complexes in osteoblasts.

Cloning of Related Family Members

In the course of the characterization of the promoter region of the gene of interest, critical regulatory elements may be identified that should bind a previously identified transcription factor. However, expression patterns or immunological data reveal that this previously identified factor cannot be responsible for the expression of the target gene in osteoblasts. Such results would be consistent with the possibility that another member of the same protein family is the functionally relevant activator. Therefore, this related family member should now be cloned. Database mining may provide a useful starting point. A second approach is based on the observation that families of transcription factors contain conserved domains, such as the DNA binding domain (DBD). The DBD from a given factor can be used directly as a probe to screen a cDNA library from the tissue of interest using reduced stringency conditions. This approach was used to clone Osf2/Cbfa1, an osteoblast-specific transcription factor that is a member of the *runt*-domain family (Ducy *et al.,* 1997). Alternatively, degenerate PCR primers that account for the redundancy of the genetic code within the DBD can be used to identify and clone related family members. This strategy was successfully used to clone members of the helix–loop–helix transcription factor family (Tamura and Noda, 1999) from osteoblasts, *Krüppel* family members from chondrocytes (Dreyer *et al.,* 1999), and Ets family members from osteoblasts (Bidder *et al.,* 2000) and chondrocytes (Iwamoto *et al.,* 2000). The novel family members should be tested using the functional methods described

above, in addition to assessing their expression pattern, in order to determine their functional relevance in the control of the expression of the gene under study.

Characterization of Cloned or Purified Transcription Factors

Optimal Cognate Identification by Binding Site Selection

Determining the DNA-binding specificity of a transcription factor is a vital step in the characterization of its interaction with DNA and the identification of its regulatory targets. The advent of the polymerase chain reaction has led to the development of a number of techniques that can help in the identification of high affinity binding sites for DNA-binding molecules. Site selection techniques can be used to determine the consensus binding sites for proteins whose target sequences are unknown. It can also provide additional information about the protein–DNA interactions of previously characterized factors and help to identify all of the target sequences for a given DNA-binding domain. The methods can also be used for structure–function analysis, in which mutated DNA-binding domains are used to examine the contribution of individual amino acids or motifs to binding site recognition.

In general, all of the available methods include four similar steps: a DNA–protein incubation step, a protein–DNA complex separation step, a DNA elution step and a PCR DNA amplification step. The variation resides in the protein–DNA complex separation step, in which some methods use electrophoretic mobility shift assays (EMSA) (Blackwell and Weintraub, 1990), immunoprecipitation using a specific antibody (CASTing) (Wright *et al.,* 1991) or an antibody directed against an epitope tag (Pollock and Treisman, 1990), GST pull down (Chittenden *et al.,* 1991; Pierrou *et al.,* 1995), affinity columns (Ekker *et al.,* 1991), filter binding (Thiesen and Bach, 1990), or immobilization on nitrocellulose membranes (Norby *et al.,* 1992). Methods based on immunoprecipitation provide the additional advantage of using crude nuclear extracts instead of purified recombinant proteins in the site selection assay. Once selected, individual binding sites are cloned into plasmids and examined by sequencing.

A pool of random-sequence oligonucleotides (10 to 25 nucleotides in length), flanked by two specific PCR primers sequences, is used as the source of potential binding sites. The oligonucleotide pool is incubated in a binding reaction with the recombinant transcription factor of interest or with an extract containing the DNA-binding protein of interest. If optimal binding conditions for the factor of interest are already known, then these should be used; alternatively, general binding conditions of moderate ionic strength can be used as a starting point.

In the selection and amplification of DNA binding site (SAAB) method (Blackwell and Weintraub, 1990), the protein–DNA complexes are separated from the pool of unbound oligonucleotides using EMSA. The bound templates are isolated by excision of the gel slice directly from the dried gels, including the paper backing. Gel slices are then incubated at 37°C for 3 hr in 0.5 ml of 0.5 M ammonium acetate, 10 mM magnesium chloride, 1 mM EDTA, and 0.1% SDS. About half of the radioactivity present in the gel slice can be recovered by this procedure. After addition of tRNA or glycogen carrier, the eluate is extracted with phenol and chloroform and then precipitated with ethanol. The precipitated oligonucleotides are resuspended and subjected to 15–35 cycles of PCR. These selected and amplified binding sites can then be subjected to further rounds of EMSA. The method has been used to identify specific DNA binding sites for several transcriptional regulatory molecules controlling gene expression in bone cells: the CBF heterotrimer controlling collagen type I transcription (Bi *et al.,* 1997), the Smad3 and Smad4 proteins required for TGF-β signaling (Zawel *et al.,* 1998), and the α-NAC transcriptional coactivator (Yotov and St. Arnaud, 1996).

In the cyclic amplification and selection of targets (CASTing) method (Wright *et al.,* 1991), DNA–protein complexes are immunoprecipitated with a specific antibody. A protein A–Sepharose slurry makes it possible to separate the bound complexes from the excess of unselected binding sites. The bound DNA is eluted from the protein A–Sepharose beads pellet using recovery buffer (50 mM Tris–Cl, pH 8, 100 mM sodium acetate, 5 mM EDTA, 0.5% SDS) and incubation at 45°C. The DNA is extracted with phenol/chloroform, precipitated, and reamplified using PCR. If an antiserum specific for the DNA-binding protein of interest is not available, the factor can be tagged with an epitope and antibodies directed against the epitope tag can be used in the procedure (Pollock and Treisman, 1990). The antibody used should not disrupt DNA–protein complexes and therefore should not be directed toward the DNA-binding domain of the factor of interest. When available, antibodies that "supershift" in EMSA should be selected.

The immunoprecipitation-based method allows for a high degree of enrichment and provides the additional advantage to be able to isolate DNA–protein complexes from crude mixtures. The ability to use crude extracts offers several advantages: first, there is no requirement for purified or overexpressed target protein. Second, the method can be used with proteins that require posttranslational modifications in order to bind DNA. Third, binding sites can be selected for proteins that bind DNA only as components of heteromeric complexes. The method has been used successfully to identify the consensus binding sites for the muscle regulatory factor myogenin, and to identify potential interactions between myogenin and other members of the helix–loop–helix regulatory family (Funk, 1992). In applications more related to the bone field, the CASTing protocol made it possible to define DNA recognition elements for the vitamin D receptor (Perez-Fernandez *et al.,* 1993) and to identify novel consensus DNA binding sites for AP-2, a transcription factor

essential for cranial closure and craniofacial development (Gee *et al.,* 1998).

Characterization of Transcription Factor Complexes by Mass Spectrometry

The molecular biology revolution permitted application of low-stringency hybridization, expression cloning (Southwestern), and degenerative RT-PCR to the identification of novel transcription factors expressed in any tissue and is responsible for the massive explosion of transcriptional regulators discovered in the past 15 years. However, the DNA binding factors represent only one salient component of the macromolecular complexes that mediate tissue-specific gene expression, and important coregulatory transactivators that may or may not contact DNA are routinely missed, identified by subsequent two hybrid or "Farwestern" cloning approaches that reflect protein–protein interactions. Recently, concomitant improvements in mass spectrometry technology (sensitivity in the 10- to 100-fmol range) and the explosion of mammalian sequence information available (ESTs and completion of sequencing the human genome) have converged to restore biochemical characterization to the forefront of transcription factor research (Yates, 1998). This section will serve to briefly orient the reader to this emerging technology and its successful application to transcriptional regulation relevant to bone biology.

All mass spectrometry methodologies have three essential components: a molecular ionization method, a mass analyzer, and an ion detector. Ions are extracted and accelerated to identical kinetic energies, directed toward an ion detector typically placed at the end of a linear flight tube (time of flight or TOF mass analyzer) or an oscillating quadrupole field (functions like a "band-pass" filter for ions of specific kinetic energies). A detailed discussion of the instrumentation/technology available for these three components is beyond the scope of this chapter, but is nicely reviewed by Suizdak (Siuzdak, 1994) and Yates (Dongre *et al.,* 1997; Yates, 1998). However, TOF separation is readily conceptualized; since ions of identical kinetic energy will experience velocities that are inversely proportional to the square root of the molecular mass ($KE = 1/2mv^2$; $v = [2KE/m]^{0.5}$). Molecules of greater mass/charge (m/z) ratios but equivalent kinetic energy (KE) will take longer to arrive at the ion detector. The capacity to separate tryptic peptides by microbore reverse-phase HPLC and directly ionize and analyze the eluted peptides by tandem mass spectrometry (Fig. 2) has revolutionized protein microsequencing and transcription factor biology. Once tryptic peptides are resolved by HPLC and ionized by coulombic field forces applied to atomized eluate, peptides of specific m/z ratios are selected by the first of two tandemly linked spectrometers. Subsequently, the ionized peptide selected is bombarded with an inert noble gas in a collision cell. Since proteins are stereotypical polymers of peptide bonds, the alpha-chain backbone fragments in a predictable fashion—generally either from the N- or the C-termini. The fragmented ionized peptides are then resolved and analyzed by the second mass spectrometer placed in tandem. Since a single parental

Table IV Common Posttranslational Modifications of Transcription Factors and DNA Binding Proteins

Modification	Amino acid	Examples	References
Phosphorylation	Ser, Thr, Tyr	CREB, STAT, Pol II, ERF, Runx2, SREBP, VDR, ER-α/β, NFAT	Cheng *et al.,* 2000 Swanson *et al.,* 1999 Okamura *et al.,* 2000 Roth *et al.,* 2000
Acetylation	Lysine (epsilon N) N-Terminus	Histones, p53, SRC1, GATA, AR, HNF4	Abraham *et al.,* 2000 Soutoglou *et al.,* 2000 Fu *et al.,* 2000
Methylation	Arg	Histones	Koh *et al.,* 2001
ADP-ribosylation	Glu	Histones, TFIIF	Anderson *et al.,* 2000
Ubiquitination	Lys	NFKB, MyoD, ER	Nawaz *et al.,* 1999
Oxidation	Cys	NFKB, AR	Staal *et al.,* 1995
Nitrosylation	Cys	NFKB	Matthews *et al.,* 1996
Proteolysis	Various	SREBP, Notch	Schroeter *et al.,* 1998
Glycosylation	Ser, Thr	SRF, SP1, Myc, PolII	Reason *et al.,* 1992

polypeptide ion was selected, the fragmented species represent daughter products derived from that peptide, differing from each other by loss of amino acid residues. The differences in mass between adjacent daughter ion peaks permit assignment to the specific amino acid lost, and the iteratively determined differences between adjacent peaks (read from high to low mass when charge is placed on the amino terminus) provide a direct readout of the peptide sequence (Fig. 2; the reader is referred to Siuzdak for a more detailed description of the fragmentation process). While isobaric amino acid pairs (same molecular weight, i.e., leucine and isoleucine; lysine and glutamine; methionine sulfoxide and phenylalanine) cannot be discriminated, the remaining unique sequence is generally sufficient to identify the peptide from a translated EST data base (e.g., see Table III). When confirmed by comparison to the completed human and mouse genomes, this latter information, coupled with the MALDI MS fingerprint of the tryptic peptides, establishes sequence identity. Thus, an admixture of tryptic peptides obtained from a purified protein constituent can give rise to a unique peptide fingerprint and sequence. Such an approach was utilized to characterize the component of the osteocalcin FGF response element binding protein (OCFREB) purified from MG63 osteosarcoma cells (*vide supra*; Willis *et al.,* 2000).

A wide variety of posttranslational modifications regulate the magnitude and duration of transcriptional activation and repression phenomenon, generally by promoting or inhibiting specific protein–protein interactions, by regulating protein turnover, or by regulating subcellular localization (Table IV). Since modifications add predictable mass increments to amino acids when tandem MS/MS techniques are applied, mass spectrometry provides the rapid identification of modified residues and clues to the modifcation. Thus, in addition to providing a valuable tool for characterizing purified macromolecular complexes, protein mass spectrometry will catalyze the identification of important posttranslational modifications that function to modulate the enzymatic process that is transcription.

Conclusions

In recent years, a great deal of information has been added to our fund of knowledge concerning osteoblast-specific gene expression, osteoblast lineage allocation, and skeletal development. Cbfa1/Osf2/Runx2, Msx2, and Fra1 have emerged as important global regulators of skeletal gene expression, osteoblast matrix synthesis, and tissue mineralization. Other homeoproteins such as Alx4 , Cart1 (Qu *et al.,* 1999; Wu *et al.,* 2000), and Bapx1 (Lettice *et al.,* 1999; Tribioli and Lufkin, 1999) have been identified by genetic means to control craniofacial and axial mineralization programs, respectively, generating defects that are suggestive of interactions with the Msx2 and Runx2 transcriptional regulatory circuits. Similarly, high-molecular-weight platform proteins of the nuclear matrix have been strongly implicated in integrating morphogenetic, metabolic, and mechanical control of osteoblast gene expression. Thus, genetic and biochemical evidence point to the formation of large macromolecular transcriptional regulatory complexes that mediate elaboration of the osteoblast phenotype during skeletogenesis. The repertoire of known osteoblast transcription factors represents the "tip" of this macromolecular "iceberg"—an important set of rate-limiting regulators, but insufficient to explain or predict all osteoblast gene expression in detail. For example, while the expression of Runx2 can be well-documented at E12.5 during murine skeletogenesis, target genes such as osteopontin and osteocalcin are not expressed until the onset of mineralization at E14.5 (Bidder *et al.,* 1998; Jiang *et al.,* 1999; Komori *et al.,* 1997). The possibility that alternative N-terminal domains of Runx2 isoforms are required for robust osteoblast gene expression implicates

additional regulation at the level of coregulator adapter comolecules (Harada *et al.,* 1999). Moreover, as highlighted by Blau and Baltimore a decade ago (Blau and Baltimore, 1991) and exemplified by reciprocal Msx2–Dlx5 regulation of OC gene expression in the osteoblast (Ducy *et al.,* 2000; Newberry *et al.,* 1998), transcriptional derepression is a fundamental mechanism that controls the timing of terminal differentiation in virtually all cell types. Finally, the DNA binding activities responsible for polypeptide growth factor, biomechanical stressors, and integrin-mediated extracellular matrix regulation (matricrine) of osteoblast gene expression are only beginning to be explored in detail—and are particularly relevant to an integrated understanding of the relationship between osteoporosis and arterial macrovascular calcification. A more complete understanding of osteoblast gene regulation by anabolic endocrine and matricrine signal cascades should lead to truly novel osteoanaoblic therapies for the pharmacologic treatment of osteoporosis—without concomitant exacerbation of clinically relevant heterotopic ossification syndromes such as aortic calcification or osteoarthritis.

Introduction

The application of *in vitro* experimental approaches to the study of skeletal biology has proved to be a highly successful endeavor. Once practiced by only a few investigators, the techniques of bone organ and cell culture are now standard practice in many laboratories, graduate students are routinely trained in performing and interpreting *in vitro* experiments, and many of the results from such studies have now attained the status of dogma.

This chapter is aimed at providing a fairly short, selective overview of *in vitro* methods in skeletal biology. It will emphasize some of the strengths and limitations of current methods for addressing biological questions and suggest some areas where new methodologic approaches will likely be needed. It is not intended to be a technical manual or an exhaustive critique of specific methods—there are simply too many to cover adequately. Rather, this chapter will hopefully complement the more detailed reviews in this volume that target specific biological issues.

In Vitro Systems: "The more things change . . . "

Bone organ (tissue) cultures have been in use since the pioneering studies of Strangeways and Fell in the 1920s (Strangeways and Fell, 1926), while the isolation and culture of bone cells came into practice nearly half a century later (Peck *et al.,* 1964; Luben *et al.,* 1976). (see Table I). During their long histories, both *in vitro* approaches have been used extensively and adapted to suit a wide range of purposes. Yet despite the development of numerous variations on these initial methodologic themes, most of the *in vitro* culture systems used in skeletal biology today are remarkably similar in principle and procedure to their early ancestors. The day-to-day techniques of tissue isolation, feeding, subculturing, cloning, and preservation are much the same as they were decades ago, with the exception that most materials are now made of disposable plasticware rather than glass, and most media are purchased ready-to-use rather than prepared from scratch. Most of the culture media now in common use were formulated in the 1960s and 1970s, and for the most part medium supplementation remains almost purely traditional. Serum-free media are used mainly for organ culture; most practitioners of cell cultures rely on "undefined" media supplemented with fetal calf serum for most purposes, although defined supplements (e.g., insulin–transferrin–selenium mixtures) are available at reasonable cost. Serum lots are still screened to make sure they properly support cell growth.

The fact that so many fundamental aspects of cell and organ culture have changed so little makes a number of points in addition to illustrating the fairly strong tendency among *in vitro* biologists not to change successful methods (i.e., "if it ain't broke don't fix it"). It demonstrates that the basic principles of *in vitro* methodology are sound, it validates the careful work of those who painstakingly established the systems, and it generates confidence that *in vitro* data from different laboratories can be readily compared and understood based on a common set of accepted methodology. Finally, it demonstrates that cell and organ culture techniques as we know and practice them are far from becoming obsolete. There is a substantial supply of important biological information available to be mined with these methods,

Table I Examples of Bone Organ Culture Systems

Tissue	Source	Use(s)	References

without a need for dramatic new methodologic advances. Yet having made the case in favor of the now-familiar techniques of cell and organ culture, there are certain areas where these methods limit our ability for further investigation. In the following sections, we will review the types of experimental systems currently used to investigate the biology of the major cell types in bone and their principal functions. We will examine a few specific uses for these model systems, identify some of the limits imposed by the current methodologies, and describe areas for possible future development.

Current Techniques and Applications

Organ Culture

General Considerations

Organ cultures offer investigators the opportunities to study a tissue system with much of its architectural hierarchy intact, but without interference from the rest of the animal and its variable systemic influences (e.g. diurnal rhythms, episodic hormonal fluctuations). The investigator's major concerns with organ culture are first that the explanted tissue remains viable, and second that it maintains its *in vivo* behavior during culture. Because tissues are often removed by a surgical procedure, some damage inevitably occurs to the explant; hence, both viability and phenotype are likely to decline with time in culture. It then becomes necessary to establish these time courses. Assessment of viability if often carried out by staining with vital dyes, such as the colorimetric redox dye MTT (Mosmann, 1983). Alternatively, fluorescent dyes selectively taken up by viable cells (CMFDA) or by dead cells (ethidium homodimer) offer sensitive means for assessing tissue viability by two simultaneous, complementary means (Poole *et al.,* 1996).

Methods for measuring tissue function or phenotype vary, depending on the traits of interest. Organ cultures of fetal or embryonic tissues frequently continue to undergo morphogenesis in culture (Gronowicz *et al.,* 1989) and these processes are usually assayed by histologic methods. Metabolic endpoints such as collagen synthesis (Kream *et al.,* 1985) or bone resorption (Raisz, 1963) are evaluated by chemical methods. Interestingly, the need to maintain a phenotype as close to that *in vivo* as possible often precludes the use of serum supplements from organ cultures, as the growth factors tend to stimulate unwanted proliferation of cells, similar to a wounding response *in vivo.* The ability of tissue explants to continue growth or tissue function *in vitro* is undoubtedly due to production by the resident cells of growth factors and cytokines.

While organ cultures maintain tissue architecture, they are somewhat limited by inherent cellular heterogeneity; few skeletal explants (with the possible exception of some cartilage biopsies) contain a cell population considered to be uniform. As a result, biochemical analyses must be interpreted with a certain degree of caution unless at some point they are well correlated with morphologic investigations. For example, how much collagen synthesis in explanted calvariae is due to osteoblasts, and how much is due to periosteal fibroblasts is not readily apparent from purely biochemical assays. A second limitation of organ culture systems (discussed further in the next section) is imposed by their need for adequate nutrition. Since organ and cell cultures rely on diffusion to provide nutrition and remove waste from tissues, the explanted tissue needs to be small and is often limited to fetal tissues.

Current Uses and Limitations

Bone organ culture systems have been used primarily to study dynamic events and their regulation; in particular, these include bone formation and matrix synthesis (Gronowicz *et al.,* 1989; Kream *et al.,* 1985), bone resorption (Raisz, 1963), and tissue morphogenesis (Vaahtokari *et al.,* 1996). All of these processes are associated with tissue growth and development, and thus are amenable to study using embryonic, fetal, or newborn tissues that have high metabolic activities and can be maintained easily over short periods in organ culture.

While bone organ cultures derived from embryonic, fetal, or neonatal tissues has been successful, cultures of postneonatal bone tissue have not. This limitation appears to preclude organ culture systems from investigations of features associated with adult, rather than neonatal or fetal, bone. These include adaptive responses to mechanical stress, cortical bone remodeling, and changes in the tissue due to age itself. The paucity of adult bone organ culture systems likely reflects more than postnatal reductions in metabolic activity. Older and larger tissues are more difficult to maintain, since in culture nutrients are supplied and wastes removed by diffusion. This becomes a particular difficulty for studies of

postneonatal bone, since the mineralized extracellular matrix poses a substantial barrier to diffusion. As a result, access of osteocytes within the bone to nutrients is limited, and accumulation of waste metabolites may occur. Bone *in vivo* is perfused by tissue fluids flowing through its matrix and its lacunar–canalicular systems. This flow is not diffusion-dependent, but is driven by blood pressure and by mechanical loading (Bronk *et al.,* 1993; Knothe *et al.,* 1998). It may also be essential to maintaining the viability of the osteocytes inside the bone. Recent findings have implicated osteocyte apoptosis, brought about either by hormonal deprivation (Tomkinson *et al.,* 1997) or by tissue microdamage (Verborgt *et al.,* 2000) as part of the trigger mechanism that initiates bone resorption. Thus the health of osteocytes may have a significant influence on the behavior of cells at both periosteal and endosteal surfaces. This finding also seems to rule out one of the traditional means of overcoming diffusion-limited nutrition in organ—using very small explants of tissue. The consequences of tissue damage caused by making small pieces of mineralized bone for explant cultures are not known, but may be substantial, especially if the biological questions under study depend on extensive cellular interactions throughout the tissue—the type of problem normally well suited to investigation in organ culture. Possible approaches to the problem of studying adult bone in organ culture include the use of very small bones (e.g., mouse or rat metatarsals) that might be maintained intact in a diffusion-limited nutrient environment or the develoment of culture devices for perfusion of intact bone tissue.

Cell Cultures

General Considerations

Cell cultures offer a distinctly different approach to *in vitro* biology than organ cultures. Whereas organ cultures depend on maintaining an architectural hierarchy resembling that *in vivo,* the cell culture approach treats mammalian cells virtually like bacterial cultures. This allows the investigator to study the cells' intrinsic functions like proliferation, differentiation, adhesion, migration, matrix synthesis, and death, as well as their interactions with each other ("cellular sociology") and with their environment. Cell culture also allows investigators to expand and select cultures for biochemical analysis, although the development of techniques like RT-PCR (Liu *et al.,* 1994) and laser capture microdissection (Simone *et al.,* 2000) have improved the ability to obtain biochemical or genetic information from small numbers of cells *in situ.*

Cell cultures are basically of two types: primary (or early passage) cultures and permanent cell lines. Like organ cultures, primary cultures are usually heterogeneous; however, also like organ cultures they are less susceptible to the time-dependent changes that occur in culture as cells adapt to the *in vitro* environment, grow at different rates, and accumulate mutations with successive cell divisions. Thus, users of early passage cultures are generally confident that these cells provide a reasonable approximation of the phenotype they exhibited *in vivo.* Consistent differences in the properties of cultured cells from donors differing in age (Ankrom *et al.,* 1998) or genetic background (Bianco *et al.,* 1998) have generally confirmed that *in vivo* phenotypes can be maintained even in heterogeneous cell cultures.

In contrast to short-term cultures, permanent cell lines are generally established with the intent of providing continuing sources of cells with a known and hopefully consistent phenotype. To help ensure cellular uniformity, most permanent lines are clonal by design, although individual sublines of a clonal population exhibit a range of phenotypes (Grigoriadis *et al.,* 1985)! Experience has shown that permanent lines can sustain the expression of a particular trait over extended periods in continuous culture (Majeska *et al.,* 1980); however, phenotypic drift and phenotypic loss are facts of life *in vitro,* and cell lines will undoubtedly need to be recloned and recharacterized.

Permanent cell lines are by definition capable of indefinite (unlimited?) growth *in vitro,* and are therefore described as "immortal." There are several pathways to immortality for a cell, but all likely involve mutation in the genes that regulate initiation or progression through the cell cycle. Spontaneous immortalization *in vivo* usually occurs as a result of neoplastic transformation, and so tumors have been a traditional source of immortalized cells (Rodan *et al.,* 1994). Spontaneous immortalization of cells *in vitro* is rare, but is exemplified by the cells which survive the "crisis" phase of culture during which most cells senesce and die (Freshney, 1987). Direct introduction into target cells of genes responsible for the immortalizing function of tumor viruses like the SV40 T antigen in conjunction with a selectable marker like the neomycin resistance gene (Jat and Sharp, 1986) have been used to generate permanent cell lines *in vitro* (Heath *et al.,* 1989; Keeting *et al.,* 1992). This is probably the method of choice for establishing permanent cell lines from normal human tissues.

Despite the ability to immortalize cells without causing a tumorigenic phenotype, there is in principle some concern about the influence of the immortal phenotype on the normal processes of differentiation. Conditional (temperature-sensitive) mutants have been created (Harris *et al.,* 1995) to eliminate the influence of the immortalization gene during the course of experiments while retaining its function for maintenance of the lines; however, not many investigators have made use of this approach. The development of transgenic mouse strains with defective cell cycle controls necessary to suppress an "immortal" phenotype *in vitro* (Chambers *et al.,* 1993) has also tended to allay fears that immortalization will have adverse effects on the behavior of differentiated cells. The animals have generally normal phenotypes *in vivo* but a propensity to develop tumors; however, *in vitro* the cells derived from normal tissues are capable of indefinite growth.

Osteoblasts and Osteoblast-Like Cells

Cells with an "osteoblast-like" phenotype have probably been the most intensively investigated of all the bone-derived cell types. Isolated from normal bone of humans and all

commonly used experimental species, as well as from bone tumors (see Tables II and III), their phenotype has been characterized at the cellular, biochemical, and genetic levels by the matrix macromolecules they produce, by their expression of other functionally relevant markers (e.g., alkaline phosphatase), and by the arrays of regulatory molecules they either recognize or produce (for discussions of bone matrix proteins, see Chapters 12–15) Finally, their phenotype has been established in a functional sense by their ability to produce morphologically characteristic matrix-rich multicellular "nodules" that mineralize, usually in the presence of organic phosphate donors (Owen *et al.,* 1990;Stein *et al.,* 1990). Patterns of gene expression and morphologic changes in cultured osteoblast-like cells appear to correlate well and resemble those seen during bone formation in developing tissues *in vivo* (Weinreb *et al.,* 1990).

While osteoblast-like cell cultures have been used for a multiplicity of purposes, most efforts seem to have been

directed toward understanding how these cells respond to an ever-growing list of systemic and local regulatory factors. These studies are reviewed extensively throughout this volume. Of particular interest from a methodologic standpoint, however, are areas of investigation that have gained momentum in recent years, including (i) investigations of cellular mechanosensitivity and (ii) use of cultured osteoblastic cells for tissue engineering applications.

Interest in the mechanisensitivity of bone cells derives largely from extensive observations at the tissue level that bone adapts its shape in response to changes in mechanical loading (Frost, 1987); translating these concepts to the cellular level has been the subject of more recent endeavors (Donahue, 1998). Experiments aimed at defining how cells can sense a mechanical signal has been investigated using osteoblast-like cells in culture as experimental models. In these studies, two approaches have been used to apply mechanical perturbation to cells. The first approach involves deformation of the substrate on which cells are cultured, the second involves fluid flow over the cultured cells. In both cases, the methods used to grow cells and to measure their responses are standard; however, unique culture apparatuses have been developed for experiments of this sort to allow the investigator both to manipulate the mechanical input and to measure it precisely. In these systems, strain application to deformable cellular substrates has been accomplished by use of vacuum (Buckley *et al.,* 1988) or stretching over a template (Schaffer *et al.,* 1994). The first system was shown to be capable of deformations much higher than those which occur in bone, and so has been used with apparent success to study cells which normally experience high strains *in vivo,* such as tendon cells (McNeilly *et al.,* 1996; Tsuzaki *et al.,* 2000). Gerstenfeld and coworkers used the second system to investigate the role of the actin cytoskeleton in the mechanical responses of osteoblasts, and changes in the production of bone matrix proteins (Meazzini *et al.,* 1998; Toma *et al.,* 1997).

The effects of fluid flow on bone cells are of particular interest because a consequence of mechanical stimulation *in vivo* is the flow of fluid through the lacunar–canalicular system (Knothe *et al.,* 1998). A number of fluid flow systems have been used to model this process; some utilize unidirectional pulsatile flow (Ajubi *et al.,* 1999), but a system to deliver bidirectional (reciprocating) flow has also been reported, with some distinct results (Jacobs *et al.,* 1998).

Bone cell culture systems have also been exploited for engineering applications. The overall objective of many bone bioengineering studies is the design of biomaterials that will enhance bone formation, with two goals: improving the interactions of orthopaedic prostheses with bony tissue and repairing osseous defects while providing a weight bearing structure in those defects. Recent knowledge of which materials are biocompatible for placement in human hosts has mainly come from the cocultures of cells and implant materials. These studies have been invaluable for assessing toxicity to osteoblasts, adhesion characteristics, osteoblast phenotypic expression, and mineralization (Davies, 1996). Bioactive bone bonding due to chemical reactions between the bone and materials has led to strong and stable interactions so that breakage due to loading often occurs inside the bone or in the material but not at the interface (Ohgushi and Caplan, 1999). Glass and calcium phosphate ceramics, nonceramic materials such as calcium carbonates, and some organic polymers are capable of bioactive bone bonding. For example, bioactive glass and bioactive glass–ceramics are able to bond bone through the formation of an hydroxyl carbonate apatite layer on their surfaces (Hench and Wilson, 1984). Titanium has also been shown to be a bioreactive material capable of bone-bonding properties under some conditions. The oxide layer of titanium, which naturally forms calcium phosphate similar to apatite, has been hypothesized to be responsible for this bone bonding characteristic (Hanawa, 1989).

Cytotoxicity to particular implant materials has been demonstrated in cocultures of osteoblasts and biomaterials. The methyl-thiazole sulfate test (MTT) measuring dehydrogenase enzymes found in metabolically active cells, has been used extensively to evaluate the effect of numerous materials—nickel, chromium, vanadium, aluminum (McKay *et al.,* 1996), zirconia and alumina ceramics (Josset *et al.,* 1999), polyethereetherketone and epoxy resin polymers with or without carbon fiber reinforcements (Morrison *et al.,* 1995), and others—on immortalized osteoblast cell lines and human bone cell cultures. Assays for alkaline phosphatase, cell growth, leakage of cytosolic lactate dehydrogenase, intracellular reduced glutathione content, protein synthesis, cell morphology, and immunocytochemical staining to detect osteoblast extracellular matrix protein synthesis have often been used in conjunction with the MTT assay to determine osteoblast viability (Josset *et al.,* 1999; McKay *et al.,* 1996; Morrison *et al.,* 1995; Oliva *et al.,* 1996). Interactions of primary rat osteoblasts and macrophages with biodegradable and porous polyesteurethane foam have also been used to assess cytoxicity (Saad *et al.,* 1996).

Enhancing cellular responses to implant materials has led to studies of alterations in the surface characteristics of implant materials. The role of implant surface topography in osteoblast attachment has been reviewed extensively (Chehroudi *et al.,* 1997; Boyan *et al.,* 1996; Larsson *et al.,* 1996) and has shown that rough or textured porous surfaces promote cell attachment (Ahmad *et al.,* 1999; Boyan *et al.,* 1996; Groessner-Schreiber and Tuan, 1992). Attachment to the implant materials is mediated through integrins and focal adhesion proteins (Krause *et al.,* 2000; Schneider and Burridge, 1994).

To improve existing biomaterials, cultures of cells with implant materials, having specific, engineered surface chemistries that stimulate osteoblast function, have been recently developed. Biomimetic surface engineering for bone regeneration has involved tethering integrin binding peptides (Arg-Gly-Asp) and heparin binding domains of bone sialoprotein to stimulate osteoblast attachment and bone formation *in vitro* (Rezania and Healy, 1999; Sofia

et al., 2001). Prefabricated biologic apatite formation on a bioactive apatite–wollastonite (AW) glass ceramic was shown to enhance mineralization more than AW alone in primary rat osteoblast cultures (Loty *et al.,* 2000) and this biomimetic apatite also stimulated the proliferation and differentiation of marrow stem cells (Yoshikawa *et al.,* 1998).

Although the ability of cultured osteoblast-like cells to produce mineralized nodules has provided a convenient *in vitro* correlate of osteogenesis, the generation of extended, higher ordered structures has not been investigated in great detail. Specifically, osteoblastic cells in culture appear to form woven bone like that seen in embryonic bone or in healing fractures, rather than the characteristic lamellar patterns observed in mature bone tissue *in vivo.* The functional requirements of osteoblasts to produce lamellar bone are not known. Some investigators have begun to examine the formation of three-dimensional structures *in vitro* both on surfaces (Castoldi *et al.,* 1997; Manduca *et al.,* 1993; Cooper *et al.,* 1998) and in collagen sponges (Mueller *et al.,* 1999). These and similar approaches may offer a starting point to understand the process of long-range matrix organization.

Finally, despite the usefulness of of osteoblast-like cell cultures for many applications, the question arises of whether the model is sometimes overextended. For example, the fluid flow mechanosensitivity experiments described above will certainly generate useful information about the mechanisms by which these cells recognize and respond to those stimuli. On the other hand, this response *in vivo* is believed to be primarily one of osteocytes. Although osteocytes and osteoblasts represent different stages in the maturation of a single cell type, it remains to be determined how closely an osteoblast-like cell can approximate an osteocyte, even *in vitro.* The ability to isolate and study "authentic" osteocytes (see below) should allow this question to be resolved fairly soon. The same question applies to bone lining cells. A monolayer of quiescent osteoblastic cells appears to be a reasonable model for lining cells, at least as a first approximation. Yet the assumptions underlying this approach remain to be validated; however, part of the problem is that the *in vivo* phenotype of lining cells is poorly understood.

Marrow Stromal Cells

The bone marrow stroma is a loose connective tissue within the marrow containing a heterogeneous population of connective tissue cells whose functions include the production of critical growth factors for hematopoietic cells (Simmons, 1996). The term "marrow stromal cells" has become an operational definition of the adherent population of proliferative cells (i.e., excluding cells like mature macrophages) derived from bone marrow. Marrow stromal cells have become of considerable interest because these populations contain multipotential "mesenchymal stem cells" capable of regenerating the entire repertoire of mesenchymally derived cell types, including osteoblasts (Cassiede *et al.,* 1996; Lazarus *et al.,* 1997).

Culture of marrow stromal cells appears technically straightforward. Total marrow isolates are obtained from "blowouts" of rat or mouse long bones (Zhang *et al.,* 1995) or from human bone biopsies or surgical specimens (Kuznetsov *et al.,* 1997; Muschler *et al.,* 1997). Either the total marrow is cultured or the nucleated cells are isolated first prior to culture. The adherent cells are allowed to grow like typical fibroblastic or osteoblast-like cells until use. Kuznetsov and Robey demonstrated that the requirements for successful initial growth of stromal cells can differ markedly among species (Kuznetsov *et al.,* 1997). Many investigators use primary marrow stromal cultures as their experimental model, but some permanent cell lines derived specifically from marrow stromal cells have been described (Matsumoto *et al.,* 1995; Benayahu *et al.,* 1989; Diduch *et al.,* 1993; Udagawa *et al.,* 1989).

Marrow stromal cell preparations, which contain precursors of all the "mesenchymal" cell lineages (osteoblasts, fibroblasts, chondrocytes, adipocytes, myocytes), have become one of the principal experimental systems used to investigate differentiation and developmental plasticity within these lineages (see Chapter 4 for a detailed review of this area). Because of their heterogeneity, some investigators have preferred clonal cell lines derived from marrow stroma (Udagawa *et al.,* 1989) or from other sources (Katagiri *et al.,* 1990, 1994) to study these differentiation pathways. Yet the heterogeneity of stromal cell preparations makes them especially well suited for *ex vivo* experiments, in which the effects of *in vivo* treatments or genetic differences on the number of osteoblastic progenitor cells in the marrow or their ability to differentiate into osteoblasts can be examined *in vitro.* For example, this approach has been used to study the effects of modulation in gonadal steroid levels (Bellido *et al.,* 1993; Jilka *et al.,* 1998) and on unweighting by hindlimb suspension (Zhang *et al.,* 1995). In studies like these, total marrow is usually isolated by standard techniques (although a novel centrifugation method (Dobson *et al.,* 1999) has been reported to give improved yields and reproducibility), and the number of osteoblastic cells or their progenitors is assesed by a colony or nodule formation assay.

Enumerative assays, which include colony and nodule formation, overcome the two principal disadvantage associated with biochemical techniques to measure a phenotypic trait: first, the outcome is a population average, and second, the assay may not be sufficiently sensitive to detect a rare phenotype. Flow cytometry is perhaps the most powerful tool for enumerative assays, since it measures the expression level of the selected traits in individual cells, and provides complete frequency distributions for them. Multiple properties can be evaluated simultaneously in many cytometers using appropriate fluorescent dyes. The most common flow cytometric assys measure DNA content or damage, including apoptosis (Hamel *et al.,* 1996) and cell surface markers, exemplified by the analysis of STRO-1 expression in human bone and marrow cell preparations (Gronthos and Simmons, 1995; Gronthos *et al.,* 1994; Simmons *et al.,* 1994).

Not all phenotypes are amenable to analysis by flow cytometry. For example, there is no clear marker to identify

a cell capable of replicating effectively at extremely low cell densities, of growing in soft agar, or of differentiating (e.g., into an osteoblast or chondrocyte) under the appropriate permissive conditions. These phenotypes must be assessed functionally. In the case of osteoblasts, cells are plated at a range of densities and grown under conditions permitting expression of an osteoblastic phenotype (ascorbic acid to promote formation of a stable extracellular matrix and an organic phosphate source to promote mineralization). Expression of the osteoblastic phenotype is then assessed, usually by counting the number of mineralized nodules. The number of nodules indicates the number of osteoblastic colony-forming units (CFU-O) present in the original plated population. With increasing dilution, fewer nodules are seen. By relating nodule number to the cells initially plated, the percentage of cells in the original population capable of becoming an osteoblastic colony is determined. Several variations of this general colony formation assay procedure have been reported (Bellows *et al.,* 1990, 1998; Falla *et al.,* 1993; Jilka *et al.,* 1998; Van Vlasselaer *et al.,* 1994); however, in all instances the Poisson distribution governs the probability of colony formation and is the basis for analysis of the data.

An alternative endpoint to mineralized nodule formation for the assessment of osteoblastic differentiation is the expression of alkaline phosphatase, a long-established marker of the osteoblast phenotpye (Majeska *et al.,* 1980; Rodan *et al.,* 1988). Alkaline phosphatase is expressed early in the course of osteoblast maturation, but activity is maintained until the cells mature ultimately into osteocytes (Owen *et al.,* 1990). Although alkaline phosphatase is highly expressed in osteoblasts, it is not completely specific for this cell type; for example, other cells in the marrow stroma probably express this enzyme (Westen and Bainton, 1979). Still, formation of mineralized nodules *in vitro* is virtually always associated with increased alkaline phosphatase expression; however, a systematic evaluation of differences in the outcome of limiting dilution assays using the two endpoints of osteoblastic differentiation have not been carried out.

In addition to its usefulness for investigating the biology of mesenchymal cell differentiation, the marrow stroma is currently the tissue of choice for mesenchymal stem cells to use in tissue engineering applications. Specifically, mesenchymal stem cells that have been expanded in culture and then induced to form bone by dexamethasone, tumor growth factor (TGF)-β, BMP-2, -4, or -7, and growth hormone have been used recently to seed composite grafts for implantation *in vivo* (Ohgushi and Caplan, 1999). Moreover, marrow stromal cells have been investigated as carriers for genes delivered *in vitro,* in the expectation that the cells will populate the host marrow while continuing to deliver the product of the *in vitro*-transfected gene (Oyama *et al.,* 1999; Suzuki *et al.,* 2000).

Although harvesting marrow stromal cells as sources of progenitors of osteoblasts or other cell types is often less involved than obtaining samples of bone or cartilage, it is still not a trivial procedure. Recent reports indicate that cells from more easily attainable sources like muscle (Lee *et al.,* 2000) and fat (Bennett *et al.,* 1991) may be capable of osteogenic differentiation.

OSTEOCYTES

Osteocytes comprise the majority of adult bone cells, but have been difficult to culture for several reasons. First, osteocyte isolation is problematic. They are the only bone cells not found at a surface; rather, they are entombed within mineralized bone matrix. Second, they represent the most highly differentiated state of the osteoblastic cell lineage and are clearly postmitotic *in vivo.* Finally, the distinctive morphology of osteocytes *in vivo* (featuring an extensive array of long, narrow cell processes) is mostly lost when the cells are removed from their matrix, and for a long time there was no other specific marker with which to identify this cell type. There have been two major technical breakthroughs in osteocyte *in vitro* culture. First was the identification by Nijweide and colleagues of a specific osteocyte antigen and the development of an immunoisolation technique to obtain these cells (Nijweide and Mulder, 1986; van der Plas and Nijweide, 1992). Unfortunately, this marker is species-specific for chicken cells. The second was the establishment of the MLO-Y4 osteocytic cell line from a T-antigen-expressing transgenic mouse (Kato *et al.,* 1997). This cell line has been used to identify further phenotypic markers of osteocytes as well as to investigate the biology of these cells. In addition to these systems, other investigators have utilized differential digestion to isolate osteocyte-enriched cell populations and characterized some of their features, particularly the cytoskeleton (Tanaka-Kamioka *et al.,* 1998).

Most studies on osteocytes in culture have focused on their responses to mechanical stimuli, based on the concept that osteocytes are the principal mechanosensitive cells in bone responsible for initiating the tissue's adaptive changes in response to mechanical loading (Donahue, 1998). Fluid flow has been the principal stimulus (Ajubi *et al.,* 1999; Westbroek *et al.,* 2000). These studies are also more fully described in Chapter 6.

The ability to study *in vitro* cells that clearly express an osteocytic, rather than an osteoblastic, phenotype *in vitro* is clearly an expermental advantage. What remains to be established, however, are the importance of the characteristic morphology of osteocytes and the presence of a mineralized matrix surrounding them. How osteocytes generate their characteristic cell processes is not known, although a paper by Reddi and collaborators showed that culture of osteoblastic cells on laminin or matrigel caused them to assume an osteocyte-like morphology in monolayer (Vukicevic *et al.,* 1990). The osteocytic environment *in vivo,* including the nature of its matrix, is poorly understood.

OSTEOCLASTS AND PREOSTEOCLASTS

The isolation and culture of osteoclasts was difficult to achieve, due to their rarity, fragility, and status as terminally differentiated, nonproliferative cells; however, these problems have been overcome, and osteoclasts are now routinely

isolated for use in short-term cultures in much the same way as osteoblastic cells. Mature osteoclasts and late-stage preosteoclasts have been obtained from several species including chick (Collin-Osdoby *et al.,* 1991) and mouse (Wesolowski *et al.,* 1995), and from human giant cell tumors (Drake *et al.,* 1996; James *et al.,* 1991, 1996). Furthermore, immortalization of osteoclast precursors has now led to osteoclastic cell lines (Hentunen *et al.,* 1998, 1999). Osteoclast isolation (Teti *et al.,* 1999) and osteoclast biology (Roodman, 1999) have been recently reviewed and are also discussed further in Chapters 7–9.

The differentiation of osteoclasts from monocytic precursors has also been intensively studied, because this process is crucial to the initiation of bone remodeling. The *in vitro* experimental systems used for such osteoclastogenesis assays are based predominantly on cocultures of hematopoietic osteoclast precursors (of the monocytic line) and mesenchymal cells that stimulate their growth and differentiation. Both cell populations are present in total bone marrow cultures; however, alternative sources of both osteoclast precursors and mesenchymal cells have been used. The common alternative source of monocytic osteoclast precursors is the spleen (Roodman, 1999), while the stromal cell component of osteoclastogenic cocultures has been supplied by a wide range of primary cultures and permanent lines of marrow stroma-derived cells or of osteoblast-like cells. Two of the principal stromal-derived regulators of osteoclastic differentiation appear to be M-CSF and RANK ligand (Itoh *et al.,* 2000).

The criteria for defining an osteoclast, established over several years of investigation, include multinucleation, the expression of tartrate-resistant acid phosphatase activity (TRAP), receptors for (or a proper response to) calcitonin, and a standard *in vitro* functional assay, the ability to create resorption pits when placed on mineralized tissue (see Chapters 7 and 8 for details). Many of these assays, in particular pit formation, are expensive, painstaking, and require specialized equipment and experience to interpret. The simplicity and convenience of counting TRAP-positive multinucleated cells has made this a very popular endpoint for *in vitro* assays of osteoclast formation, and experience has apparently confirmed its validity.

Osteoclast cultures have been used mainly to study the mechanisms that control the function of this cell, and also to identify the factors controlling osteoclast differentiation. These lines of investigation have been enormously productive; however, there are certain areas which have yet to be fully examined, and to do so *in vitro* may require novel methods. For example, we have little knowledge of the factors which control the ongoing activity of osteoclasts during the resorption process. In particular, we do not know the role of nearby cells. Osteoclastic resorption occurs as part of a multicellular unit that forms new osteons in cortical bone or "hemiosteons" on trabecular surfaces (Parfitt, 1994). Among the cells potentially capable of exerting influence on the resorbing osteoclasts are osteocytes, endothelial cells (which remain close behind the osteoclast "cutting cone" and provide the entry point for new monocytes), and the perivascular cells, osteoblasts, and other mesenchymal cells in the vicinity. While pit assays can assess the intrinsic ability of osteoclasts to degrade mineral and osteoid, removal of devitalized tissue does not allow evaluation of the roles played by these cells. Yet measuring osteoclast activity *in vitro* on bone that contains these cellular components will require a substantial development in methodology.

A second area of bone remodeling where *in vitro* systems have yet to fully approximate the *in vivo* situation is the initial stage of osteoclast recruitment. These processes involve two cell types so far underrepresented by *in vitro* models of bone cells: the lining cell and the endothelial cell. Bone remodeling is a targeted process that requires osteoclast progenitor cells to exit the vasculature at specific sites of incipient resorption. How the endothelium changes at those points to allow monocyte penetration is currently unknown. The necessary cell types are available to examine these questions *in vitro,* and mechanistic examples exist in the literature of inflammation (Heil *et al.,* 2000); however, the experimental system needs to be developed.

COCULTURE SYSTEMS

In addition to normal cellular interactions in bone, *in vitro* systems have been used to model pathologic conditions as well. Cancer has been a major focus, in particular breast cancer, prostate cancer, and melanoma. Each of these forms has marked skeletal effects; myeloma and metastatic breast cancer cause dramatic local bone resorption; metastatic prostate cancer produces lesions that are mainly osteogenic (Boyce *et al.,* 1999). In each case tumor cells produce deleterious effects on the skeleton indirectly, by regulating the actions of host osteoblasts or osteoclasts; consequently studies using *in vitro* model systems have been primarily directed toward defining the mechanisms by which the cancer cells signal and modulate host cells. In the case of myeloma (Michigami *et al.,* 2000) and breast cancer (Mbalaviele *et al.,* 1996; Thomas *et al.,* 1999), host– tumor interactions promoting osteoclastogenesis have been examined in marrow cell-based cultures. Prostate cancer cells have also been cocultured with marrow stromal cells (Lang *et al.,* 1997, 1998) and with osteoblast-like cell lines (Koutsilieris *et al.,* 1997; Reyes-Moreno *et al.,* 1995, 1998; Akoum *et al.,* 1996) to identify the putative signaling pathways running in both directions between these cells; i.e., those responsible for stimulating osteoblastic activity and those which promote the growth and survival of the metastatic tumor cells. Finally, *in vitro* systems have been used to investigate the effects of chemotherapeutic drugs (Choki *et al.,* 1998; Koutsilieris *et al.,* 1999a,b, Akoum *et al.,* 1996). Studies showing that bisphosphonates inhibit osteoclast function (Hughes *et al.,* 1995), indicating their potential usefulness to limit tumor-induced osteolysis, have led to direct indications that these compounds may also directly act on tumor cells (Boissier *et al.,* 2000).

Summary

It has been possible to isolate, culture, and study not only bone tissue but also cells representing most of the morphologically distinct cell types associated with bone. The information gathered so far with these techniques has been an invaluable aid to our understanding of skeletal biology. The challenges in methodology now seem to be less of breakthrough than of refinement. Fundamental methods of bone cell and tissue culture, and the means to analyze cell behavior *in vitro,* are largely validated and available to all investigators. These model systems in their current state will continue to be convenient assay systems, useful for characterizing the differences at the cellular level which result from genetics, age or disease. Yet to understand how those cellular differences are translated into alterations at the tissue level will require improvement in the modeling of bone cell interactions with each other and with their environment.

Introduction

In order to meet the ever-changing biophysical and chemical needs of the living organism, bone undergoes continuous turnover and remodeling. As discussed elsewhere in this book in more detail, turnover of the skeletal matrix relies on the activity of two major types of cells, namely, bone-forming osteoblasts and bone-resorbing osteoclasts. Accordingly, bone remodeling is achieved by two counteracting processes, i.e., bone formation and bone resorption. Although the various serum and urinary markers of bone turnover include both cell-derived enzymes and nonenzymic peptides, they are usually classified according to the metabolic process they are considered to reflect. For clinical purposes, therefore, markers of bone formation are distinguished from indices of bone resorption (Tables I and II). It should be borne in mind, however, that some of these compounds may reflect, at least to a certain degree, both bone formation and bone resorption (e.g., urinary hydroxyproline) and that most, if not all, of these markers are present in tissues other than bone and may therefore be influenced by nonskeletal processes as well. Third, changes in biochemical markers of bone turnover are usually not disease-specific, but reflect alterations in skeletal metabolism independent of the underlying cause (Tables V–VII). Keeping this in mind and the fact that abnormal biochemical results should always be interpreted within the context of the technical (variablity!) and clinical picture is essential to the meaningful use of biomarkers in the assessment of skeletal disorders.

Under normal conditions, bone formation and bone resorption are coupled to each other, and the long-term maintanance of skeletal balance is achieved through the intricate action of systemic hormones (see Chapters 24–36) and local mediators (see Chapters 37–55). In contrast, metabolic bone diseases, states of increased or decreased mobility, therapeutic interventions, etc., are usually characterized by more or less pronounced and sometimes only transient imbalances in bone turnover. While the long-term results of such imbalances (i.e., changes in bone mass) are assessed with densitometric techniques, the principal domain of bone biomarkers is in the detection of the imbalance itself, and

the classification of low or high, decreased or increased bone turnover.

Basic Aspects

In addition to the cells, bone consists of mineral, proteins, and other macromolecules. The mineral phase of bone is principally composed of crytalline hydroxyapatite and accounts for 60–70% of the weight of bone. The organic phase of bone is principally composed of collagen (90%) and other smaller matrix proteins, glycoproteins, and proteoglycans. The cellular and extracellular components of the skeletal matrix form the basis for the development of biochemical markers that specifically reflect either bone formation or bone resorption.

Throughout life the skeleton undergoes continuous remodeling with removal of old bone and replacement with new bone. Bone turnover is always initiated by osteoclasts eroding a mineralized surface. When osteoclasts resorb bone, they secrete a mixture of acid and neutral proteases which act sequentially to degrade the collagen fibrils into molecular fragments. The biochemical markers of bone resorption therefore include collagen breakdown which include hydroxyproline, hydroxylysine glycosides, and the pyridinoline cross-links. These cross-links range in size from the free amino acids to segments of the N-telopeptide and C-telopeptide domains. Other markers of bone resorption include tartrate-resistant acid phosphatase and bone sialoprotein (Table II). The process of bone resorption is followed by the recruitment of osteoblasts to the outer edge of the erosion cavity. The osteoblasts secrete new bone matrix (osteoid) and gradually fill in the resorption cavity. The biochemical markers of bone formation are products of osteoblastic synthesis. These include N- and C-propeptides of type I collagen, osteocalcin, and bone-specific alkaline phosphatase (Table I).

Markers of Bone Formation

ALKALINE PHOSPHATASE

Alkaline phosphatase (ALP) belongs to a large group of proteins which are on attached to the extracellular surface of cell membranes via a carboxy-terminal glycan-phosphatidylinositol (GPI) anchor (Low and Saltiel, 1988). Four gene loci code for ALP: the three tissue-specific genes encode the intestine, mature placenta, and germ-cell enzymes and the tissue-nonspecific (tns) gene is expressed in numerous tissues (including bone, liver, kidney, and early placenta). Tissue nonspecific ALPs are the products of a single gene, but tissue-specific differences are found in their electrophoretic mobility, stability to heat, and sensitivity to a variety of chemical inhibitors. These differences are due to variations in their carbohydrate side chains (Weiss *et al.,* 1988). Since the two most common sources of elevated alkaline phosphatase levels are liver and bone, a number of techniques have been developed which rely on the differences in the carbohydrate side chains to distinguish between bone and liver isoforms.

Table I Biochemical Markers of Bone Formation[a]

Marker (abbreviation)	Tissue of origin	Analytical specimen	Analytical method	Remarks/specificity
Total alkaline phosphatase (total ALP)	Bone, liver, intestine, kidney, placenta	Serum	Colorimetric	Attached to the extracellular surface of cell membranes; may play a role in matrix mineralization. Specfic for bone formation only in the absence of liver or biliary disease.
Bone-specific alkaline phosphatase (bone ALP)	Bone	Serum	Colorimetric, electrophoretic, precipitation, IRMA, EIA	Attached to the extracellular surface of cell membranes; may play a role in matrix mineralization. Specific product of osteoblasts. Carbohydrate side-chain differences confer bone specificity. Some assays show up to 20% cross-reactivity with liver isoenzyme.
Osteocalcin (OC)	Bone, platelets	Serum	RIA, ELISA (See also Table III)	Contains calcium-binding amino acid, γ-carboxyglutamic acid (Gla), which facilitates interaction with hydroxyapatite. Specific product of osteoblasts; many immunoreactive forms in blood; some may be derived from bone resorption.
Carboxy terminal propeptide of type I procollagen (PICP)	Bone, soft tissue, skin	Serum	RIA, ELISA	Specific product of proliferating osteoblasts and fibroblasts.
Amino-terminal propeptide of type I procollagen (PINP)	Bone, soft tissue, skin	Serum	RIA, ELISA	Specific product of proliferating osteoblast and fibroblasts; partly incorporated into bone extracellular matrix.

[a]Nomenclature and abbreviations follows a recent proposal by a working group of the International Osteoporosis Foundation [Delmas *et al.* (2000) *Osteoporosis Int.* **11**].

Table II Biochemical Markers of Bone Resorption[a]

Marker (Abbreviation)	Tissue of origin	Analytical specimen	Analytical method	Remarks/specificity
Hydroxyproline, total and dialyzable (Hyp)	Bone, cartilage, soft tissue, skin	Urine	Colorimetric HPLC	Present in all fibrillar collagens and partly collagenous proteins, including C1q and elastin. Present in newly synthesized and mature collagen; i.e., both collagen synthesis and tissue breakdown contribute to urinary hydroxyproline.
Pyridinoline (PYD)	Bone, cartilage, tendon, blood vessels	Urine Serum	HPLC ELISA	Collagens, with highest concentrations in cartilage and bone; absent from skin; present in mature collagen only.
Deoxypyridinoline (DPD)	Bone, dentin	Urine Serum	HPLC ELISA	Collagens, with highest concentration in bone; absent from cartilage or skin; present in mature collagen only.
Carboxy terminal cross-linked telopeptide of type I collagen (CTX-MMP)	Bone, skin	Serum	RIA	Collagen type I, with highest contribution probably from bone; may be derived from newly synthesized collagen.
Amino-terminal cross-linked telopeptide of type I collagen (NTX-I)	All tissues containing type I collagen	Urine Serum	ELISA CLIA RIA	Collagen type I, with highest contribution from bone.
Carboxy terminal cross-linked telopeptide of type I collagen (CTX-I)	All tissues containing type I collagen	Urine (α/β) Serum (β only)	ELISA RIA	Collagen type I, with highest contribution probably from bone. Isomerization of aspartyl to β-aspartyl occurs with aging of collagen molecule.
Hydroxylysine glycosides	Bone, soft tissue, skin, serum complement	Urine	HPLC	Hydroxylysine in collagen is glycosylated to varying degrees, depending on tissue type. Glycosylgalactosyl-OHLys in high proportion in collagensof soft tissues, and C1q; Galyctosyl-OHLys in high proportion in skeletal collagens.
Bone sialoprotein (BSP)	Bone, dentin, hypertrophic cartilage	Serum	RIA ELISA	Acidic, phosphorylated glycoprotein, synthesized by osteoblasts and osteoclastic-like cells, laid down in bone extracellular matrix. Appears to be associated with osteoclast function.
Tartrate-resistant acid phosphatase (TRACP)	Bone Blood	Plasma Serum	Colorimetric RIA ELISA	Six isoenzymes found in human tissues (osteoclasts, platelets, erythrocytes). Band 5b predominant in bone (osteoclasts). Enzyme identified in both the ruffled border of the osteoclast membrane and the secretions in the resorptive space.

[a]Nomenclature and abbreviations follows a recent proposal by a working group of the International Osteoporosis Foundation [Delmas *et al.* (2000) *Osteoporosis Int.* **11**].

Early methods included heat denaturation, chemical inhibition of selective activity, gel electrophoresis, and precipitation by wheat germ lectin (Calvo *et al.,* 1966). Bone-specific immunoassays are the most commonly used method today.

Commercial kits are available which utilize monoclonal antibodies with preference for the bone isoform. Alkphase-B (METRA Biosystems, Mountain View, CA) uses a single monoclonal anti-body which is bound to a microtiter plate and captures alkaline phosphatase from the sample and activity of the bound enzyme is measured directly (Gomes *et al.,* 1995). A two-site immunoassay (Tandem-R-Ostase, Hybritech, San Diego, CA) relies on the use of two monoclonal antibodies, both of which react preferentially with the bone isoform. This assay measures mass of the enzyme (Garnero and Delmas, 1993). A second kit from Hybritech, Tandem-MP-Ostase, is an EIA which measures the activity of antibody-bound enzyme. Comparisons of mass and activity-based immunoassays show that two methods generally provide similar clinical information. However, demonstrated variations in glycosylation patterns raise the question of immunological heterogeneity in the bone isoform which may affect the mass to activity ratio (Kress, 1998).

There is a great deal of inter-individual variation in ALP levels, but for any one individual, values change little with time. ALP is cleared from the blood very slowly; the half-life varies from 40 hr for bone to 7 days for placental isoforms (Crofton, 1982). Biological within day variation of total alkaline phosphatase is estimated to be less than 4%. There is some evidence of a slight diurnal variation in ALP activity that may derive from the bone (Nielsen *et al.,* 1990).

OSTEOCALCIN

Osteocalcin is a small protein synthesized by mature osteoblasts, odontoblasts, and hypertrophic chondrocytes. It is characterized by the presence of three residues of the calcium-binding amino acid, γ-carboxyglutamic acid (Gla). Osteocalcin is thought to interact directly with hydroxyapatite in bone through its Gla residue (Hauschka *et al.,* 1989).

Osteocalcin is primarily deposited in the extracellular matrix of bone, but a small amount enters the blood. Serum osteocalcin is a sensitive and specific marker of osteoblastic activity and its serum level reflects the rate of bone formation. There are several commercial kits for human osteocalcin (Table III), although considerable inconsistency results when comparing values from these various assays and wide variations are reported in control and patient populations (Gundberg, 1998; Gundberg and Nishimoto, 1999). Various fragments of osteocalcin can circulate (Gundberg and Weinstein, 1986; Garnero *et al.,* 1994a; Taylor *et al.* 1990). Commercial and research assay variability is thought to be the result of differences in the ability of the various antibodies to recognize these fragments. Several laboratories have developed two-site immunoassays with the intention of measuring only the intact molecule. However, rapid loss of immunoreactivity is observed with these assays when samples are left at room temperature for a few hours (Colford *et al.,* 1999; Garnero *et al.,* 1992; Monaghan *et al.,* 1993; Parvianen *et al.,* 1994).

A new generation of assays is based upon studies which suggest that intact osteocalcin is degraded to a large N-terminal- mid-molecule fragment in the range of residues 1–43 (OC1–43). The large N-terminal mid-molecule fragment is thought to be generated by proteolysis in the circulation or during sample processing and storage, but there is some evidence that the osteoblast is an additional source of the fragment (Gundberg *et al.,* 2000). One study found that the intact molecule represents only about one-third of the circulating osteocalcin immunoreactivity. One third is comprised of a large N-terminal mid-molecule fragment and another third by several other smaller fragments (Garnero *et al.,* 1994a). Osteocalcin levels decrease with incubation at room temperature when measured by conventional radioimmunoassays (RIAs) or by intact assays, but values are stable with an assay that recognizes both the intact and large N-terminal mid-molecule fragment. With this assay apparent instability of osteocalcin in the circulation and during sample handling is eliminated and the correlation with

Table III Commercially Available Kits for Osteocalcin

Name	Company	Type
ELSA-OST-NAT	CIS-bio International, Gif-sur-Yvette, France	IRMA
Intact Osteocalcin	Biomedical Technologies, Stoughton, MA	ELISA
Human Osteocalcin	Quest, San Juan Capistrano, CA	IRMA
N-tact Osteo- SP	Incstar Corporation Stillwater, MN	IRMA
ELSA-OSTEO	CIS-bio International Gif-sur-Yvette, France	IRMA capture: 25–37 detection: 5–13
Active Human Osteocalcin	Diagnostic Systems Laboratories, Webster, TX	IRMA capture:? detection: 30–49
N-Mid Osteocalcin	Osteometer Biotech, Rodovre, Denmark	IRMA capture: 20–43 detection: 7–19
Mid-tact OC	Biomedical Technologies, Stoughton, MA	ELISA capture:5–19 detection: 21–43
BGP	Mitsubishi Yuka IDS, Boldon, Tyne and Wear, UK	IRMA capture: 12–33 detection: 30–49
Ostk-PR	CIS-bio International, Gif-sur-Yvette, France	RIA; polyclonal antibody to bovine OC
Osteocalcin	Diagnostic Systems Laboratories, Webster, TX	RIA; polyclonal antibody to human OC
OSCAtest	Brahms- Henning, Berlin, Germany	RIA; polyclonal antibody to human OC
NovoCalcin	METRA Biosystems, Mountain View, CA	ELISA; single monoclonal antibody to bovine OC

bone density is improved (Minisola *et al.,* 1997; Dumon *et al.,* 1996; Rosenquist *et al.,* 1995).

The chief route of circulating osteocalcin catabolism is renal glomerular filtration and degradation. The plasma half-life is about 20 min in humans. Immunoreactive fragments of osteocalcin have also been reported in the urine (Taylor *et al.,* 1990). Osteocalcin levels follow a circadian rhythm characterized by a decline during the morning to a low around noon, followed by a gradual rise which peaks after midnight (Gundberg *et al.,* 1985). The difference between the peak and nadir in a 24 hr period can range from 10 to 20% depending upon the assay used.

PROCOLLAGEN PEPTIDES

All collagens contain molecular domains of triple-helical conformation (see Chapter 12). The newly translated polypeptide, a pre-pro-α chain, includes a signal sequence and amino (N)- and carboxyl (C)-terminal propeptide extensions. During collagen synthesis, the C-propeptides guide the selection and association of the individual pro-α chains and prevent premature intracellular fiber formation. Specific extracellular endoproteinases cleave the procollagen molecule at precise sites in each chain. (Fig. 1) The C-terminal endoproteinase is identical to bone morphogenic protein (BMP) (Kessler *et al.,* 1996). The C-propeptide (PICP), which is a trimeric globular glycoprotein, is stabilized by disulfide bonds and circulates as a single molecule (Olsen *et al.,* 1977). It has a serum half-life of 6–8 min and is cleared in the liver endothelial cells by the mannose-6-phosphate receptor (Smedsrod *et al.,* 1990). The procollagen type I aminoterminal propeptide (PINP) is a partly globular, partly helical (collagenous) 35-kDa protein. PINP circulates mainly as the intact trimeric molecule but monomers are also found (Brandt *et al.,* 1999). The intact molecule is cleared from the circulation by the scavenger receptor of liver endothelial cells (Kivirikko and Myllyla, 1980). There have been suggestions that a low-molecular-weight, degraded form of PINP monomer also circulates (Melkko *et al.,* 1996) .

The procollagen extension peptides are cleaved from the newly formed molecule in a stoichiometric relationship with collagen biosynthesis. Therefore, they should reflect bone formation in a manner analogous to the assessment of C-peptide for endogenous insulin production. However, because type I collagen is also a component of several soft tissues (fibrocartilage, tendon, skin, gingiva, intestine, heart valve, and large vessels) there is a potential contribution to circulating procollagens from soft tissue synthesis of type I collagen. Nevertheless, because the rate of turnover of collagen in bone is faster than in other tissues, changes in procollagen concentrations are assumed to reflect changes primarily in bone collagen synthesis. Similar to other markers, PICP and PINP demonstrate a circadian rhythm with peak values occurring in the early morning hours and nadirs in the afternoon (Hassager *et al.,* 1992; Saggese *et al.,* 1994).

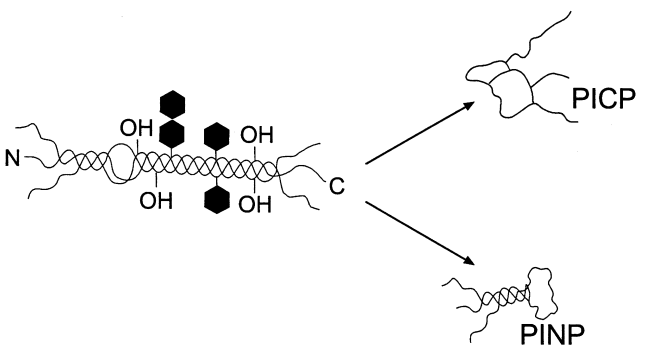

Figure 1 Procollagen Peptides. Type I collagen polypeptides are synthesized as pre-pro-α chains which contain a peptide secretory sequence and amino (N)- and carboxyl (C)-terminal extension peptides. These extension peptides guide helical folding of the molecule. After secretion, the N- and C-terminal extension peptides are cleaved by specific peptidases and the extension peptides can enter the circulation.

Assays for the measurement of PICP are based on polyclonal antisera made against purified collagen isolated from human skin or lung fibroblast cultures (PICP, Orion Diagnostics, Espoo, Finland, distributed in the United States by Diasorin, INCStar, Stillwater, MN). Another assay (Metra BioSystems, Mountain View, CA) uses an enzyme-linked immrosorbant assay (ELISA) format. Several assays have also been developed to measure PINP in blood. Early research assays used synthetic peptides for antibody production and assay reagents and results with these assays are variable. Meanwhile, antibodies have been made to authentic PINP. Depending upon the assay format, these measure either the the intact trimeric form of PINP (intact PINP) only or both the intact trimeric plus the monomeric forms (total PINP)(Melkko *et al.,* 1996; Orum *et al.,* 1996). One assay which measures only intact PINP is in commercial format (PINP, Orion Diagnostics, distributed in the United States by Diasorin, INCStar).

Studies indicate that PINP is a better measure of changes in rate of bone collagen synthesis than PICP. In contrast to other measures of bone turnover, there are only slight increases in PICP after the menopause and PICP correlates only weakly with spinal bone mineral density (Charles *et al.,*1994; Minisola *et al.,* 1994). Measurement of intact PINP appears to be more sensitive than total PINP and may provide more specific clinical information (Brandt *et al.,* 1999; Orum *et al.,* 1996; Chandani *et al.,* 2000; Dominguez *et al.,* 1998).

Markers of Bone Resorption

HYDROXYPROLINE

Hydroxyproline (Hyp) is present in essentially all tissues and all genetic types of collagen (Chapter 72). Hydroxyproline is derived from the breakdown of collagen. The majority of the the breakdown products are reabsorbed by the renal tubules and broken down in the liver while only about 10% of is excreted in the urine. Most are contained in di- and tripeptides (Prockop and Kivirikko, 1967; Smith, 1980). The remaining peptides in the urine are of approximately 5 kDa. There is a small amount of the free imino acid in urine. Hydroxyproline can never be reincorporated into newly synthesized collagen (Prockop, 1964). However, both collagen synthesis and tissue breakdown con-

tribute to urinary hydroxyproline. Colorimetric methods or high-performance liquid chromatography (HPLC) are commonly used to measure urinary hydroxyproline.

Although, urinary Hyp has the longest history of use as a resorption, it has now been largely replaced by other bone resorption markers. The main reasons are its lack of specificity for bone, the need to restrict intake of gelatin and other collagen-rich foods to avoid the contributions of exogenous Hyp to urinary measurments, and the contributions of Hyp from the degradation of newly synthesized collagen (Calvo *et al.,*1996).

COLLAGEN CROSS-LINKS

Pyridinoline and Deoxypyridinoline (Chapter 13) Newly deposited collagen fibrils in the extracellular matrix are stabilized by intramolecular and intermolecular cross-links. The main cross-links in skeletal tissues are the trivalent structures, deoxypyridinoline (DPD) and pyridinoline (PYD). The pyridinoline cross-links occur at two sites placed symmetrically at about 90 residues from the ends of the 1000-residue helical domain in the collagen fibril (Fig. 2). Pyridinolines act as mature cross-links in types I, II, and III collagens of all major connective tissues other than skin (Eyre *et al.,* 1984, 1988). This includes type I collagen of bone, dentin, ligaments, fascia, tendon, vascular walls, muscle, and intestine. In all tissues PYD predominates, with Dpy being the minor component. However, DPD is most abundant in bone and is considered the more bone-specific marker since bone represents the major reservoir of total collagen in the body and turns over faster than most major connective tissues. This conclusion is supported by the strong correlations between DPD and resorption rates as determined by radio tracer kinetics (Eastell *et al.,* 1997).

Since only 40–50% of the cross-links are free, many investigators have measured total pyridinolines (peptide bound plus free). These analyses are performed by acid hydrolysis of the urine sample to liberate peptide-bound and conjugated forms, followed by solid-phase extraction, separation by HPLC, and quantitation by fluorescence (Eyre *et al.,* 1984; Black *et al.,* 1988, 1989). Recent advances in chromatographic methods have allowed direct analysis of urine without acid hydrolysis. Good correlations are found between free and total cross-links in normal subjects and in patients with disorders associated with increased bone resorption.

The cross-link markers provide distinct advantages over urinary Hyp. First, they are not influenced by dietary intake (Colwell *et al.,* 1993). Second, they are formed only at the final stages of fibril formation and are therefore unaffected by degradation of newly synthesized collagen. Finally, they are not further metabolized nor are they reused in collagen biosynthesis.

Several direct immunoassays for the cross-links and a number of ELISA systems have been reported (Seyedin *et al.,*1993; Robins *et al.,* 1994; Gomez *et al.,* 1996). Commercial kits are available which measure both DPD and PYD in combination (Pyrilinks II, METRA Biosystems) or DPD alone (Pyrilinks D, METRA Biosystems). Direct comparison of the immunoassays with HPLC shows a high correlation between the methods.

Cross-Linked Telopeptides There are several assays that are based on measurement of peptides associated with the cross-link regions in collagen. These assays are derived from peptides at both ends of the collagen type I molecule. An assay based on a cross-linked peptide from the N-terminal telopeptide of collagen type I, referred to as NTX-I, is based on a monoclonal antibody raised against a peptide isolated from urine of a patient with Paget's disease of bone (Hanson *et al.,* 1992). The antibody specifically recognizes the cross-linked α2(I)N-telopeptide sequence, QYDGKGVG, and in which K (lysine) is involved in the trivalent cross-linkage (Eyre, 1995). *In vitro* studies show that NTX-I can be quantitatively released from bone by the action of cathepsin K, a specific protease of the osteolast. (Atley *et al.,* 2000). The NTX-I ELISA is available in a commercial, microtiter-plate format (Osteomark, Ostex International Inc., Seattle, WA). The assay measures the NTX-I peptide in spot urines,

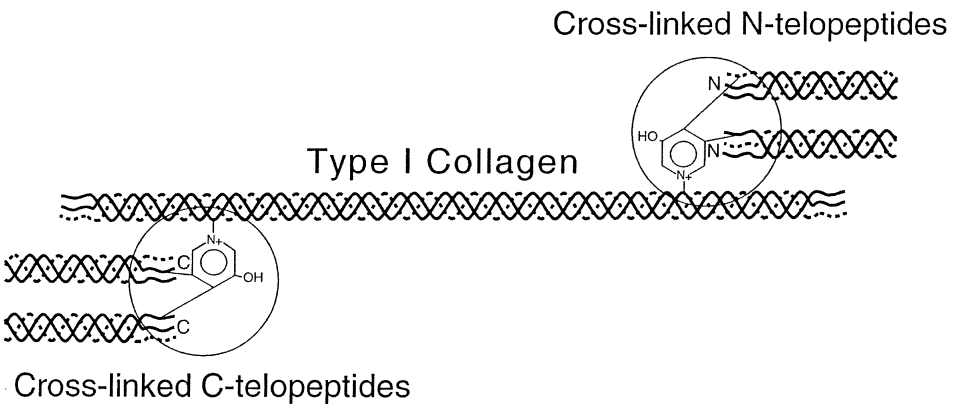

Figure 2 Cross-linked N- and C-telopeptides of type I collagen. The pyridinoline cross-links occur at two intermolecular sites in the collagen fibril: the aminoterminal telopeptide (NTX-I) and the carboxyterminal telopeptide (CTX-I; CTX-MMP).

calibrated in molar equivalents of type I collagen and results are normalized to creatinine. Recently the assay has been developed for use in serum (Clemens *et al.,* 1997).

Several assays for the measurement of the C-terminal telopeptide of type I collagen (CTX-I) in urine have been developed. One assay measures the C-terminal type I collagen telopeptide in serum. The antigenic determinant requires a trivalent cross-link and is generated by matrix metalloproteinase digestion of type I collagen (Risteli and Risteli, 1999). The assay is therefore termed CTX-MMP (previously ICTP). Another assay is based on a polyclonal antibody raised against a synthetic eight-amino-acid peptide (EKAHDGGR) derived from a segment of the C-telopeptide of the collagen α1(I) chain. This assay recognises only a form of the peptide containing an β-aspartyl peptide bond (AHD-β-GGR). The isomerization of aspartyl to a-aspartyl residues occurs over extended periods of time and is associated with the aging of proteins and peptides (Bonde *et al.,* 1997) . The isomerization process reaches a maximum 3 years after the bone is mineralized and thus this assay measures the degradation of relatively old bone (Fledelius *et al.,* 1997) Another CTX-I assay measures only the nonisomerized form of this octapeptide and presumably measures the degradation of relatively young bone (α-Ctx) (Bonde *et al.,* 1997). Both of these assays and a recently developed serum CTX-I assay are commercially available (Osteometer BioTech, Denmark).

Galactosyl Hydroxylysine

Hydroxylysine, another modified amino acid particular to collagens is glycosylated to varying degrees depending on the tissue type (Segrest and Cunningham, 1970). Two glycosides are formed, galactolysyl hydroxylysine (Gal-Hyl) and glucosyl galactosyl hydroxylysine (Glc-Gal-Hyl). Because of tissue-specific differences, Gal-Hyl is considered to be relatively specific to bone collagen degradation (Krane *et al.,* 1977). Glycosylated hydroxylysine residues appear not to be reused or catabolized when collagen is degraded. Furthermore, they do no appear to be absorbed in significant levels from a normal diet (Segrest and Cunningham, 1970). An HPLC method has been employed for measuring Gal-Hyl involving dansylation of the lysine, resolution by reversed-phase HPLC and detection by fluorescence (Moro *et al.,* 1984; Yoshihara *et al.,* 1993). This assay generally shows good correlations with other resorption markers (Moro *et al.,* 1997).

Tartrate-Resistant Acid Phosphatase

During bone resorption, osteoclasts secrete acid and enzymes into the space between the ruffled border of the osteoclast and the surface of the bone. The enzyme, tartrate-resistant acid phosphatase (TRACP) has been identified in both the ruffled border of the osteoclast membrane and the secretions in the resorptive space (Minkin, 1982). Six isoenzymes (Types 0–5) of acid phosphatase have been identified by electrophoresis of human tissues (Yam, 1974). Band 5 is expressed by osteoclasts, alveolar and monocyte-derived macrophages, and the placenta (Cheung *et al.,* 1995). On the basis of the catalytic and ionic properties and carbohydrate content, two isoenzymes of band 5 TRACP have been identified. Both band-5 acid phosphatases are resistant to tartrate inhibition. Band 5a TRACP is sialylated, whereas band 5b, which is predominant in bone, lacks sialic acid and pH optima of the two isoforms differ (Whitaker *et al.,*1989; Lam *et al.,* 1978, 1980; Schiele *et al.,* 1988).

TRACP activity in serum reflects bone resorption rates (Yam, 1974). However, difficulty in distinguishing the osteoclastic enzyme in serum from other tissue acid phosphatases and instability of the enzyme in serum have presented the greatest technical problems. TRACP activity in serum has been measured kinetically (Whitaker *et al.,*1989; Lam *et al.,* 1978, 1980; Schiele *et al.,* 1988; Lau *et al.,* 1987), and more recently by immunoassay (Cheung *et al.,* 1995; Kraezlin *et al.,* 1990; Halleen *et al.,* 2000), but these methods vary in specificity for the osteoclast-derived isoenzyme. Recent assays employed an antibody produced against TRACP from a bone extract. This method showed good correlation between immunoreactivity and enzyme activity, little cross-reaction with acid phosphatases from nonosteoclastic sources, and sensitivity to changes in bone turnover after 6 months of estrogen replacement therapy (Halleen *et al.,* 2000).

Bone Sialoprotein

Bone sialoprotein (BSP) is an acidic, phosphorylated glycoprotein that is synthesized by osteoblasts and osteoclastic-like cell in culture. It has an unglycosylated mass of 33 kDa (glycosylated: 70–80 kDa). Although the function of BSP is still not fully understood, BSP stimulates hydroxyapatite formation *in vitro* and appears to mediate cell–cell interactions via an integrin binding site (Chapter 17). BSP is relatively restricted to bone but it is also expressed by trophoblasts and is strongly upregulated by many tumors. Recently it has been suggested that BSP may play a role in angiogenesis associated with bone formation, tumor growth, and metastasis (Bellahcene *et al.,* 2000). A small amount of BSP is found in the circulation and as such is a potential marker of bone turnover (Seibel *et al.,* 1996).

Variability

Variability can have a serious impact on the clinical interpretation of levels of markers of bone turnover in metabolic bone disease, particularly in diseases such as osteoporosis where only subtle differences in markers are found. The analytical precision of both the manual and the automated assays is minimal. Thus the major component of variability is preanalytical variability. The sources of preanalytical variability can be considered to fall into broad categories: (1) uncontrollable sources such as age, gender, menopausal status, drugs, or recent fracture and (2) controllable sources such as circadian, menstrual, or exercise effects.

Uncontrollable Sources of Variability

Age and Gender

Levels of markers of bone turnover are highest in the first 2 years of life (Szulc *et al.,* 2000). They decrease during childhood but increase again during puberty to 4–10 times the adult level (Blumsohn *et al.,* 1994a) and then decrease to adult levels. The pattern of change in markers with age is different in men and women. The pubertal increase occurs later in boys than in girls and levels of markers do not reach a nadir until the fifth or sixth decade, after which they may increase slightly in eighth and ninth decades (Fatayerji and Eastell, 1999). In women, marker levels reach a nadir in the fourth and fifth decades and then increase rapidly (Garnero *et al.,* 1996a) at the menopause and remain elevated into the eighth and ninth decades. Mean concentrations of urinary telopeptides are up to 100% higher and serum telopeptides 55–70% higher in postmenopausal women than in premenopausal women, whereas bone formation markers are between 20 and 50% higher (Clemens *et al.,* 1997; Ravn *et al.,* 1996; Woitge *et al.,* 1996). However, there is considerable overlap between the two groups with only 25% of postmenopausal women having levels of markers above the premenopausal reference range (Garnero *et al.,* 1996b).

Ethnicity

There are no consistent differences in bone turnover markers in young blacks and whites (Henry and Eastell, 2000) although in peri- and postmenopausal women there is a trend for levels to be 5–15% lower in black women than in white women (Bikle *et al.,* 1999). In Asian women, uNTX tends to be higher than in white women, but bone formation markers are similar (Alekel *et al.,* 1999).

Oral contraception

Oral contraception may decrease bone turnover slightly in late premenopausal women but in general has little impact on the levels of bone turnover markers. In women ages 20 to 30 years uDPD and uPYD excretion is lowered (Paoletti *et al.,* 2000), while in women in the fifth decade there is a consistent 15–30% decrease in total bone turnover (Garnero *et al.,* 1995).

Fracture

Fracture healing has a significant effect on levels of markers of bone turnover. In the first and second week after fracture they increase rapidly and reach a peak within 8 weeks (Ingle *et al.,* 1999; Ohishi *et al.,* 1998). Markers of bone formation tend to increase more (20–55%) and remain elevated for longer (6–12 months) than markers of bone resorption (6 months).

Pregnancy

Large increases in markers of bone turnover are observed during pregnancy and lactation. Bone resorption, followed by bone formation, starts to increase in the second trimester. At term, urinary NTX-I, CTX-I and pyridinolines are two- to threefold higher than before pregnancy (Naylor *et al.,* 2000). Bone formation markers, with the exception of osteocalcin, are increased by 35–100% in the third trimester (Cross *et al.,* 1995; Naylor *et al.,* 2000; Rodin *et al.,* 1989). The lack of change in osteocalcin may be due to degradation by the placenta and the increase in renal function during pregnancy. Markers decrease gradually in the first 6 to 12 months postpartum in all mothers, but in lactating mothers the decrease is less rapid (Kent *et al.,* 1990; Yamaga *et al.,* 1996). Once lactation ceases, markers gradually return to the levels found in the nonlactating premenopausal women (Kalkwarf *et al.,* 1999).

Immobilization

Immobilization leads to an increase in bone resorption which is proportional to the degree of immobilization (Lips *et al.,* 1990). During complete bedrest, uNTX, uDPD, uPYD, and sCTX-MMP increase by 30–80%. The increase in bone resorption occurs rapidly: NTX-I is increased by up to 50% within the first week (Inoue *et al.,* 2000; Zerwekh *et al.,* 1998). During remobilization marker levels gradually return to normal.

Drugs and Diseases

Several types of drugs prescribed for conditions other than metabolic bone disease can substantially affect levels of biochemical markers of bone turnover. Corticosteroids suppress levels of markers of bone formation, particularly osteocalcin which may be depressed by 50% (Oikarinen *et al.,* 1992). Markers of bone resorption are generally unaffected (Ebeling *et al.,* 1998). Short-term high-dose heparin treatment and thiazide both supress bone turnover, osteocalcin being reduced by 40 and 25% respectively (Cantini *et al.,* 1995; Perry *et al.,* 1993). Anticonvulsant treatment leads to a threefold increase in urinary pyridinoline (Ohishi *et al.,* 1996).

Variability of markers of bone turnover may also be affected by concomitant diseases which affect the synthesis of nonosseous sources of markers and/or clearance of specific markers. For instance in liver disease, collagen-derived markers are increased, probably due to the increase in fibrotic tissue and impaired clearance of procollagens (Guanabens *et al.,* 1998); in renal impairment osteocalcin is increased due to decreased clearance by the kidney (Delmas *et al.,* 1983) and in rheumatoid arthritis increased levels of pyridinoline cross-links are derived from inflamed synovium and increased in degradation of cartilage (Gough *et al.,* 1994).

Controllable Sources of Variability

Circadian

Circadian variability probably has more impact on preanalytical variability of markers of bone turnover than any other factor. Both resorption and formation markers exhibit significant circadian rhythms increasing at night, reaching a peak between 01.30 and 08.00 and falling during the day to

a nadir in the afternoon (Blumsohn *et al.,* 1994b; Eastell *et al.,* 1992). The amplitude of the rhythm is greater for resorption markers than for formation markers. For serum CTX-I and urinary DPD the amplitude of the rhythm may be as much as 80% of the 24 hr mean, whereas for PICP and osteocalcin it is 5–20% of the 24-hr mean (Blumsohn *et al.,* 1994b; Greenspan *et al.,* 1997; Wichers *et al.,* 1999). The importance of precise timing of sample collection cannot be overemphasised. For example if urinary NTX-I is measured in samples collected at 07.00 and at 15.00, there will be a 50% difference which is comparable to the change in NTX-I expected after 6 months of HRT.

MENSTRUAL

The variation in levels of markers of bone turnover during the menstrual cycle is small, less than 20% (Gorai *et al.,* 1998), and may be regarded as insignificant.

SEASONAL

Woigte *et al.* (1998a, 2000a) have demonstrated that there is seasonal variability in markers of bone turnover of up to 12% with levels being 20% higher in winter than in summer. Seasonal changes depend on the latitude and possibly diet of the population (Rosen *et al.,* 1994).

EXERCISE

The effect of exercise on levels of bone markers depends on several factors including the age of the subject, the type and intensity of the exercise, and whether it is aerobic or anaerobic (Woitge *et al.,* 1998b). The acute effect of exercise may be to increase collagen turnover (PICP, CTX-MMP, and urinary pyridinolines) by up to 20% (Wallace *et al.,* 2000) either transiently or for as much as 72 hr depending on the type of exercise (Landberg *et al.,* 1999). Although it is difficult to define the precise effect of exercise on bone turnover it is advisable to that subjects do not exercise for 24 hr before samples are collected for the measurements of markers of bone turnover.

Within Subject Variability

In the interpretation of markers of bone turnover, within-subject variability should be kept to a minimum. Table IV summarizes the published data on the short (<8 weeks)- and long-term (>8 weeks) within-subject variability of markers of bone turnover. The greatest variability is found in the urinary markers of bone resorption. The variability of the newer serum markers of bone resorption is smaller and similar to that of the formation markers which are also measured in serum (Eastell *et al.,* 2000). It should be borne in mind that these values were derived from well controlled research studies and that in clinical practice within-subject variability will be greater. It should also be noted that published values for the variability of a marker depend on the subjects, the length of study and on the method of calculation of the coefficient of variation. Uncontrollable sources of variability can be accounted for by using the appropriate age- and gender-specific reference ranges and by using published data to account for other sources such as drugs and fracture healing. Controllable sources of variability can be minimized by standardizing the timing and conditions of sample collections. The within subject variability of markers can also be minimized by measuring multiple samples or by making a single measurement of pooled samples (Popp-Snijders *et al.,* 1996).

Clinical Use

Metabolic Bone Diseases

PAGET'S DISEASE OF BONE

Paget's disease of bone is the paradigm of high turnover skeletal disorders. The active disease is characterized by a brisk increase in both osteoblast and osteoclast function (see Chapter 71). Not surprisingly, changes in bone metabolic markers are usually very pronounced during active states. While the diagnosis of Paget's disease of bone and the extent of skeletal involvement is assessed primarily through radiographic analysis and bone scans, biochemical markers of bone metabolism are used to define the activity of the disease and its response to treatment.

Alkaline phosphatase activity is the classical biochemical marker of activity in Paget's disease of bone. Serum levels of both the total (total ALP) and bone-specific (bone ALP) enzymes are markedly increased in the active state, whereas normal or only slightly elevated levels may be seen in patients with mono-ostotic or inactive disease (Adami *et al.,* 1993; Alvarez *et al.,* 1995, 2000; Braga *et al.,* 1993; Deftos *et al.,* 1991; Duda *et al.,* 1988; Hyldstrup *et al.,* 1988; Garnero and Delmas, 1993; Moss, 1982, 1984a,b; Panigrahi *et al.,* 1994). Particularly high levels of serum bone ALP are typically seen in patients with involvement of the skull, and in rare cases of sarcomatous degeneration of Pagetic bone. In most cases, serum levels of both total and bone ALP are highly correlated with measurements of serum procollagen propeptides (but not of osteocalcin) and with the urinary concentrations of various bone resorption markers (Alvarez *et al.,* 1995; Deftos *et al.,* 1991; Hyldstrup *et al.,* 1988; Kaddam *et al.,* 1994; Torres *et al.,* 1989). These observations strongly indicate that even in the active stage of Paget's disease, coupling of anabolic and catabolic processes is still preserved.

Serial measurements of serum total or bone ALP may be employed to monitor the therapeutic response (Garnero and Delmas, 1993, Alvarez *et al.,* 1995, 2000; Woitge *et al.,* 2000) and also to detect a recrudescence of disease activity in the stable patient (Fig. 3). However, although posttherapeutic changes of bone ALP are somewhat more pronounced than those of total ALP, its longitudinal diagnostic sensitivity is rarely superior to that of total ALP.

Although osteocalcin is considered to be a specific osteoblast product, its serum concentrations are often low in pagetic patients, even if high levels of serum total or bone

Table IV Total within Subject Variability of Markers of Bone Turnover

Marker	Short-term CVti (%)	Study period	References	Long-term CVti (%)	Study period	References
Formation						
OC	6.5–12.7	1–4 Weeks	Jensen *et al.,* 1994[a]; Panteghini *et al.,* 1995[a]; Braga de Castro *et al.,* 1999	7.7–27.3	6–9 Months	Hannon *et al.,* 1998[b]; Gertz *et al.,* 1994

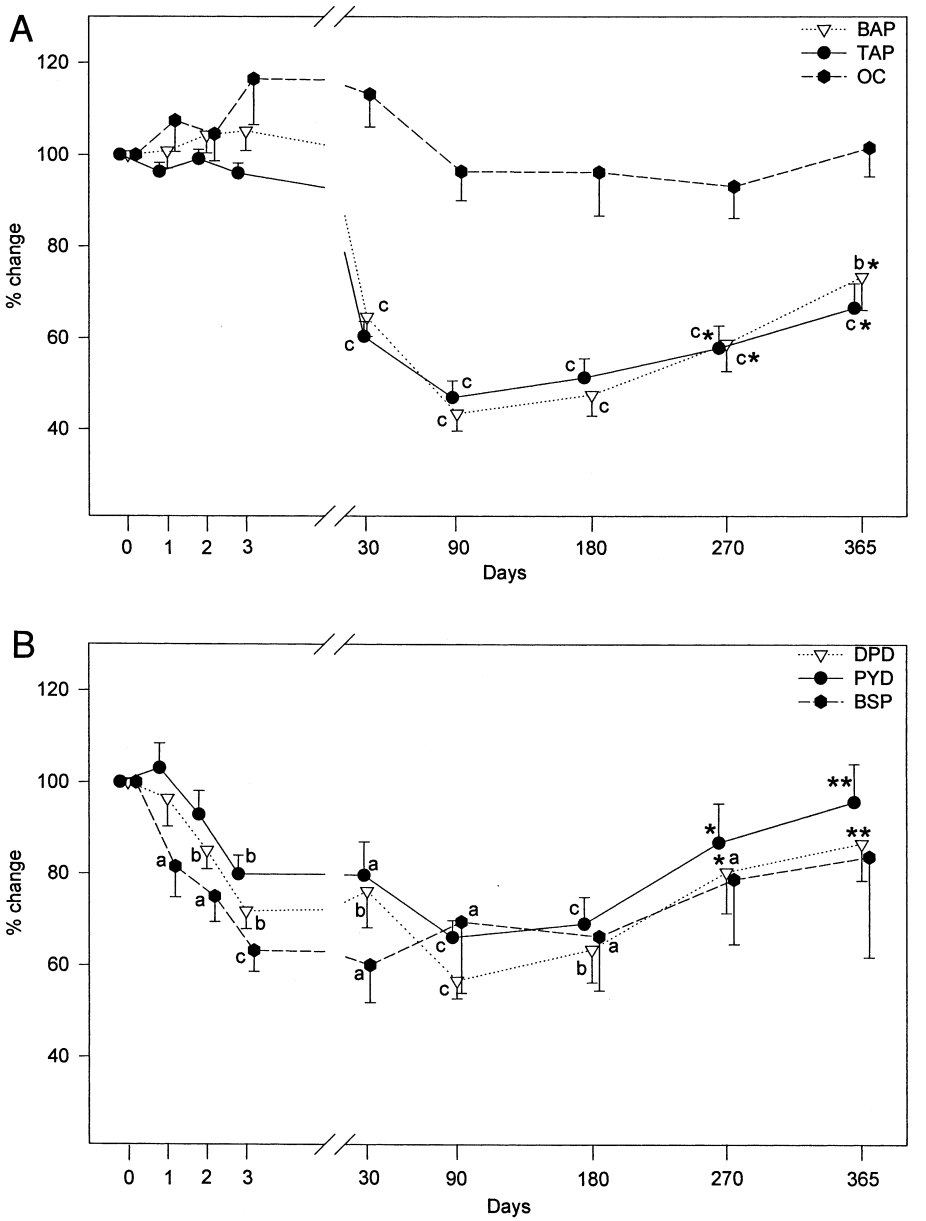

Figure 3 Effect of ibandronate treatment on markers of bone turnover in patients with Paget's disease of bone. Patients were treated with a single dose of 2 mg Ibandronate at day 0 and followed for 1 year. Results are mean ± SE. (A) Bone formation markers. Note that total ALP (TAP) and bone-specific ALP (BAP) show almost identical curves during the entire study period. (B) Bone resorption markers. Reprinted with permission from Woitge *et al.* (2000).

ALP, and urinary pyridinium cross-links are observed. Consequently, correlations of osteocalcin with other markers of bone formation or resorption are usually weak (Duda *et al.,* 1988; Ebeling *et al.,* 1992; Kaddam *et al.,* 1994; Papapoulos *et al.,* 1987), and unlike other markers of bone turnover, serum osteocalcin levels tend to rise after bisphosphonate treatment (Papapoulos *et al.,* 1987). Although the reasons for these discrepancies are currently not well understood, most authors seem to agree that osteocalcin measurements are of no particular value in Paget's disease of bone.

Serum levels of the carboxyterminal procollagen type I propeptide (PICP) are usually elevated in Paget's disease of bone. While earlier reports show changes in PICP concentrations comparable to those of serum total ALP (Simon *et al.,* 1984), newer studies utilizing different antibodies observed only minor variations in PICP levels with *Z* scores 15 times lower than those of serum bone ALP (Ebeling *et al.,* 1992). Interestingly, in the latter study, no changes are seen in the serum levels of the aminoterminal propeptide of procollagen type I (PINP), whereas in contrast, significantly elevated levels of the aminoterminal propeptide of type III procollagen (PIIINP) and declining levels following bisphosphonate treatment have been observed (Simon *et al.,* 1984).

Table V Factors Affecting the Serum Levels of Total Alkaline Phosphatase

Increase	Decrease	Increase or decrease
Somatic growth	Growth hormone deficiency	
Paget's disease of bone	Hypoparathyroidism	
Rickets and osteomalacia	Hypothyroidism	
Renal osteodystrophy	Familial or sporadic hypophosphatasemia	
Hyperparathyroidism (severe)	Achrondroplasia	
Thyrotoxicosis		
Acromegaly (active)		
Skeletal malignancies (osteosarcoma)		
Multiple myoloma		
Metastatic bone disease (osteoblastic)		
Osteogenesis imperfecta		
Fibrous dysplasia		
Familial hyperphosphatasemia		
Idiopathic hyperphosphatasemia		
Hyperostosis frontalis interna		
Recent fractures		
Age	Anemia (severe)	Race
Hepatic and biliary diseases, incl.		Diurnal rhythms
Hepatotoxicity and malignancies		Seasonal rhythms

Late pregnancy (placental AP)		
Treatment with	*Treatment with*	
Corticosteroids	Bisphosphonates	
Anticonvulsants	Calcitonin	
Fluorides	Estrogen	
Growth hormones		
Vitamin D_3		

In untreated patients with active Paget's disease of bone, a marked elevation is generally observed in the urinary excretion of pyridinium cross-links and cross-linked collagen telopeptides (Robins, 1982; Robins *et al.,* 1991, 1994; Woitge *et al.,* 1999) (Figs. 3 and 4). These changes are usually more pronounced than those seen with urinary Hyp, hydroxylysine glycosides, and serum TRACP (Colson *et al.,* 1990; Michalsky *et al.,* 1995; Patel *et al.,* 1995; Scarnecchia *et al.,* 1991), suggesting that the cross-link-related markers provide the most sensitive index of bone resorption in Paget's disease of bone. Longitudinal studies monitoring the effect of intravenous bisphosphonates on bone turnover in pagetic patients generally demonstrate a rapid decrease in the urinary excretion of cross-link components (Robins *et al.,* 1991; Knaus *et al.,* 1996; Woitge *et al.,* 2000) (Fig. 3). Bisphosphonate treatment appears to have more pronounced effects on the excretion of the cross-linked telopeptide (peptide-bound) components than on the peptide-free pyridinium derivates (Garnero *et al.,* 1995a). However, it is neither clear whether the differences between cross-link markers observed after bisphosphonate therapy are due to changes in skeletal or extraskeletal metabolism, nor whether these differences are indicative of the clinical sensitivity and usefulness of the various markers. (Woitge *et al.,* 1996; Woitge and Seibel, 1997). In contrast, much evidence has accrued that posttherapeutic changes in urinary Hyp, hydroxylysine glycosides, serum bone ALP, and TRACP occur either later or are less pronounced than those of the cross-link derivatives (Garnero *et al.,* 1995a; Knaus *et al.,* 1996; Robins *et al.,* 1994; Woitge *et al.,* 2000).

Serum total TRACP and the osteoblast-specific TRACP5b are both highly elevated in active Paget's disease of bone (Halleen *et al.,* 2000). Similarly, BSP is found in high concentrations in patients with active disease (Seibel *et al.,* 1996; Woitge *et al.,* 1999). After treatment with bisphosphonates, a rapid and sustained fall in sBSP levels is seen (Woitge *et al.,* 2000).

When the various biochemical markers of bone turnover are compared with regard to their discriminative power, serum total and bone ALP activities and the urinary pyridinoline cross-links appear to provide the most useful information (Alvarez *et al.,* 1995). However, as pagetic bone lesions

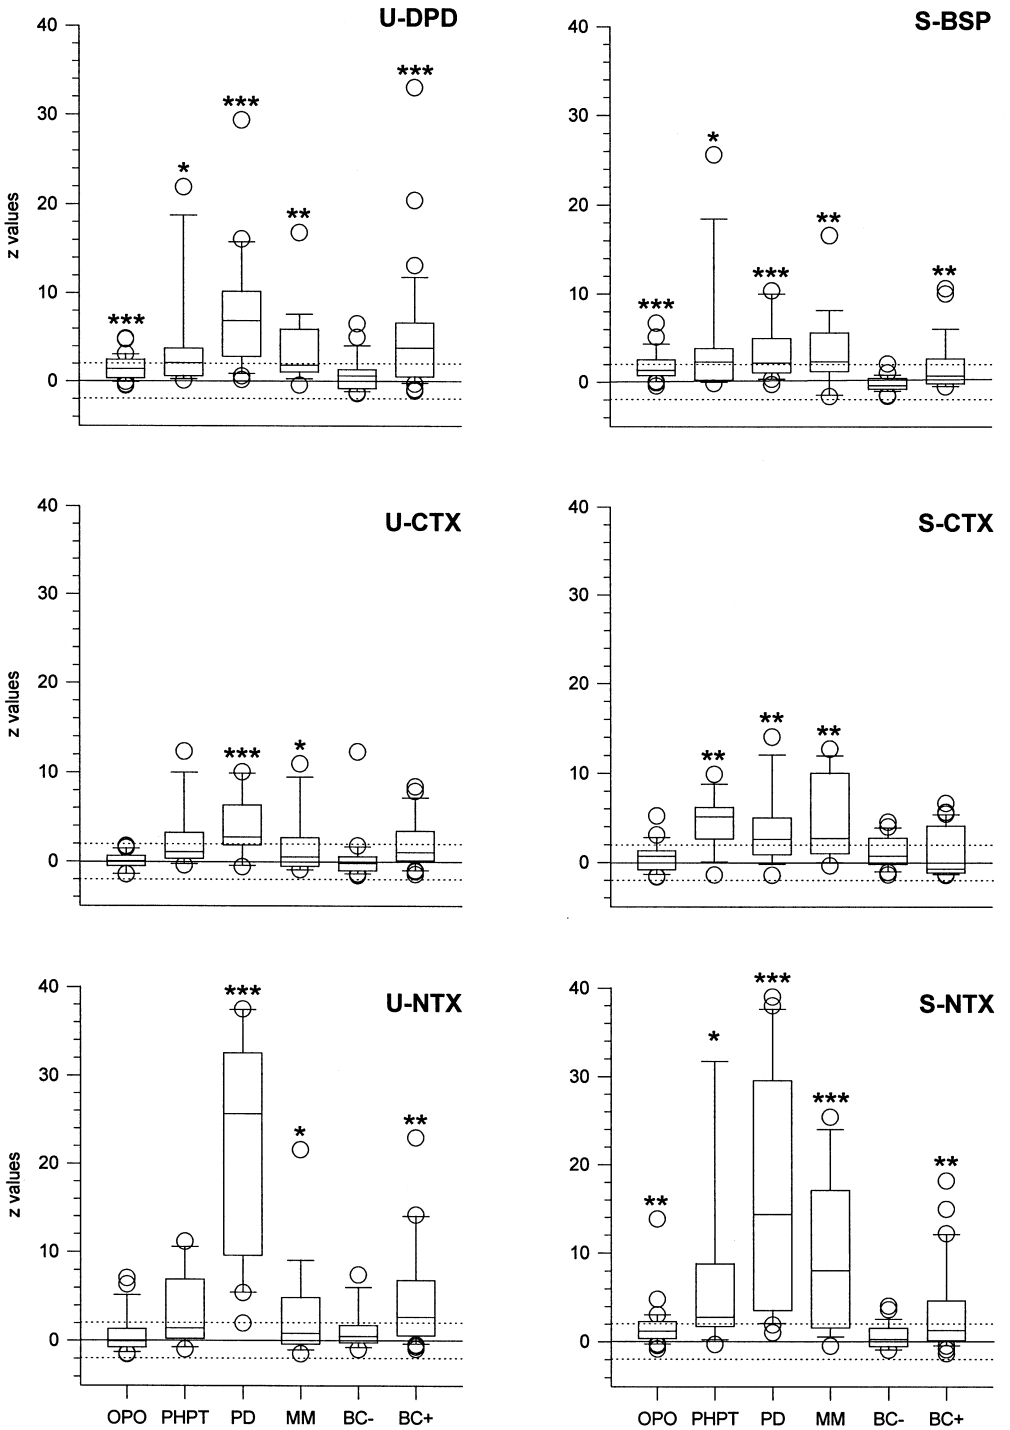

Figure 4 Serum and urinary markers of bone resorption in metabolic bone diseases. OPO, osteoporosis; PHPT, primary hyperparathyroidism; PD, Paget's disease of bone; MM, multiple myeloma; BC-, breast cancer without bone metastases; BC+, breast cancer with bone metastases. DPD, deoxypyridinoline; BSP, bone sialoprotein; CTX-I, C-terminal telopeptide of type I collagen; NTX-I, N-terminal telopeptide of type I collagen; S, serum; U, urine. Shown are box-and-wisker plots, where the horizontal line within the box represents the group median. Circles are individual values above and below the 95th percentile, respectively. All values are *z* values as compared to a healthy, age-matched population. The zero (solid) line represents the mean of the control group, the dotted lines the upper and lower limit of normal, respectively ($\pm$ 2 SD). Table VI Factors Affecting the Serum Levels of Osteocalcin

Increase	Decrease	Increase or decrease
Somatic growth	Growth hormone deficiency	Metastatic bone disease
Acromegaly	Hypoparathyroidism	Hypercalcemia of malignancy
Hyperparathyroidism	Hypothyroidism	Osteomalacia
Hyperthyroidism	Senile osteoporosis (intact OC)	Paget's disease of bone
Malignancies		Postmenopausal osteoporosis
Renal osteodystrophy		
Osteogenesis imperfecta		
Recent fractures		
Senile osteoporosis (undercarboxylated OC)		
Age beyond 50 years	Alcoholism	Race
Female sex	Anorexia nervosa	Diurnal rhythms
Chronic renal failure	Liver disease	Menstrual cycle
Exercise	Microprolactinoma	Seasonal rhythms
Lactation	Pregnancy	Osteoarthritis
Obesity		Rheumatoid arthritis
Treatment with	*Treatment with*	
Fluorides	Bisphosphonates	
Growth hormones	Calcitonin	
Thyroid hormones (TSH-suppressive)	Corticosteroids	
Vitamin D_3	Estrogen	
Anticonvulsants		

usually represent a severe perturbation of bone metabolism, the diagnosis does not require extremely sensitive methods. Metabolic changes might therefore be easily monitored by markers such as serum total ALP or urinary Hyp. At least in active Paget's disease of bone, most of the newer metabolic markers do not extend any particular benefit over the conventionally used indices.

Primary Hyperparathyroidism

Primary hyperparathyroidism (PHPT) is characterized by overproduction of parathyroid hormone which usually results in hypercalcemia, hypophosphatemia, and hypercalciuria. While in years past, PHPT was associated with gross bone involvement, symptomatic bone pain and significantly elevated levels of serum bone ALP, the clinical profile of the disorder has now changed toward a predominance of asymptomatic cases. Nonetheless, accelerated bone turnover and loss of predominantly cortical bone is seen in many patients with PHPT (Silverberg *et al.,* 1989; Cortet *et al.,* 2000).

In asymptomatic PHPT, serum total bone ALP is usually not significantly elevated, although in active disease, levels tend to be found in the upper third of the normal range (Silverberg *et al.,* 1995). In contrast, symptomatic patients often show elevated levels of both serum total bone ALP and osteocalcin (OC) (Minisola *et al.,* 1989). Both serum total bone ALP and OC correlate positively with serum calcium concentrations (Charles *et al.,* 1986; Hyldstrup *et al.,* 1988; Parfitt *et al.,* 1987; Yoneda *et al.,* 1986), other markers of bone formation and resorption (Arbault *et al.,* 1995; Minisola *et al.,* 1989; Stepan *et al.,* 1983; Torres *et al.,* 1989; Yoneda *et al.,* 1986), but inversively with bone mineral density measurements (Minisola *et al.,* 1989; Pfeilschifter *et al.,* 1992; Yoneda *et al.,* 1986). Following successful parathyroidectomy, serum concentrations of total bone ALP and OC usually decline within several weeks to months (Deftos *et al.,* 1982; Seibel *et al.,* 1992; Silverberg *et al.,* 1999).

Due to other sources such as the liver, serum total bone ALP is considered somewhat unspecific for bone. Efforts have therefore been made to develop assays for the measurement of the bone-specific isoenzyme of bone ALP. Among the numerous methods described, electrophoretic separation, lectin precipitation, and immunoassay techniques have now reached routine clinical applicability. So far, clinical studies have confirmed a higher specificity (i.e., a lower number of false positive results) for the bone-specific assays, but sensitivity seems to remain a controversial issue. While some studies found the bone-specific isoenzyme to be a more sensitive parameter of bone involvement than total bone ALP (Braga *et al.,* 1993; Garnero and Delmas, 1993), other reports found no improvement in the discrimination between normals and patients with PHPT (Stepan *et al.,* 1987a; Silverberg *et al.,* 1991; Woitge *et al.,* 1996; Woitge and Seibel, 1997). For clinical purposes, neither serum total or bone-specific bone ALP nor serum osteocalcin seems to possess distinct diagnostic value in PHPT, but serial measurements may be useful in the follow-up and monitoring of individual patients.

[e]Inversely correlated with stage of disease.
[f]Osteoblastic metastases.
[g]Osteolytic metastases.

The amino- and carboxyterminal propeptides of procollagen are considered markers of osteoblast activation and of skeletal collagen synthesis. Significant correlations with cancellous bone formation have been demonstrated for the carboxyterminal propeptide (Parfitt *et al.,* 1987), and at least the amino-terminal propeptide seems to be a useful marker of bone metabolism in PHPT (Ebeling *et al.,* 1992; Coen *et al.,* 1994; Minisola *et al.,* 1994).

As PTH is known to stimulate osteoclast activity indirectly, changes in bone resorption markers are to be expected. However, in most patients with asymptomatic or mild PHPT, urinary Hyp is normal or only slightly elevated (Hyldstrup *et al.,* 1984, Silverberg *et al.,* 1989; Seibel *et al.,* 1992). This observation can be largely attributed to the low specificity of Hyp to skeletal tissues. In contrast, urinary concentrations of the pyridinium cross-links of collagen, pyridinoline and deoxypyridinoline, are elevated in approximately two-thirds of patients with asymptomatic or mild PHPT (Seibel *et al.,* 1992; Silverberg *et al.,* 1999). For obvious reasons, the changes seen in these patients are of lesser magnitude than those observed in Paget's disease of bone, and the individual values tend to vary within a wide range (Robins *et al.,* 1991; Seibel *et al.,* 1992; Minisola *et al.,* 1997; Woitge *et al.,* 1999, 2000) (Fig. 4). This variation is explained, at least in part, by the fact that the urinary concentrations of PYD and DPD closely correlate with the disease activity. After successful parathyroidectomy, urinary levels of both cross-linked compounds fall quickly. These changes precede those of urinary Hyp and serum alkaline phosphatase by approximately 6 months. Pyridinium cross-links thus may be good markers for monitoring the postsurgical correction of elevated bone remodeling (Seibel *et al.,* 1992; LoCascio *et al.,* 1994; Guo *et al.,* 1996).

Total serum TRACP is often elevated in patients with PHPT (Kraenzlin *et al.,* 1990). A correlation with the extent of bone involvement (Stepan *et al.,* 1987a), other markers of bone metabolism (Scarnecchia *et al.,* 1991) and histomorphometric parameters of bone resorption (Colson *et al.,* 1990) has been described. Remarkably, elevated serum TRACP values decline to the normal range within days after successful parathyroidectomy, preceding changes in serum bone ALP or OC (Scarnecchia *et al.,* 1991; Stepan *et al.,* 1987a, de la Piedra *et al.,* 1994). More recently, osteoclast-specific TRACP5b has been studied and significantly elevated serum levels have been reported (Halleen *et al.,* 2000).

Although very few studies are presently available, serum BSP also seems to be a valid marker of bone turnover in patients with PHPT. In a cross-sectional study, serum BSP

levels were significantly elevated over normal, and a positive correlation was observed with both urinary PYD and DPD (Seibel *et al.,* 1996; Woitge *et al.,* 1999) (Fig. 4).

Postmenopausal and Senile Osteoporosis

In contrast to metabolic bone diseases such as Paget's disease and renal osteodystrophy, osteoporosis is a condition where subtle modifications of bone turnover can lead to a substantial loss of bone mass after a long period of time (Chapter 73). The slight abnormalities explain why most conventional markers, like serum total ALP and urinary hyp, are in the normal range in most patients with osteoporosis.

Prediction of Bone Loss A single measurement of bone mineral density can provide a useful estimate of fracture risk. However, besides bone mass level, bone loss is also regarded as a potential predictor of fracture risk (Kanis, 1994). Longitudinal studies of early postmenopausal women suggest that about 35% lose significant amounts of bone mineral rapidly (the so-called "fast losers"), whereas 65% lose bone mineral more slowly ("slow losers") (Christiansen *et al.,* 1987, 1990). The rate of bone loss in postmenopausal women may be assessed indirectly by the use of biochemical markers. Several studies have shown a sharp increase by about 30 to 100% of both formation and resorption markers at the menopause and a return to premenopausal levels after a few months of hormone replacement therapy (Christiansen *et al.,* 1985; Crilly *et al.,* 1980; Seibel *et al.,* 1993; Stepan *et al.,* 1987b). In addition, fast losers appear to have elevated concentrations of these markers compared to slow losers (Christiansen *et al.,* 1987, 1990; Dresner-Pollak *et al.,* 1996). These early studies mostly examined bone loss from the forearm and are in keeping with the results using recently developed markers to predict forearm bone loss over 4 years (Garnero *et al.,* 1999a). These new markers have similar predictive value for forearm, hip, and spine bone loss (Rogers *et al.,* 2000; Marcus *et al.,* 1999; Ross and Knowlton, 1998) (Fig. 5).

Despite these encouraging results, no consensus has been reached about whether biochemical markers provide a significant benefit in the context of identifying fast bone losers. First of all, more data are needed to show that fast losers identified soon after the menopause will remain fast losers. Hui *et al.,* (1990) found that bone mass measurements at the forearm showed poor correlations between rates of loss in sequential 5-year periods. In other words, the predictive relationship between biochemical measurements and the rate of bone loss could likewise vary with time (Blumsohn and Eastell, 1992). Furthermore, biochemical markers reflect the rate of turnover in the whole skeleton, instead of the turnover at a particular skeletal site. In fact, in the studies of Christiansen *et al.,* (Christiansen *et al.,* 1987, 1990; Hansen *et al.,* 1991), the panel of biochemical markers predicts bone loss only in the proximal forearm. Finally, the interpretation of biochemical markers clearly depends upon the timing of the sample with respect to the interval since menopause, since rates of loss are greatest in the immediate postmenopausal period. More long-term prospective studies are needed to assess the accuracy of biochemical markers in the prediction of bone loss at different skeletal sites.

Bone Turnover in Subjects with Osteoporotic Fractures In patients with untreated osteoporosis, biochemical markers of bone turnover may vary over a wide range of values and may often exceed the normal range. Despite the somewhat heterogenous results of the various assays for markers of bone turnover, most studies in postmenopausal osteoporotic women indicate a higher rate of both resorption and formation (Seibel *et al.,* 1993; Eastell *et al.,* 1993; Garnero *et al.,*

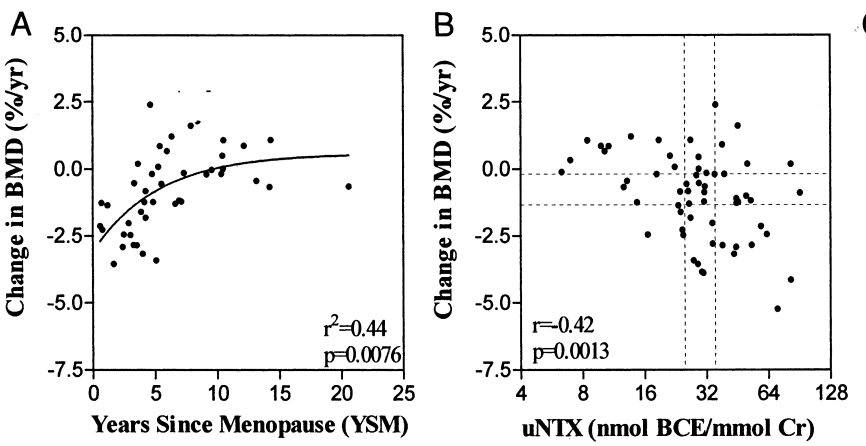

Figure 5 The relationship between change in bone mineral density of the spine and bone turnover. (A) Note how the bone loss is most rapid in the first 5 years after the menopause. (B) The higher the rate of bone resorption (measured by NTX-I in a second morning void urine sample and expressed as a ratio to creatinine) the greater the rate of bone loss. (C) The ability of bone resorption markers to classify individuals into tertile of bone loss is poor with a kappa score of less than 0.2, making this approach unsuitable for use in the individual. Adapted from Rogers *et al.* (2000).

1994a; Kushida *et al.,* 1995). Nevertheless, none of the currently available biochemical markers provides sufficient diagnostic information to be useful in the screening for the presence or likelihood of vertebral fractures (Seibel *et al.,* 1994).

In hip fracture patients studied immediately after the fracture occurred, resorption markers appear to be increased to a greater extent than formation markers (Akesson *et al.,* 1993, 1995a,b; Cheung *et al.,* 1995a), suggesting an imbalance between bone formation and bone resorption. It remains possible that this potential uncoupling of formation and resorption partly reflects the effect of age or also events associated with hip fracture. In postmenopausal women, Kelly *et al.* (1989) provided evidence for a decline in formation markers in elderly postmenopausal women, whereas resorption markers remain at the same level. The observed abnormalities in bone turnover in patients with vertebral and hip fractures may play a role in the decrease of bone mass and consequently the increased bone fragility that characterizes the osteoporotic fracture.

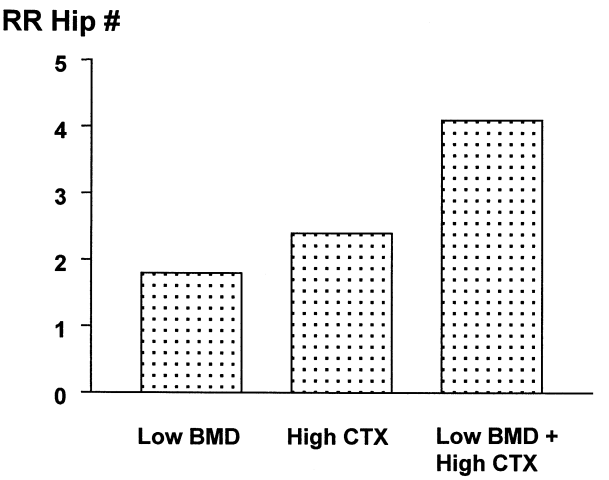

Figure 6 Predictive value of bone mineral density and bone turnover. The risk of hip fracture is higher in women with low hip bone mineral density ($T < -2.9$), high urinary CTX-I ($T > 2$), and even higher with both low bone mineral density ($T < -2.5$) and high urinary CTX-I ($T > 2$). Figure produced from data based on Garnero *et al.* (1998).

Prediction of Osteoporotic Fractures (Chapter 74) High rates of bone turnover may be associated not only with bone loss but also with a disruption of the trabecular network that gives bone its structural integrity. Loss of connectivity through disruption of the trabecular network is not necessarily reflected in a decrease of bone mass. In other words, biochemical markers may be independent predictors of fracture by providing insight into this qualitative feature of bone.

In a 12-year follow-up study, vertebral fractures occurred in those subjects with the highest rates of loss, as assessed by a panel of biochemical markers (Hansen *et al.,* 1991). In a prospective study (including 17 incident hip fractures), we obtained evidence that both urinary pyridinoline cross-links (as determined by HPLC) and free deoxypyridinoline (as determined by ELISA) are associated with an increased hip fracture risk (van Daele *et al.,* 1996). Similar results have been obtained in a larger prospective study of 120 elderly women who sustained a hip fracture during a 22-month follow-up study (Garnero *et al.,* 1996). In both studies, markers of formation (i.e., serum osteocalcin and bone alkaline phosphatase) were not associated with an increased hip fracture risk. However, in two recent studies high levels of bone alkaline phosphatase were associated with increased fracture risk (Ross *et al.,* 2000; Garnero *et al.,* 2000).

A different situation may be present in elderly subjects with osteoporosis. In this population, the effect of aging per se and possibly also a deficiency in vitamins K and D may lead to an impairment in the γ-carboxylation of osteocalcin and ultimately to an increase in the proportion of partially undercarboxylated circulating osteocalcin. Certain studies indicate that the proportion of undercarboxylated osteocalcin in serum may be an important determinant of femoral bone mineral density in elderly women, as high serum levels of undercarboxylated osteocalcin were associated with a low bone density at the hip and an increased risk of hip fractures (Szulc *et al.,* 1993).

Taken together, present evidence indicates that older individuals with increased bone resorption and perhaps increased bone formation are at increased risk of hip fracture. Indeed, the information is complementary to that provided by bone mass measurements. Thus, those women with high bone resorption and low bone density or low bone mineral density or ultrasound values are at high risk of hip fracture (Garnero *et al.,* 1998) (Fig. 6). These observations, together with the increasing rate of bone loss with age (Ensrud *et al.,* 1995; Jones *et al.,* 1994), provide a rationale for designing intervention strategies to reduce bone turnover in these elderly subjects to levels found in premenopausal women.

Selection and Follow-up of Treatment Biochemical markers may be helpful in choosing therapies that will yield the best results. A retrospective analysis of a group of elderly osteoporotic women treated with salmon calcitonin showed that the women with baseline high bone turnover had the best response to treatment in terms of an increase of bone mineral density (Civitelli *et al.,* 1988). Similar results have been obtained by other investigators (Garnero *et al.,* 1994b; Overgaard *et al.,* 1990; Ravn *et al.,* 1999). In fact, these results show that high bone turnover and consequently a larger remodeling space may permit a larger gain of bone mass in response to treatment with an antiresorptive agent. Nevertheless, the association is not sufficiently strong in the individual to predict who will have a good bone densitometric response to therapy.

Bone mass measurements are the accepted approach for monitoring treatment. Serial measurements can be used to identify patients who do not respond to treatment and may well improve their compliance with treatment. In addition, the larger the increase in bone mass at the hip, the greater the reduction in the risk of spine fracture (Hochberg *et al.,* 1999). However, the relatively small changes in bone mass

measurements observed in relation to their precision error precludes an effect of treatment to be observed after a short therapeutic period (Eastell, 1996). Furthermore, the spine is the most responsive site but it is often affected by degenerative changes especially in older individuals.

Biochemical markers have several properties that make them suitable for treatment monitoring. Significant changes in biochemical markers are usually seen within a few months of treatment. In response to hormone replacement therapy, changes of 50 to 100% have been reported, and in postmenopausal osteoporotic women, treatment with bisphosphonates led to decreased levels of most resorption and formation markers to a similar extent (Garnero *et al.,* 1994b; Braga de Castro *et al.,* 1999) (Fig. 7). Smaller changes in bone turnover markers have been reported for intranasal calcitonin (Chesnut *et al.,* 2000; Kraenzlin *et al.,* 1996) and for raloxifene (Delmas *et al.,* 1997). Therefore, despite biological variability of biochemical markers (see Chapter 93), the ratio of change to variability (the "signal-to-noise ratio") for the biochemical markers appears to be better at 3 to 6 months than at bone mass measurements made at 1 to 2 years.

There have been several methodological approaches to assessing the response to therapy. In the least significant change approach (Braga de Castro *et al.,* 1999; Hannon *et al.,* 1998; Rosen *et al.,* 1998) (Fig. 7), the variability of the marker is calculated as a coefficient of variation and this estimate is multiplied by a constant (2.77) to obtain the change (two-tailed) that can be considered significant (at $P = 0.05$) based on single measurements at baseline and follow-up. Changes less than this should be interpreted with caution; small decreases in bone markers may be subsequently followed by increases, the so-called "regression toward the mean" phenomenon (Cummings *et al.,* 2000). An alternative approach is to estimate the change in the marker that is associated with a 90% specificity of response as defined by bone density response (Garnero *et al.,* 1999b). This approach results in cutoffs that are similar to the least significant change approach, e.g., a decrease in bone alkaline phosphatase of 40%.

With respect to the response to antiresorptive agents, Garnero *et al.* [1995] showed that estrogens and bisphosphonates may affect the pattern of bone collagen degradation differently. Bisphosphonate treatment produced a marked decrease in the urinary excretion of high-molecular-weight ("peptide bound") collagen degradation products (e.g., the aminoterminal collagen type I telopeptide) without significant changes in the excretion of free pyridinolines. This behavior is in sharp contrast with the effects of estrogen therapy, which results in a decrease of both free and peptide-bound cross-links.

There have been no studies to examine the relationship between the change in bone turnover marker and the fracture risk during treatment with antiresorptive therapy. However, there are significant inverse relationships between the change in bone turnover markers and change in bone mineral density. When these relationships are examined in a population treated with a single dose of drug the correlation coefficient with spine and hip bone mineral density is in the order of 0.3 to 0.4 [Greenspan *et al.,* 1998]. This relatively low correlation is likely to be a consequence of the difficulty in measuring small change in bone mineral density.

Taken together, the correlation between the early changes in biochemical markers and the subsequent changes in bone mass suggest that markers of bone turnover are helpful in monitoring therapy. At present, the markers with the highest clinical utility are deoxypyridinoline measured by HPLC, the peptide-bound cross-links measured in urine or serum (for bone resorption), and serum bone-specific alkaline phosphatase and osteocalcin (for bone formation). Whether combinations of biochemical markers will add to the usefulness of single measurements remains to be elucidated.

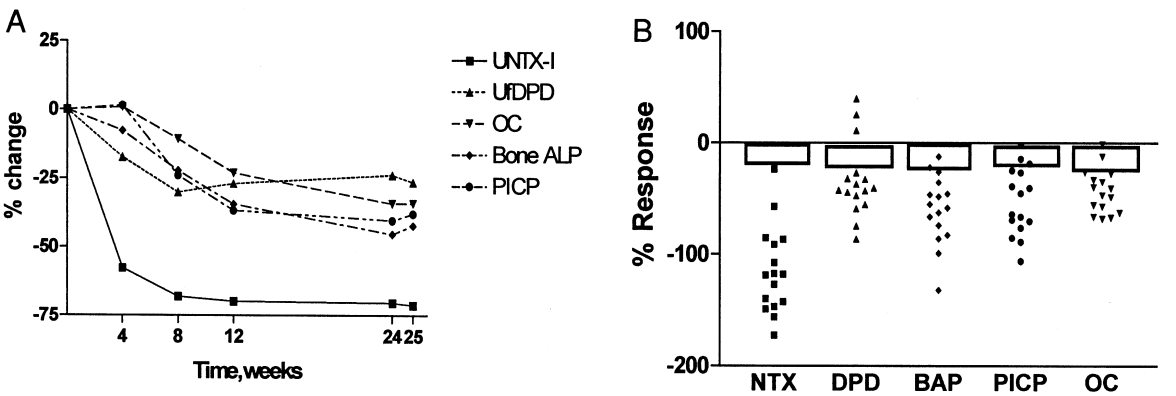

Figure 7 Effect of alendronate therapy on bone turnover markers over 6 Months. (A) Note how the bone resorption markers are suppressed within 4 to 8 Weeks of starting therapy; the decrease in bone formation markers is somewhat slower. (B) The boxes show the least significant change bounds for each marker. Note that most patients show a response to treatment at 6 months. Patients entering studies such as this are highly selected; in clinical practice, patients may have secondary osteoporosis that prevents them responding to therapy, or they may not comply with instructions. Adapted from Braga de Castro *et al.* (1999).

Changes in Bone Metabolism Induced by Immunosuppressive Agents

GLUCOCORTICOSTEROIDS

Prolonged administration of high-dose glucocorticosteroids (GCs) leads to bone loss (Chapter 41). Although the exact mechanisms of glucocorticoid-induced bone loss are still obscure, both osteoblast and osteoclast function are affected and an uncoupling of bone formation and resorption may be present.

It has been long appreciated that GCs inhibit osteoblastic collagen synthesis and matrix formation (Lukert and Raisz, 1990; Lukert *et al.,* 1986). This is usually reflected by a significant fall in serum OC, total and bone-specific ALP, and the procollagen propeptides (Ekenstam *et al.,* 1988; Prummel *et al.,* 1991; Reid *et al.,* 1986). Therefore, GCs appear to affect osteoblast function on several levels, including collagen synthesis, matrix maturation, and matrix mineralization. Other studies indicate that the inhibition of cellular mediators such as insulin-like growth factor 1 are of pivotal importance in GC-induced changes of bone cell function (Okazaki *et al.,* 1994).

In contrast to the changes seen in markers of bone formation, GC treatment can lead sometimes to rapid and persistent increments in bone resorption markers such as urinary pyridinium cross-links. Again, interference of GCs with osteoclast function and calcium metabolism seem to be rather complex and not well understood. Intestinal calcium absorption is usually inhibited, while renal calcium excretion may be greatly increased. The resulting, often transient, hypocalcemia possibly leads to secondary hyperparathyroidism, which in turn may be responsible for subsequent osteoclast activation (Libanati *et al.,* 1992). Additionally, GCs may exhibit direct effects on both PTH secretion and osteoclast function, leading to the observed changes in bone resorption. However, there is also now abundand evidence to argue against an important role for secondary hyperparathyroidism in GC-induced osteoporosis.

CYCLOSPORINES

Experimental and clinical investigations indicate that cyclosporines (CSs) and related immunosuppressants can also cause bone loss. In transplant recipients, CSs are rarely used as a single drug, so data from clinical studies are difficult to interpret. The complex but additive effects of diuretics, GCs, and CS on bone metabolism always have to be taken into account. Therefore, the most substantial data on the effect of CS alone on bone turnover are available from experimental studies.

Intravenous administration of cyclosporines A and G (CSA, CSG) to rats at doses comparable to those used in human transplant recipients leads to rapid bone loss (Movsowitz *et al.,* 1988; Schlosberg *et al.,* 1989). In these *in vivo* models, increased serum levels of calcitriol, osteocalcin, and alkaline phosphatase indicate stimulation of osteoblast function, whereas higher urinary concentrations of calcium, hydrodioxyproline, and pyridinium cross-links point also to enhanced bone resorption (Joffe *et al.,* 1992; Movsowitz *et al.,* 1988; Orcel *et al.,* 1989; Schlosberg *et al.,* 1989; Stein *et al.,* 1991). The latter effect may be attenuated by simultaneous administration of estrogens or calcitonin, suggesting that CS-induced *in vivo* bone resorption appears to be mediated by osteoclasts (Joffe *et al.,* 1992; Stein *et al.,* 1991). *In vitro,* CSA seems to inhibit not only osteoclast recruitment and maturation (Orcel *et al.,* 1991), but also basic and PTH-stimulated bone resorption (Stewart *et al.,* 1986, 1989). These observations indicate that the *in vivo* effects of CS on bone turnover may be mediated by and dependent on the function of immunocompetent cells and their specific mediators (Kahan, 1989; Stewart and Stern, 1989). Furthermore, direct effects of CS on renal and gonadal function (nephrotoxicity, hypogonadism) may also influence calcium balance and bone turnover.

Posttransplantation Bone Loss

Changes in bone metabolism following organ transplantation are complex. Preexisting diseases, the sequelae of long-standing hepatic, renal, cardiac, and/or pulmonary failure, immobilization, hypogonadism, and the (side) effects of various therapeutic agents may all have their own negative effects on bone metabolism. Changes in biochemical markers after organ transplantation are therefore influenced by a multitude of factors and do not indicate a specific etiological basis.

HEART TRANSPLANTATION

Prior to heart transplantation, bone mass is usually somewhat lower than normal, and accelerated bone turnover may be seen (Shane *et al.,* 1995). In these patients, elevated serum levels of osteocalcin and calcitriol seem to be associated with a higher risk of posttransplantation fractures, whereas hyperparathyroidism appears to act as a protective factor (Shane *et al.,* 1996).

The development of osteoporosis following heart transplantation has been recognized as a major problem (Shane *et al.,* 1996; Glendenning *et al.,* 1999; Leidig-Bruckner, 2001). Bone loss is most pronounced during the first 6 months after transplantation and may be as much as 20% from baseline (Shane and Epstein, 1994; Epstein *et al.,* 1995; Shane *et al.,* 1993; Valimaki *et al.,* 1999; Stempfle *et al.,* 1999). At this time, serum osteocalcin values are almost invariably suppressed, probably due to high doses of glucocorticosteroids given during the first months after transplantation. This suppression of osteoblast function is accompanied by a significant rise in the excretion of Hyp and pyridinium cross-links, which is usually attributed to the synergistic effects of glucocorticoids, cyclosporins, and diuretics, but also to the development of toxic kidney damage and hypogonadism (Stempfle *et al.,* 1995).

Approximately 6 months after transplantation and probably due to the reduction of oral glucocorticoids, serum osteocalcin and urinary cross-link concentrations return to baseline values, indicating normalization of bone turnover and the end of the high-risk period. Interestingly, an inverse correlation between serum osteocalcin levels and the rate of bone loss

has been reported for this time point (i.e., 6 months post-TPX), and serum osteocalcin levels were shown to be a predictor of the prospective bone loss at the lumbar spine of these patients (Sambrook *et al.,* 1994a,b). Given these and other observations, measurements of serum osteocalcin appear to be of some clinical relevance in the management and follow-up of cardiac transplant recipients. However, one should be aware of the fact that in some patients, a rise in serum osteocalcin levels may reflect the development of cyclosporine-associated renal insufficiency rather than normalization of bone turnover.

KIDNEY TRANSPLANTATION

All patients with long-standing renal failure show more or less pronounced signs of skeletal involvement, the most common being secondary hyperparathyroidism, osteomalacia, osteoporosis and adynamic bone pathology (for review, see Hruska and Teitelbaum, 1995). In these patients, biochemical markers of bone metabolism may vary considerably, depending on renal function, type of bone involvement, and treatment. Serum calcium levels are usually low, but may increase with the use of calcitriol. Alkaline phosphatase activities are high in secondary hyperparathyroidism and osteomalacia, but may be low in adynamic bone disease or aluminum intoxication. Serum osteocalcin levels are almost always elevated due to the accumulation of osteocalcin fragments detected in most assays. Therefore, serum osteocalcin is not a valuable marker of bone formation in patients with renal failure (Gundberg and Weinstein, 1986). The urinary excretion of PYD and DPD decrease below a glomular filtration rate of 25 ml/min. Anuric patients usually show greatly elevated serum concentrations of both free and peptide-bound cross-link components (Urena *et al.,* 1994).

Following renal transplantation, most patients sustain bone loss, although changes are usually not as pronounced as in cardiac or hepatic transplantation. The biochemical profile is often variable (Reusz *et al.,* 2000). Immediately after transplantation, most patients exhibit a dramatic fall in serum osteocalcin values, which may in fact decrease to subnormal levels. This observation is obviously not explained by the mere improvement of peptide clearance, but rather probably reflects the deleterious effects of glucocorticoids on bone formation. A suppression of osteoblast activity may also result in a transient decrease of serum alkaline phosphatase activity (Boiskin *et al.,* 1989; Julian *et al.,* 1991; Schmidt *et al.,* 1989). However, persistent elevations of the enzyme have been reported after transplantation, possibly due to the stimulating effects of cyclosporine (Loertscher *et al.,* 1983; Withold *et al.,* 1995). In most patients, a slow rise in the urinary excretion of pyridinium cross-links reflects increased bone resorption. As in cardiac patients, serum OC levels tend to return to the normal range within 6 to 12 months after transplantation (Boiskin *et al.,* 1989; Schmidt *et al.,* 1989). In some patients, an increase in parathyroid hormone or procollagen type I propeptide may be observed several months after renal transplantation (Degenhardt *et al.,* 1995; Schmidt *et al.,* 1989).

Metastatic Bone Disease

The occurrence of bone metastases is usually associated with a profound disruption in skeletal equilibrium and an uncoupling of bone formation and resorption processes (see Chapters 60 and 61). While widespread metastatic disease is difficult to treat, antiresorptive agents such as bisphosphonates may be helpful during earlier stages of skeletal involvement. Early diagnosis and monitoring of bone metastases are therefore of major clinical and therapeutic importance.

The diagnostic workup of the patient with suspected bone metastases usually includes bone scanning and radiographic evaluation, biochemical, and sometimes histological techniques. Although serological tumor markers such as CEA, PSA, or CA 15-3 are valuable tools in monitoring the course of primary and secondary malignancies, they do not reflect the changes in skeletal metabolism associated with the occurrence of bone metastases. This aspect of malignant bone disease may be revealed by the use of biochemical markers of bone metabolism (for current review, see Demers *et al.,* 2000).

Depending on the extent and the progression of the lesion, osteoblastic bone metastases of primary breast or prostate cancer are often associated with more or less pronounced changes in serum total and/or bone ALP (Epstein, 1988; Francini *et al.,* 1990). During early stages, when bone formation and bone resorption are still coupled to each other, a correlation between serum total and bone ALP and other markers of bone formation (OC, PINP) or of bone resorption (urinary calcium or Hyp) is occasionally observed (Blomqvist *et al.,* 1987). In breast cancer, local progression of bone metastases appears to be assessed more accurately by monitoring serum total ALP than by CEA or CA 15-3 (Francini *et al.,* 1990). In hypercalcemia of malignancy (HOM), however, serum total ALP and urinary Hyp excretion may diverge, thus reflecting an uncoupling of bone formation and resorption (Torres *et al.,* 1989). If the lytic component predominates, a dissociation even between formation markers such as bone ALP and OC may be observed (Duda *et al.,* 1988). This deviation is usually attributed to the fact that OC is associated with mineralization processes, whereas serum bone ALP is considered to reflect the synthesis and maturation of the organic matrix itself. In these cases, normal serum bone ALP levels may be misinterpreted as a sign of intact bone metabolism.

Normocalcemic patients with metastatic osteopathy often show elevated serum OC levels (Slovik *et al.,* 1984; Stracke *et al.,* 1985). However, with the development of hypercalcemia due to skeletal metastases, osteocalcin values may decrease into or below the lower range of normal (de la Piedra *et al.,* 1987; Torres *et al.,* 1989). In humoral hypercalcemia of malignancy, variable serum OC levels are seen (Body *et al.,* 1986). Interestingly, metastastic spread to bone appears to be associated with a loss of otherwise detectable correlations between serum OC and other markers of bone turnover (Carlson *et al.,* 1992; de la Piedra *et al.,* 1987; Duda *et al.,* 1988; Torres *et al.,* 1989). In contrast, soft-tissue metastases

apparently have no influence on serum OC whatsoever (Stracke *et al.,* 1985).

A reduction in serum OC values is usually seen after chemotherapy (Slovik *et al.,* 1984) and in hypercalcemic patients following bisphosphonate treatment (Body *et al.,* 1986). Serum OC may therefore be used for therapeutic monitoring.

In multiple myeloma, osteoblast-inhibiting factors and low rates of bone formation are detectable in about 80% of all patients (Evans *et al.,* 1989), while the remaining 20% show biochemical signs of accelerated bone turnover. Interestingly, an inverse correlation between serum OC levels and the disease stage (Durie-Salmon) has been shown in patients with multiple myeloma, a low serum OC typically being associated with a significantly shorter survival time. Also, patients with hypercalcemia due to extensive osteolytic lesions exhibit lower OC levels than the total population of hypercalcemic myeloma patients (Bataille *et al.,* 1987). Following chemotherapy-induced remission of the disease, serum OC values generally tend to return to the normal range (Carlson *et al.,* 1992). Thus, serum OC appears to have greater prognostic value than conventional markers such as hemoglobin, β2-microglobulin, and lactate dehydrogenase (Carlson *et al.,* 1992).

In normocalcemic patients with metastatic breast cancer, a close correlation between serum levels of the aminoterminal propeptide of type III procollagen (NPIIIP, a marker of collagen synthesis in connective tissues), total ALP, OC, and urinary Hyp has been described (Blomqvist *et al.,* 1987). Serum NPIIIP appears to be a sensitive marker that accurately reflects therapeutically induced remission of skeletal metastases. This high sensitivity of NPIIIP may be due to the fact that the metastatic process originates in the bone marrow (which is rich in type III collagen) and only later spreads to mineralized bone.

Tumor-induced release of calcium from mineralized tissues is usually compensated by an increased renal excretion, and hypercalciuria is a feature often seen in patients with metastatic spread to bone. However, one should bear in mind that the urinary excretion of calcium is also influenced by renal function and by dietary intake. In most tumor patients, calciuria does not correlate well with other markers of bone resorption or of bone formation (Blomqvist *et al.,* 1987; Coombes *et al.,* 1983). However, at comparable serum calcium levels, patients with breast cancer and skeletal metastates show significantly higher urinary calcium concentrations than women in whom the malignant disease is restricted to soft tissues only. Although under certain conditions hypercalciuria may precede radiographic detection of osteolytic lesions, no relationship is generally observed with the extent of skeletal involvement (Campbell *et al.,* 1983). Following bisphosphonate therapy, a significant decrease in hypercalciuria is associated with a normalization of initially increased erosion surfaces and reduced trabecular volume (Body and Delmas, 1992; Clarke *et al.,* 1992).

In general, urinary calcium excretion appears to be a sensitive but nonspecific marker of skeletal metabolism. Nonetheless, its role in the therapeutic monitoring and clinical follow-up of metastatic bone disease is undisputed. It should be noted, however, that in addition to the factors mentioned earlier, urinary calcium excretion in tumor patients may be influenced by tumor-induced mediators such as parathyroid hormone-related peptide. Paraneoplastic phenomena of this kind could also explain the discrepancy observed between the excretion of calcium and hydroxypyridinium crosslinks in humoral hypercalcemia of malignancy (Body and Delmas, 1992).

The urinary excretion of Hyp is significantly higher in breast cancer with overt metastatic bone disease than in subjects with tumors that have not metastasized (Powles *et al.,* 1976). At the same time, urinary Hyp seems to be a sensitive marker to predict the therapeutic response to antineoplastic therapy (Blomqvist *et al.,* 1987). In prostate cancer metastatic to bone, a rapid fall in urinary Hyp values is usually seen during biphosphonate treatment (Clarke *et al.,* 1992). Patients with hypercalcemia of malignancy have consistently elevated urinary Hyp concentrations (Blomqvist *et al.,* 1987).

The urinary excretion of pyridinium cross-links is increased in approximately 80–90% of all tumor patients with bone metastases (Paterson *et al.,* 1991; Body and Delmas, 1992; Coleman *et al.,* 1992; Pecherstorfer *et al.,* 1995) (Fig. 8). Furthermore, preliminary data suggest that cross-link excretion may rise even before skeletal metastases are evident by conventional imaging techniques (Paterson *et al.,* 1991; Pecherstorfer *et al.,* 1995). However, given the high sensitivity of pyridinium cross-links for collagen breakdown, systemic effects of tumor growth on bone metabolism and humoral PTHrP-mediated bone resorption may contribute to elevated urinary cross-link concentrations without evidence of skeletal involvement (Pecherstorfer *et al.,* 1995). Serum CTX-MMP, a high-molecular-weight component released during collagen breakdown, has also been shown to be a sensitive marker of osteolytic bone destruction in multiple myeloma, and appears to predict disease progression independently from immunoglobulin production (Risteli and Risteli, 1999; Horiguchi *et al.,* 2000).

Following intravenous bisphosphonate treatment of hypercalcemic patients, regression of hypercalciuria (Coleman *et al.,* 1992) and elevated Hyp excretion (Body and Delmas, 1992) appear to be more pronounced than the decrease in hydroxypyridinium cross-links. Interestingly, in our own experience, a renewed increase in urinary cross-links is observed only 10–14 days after pamidronate therapy. No correlation is detectable between calcium and cross-link excretion (Coleman *et al.,* 1992; Pecherstorfer *et al.,* 1995), a finding that again suggests that demineralization and destruction of the intercellular matrix are distinct processes in the course of skeletal metastases. Local radiotherapy of painful lesions leads to a reduction in bone resorption markers (Hoskin *et al.,* 2000).

Compared to healthy subjects or tumor patients at the premetastatic stage, patients with bone metastases usually show elevated serum TRACP levels (Scarnecchia *et al.,* 1991; Tavassoli *et al.,* 1980; Wada *et al.,* 1999), which respond to

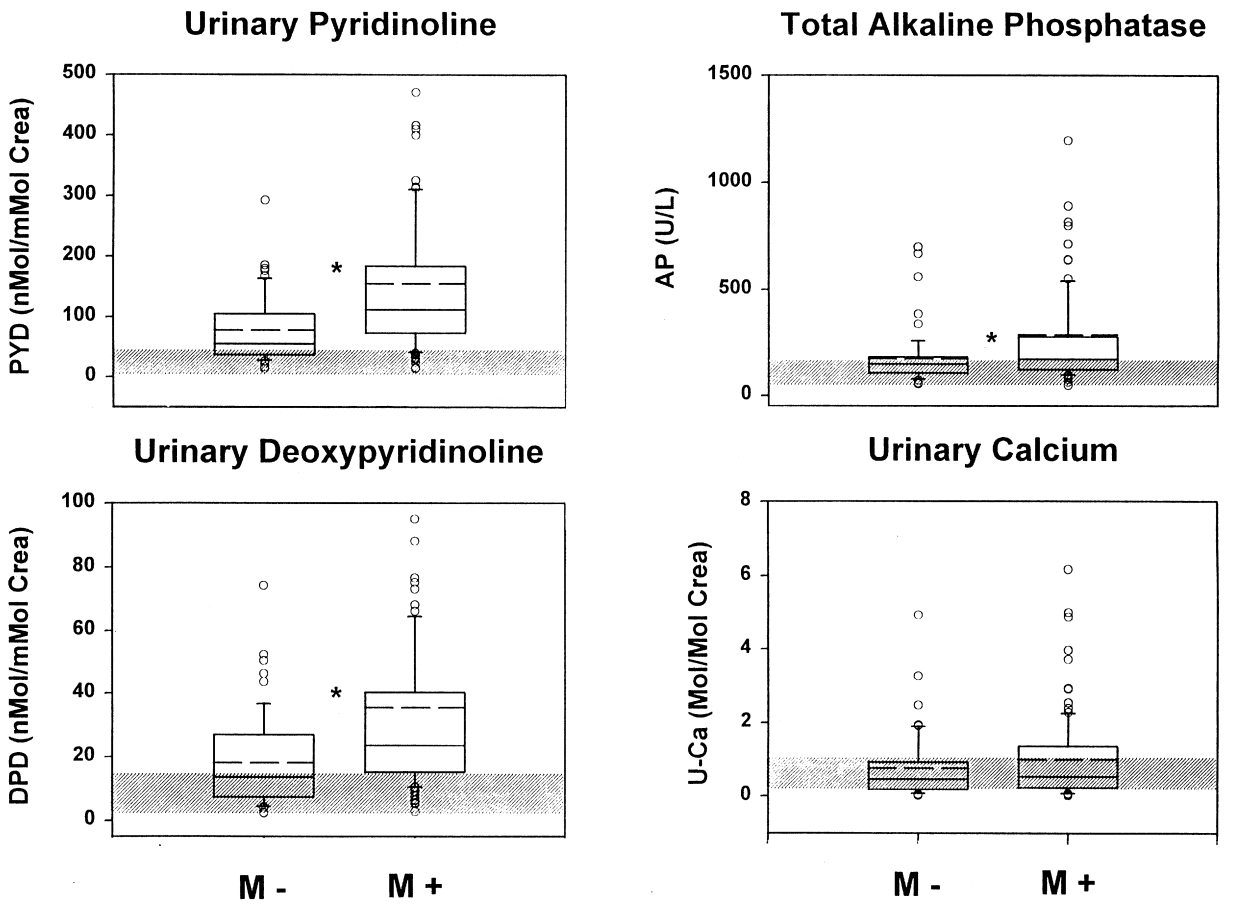

Figure 8 Markers of bone turnover in metastatic bone disease. Urinary pyridinium cross-links, calcium and serum alkaline phosphatase in tumor patients with (M+) and without (M−) skeletal metastases. The shaded area indicates the normal range. Reprinted with permission from Pecherstorfer *et al.* (1995).

bisphosphonate treatment (Lau *et al.,* 1987). Differentiation of serum total acid phosphatases can be of particular interest in patients with metastatic prostate cancer: while the fraction sensitive to tartrate inhibition is produced by the tumor itself, elevated serum levels of tartrate-resistant acid phosphatase are of skeletal origin and indicate the presence of osteoclast activation (Tavassoli *et al.,* 1980).

Serum bone sialoprotein (BSP) are significantly increased in patients with metastatic bone disease compared ot healthy controls (Seibel *et al.,* 1996; Karmatschek *et al.,* 1997; Woitge *et al.,*1999) (Fig. 2). Also, serum BSP has also been shown to be a strong indicator of future metastases in breast cancer patients (Diel *et al.,* 1999).

In summary, biochemical markers of bone turnover may be useful tools in the diagnosis, monitoring, and follow-up of malignant diseases and their metastatic spread to bone. Markers of bone resorption appear to be of greater clinical value than formation markers, as they reflect the destructive behavior of invasive skeletal metastases. Presently, most clinical experience is available for urinary Hyp, which generally allows a relatively accurate assessment of osteolytic activity. However, the development of convenient immunoassays for the determination of pyridinium cross-links is likely to supplant Hyp in the foreseeable future, as they have for other clinical uses of bone marker.

Acknowledgment

M. J. S. thanks Mrs. Beatrice van der Velden for excellent editorial help with the manuscript.

CHAPTER 91

Methods and Clinical Issues in Bone Densitometry and Quantitative Ultrasonometry

Glen M. Blake and Ignac Fogelman
Department of Nuclear Medicine, Guy's Hospital, London SE1 9RT, United Kingdom

Introduction

Measurement of bone mineral density (BMD) has become an essential element in the evaluation of patients at risk for osteoporosis (Kanis *et al.,* 1997). Growing awareness of the impact of osteoporosis on the elderly population (Jacobson *et al.,* 1992; Koval *et al.,* 1995) and the consequent costs of healthcare (Ray *et al.,* 1997), together with the development of new treatments to prevent fractures (Black *et al.,* 1996; Cummings *et al.,* 1998; Ettinger *et al.,* 1999; Reginster *et al.,* 2000), have led to a rapid increase in the demand for bone densitometry services. Since its introduction in 1987, dual X-ray absorptiometry (DXA) has become the measurement technique most associated with the rapid growth in the clinical applications of bone densitometry (Genant *et al.,* 1996; Blake and Fogelman, 1997a). With its high precision, DXA is well suited to be used in the diagnosis of osteoporosis, to aid decisions about treatment and to monitor patients.

The Definition of Osteoporosis

In the early 1990s, a Consensus Meeting defined osteoporosis as "a systemic skeletal disease characterized by low bone mass and microarchitectural deterioration of bone tissue, with a consequent increase in bone fragility and susceptibility to fracture" (Consensus Development Conference, 1993). It should be noted that this definition does not require an individual to have sustained a fracture before a diagnosis of osteoporosis is made, but introduces the concept of low bone mass and its relationship to increased fracture risk. While it could be argued that it is wrong to define a disease on the basis of what is essentially a risk factor, i.e., low bone density, there is nevertheless some logic to this as fractures tend to occur late in the disease process, when skeletal integrity is already severely compromised. It is therefore desirable to identify those individuals at high risk with a view to instituting treatment to prevent fractures from occurring.

Today, there is general agreement that BMD measurements are the most effective way of identifying these patients. Indeed, the widespread availability of bone densitometry systems has led to working definitions of osteoporosis that are increasingly based on measurements of BMD. In particular, in 1994 a World Health Organization (WHO) Study Group recommended a clinical definition of osteoporosis based on expressing BMD measurements in standard deviation (SD) units called *T* scores (WHO, 1994; Kanis *et al.,* 1994). The *T* score is calculated by taking the difference between a patient's measured BMD and the mean BMD of healthy young adults matched for gender and ethnic group, and expressing the difference relative to the young adult population SD:

$$T\ \text{score} = \frac{\text{measured BMD} - \text{young adult mean BMD}}{\text{young adult standard deviation}}. \quad [1]$$

A *T* score result therefore indicates the difference between the patient's BMD and the ideal peak bone mass achieved by a young adult.

Table I The WHO Study Group Recommendations for the Definitions of Osteoporosis and Osteopenia (WHO, 1994; Kanis *et al.,* 1994)

Terminology	*T* Score definition
Normal	$T \geq -1.0$
Osteopenia	$-2.5 < T < -1.0$
Osteoporosis	$T \leq -2.5$
Established osteoporosis	$T \leq -2.5$ in the presence of one or more fragility fractures

The WHO report recommended that a woman should be classified as having osteoporosis if she has a *T* score ≤ -2.5 (Table I). An intermediate state of low bone mass (osteopenia) was also proposed, defined by a *T* score between -2.5 and -1. A *T* score ≥ -1 was taken to be normal. Finally, a fourth state, established osteoporosis, denoted osteoporosis as defined above, but in the presence of one or more fragility fractures.

The WHO classification of BMD measurements to show osteoporosis, osteopenia, or normal skeletal status was intended to identify patients with high, intermediate, and low risk of fracture, respectively. However, it is important to recognize that the specific *T* score thresholds listed in Table I refer only to X-ray absorptiometry measurements of the spine, hip, or forearm. As will be discussed later, these definitions cannot automatically be applied to other BMD measurement sites, or to other methodologies such as quantitative computed tomography or quantitative ultrasonometry, without careful evaluation.

The rationale for the WHO definition of osteoporosis is that it captures around 30% of all white postmenopausal women, a figure that approximates to the lifetime risk of fracture for a 50-year-old woman. In comparison, it can be argued that the WHO definition of osteopenia captures too high a percentage of women to be clinically useful, and nowadays this term is being used less often, particularly in the context of therapeutic decision making. In contrast, the WHO definition of osteoporosis has had a major influence on clinical practice, to the extent that if the question is: "Does this patient have osteoporosis, yes or no?", this is now regarded as a *T* score issue.

Alongside the *T* score, another useful way of expressing BMD measurements is in *Z* score units (Blake and Fogelman, 1997b). Like the *T* score, the *Z* score is expressed in units of the population SD. However, instead of comparing the patient's BMD with the young adult mean, it is compared with the mean BMD expected for a healthy normal subject matched for age, gender, and ethnic origin:

$$Z \text{ score} = \frac{\text{measured BMD} - \text{age-matched mean BMD}}{\text{age-matched standard deviation}}. \quad [2]$$

Although not as widely used as *T* scores, the *Z* score nevertheless remains a useful concept because it expresses the patient's risk of sustaining an osteoporotic fracture relative to their peers. Typically, every reduction of 1 SD in BMD equates to an approximately twofold increase in the likelihood of fracture (Marshall *et al.,* 1996). It follows that patients with a *Z* score <-1 are at a significantly increased risk of fracture compared with individuals with a normal bone density for their age.

Techniques Available for Bone Densitometry Studies

Table II lists the methods currently available for the noninvasive assessment of the skeleton for the diagnosis of osteoporosis and/or the evaluation of an increased risk of fracture. These include dual X-ray absorptiometry (DXA), spinal quantitative computed tomography (QCT), peripheral DXA (pDXA), peripheral QCT (pQCT), radiographic absorptiometry (RA), and quantitative ultrasonometry (QUS). These techniques differ substantially in physical principles, in clinical discrimination and utility, and in general availability and cost. Each is reviewed briefly below. The reader can find further information about these techniques in several comprehensive reviews (Cann, 1988; Genant *et al.,* 1996; Grampp *et al.,* 1997; Glüer *et al.,* 1997; Blake *et al.,* 1999; Njeh *et al.,* 1999a).

Dual X-ray Absorptiometry

Over the past decade, DXA has established itself as the most widely used method of measuring BMD because of its advantages of high precision, short scan times, low radiation dose and stable calibration. DXA equipment (Fig. 1) allows scanning of the spine (Fig. 2A) and hip (Fig. 2B), usually regarded as the most important measurement sites because they are frequent sites of fractures that cause substantial impairment of quality of life, morbidity, and mortality. A measurement of hip BMD has been shown to be the most reliable way of evaluating the risk of hip fracture (Cummings *et al.,* 1993; Marshall *et al.,* 1996; Black *et al.,* 2000). Also, because of the metabolically active trabecular bone in the vertebral bodies, the spine is regarded as the optimum site for monitoring response to treatment (Eastell, 1998).

The fundamental principle behind DXA is the measurement of the transmission through the body of X-rays of two different photon energies. Because of the dependence of the attenuation coefficient on atomic number and photon energy, measurement of the transmission factors at two energies enables the "areal" densities (i.e., the mass per unit projected area) of two different types of tissue to be inferred (Blake and Fogelman, 1997a). In DXA scans these are taken to be bone mineral (hydroxyapatite) and soft tissue, respectively. Radiation dose to the patient is very low (1 to 10 μSv) (Njeh *et al.,* 1999b) and is comparable to the average daily dose from natural background radiation of 7 μSv.

Table II Characteristics of Different Bone Densitometry Techniques

Technique[a]	Regions of interest	Units reported	Precision (%CV)	Effective dose (μSv)
DXA	PA spine	BMD (g/cm^2)	1	1–10
	Proximal femur		1–2	1–10
	Total body		1	3
QCT	Spine	BMD (g/cm^3)	3	50–500
pDXA	Forearm	BMD (g/cm^2)	1–2	0.1
	Calcaneus		1–2	0.1
pQCT	Forearm	BMD (g/cm^3)	1–2	1–3
RA	Phalanx	BMD (g/cm^2)	1–2	10
QUS	Calcaneus	BUA (dB/MHz)	2–5	None
	Calcaneus	SOS (m/s)	0.1–1	None
	Tibia	SOS (m/s)	1–2	None
	Multi-site	SOS (m/s)	1–2	None

Note. [a] DXA, dual-energy X-ray absorptiometry; QCT, quantitative computed tomography; pDXA, peripheral pDXA; QCT, peripheral QCT; RA, radiographic absorptiometry; QUS, quantitative ultrasonometry.

It is widely recognized that the accuracy of DXA scans is limited by the variable composition of soft tissue. Because of its higher hydrogen content, the attenuation coefficient of fat is different from that of lean tissue. Differences in the soft tissue composition in the path of the X-ray beam through bone compared with the adjacent soft tissue reference area will cause errors in the BMD measurements (Tothill and Pye, 1992). Svendsen *et al.* (1995) reported a cadaver study in which the effect of fat inhomogeneity on the random accuracy errors for BMD measurements in the spine, hip, and forearm were examined. The root mean square accuracy errors were reported to be 3% for forearm, 5% for spine, and 6% for femoral neck and total hip BMD. The population SD (Eq. (1)), which is typically about 10% of the mean young adult BMD, includes the random errors due to the effects of these variations in body composition.

The first generation of DXA scanners used a pinhole collimator, producing a pencil beam coupled to a single scintillation detector in the scanning arm. Since then the most significant development has been the introduction of new systems that use a slit collimator to generate a fan beam coupled to a linear array of solid-state detectors. As a result, image resolution has improved, and scan times have shortened from around 5–10 min for the early pencil beam models to

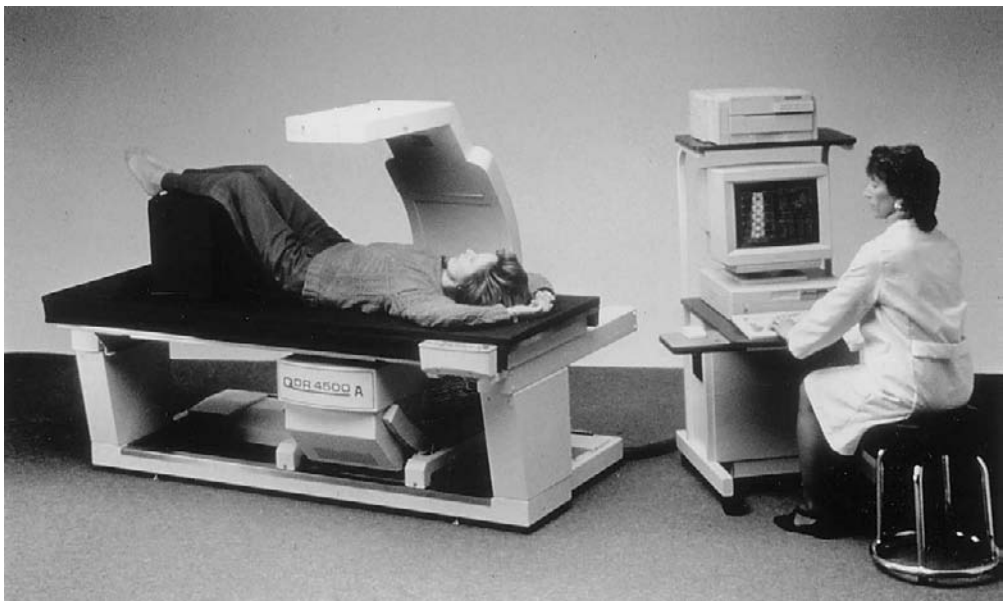

Figure 1 The QDR4500 fan-beam DXA scanner (Hologic Inc., Bedford, MA). Densitometers such as this are most frequently used for measuring spine and hip BMD, but can also be used for total body, forearm, and lateral projection studies of the spine.

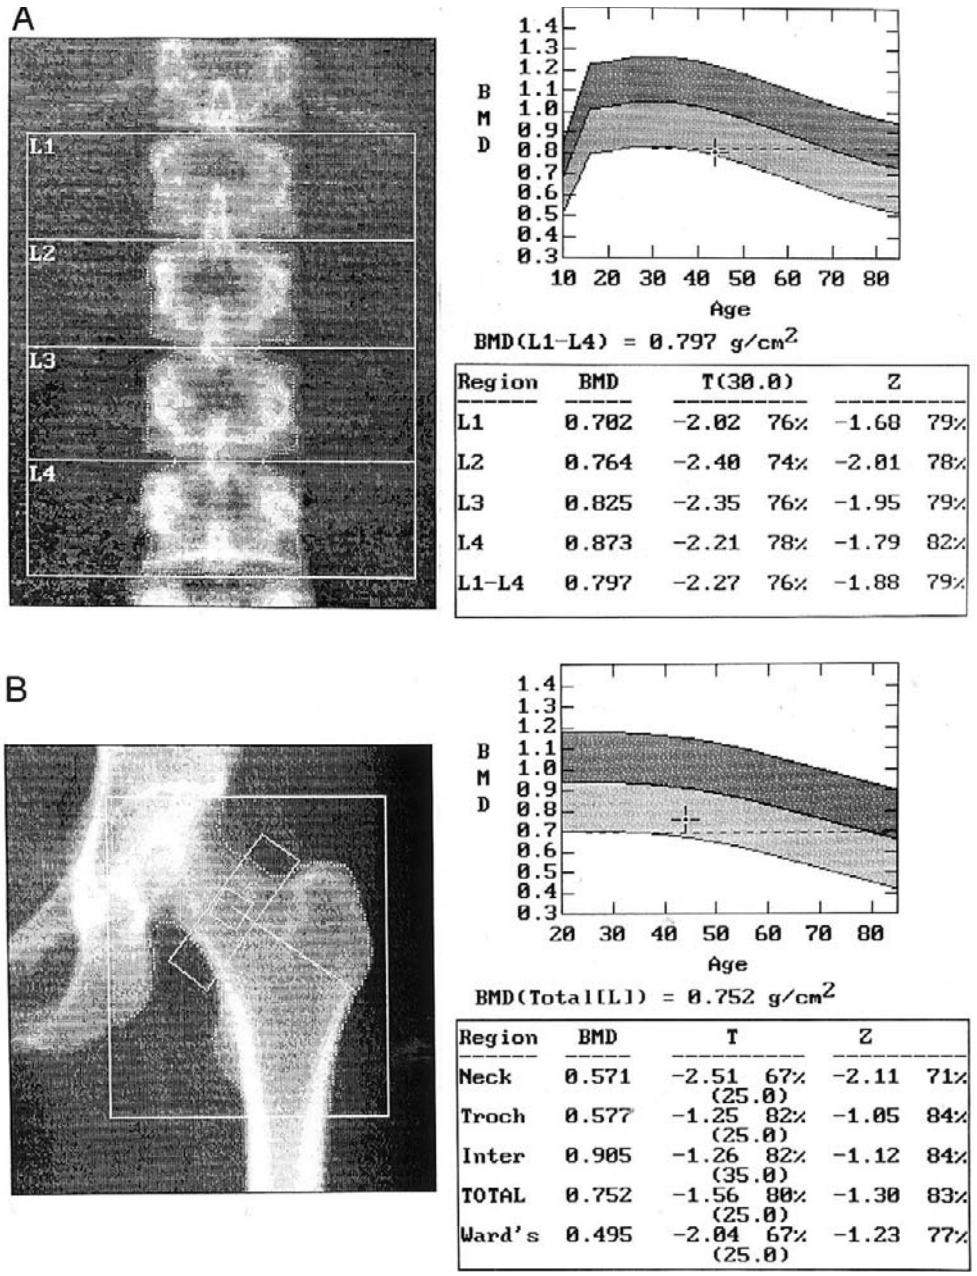

Figure 2 (A) Part of a computer printout from a DXA scan of the spine. The printout shows (clockwise from left): (1) scan image of lumbar spine, (2) patient's age and BMD plotted with respect to the reference range, (3) BMD figures for individual vertebrae and total spine (L1–L4) together with interpretation in terms of *T* scores and *Z* scores. (B) Part of a computer printout from a DXA scan of the hip. The printout shows (clockwise from left): (1) scan image of proximal femur; (2) patient's age and BMD for the total femur ROI plotted with respect to the NHANES III reference range; (3) BMD figures for five different ROIs in the hip (femoral neck, greater trochanter, intertrochanteric, total femur, and Ward's triangle) together with interpretation in terms of *T* scores and *Z* scores using the NHANES III reference range.

10–30s for the latest fan beam systems. Radiation dose to patients is generally higher for fan-beam systems compared with pencil beam, and the resulting increased scatter dose to technologists may require precautions to limit exposure such as placing the operator's console further away from the scanning table (Patel *et al.,* 1996).

Quantitative Computed Tomography

QCT has the advantage that it determines the true three-dimensional ("volumetric") bone density (units: mg/cm^3) compared with the two-dimensional areal density measured by DXA. QCT is usually applied to measure the trabecular bone in the vertebral bodies (Fig. 3) (Cann *et al.,* 1988).

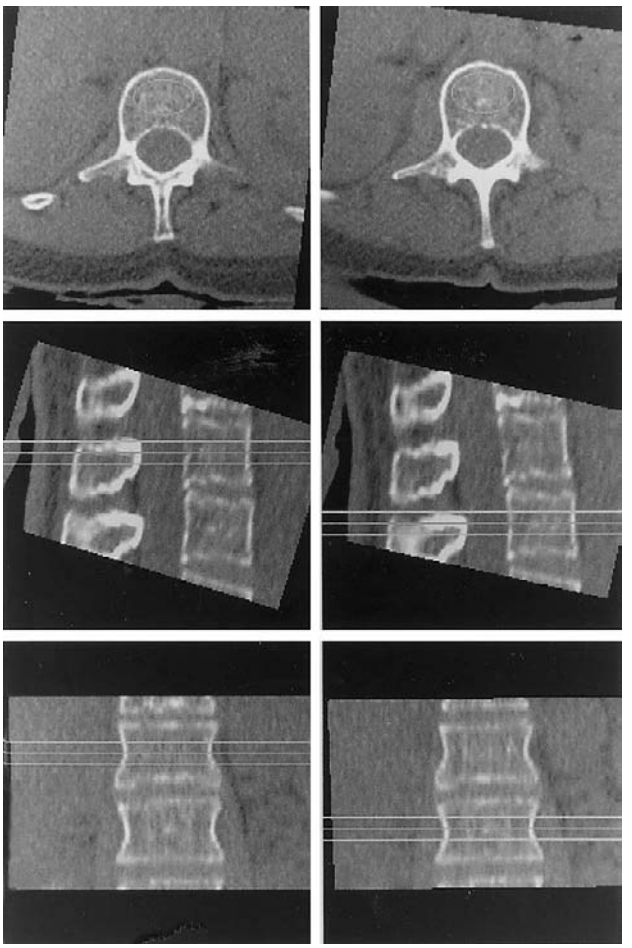

Figure 3 Part of a computer printout from a QCT scan of the spine showing transverse, sagittal, and coronal images of two lumbar vertebrae. The study was analyzed using a commercially available QCT software package (Mindways Software Inc, San Francisco, CA).

The measurement can be performed on any clinical CT scanner, provided that the patient is scanned with an external reference phantom to calibrate the CT numbers to bone equivalent values. Most CT manufacturers provide a software package to automate the placement of the regions of interest (ROIs) within the vertebral bodies. Patient dose is much lower than for standard CT scans, provided that the examination is performed correctly (Kalender, 1992). QCT studies are generally performed using a single kilovolt setting (single-energy QCT), when the principal source of error is the variable composition of the bone marrow. However, a dual-kilovolt scan (dual energy QCT) is also possible. This reduces the accuracy errors, but at the price of poorer precision and higher radiation dose. The advantage of spinal QCT is the high responsiveness of the vertebral trabecular bone to aging and disease (Cann, 1988; Grampp *et al.,* 1997). The principal disadvantage is the cost of the equipment.

Peripheral DXA, Peripheral QCT, and Radiographic Absorptiometry

Despite the expansion in the number of osteoporosis clinics, in most countries there are inadequate resources to meet demand, and DXA scans are not available to all patients who could conceivably benefit. Furthermore, conventional DXA scanning is perceived as costly, not least because of the need to refer patients to hospital-based facilities. Thus, despite the widespread popularity of BMD studies of the spine and femur, recent years have seen a revival of interest in small, low-cost, X-ray absorptiometry devices dedicated to scanning the peripheral skeleton (Glüer *et al.,* 1997). The first bone densitometers were forearm scanners that used the technique of single photon absorptiometry (SPA) based on a ^{125}I radionuclide source (Cameron and Sorensen, 1963). Follow-up of patients after SPA studies has shown that forearm bone density measurements can predict fracture risk over 25 years (Düppe *et al.,* 1997). In recent years the technology has been updated by replacing the radionuclide source with a low-voltage X-ray tube ($40-60\ kV_p$) and using the principles of DXA to perform BMD scans of the distal radius (Fig. 4) and the calcaneus. The advantages of pDXA systems include the small footprint of the devices, relatively low cost, and an extremely low radiation dose of around 0.1 μSv (Patel *et al.,* 1999).

Just as pDXA devices were developed as an alternative to DXA scanning of the central skeleton, small dedicated pQCT systems are also available for measuring the forearm (Glüer *et al.,* 1997). These devices have the advantage of separating the trabecular and cortical bone of the ultradistal radius and of reporting volumetric density. Although widely used in some countries in Europe, they have been primarily limited to research studies in the United States (Baran *et al.,* 1997).

Radiographic absorptiometry (RA) is a technique that was developed many years ago for assessing bone density in the hand, but has recently attracted renewed interest (Glüer *et al.,* 1997). It has the advantage of using conventional X-ray equipment with the addition of a small aluminum wedge in the image field for calibration. The radiographic image is captured on a PC and then processed automatically using a specially developed software application to measure BMD in the phalanges. The main advantage of RA is its potential for general use based on the widespread availability of conventional film radiography.

Peripheral X-ray absorptiometry methods such as those described above have obvious advantages when selecting bone densitometry methodologies suitable for use in physicians' offices or in primary care. However, epidemiological studies suggest that the discriminatory ability of peripheral BMD measurements to predict spine and hip fractures is rather lower than for spine and hip BMD measurements (Marshall *et al.,* 1996). Also, changes in forearm BMD in response to estrogen and other treatments for osteoporosis are relatively small, making such measurements less suitable than spine BMD for monitoring patients' response

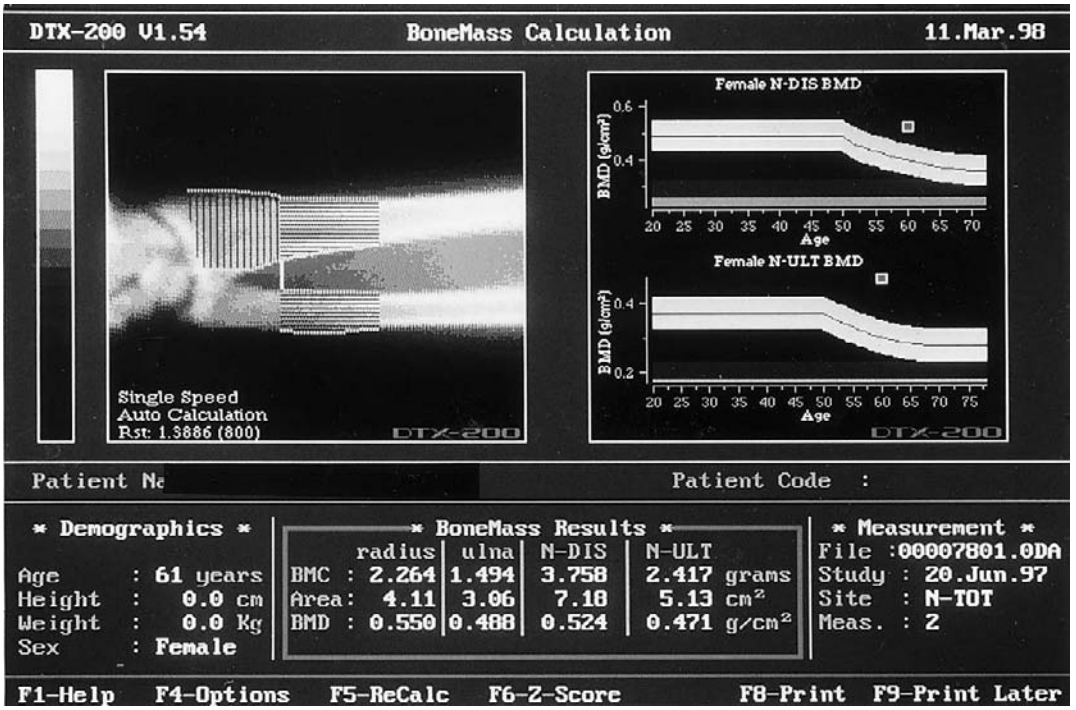

Figure 4 Computer printout from a pDXA scan of the distal forearm. The scan was performed on a DTX-200 system (Osteometer Meditech, Hawthorne, CA).

(Faulkner, 1998). Finally, although the radiation doses to patient and operator are both extremely small, pDXA and pQCT devices are subject to government regulatory requirements controlling the use of X-ray equipment, including the training of technologists and physicians in the principles of radiation safety.

Quantitative Ultrasonometry

QUS for measuring the peripheral skeleton has raised considerable interest in recent years (Njeh *et al.,* 1997, 1999a). There is a wide variety of equipment available, with most devices using the heel as the measurement site (Fig. 5). The calcaneus is chosen because it encompasses a large volume of trabecular bone between relatively flat faces and is readily accessible for transmission measurements. The physical principles of QUS measurements are outlined in Fig. 6. An ultrasound pulse passing through cancellous bone is strongly attenuated as the signal is scattered and absorbed by trabeculae (Fig. 6A). The power spectrum of the pulse transmitted through the patient's heel is compared to a reference trace measured through water alone (Fig. 6B). The additional attenuation measured through the patient's heel (measured in decibels (dB)) increases linearly with frequency, and the slope of the relationship is referred to as the broadband ultrasonic attenuation (BUA: units dB/MHz) (Fig. 6C). BUA is reduced in patients with osteoporosis, because there are fewer trabeculae in the calcaneus to attenuate the signal. As well as BUA, most QUS systems also measure the speed of sound (SOS) in the heel by dividing the distance between the ultrasound transducers by the propagation time (units: m/s) (Fig. 6A). SOS values are reduced in patients with osteoporosis because, with the loss of mineralized bone, the elastic modulus of the bone is decreased. Some manufacturers combine the BUA and SOS values into a single parameter referred to as "stiffness" or the "quantitative ultrasound index" (QUI). These combinations have no particular physical meaning, but may improve precision and

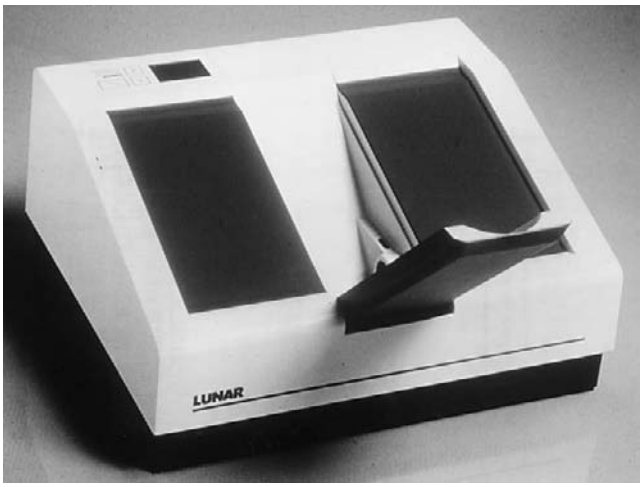

Figure 5 The Achilles system for performing QUS measurements in the heel (Lunar Corp., Madison, WI). Devices such as this measure BUA and SOS in the calcaneus. The two measurements are combined into a single index ("stiffness") which is claimed to improve discrimination compared with BUA or SOS alone.

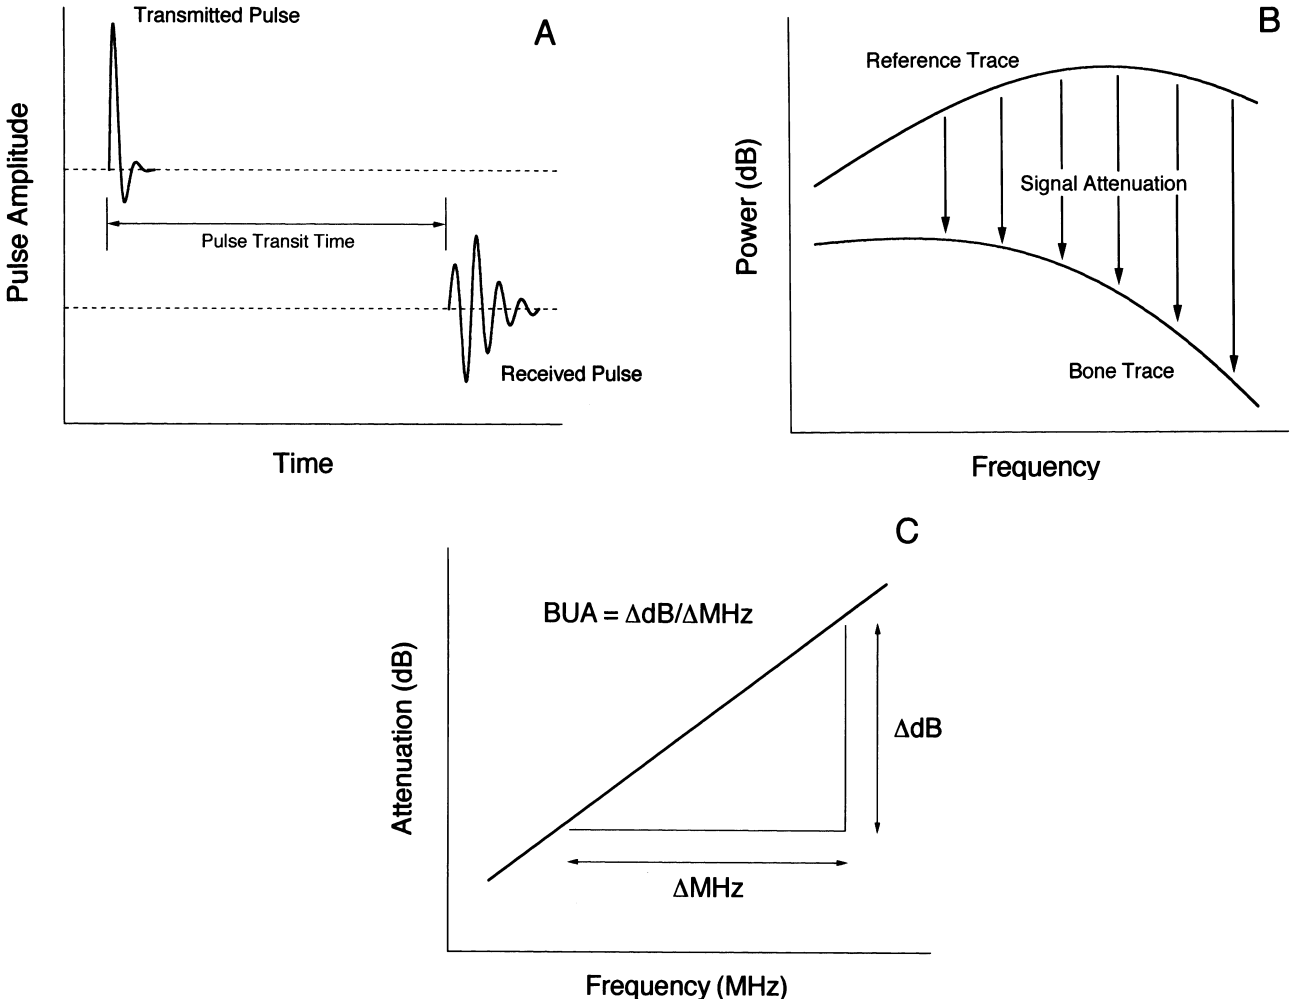

Figure 6 The physical principles behind the measurement of BUA and SOS. (A) The received pulse is digitized and Fourier analysis used to determine the power spectrum. The pulse transit time is used for the SOS measurement. (B) The power spectrum of the signal transmitted through the patient's heel is compared with a reference trace from a signal transmitted through water. The difference between the two traces is the attenuation due to the patient's heel. (C) When the attenuation through the patient's heel is plotted against frequency, a linear relationship is found at frequencies below 1 MHz. BUA is defined as the slope of the regression line and is measured in units of dB/MHz.

discrimination by averaging out errors such as those caused by temperature variations (Nicholson and Bouxsein, 1999). With most early-generation QUS devices, the patient's foot was placed in a water bath to couple the ultrasound signal to the heel. However, most later devices are dry contact systems in which rubber pads covered with ultrasound gel are pressed against the patient's heel.

A major attraction of bone ultrasound devices is that they do not use ionizing radiation, and therefore avoid the regulatory requirements for X-ray systems mentioned above. Also, the instrumentation is relatively inexpensive and several devices, especially among the dry systems, are designed to be portable. Therefore ultrasound systems could be made much more widely available than conventional DXA scanners, which are largely restricted to hospital-based osteoporosis clinics. Moreover, recent evidence from several large prospective studies confirm that QUS measurements are predictive of hip fracture risk (Hans *et al.,* 1996; Bauer *et al.,* 1997; Pluijm *et al.,* 1999).

There remain, however, a number of difficulties in the interpretation of QUS measurements. In general, the fracture studies mentioned above were conducted in elderly populations aged $\geq$70 years, examined only hip fracture risk, and used the earlier generation of water-based calcaneal QUS systems. Another difficulty is that QUS measurements are not readily encompassed within the WHO definitions of osteoporosis and osteopenia (Faulkner *et al.,* 1999; Delmas, 2000). Recently, Kanis and Glüer (2000) proposed that hip BMD should be the "gold standard" for the definition of osteoporosis and that in the case of peripheral methodologies such as QUS, intervention thresholds should be devised so that measurements are interpreted in terms of a fracture risk equivalent to that determined by hip DXA.

There are also a number of technical limitations to QUS. Due to the wave physics of the signal, measurements may be affected by errors due to diffraction and phase cancellation (Petley *et al.,* 1995). Also, many devices use a foot support that positions the patient's heel between fixed transducers.

Thus the measurement site is not readily adapted to different sizes and shapes of the calcaneus, and the exact anatomical site of the measurement varies from patient to patient. Furthermore, as a measurement site the calcaneus has the disadvantage of being sensitive to the amount of exercise the patient takes. The problem of ensuring an anatomically consistent measurement site may be solved by imaging QUS systems that perform a faster scan of the heel and enable a more consistent placement of the ROI (Fournier *et al.,* 1997). Finally, it is widely accepted that the relatively poor precision of QUS measurements makes most devices unsuitable for monitoring patients' response to treatment (Glüer, 1997). In general, the phantoms provided with QUS devices are not particularly anthropomorphic, and thus the problem of poor precision may be compounded by limitations in instrument quality control.

The Relationship between Different Types of Measurement

The spine and femur are generally regarded as the most important DXA measurement sites because they are the sites of the osteoporotic fractures that cause the greatest impairment of quality of life, morbidity, and mortality. Many would still consider spine BMD the optimum measurement because of its sensitivity to the changes associated with aging, disease, and therapy. However, it has the disadvantage that, with advancing age, measurements are often affected by the presence of degenerative changes that lead to the artificial elevation of BMD values. This becomes an increasing problem after the age of 70, but can occur earlier. Others would argue that hip BMD is the most useful measurement, since it is the most predictive of hip fracture (Cummings *et al.,* 1993; Marshall *et al.,* 1996; Black *et al.,* 2000), which is clinically the most important fracture. In the research community, a consensus is developing that the total femur should be the "gold standard" for bone densitometry measurements (Kanis and Glüer, 2000; Black, 2000). In practice, when DXA measurements are carried out, spine and hip BMD are usually both available for evaluation.

As osteoporosis is common and is a primary care disease, there is a need for a "simpler" evaluation of BMD than DXA, which is generally found only in large hospitals. There is therefore considerable interest in pDXA and QUS devices, as such systems are smaller and cheaper than DXA. Since osteoporosis is a systemic disease, bone loss is not limited to the axial skeleton. However, correlation coefficients between BMD measurements at different skeletal sites are typically around $r \approx 0.6–0.7$, and thus a measurement at one site is far from being a perfect predictor of that at any other. Correlations between QUS and BMD measurements are even poorer, with coefficients of around $r \approx 0.4–0.5$. Thus, whatever intervention threshold is chosen as the basis for recommending treatment, different groups of patients will be selected depending on the measurement site and technology in use. This raises the question of whether there is any one type of measurement that performs better than the others at identifying the patients most at risk of an osteoporotic fracture.

Which Measurement Is Best?

The most rigorous and convincing method of comparing the ability of different measurement sites and methodologies to predict osteoporotic fractures is through a prospective study of incident fractures. One of the largest and most ambitious of these studies is the Study of Osteoporotic Fractures (SOF), which involved more than 9000 women age 65 years and over recruited in four regions of the United States. A commonly used descriptive approach to presenting data from such studies is to divide subjects into four quartiles based on their baseline BMD values and plot the fracture risk for each quartile. Fig. 7 shows SOF data for hip fracture risk plotted in this way (Cummings *et al.,* 1993). The data show that patients in the lowest quartile of hip BMD have approximately 10 times the risk of hip fracture of patients in the highest quartile.

It is conventional to perform a statistical analysis of epidemiological studies of fracture risk using a "gradient of risk" model in which fracture risk increases exponentially with decreasing BMD (Jergas and Glüer, 1997). Mathematically, this can be done using either logistic regression or proportional hazard models (Hui *et al.,* 1995). The results are expressed in terms of the relative risk (RR), which is the increased risk factor for each 1 SD decrease in BMD. Fig. 8 shows SOF data presented by Black *et al.* (2000) for the RR values for hip fracture risk for different BMD sites. With around 250 fracture cases included in this analysis, the study presents highly statistically significant evidence that hip fracture risk is best predicted by a measurement of femur BMD.

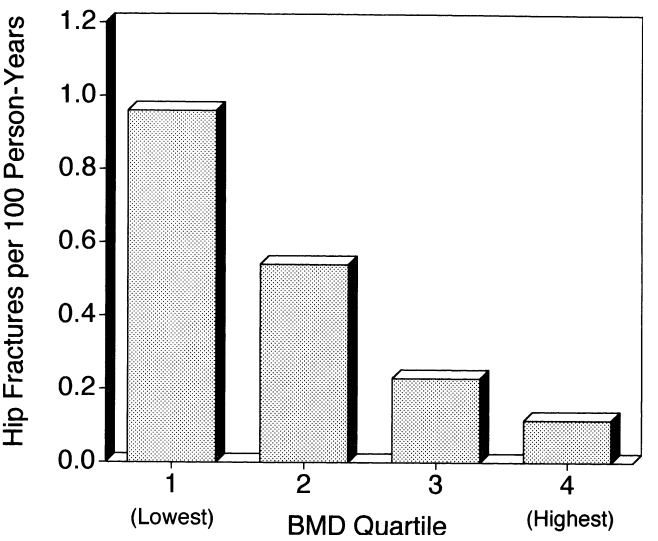

Figure 7 Incidence of hip fracture by BMD quartile for femoral neck BMD. Data from Cummings *et al.* (1993).

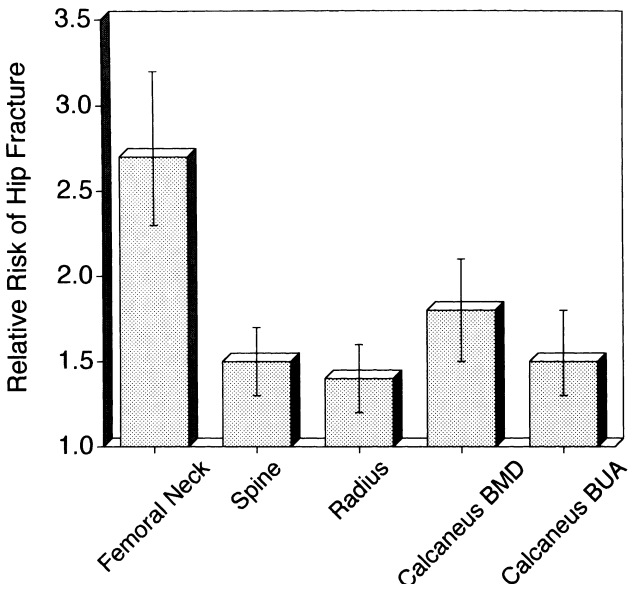

Figure 8 Relative risk (RR) values for 5-year hip fracture incidence for BMD measurements of the femoral neck, lumbar spine, forearm, and calcaneus and BUA measurements of the calcaneus. RR is the increased risk of fracture for a 1 SD decrease in BMD or BUA. The figure is drawn from SOF study data reported by Black *et al.* (2000) and is based on approximately 250 cases of hip fracture recorded in the study population of 9000 white women age 65 years and over.

For a wider view of the merits of measurement sites other than the hip, a metaanalysis of fracture studies is required. Such an analysis was published by Marshall *et al.* (1996), and their collated data for the prediction of different types of fracture from BMD measurements at different skeletal sites are shown in Fig. 9. While these results confirm that hip BMD is best for predicting hip fracture, the degree to which spine BMD best predicts vertebral fracture or a radius BMD forearm fracture is less conclusive. Interestingly, when assessed by the ability to predict fractures occurring at any site, risk ratio figures for different measurement sites are closely comparable.

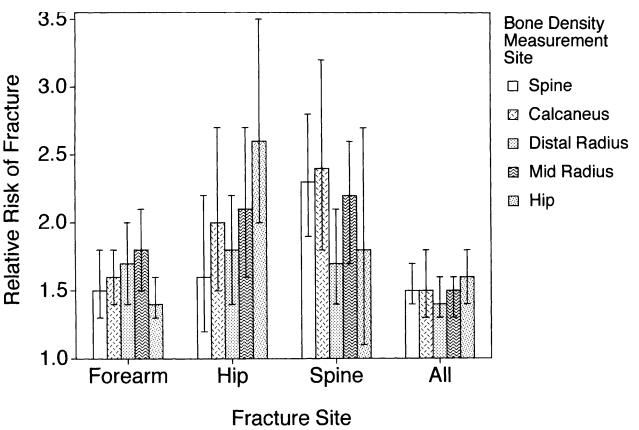

Figure 9 Relative risk (RR) values for fractures at different skeletal sites for bone density measurements in the spine, calcaneus, distal radius, mid-radius, and hip. Data are taken from the metaanalysis of prospective studies collated by Marshall *et al.* (1996).

In summary, there is now compelling evidence that a measurement of hip BMD is the most reliable way of predicting hip fracture risk. However, for other fracture sites, or for all fractures taken together, any differences between the various types of BMD measurement have yet to be conclusively established. Recent studies extend these conclusions to include QUS measurements of the calcaneus. Hans *et al.* (1996) reported RR results for hip fracture of 2.0 for BUA and 1.7 for SOS based on women age 75 years and over enrolled in the EPIDOS study, while Bauer *et al.* (1997) reported similar findings from the SOF study. Following these reports, there was general agreement that QUS devices could have an important role in the assessment of fracture risk, particularly in elderly women (Glüer, 1997). The most recent data from the SOF study give a rather lower RR value of 1.5 for heel BUA, a figure comparable to forearm BMD (Fig. 8) (Black *et al.,* 2000), and the clinical implications of this result with regard to the more widespread application of QUS is not yet clear.

The Interpretation of BMD Results: Reference Ranges

If the WHO criterion of a T score ≤ -2.5 is used to define osteoporosis, then it is apparent that any errors in the mean BMD or population SD of the reference group could lead to significant differences in the apparent incidence of osteoporosis when applied to other populations. The majority of centers providing a scanning service use reference ranges provided by the equipment manufacturers, and issues over the accuracy of these ranges have caused controversy in the past (Faulkner *et al.,* 1996). This continues to be a problematic area in view of the large number of new devices which are being introduced for the assessment of the skeleton. However, for DXA the problem is now largely resolved after a report by the International Committee for Standards in Bone Measurement (ICSBM) (Hanson, 1997), which recommended that hip BMD measurements should be interpreted using the total femur region of interest and the hip BMD reference ranges derived from the US NHANES III study (Looker *et al.,* 1998). The NHANES III project studied a nationally representative sample of over 14,000 men and women with approximately equal numbers of non-Hispanic white, non-Hispanic black, and Mexican Americans. The ICSBM report recommends use of the total femur ROI instead of the previously widely used femoral neck site because of its improved precision and the fact that it is the hip region most readily implemented on all DXA manufacturers' systems.

Many centers have already acted upon these recommendations, and they are increasingly being used for scan reporting. It is important to note that these changes affect the percentage of patients who are diagnosed as having osteoporosis at the hip. Using the total femur ROI and the NHANES III

reference range, rather fewer patients will be diagnosed as having osteoporosis than using the femoral neck ROI and the manufacturer's original reference range (Chen *et al.,* 1998). There is no definite right or wrong answer in this situation. What is more important is to have a consistent approach, and it is certainly highly desirable to have universally accepted BMD criteria for the diagnosis of osteoporosis.

One advantage of presenting bone densitometry results in terms of *T* scores is that they avoid the confusion caused by the raw BMD figures that differ for different manufacturers' equipment (Genant *et al.,* 1994). The ICSBM Committee has addressed this issue by publishing equations which allow each manufacturer to express their BMD values on a consistent scale in standardized units (sBMD: units mg/cm^2) (Steiger, 1995; Hanson, 1997). In practice sBMD units are seldom used in the clinical management of patients but can be useful in some research applications.

The Clinical Use of Bone Densitometry

With the development of new treatments for preventing osteoporosis and the wider availability of bone densitometry equipment, much debate has centered on the issues of the clinical indications for the diagnostic use of bone densitometry and recommendations for the initiation of treatment based on the findings. In the United States, an influential report was published by the National Osteoporosis Foundation (NOF, 1998a). In Europe similar reports have been issued by the European Foundation for Osteoporosis (EFFO) (Kanis *et al.,* 1997; Kanis and Glüer, 2000), and in the United Kingdom by the Royal College of Physicians (RCP, 1999).

The NOF report included a sophisticated set of guidelines for therapeutic intervention. Various nomograms were developed that incorporate age, BMD, and four other risk factors for osteoporosis (Table III). An interesting aspect of the NOF approach is that the calculations for therapeutic intervention are based on the concept of a quality adjusted life year (QALY) valued at $30,000. This is a relatively high value, and one that would not be considered appropriate for application in Europe. This implies that there may have to be different BMD criteria for therapeutic intervention in different countries throughout the world. It also follows from the NOF approach that there will be different thresholds for intervention depending on the cost of treatment. While the NOF report is an extremely important document, with an extensive review of the relevant background information, it is nevertheless complex, and it is unlikely that primary care physicians will instigate treatment based on such a scheme. The NOF subsequently published a physicians' handbook with simplified recommendations which included the availability of BMD measurements for all women over the age of 65 years and in all postmenopausal women under the age of 65 in whom clinical risk factors are present (NOF, 1998b).

Clinical guidelines for the prevention and treatment of osteoporosis in the United Kingdom were recently published by the Royal College of Physicians (RCP, 1999). These concluded that at present there is no consensus for a policy of population screening using BMD scans. Instead, a case-finding strategy is recommended for referring patients for bone densitometry based on a list of widely accepted clinical risk factors for osteoporosis (Table IV). The list is identical to that published in the EFFO report (Kanis *et al.,* 1997). The RCP report also recommended *T* score of ≤ -2.5 at the spine or hip as the basis for instigating therapy.

It is important to emphasize that the WHO definition of osteopenia ($-2.5 < T < -1$) is not useful in isolation with regard to decisions about treatment, since it captures too high a percentage of postmenopausal women and, in fairness, was never intended to be used in this way. A considerable body of evidence indicates that it is the patients with the most severe

Table III Risk Factors for Osteoporosis Additional to Age and BMD Incorporated in the NOF Guidelines for Therapeutic Intervention

- History of fracture after age 40
- History of hip, wrist, or vertebral fracture in a first-degree relative
- Being in lowest quartile for body weight (≤57.8 kg (127 lb))
- Current cigarette smoking habit

Note. Reproduced from National Osteoporosis Foundation guidelines (NOF, 1998a,b).

Table IV Risk Factors Providing Indications for the Diagnostic Use of Bone Densitometry

1. Presence of strong risk factors
   - Estrogen deficiency
     - Premature menopause (age <45 years)
     - Prolonged secondary amenorrhoea (>1 year)
     - Primary hypogonadism
   - Corticosteroid therapy
     - Prednisolone >7.5 mg/day for 1 year or more
   - Maternal family history of hip fracture
   - Low body mass index (<19 kg/m^2)
   - Other disorders associated with osteoporosis
     - Anorexia nervosa
     - Malabsorption syndrome
     - Primary hyperparathyroidism
     - Posttransplantation
     - Chronic renal failure
     - Hyperthyroidism
     - Prolonged immobilization
     - Cushing's syndrome
2. Radiographic evidence of osteopenia and/or vertebral deformity
3. Previous fragility fracture, especially of the hip, spine, or wrist
4. Loss of height, thoracic kyphosis (after radiographic confirmation of vertebral deformities)

Note. Table reproduced from the Royal College of Physicians guidelines (RCP, 1999)

disease who benefit most from anti-resorptive therapies such as bisphosphonates (Cummings *et al.,* 1998). Thus there seems to be a consensus supporting the use of a spine or hip *T* score of ≤ -2.5 as the appropriate intervention threshold for instigating treatment in white women. However, it is important to take all the other relevant clinical factors into account such as those listed in Tables III and IV. In particular, the age of the patient and whether there is a history of previous fragility fractures are important independent predictors of future fracture risk. No consensus has yet emerged on what intervention thresholds are appropriate in men and other ethnic groups. However, the revised guidelines recently published by Kanis and Glüer (2000) suggest that the same absolute BMD thresholds applied to white women may also be applicable to these other groups.

The Interpretation of Peripheral Measurements

In recent years the WHO definition of osteoporosis as a *T* score ≤ -2.5 has been widely adopted as a basis for therapeutic decision making. However, a disadvantage is that due to different age-related changes in *T* score for different technologies and measurement sites, patients will cross the $T = -2.5$ threshold at different ages depending on what type of measurement is made (Fig. 10). To understand the clinical consequences of this, one needs to convert the threshold of $T = -2.5$ to an equivalent *Z* score value. It is clear from Fig. 10 that methodologies for which the mean *T* score falls more slowly with age will require patients to achieve a more negative *Z* score before the $T = -2.5$ threshold is triggered. With this information, and assuming that the distribution of *Z* score values is gaussian, it can be estimated that at age 65 the percentage of patients with a *T* score ≤ -2.5 for the Hologic Sahara QUS device, DXA femoral neck BMD, DXA spine BMD, and spine QCT are 3, 16, 24, and 60%, respectively (Blake and Fogelman, 2001). It is therefore clear that large differences in the numbers of patients recommended for treatment could arise depending on the type of bone densitometry equipment used. To be fair to the WHO report, its recommendation for defining osteoporosis was only intended to apply to BMD measurements of the spine, femoral neck, or forearm. However, only recently has it become widely appreciated that the WHO criteria cannot be applied uncritically to other types of measurement (Faulkner *et al.,* 1999; Delmas, 2000; Miller, 2000). Given the need to make greater use of the small, low-cost devices for scanning the peripheral skeleton if the many millions of women most at risk are to be identified and treated, it is important to consider what approaches to the interpretation of bone density measurements can be adopted to ensure the greatest degree of consistency between the different methodologies.

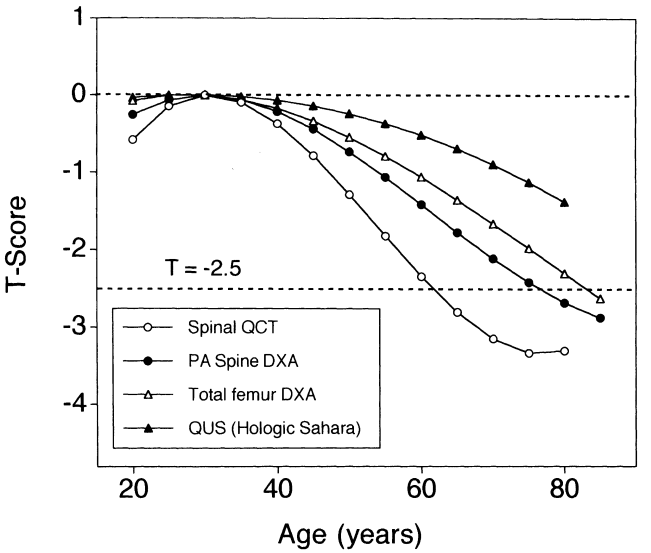

Figure 10 Age-related decline in mean *T* score for white female subjects for DXA of the lumbar spine (Hologic manufacturer's reference range); DXA of the femoral neck (NHANES III reference range (Looker *et al.,* 1998)); QCT of the spine (reference data from Cann *et al.* (1985)); Quantitative ultrasound measurements of the calcaneus. Reference data from *Frost et al.* (1999).

The inconsistency between different *T* score figures, taken with confirmation from fracture studies that strengthens evidence that femur BMD is the best measurement for predicting hip fracture (Black *et al.,* 2000), have led to recommendations that the femur should be adopted as the gold standard site for the diagnosis of osteoporosis (Kanis and Glüer, 2000; Black, 2000). However, a way is needed to ensure that broadly comparable treatment decisions can be made using other methodologies such as pDXA and QUS. Recently, several reports have proposed that other measurement modalities such as pDXA and QUS should be utilized by establishing device specific thresholds that correspond to a 5-year hip fracture risk equal to that set by a femoral neck *T* score of -2.5 (Kanis and Glüer, 2000; Black, 2000). Although no formal recommendations have yet been publicized, it is clear that some such approach is required to ensure that proper use can be made of the many different types of peripheral device now available.

The Problem of Identifying Different Patients for Treatment

Given the range of different types of measurement, there is clearly cause for concern about the potential for conflicting findings between different techniques. If two types of measurement were to correlate perfectly ($r = 1.0$), they would identify exactly the same patients in the at-risk group. However, in practice different types of measurement often correlate poorly, with $r \approx 0.6-0.7$ between BMD results from different sites and $r \approx 0.4-0.5$ between QUS and BMD measurements. This raises the issue of how concerned clinicians should be that, due to the imperfect correlations, different patients are selected for treatment on the basis of different sites and techniques.

To understand this problem, it should be borne in mind that there is no such thing as an absolute fracture threshold. As demonstrated by the quartile plot of fracture incidence (Fig. 7), there will always be a substantial overlap between measurements from fracture and nonfracture patients, and absolute discrimination between these groups is not possible using any type of BMD measurement. Depending on the rules agreed for the clinical interpretation of BMD measurements, only a certain percentage of all those patients scanned who later go on to sustain a fracture will be included in the at-risk group. It is therefore clear that, depending on the correlation coefficient between them, different types of measurement are identifying different individuals from this fracture group. More detailed analysis shows that the most successful technique (i.e., the measurement that captures the largest percentage of future fracture cases) is the one with the highest RR value (Blake and Fogelman, 2001).

It is clear that bone densitometry studies provide a measure of fracture risk that is analogous to assessment of blood pressure with regard to the risk of stroke or measurement of cholesterol with regard to the risk of developing ischemic heart disease (Marshall *et al.,* 1996). It is important to distinguish the concepts of risk as applied to an individual and to a population. Although BMD may be the most important single risk factor for fracture, osteoporotic fractures are nevertheless multifactorial and, in addition to low bone density, will depend upon other issues such as accidents and the propensity to fall. BMD measurements are well suited to the study of populations, where they are effective in identifying patients who have a higher than average risk of fracture, but are less good at identifying those specific individuals who will later sustain a fracture.

Summary and Conclusions

During the past decade the pace of technological innovation has been rapid, with the introduction of many new or improved radiological devices for the noninvasive assessment of patients' skeletal status. DXA scanning of the hip and spine remains the "gold standard," although there is now a wider appreciation of the need for smaller, cheaper devices for scanning the peripheral skeleton if the many millions of women most at risk of a fragility fracture are to be identified and treated. Several sets of guidelines for the clinical use of bone densitometry have been published, and most have included recommendations for intervention thresholds for initiating treatment in white women. The WHO criterion of a T score ≤ -2.5 has been especially influential, although cannot automatically be applied to the newer peripheral techniques such as QUS or in men and patients from other ethnic groups.

At the present time, most experts do not advocate mass screening of the population for osteoporosis, and instead the guidelines recommend a case-finding strategy based on identifying patients with generally accepted clinical risk factors. However, with the widespread availability of QUS systems, this view may change. The advantages of QUS outlined above mean that it may have a role in many specialist departments and primary care facilities. However, in view of the large number of commercial devices available, there are concerns about whether all the reference ranges are accurate and appropriate. As emphasized above, the WHO definition of a T score of ≤ -2.5 cannot automatically be applied to QUS, and there is a consensus emerging toward defining intervention thresholds for peripheral devices based on estimates of absolute fracture risk. It seems premature to advocate the routine use of QUS until these issues have been resolved and appropriate clinical strategies have been agreed upon. Nevertheless, it is probable that ultrasound will be widely used for the assessment of the skeleton within the next 5 to 10 years, and at that point there would effectively be screening for osteoporosis.

CHAPTER 92

Controversial Issues in Bone Densitometry

Paul D. Miller
University of Colorado Health Sciences Center and Colorado Center for Bone Research, Lakewood, Colorado 80227

Bone densitometry is an extremely valuable tool for the diagnosis of osteoporosis, assessment of fracture risk, tracking the course of disease states that alter bone remodeling, and monitoring the response to treatment for osteoporosis and other metabolic bone diseases (Miller *et al.,* 1999; Miller and Bonnick, 1999). As clinical approaches to osteoporosis have expanded, with more diagnostic and therapeutic agents, questions regarding the utility of bone mass measurements have also increased. This chapter will discuss key controversial issues that have recently become prominent. The issues to be addressed are:

1. discrepancies in *T*-score determination among bone densitometers;
2. prevalence versus risk in reporting bone mineral density device results;
3. differences in ethnic- and gender-specific databases among different bone density devices;
4. value and limitations of serial bone mineral density measurements.

Discrepancies in *T* Score Determination among Bone Densitometers

In 1994, a working group of the World Health Organization (WHO) established levels of bone mineral density (BMD) that could be used for the diagnosis of osteoporosis. The basis for the well-known cutoff for the diagnosis of osteoporosis (*T* score less than −2.5) was data examining both prevalence and risk of fragility fractures in elderly postmenopausal Caucasian women (WHO Study Group, 1994). This *T* score value was intended to be used as an epidemiological cutoff to describe a BMD level which could diagnose osteoporosis in the absence of a fragility fracture. In practice, this *T* score has been applied broadly to patients of both genders and various ethnicities. In addition, it has been used for the assessment of premenopausal women and patients receiving chronic glucocorticoid therapy. The appropriateness of extrapolating the WHO cutoff levels to men, various ethnic groups, patients with secondary causes of osteoporosis, and premenopausal women will be discussed later.

The WHO established the BMD-cutoffs for the diagnosis of osteoporosis, using the *T*-score, which is the number of standard deviations (SD) a patient's BMD is from the young normal mean BMD, rather than the absolute BMD value, to reduce the effect of measured differences in BMD produced by different equipment at identical skeletal sites. These differences are due to the different ways that manufacturers calibrate BMD with their devices and to different regions of interest (ROI) assessed by the different scanners. The WHO used the comparison of a patient's BMD to the young normal reference population rather than an age-matched reference population because defining osteoporosis on the basis of age-matched data would not detect the true prevalence of low bone mass in the elderly population since bone loss is a universal process of aging. The prevalence of osteoporosis would not increase with age if age-matched comparisons were used, and that is not logical. At the time of the WHO deliberations, there were very few bone densitometer devices available. Therefore, there were a limited number of reference databases from which the *T* score could be derived.

Each manufacturer of densitometry equipment has an adequate database, especially for the Caucasian female population. Yet, because the young normal reference populations are not consistent among the manufacturers, a patient's *T* score at

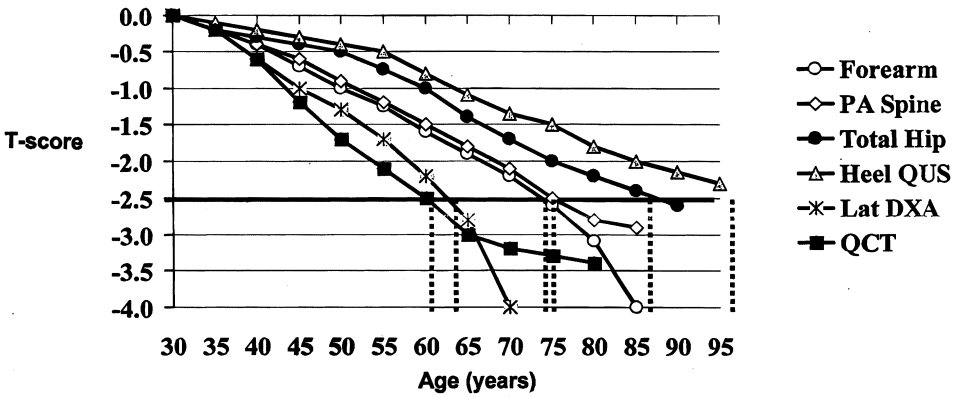

Figure 1 Age-related decline in mean Caucasian female *T* scores for different BMD technologies based on manufacturer reference ranges. The hip DXA reference data are from the NHANES study. The DXA normative data for the PA spine (L1–L4), lateral spine (L2–L4), and forearm (one-third region) were obtained from the Hologic QDR-4500 densitometer. Heel normative data were taken from the estimated BMD for the Hologic Sahara ultrasound unit. Spinal QCTs are those used by the Image Analysis reference system. Reproduced from Faulkner *et al.* (1999).

a specific skeletal site may differ depending on the equipment used. This may lead to different WHO classifications, based solely on inconsistent young normal databases (Ahmed *et al.,* 1997; Simmons *et al.,* 1997). This *T*-score discrepancy is compounded if a patient's BMD is measured at different skeletal sites using different technologies (e.g., dual-energy X-ray absorptiometry (DXA) of the hip vs ultrasound of the heel) (Faulkner *et al.,* 1999). Figure 1 demonstrates this discrepancy, which may lead to different diagnostic conclusions. For example, using heel ultrasonometry, patients, on average, must be 107 years of age before they fall, on average, below the WHO diagnostic threshold of −2.5. In contrast, using lateral spine DXA, patients, on average, are 60 years of age when they are classified as osteoporotic by WHO criteria (Faulkner *et al.,* 1999). This discrepancy is due to: (1) inconsistent young normal reference databases among the devices, and (2) differences in the biology of bone, cortical vs cancellous, with varying rates of bone loss from these sites after the menopause.

Data suggest that if the BMD is measured on a patient at the spine and the hip using the same DXA machine, the *T*-score derived from different young normal populations may be very different (Table I) (Ahmed *et al.,* 1997; Simmons *et al.,* 1997). These data included over 2000 postmenopausal Caucasian women who were scanned at the PA spine and femoral neck using the same central DXA machine. Their *T* scores were calculated using a young normal population obtained at the study site and a young normal population provided by the manufacturer. Table I demonstrates that, for example, when the *T* score was calculated from the study site young normal database vs the manufacturer's young normal database at the hip, the percentage classified as osteoporotic by WHO criteria (in parentheses) increased from 3 to 23%. This difference cannot be due to bone biology or different devices since the same skeletal site was measured on the same DXA machine. These differences, therefore, are due to the differences in the two young normal reference populations from which the *T* scores were derived. If one examines the equation for the determination of the *T* score, it is clear that if the mean BMD or the SD of the mean of the young normal reference population are not identical, then the derived T-score will be different:

$$T\text{ score} = \frac{\text{patient's BMD} - \text{mean BMD of the young normal reference population}}{\text{SD of the young normal reference population}}.$$

The only database consistently being used by manufacturers is the National Health and Nutrition Examination III (NHANES III) database, which includes both young normal and age-matched BMD data from males and females of various ethnic backgrounds (Looker *et al.,* 1995). The FDA Regulatory Device Division strongly urged the manufacturers to incorporate the NHANES III hip database into their software, when it was demonstrated that the *T* score at the hip could differ by as much as 1.0 SD in the same patient as a function of which database was used (Faulkner *et al.,* 1996). The use of the NHANES III database uniformly across all machines has removed this source of *T*-score discrepancy. For the most part, manufacturers have incorporated this consistent database, yet, some software may not include NHANES III, or may allow the operator to include/exclude it. Each operator and analysis physician need to know which normal database is being used, and the implications if different databases are used when *T* scores from different central DXA machines are compared.

Additional data suggest that the *T*-score discrepancy may be reduced by using a common young normal database, even when patients are measured using different technologies at different skeletal sites (Greenspan *et al.,* 1995). The authors measured the BMD of elderly subjects using a variety of heel ultrasound devices, heel DXA and hip DXA. The subjects' *T* scores were calculated using a small ($n = 55$) yet consistent young normal database. Despite using different technologies and measuring different skeletal sites, the *T* scores were similar. These results, which have been confirmed by other

Table I Classification, Using the WHO Criteria, of a Group of Patients Using *T* Scores Calculated from a Group of Study Young Normals vs the Manufacturer's Young Normals

	Spine no. (%)		Femur no. (%)	
WHO criteria	Study young norm	Manufacturer young norm	Study young norm	Manufacturer young norm
$T > -1.0$	1320 (64)	990 (48)	1385 (67)	625 (30)
$-2.5 < T < -1.0$	625 (30)	759 (37)	626 (30)	970 (47)
$T < -2.5$	123 (6)	319 (15)	57 (3)	473 (23)
Total	2068	2068	2068	2068

Note. Modified from Ahmed AIH *et al.* (1997).

studies, suggest that despite differences in bone structure or varying rates of bone loss, diagnostic discordance can be minimized by using a consistent young normal database.

On May 17, 1999, the FDA Regulatory Device Panel met to consider ways of mitigating the *T*-score discrepancies, which were becoming more apparent as more devices were being used for testing in the United States. One solution offered was to abolish the *T* score and move to absolute BMD determinations and absolute fracture risk estimation. This approach has merit since low BMD is a very important risk factor for the estimation of fracture risk, and all devices (central and peripheral) are nearly equal in their ability to predict fracture risk at skeletal sites other than those measured (i.e., heel or wrist or finger measurements can be used predict hip or spine fracture) in the elderly population (Marshall *et al.,* 1996). Finally, data suggest that when other risk factors are removed, thereby isolating BMD, the absolute vertebral or hip fracture risk is identical for men and women at the same BMD level (Ross *et al.,* 1993; De Laet *et al.,* 1998). One of the limitations of linking absolute BMD to absolute fracture risk is that the absolute BMD also differs between manufacturers even at the same skeletal site. Though a standardized BMD (sBMD) has been established for both the spine and hip DXA on all three central DXA manufacturers' equipment (Steiger, 1995; Hanson, 1997), the relationship between sBMD and fracture risk is unknown. Hence, the currently defined relationships between absolute BMD and fracture risk are manufacturer-specific. The standardized database project described below will establish an sBMD for all currently available central and peripheral devices that is related to vertebral and hip fracture risk.

The International Osteoporosis Foundation (IOF) has recommended that *T* scores for the diagnosis of osteoporosis be calculated only for the hip and that all other measurements be used for risk prediction (Kanis and Gluer, 2000) as a means of dealing with the *T*-score discrepancy. Such a proposal has merit and may work well in those countries that have either no reimbursement schedules for densitometry or a payment system that is not linked to diagnostic, ICD-9 codes (International Classification of Diseases). However, in the United States reimbursement is linked to a diagnosis which requires clear, definable criteria. Hence, the recommendation of the International Society of Clinical Densitometry and the National Osteoporosis Foundation (NOF) to retain the *T* score for diagnostic purposes was accepted by the FDA Regulatory Device Panel.

The short-term solution for alleviating *T*-score discrepancies is to establish a "*T*-score equivalence" among the various devices. The *T*-score equivalence will be calculated primarily from data available from the Study of Osteoporotic Fractures (SOF) (Black *et al.,* 1992). Since the prevalence of osteoporosis varies as a function of the device used, the site measured, and differences in young normal databases, fracture risk would be used as the basis for calculations of equivalency. Using 5-year absolute risk figures for hip fracture in the elderly population (average age 70 years), this analysis established the feasibility of identifying a *T* score as equivalent to a given fracture risk for each device. Table II shows the various *T*-score cutoff points, derived from different young normal databases using various devices, which yield a 6% risk of hip fracture in the 70-year-old population. It is apparent that in this age group a *T* score of -2.0 from a heel ultrasound measurement is equivalent to a *T* score of -2.5 at the femoral neck for determining hip fracture risk over the next 5 years. Hence, the *T*-score equivalence for ultrasonometry of the heel is -2.0.

The concept of *T*-score equivalence offers a temporary solution to discrepancies in *T*-scores. A physician, using a particular BMD device, would know the *T*-score cutoff derived from that device which predicts the same hip fracture

Table II *T* Score Cutoff Points for Various Bone Density Devices Based on Equal Hip Fracture Risk (6%)

		BMD	
Site/technology	Hip fx risk (5 yr) (%)	Value	*T* score
Femoral neck/DXA	6	0.58[a]	−2.5
Spine/DXA	6	0.63	−3.8
Calcaneus/ultrasound	6	46.8	−2.0

[a]Reference point, 0.58 g/cm^2 is $T = -2.5$ at the femoral neck by Hologic DXA.

risk as a *T* score of −2.5 derived from DXA at the *femoral neck*. The *T*-score equivalence analysis also has problems, which include:

1. SOF data were not determined concurrently on all devices in a prospective fashion, since different devices were introduced into the trial at different times;
2. fractures, other than the hip, have not yet been assessed and the data may be inadequate;
3. some manufacturers do not have adequate hip fracture data;
4. the data available do not include the early postmenopausal population.

The long-term solution to the *T*-score discrepancy is either to abolish the *T* score and move to a standardized absolute BMD cutoff level linked to absolute fracture risk and/or to reduce the *T*-score differences by developing consistent young normal and elderly reference databases which would be incorporated into all bone mass measurement devices. This data would be collected at the same time point from all skeletal sites on all measurements devices.

The development of a consistent BMD database, would require at least 2 years to complete. This database would require 2000 young normal women of various ethnicities and 3500 older women, both with and without prevalent vertebral fractures who would have BMD measurements performed on all available FDA-approved devices. In addition, a case-controlled study of 100 women with hip fractures would be conducted. This study would define how much of the *T*-score discrepancy is due to site-specific differences in rates of bone loss, machine variance, and inconsistent young normal reference populations. In addition, by completing the fracture cohort with all devices, analysis could establish an sBMD for all devices linked to fracture risk. This information would make it possible to decrease the discordance in *T* scores and thereby improve the diagnostic capability of the various bone mass measurement devices. It would also define an sBMD, which is a single number for all devices, linked to vertebral and hip fracture risk.

Prevalence versus Risk in Reporting Bone Mineral Density Device Results

The second controversial issue in bone densitometry is the use of prevalence versus risk for reporting BMD results. Prevalence is used for diagnosis and risk is used for fracture prediction. The prevalence of osteoporosis by WHO criteria is dependent upon:

1. the young normal database used;
2. the cutoff point chosen to define osteoporosis (i.e., −2.0 SD vs −2.5 SD);
3. the skeletal site measured;
4. the accuracy of the measurement; and
5. the gender and ethnic group used to define prevalence.

The cutoff point chosen determines the prevalence, which is the percentage of a population that is diagnosed with osteoporosis. In 1992, the WHO strongly considered using a *T*-score of −2.0 as the cutoff point. Estimates of the number of women with osteoporosis using this cutoff were undertaken (Melton *et al.,* 1992). In 1994 the WHO decided that a *T* score of −2.5 would be the cutoff point for the diagnosis of osteoporosis in the postmenopausal population. Therefore, a revised calculation of the number of women with osteoporosis was necessary (Melton, 1995). In the postmenopausal population, measurements of the same skeletal site using the same machine and a consistent young normal reference database for the calculation of the *T* score, will determine the prevalence of osteoporosis defined by a given cutoff point. The prevalence would increase if the cutoff point were changed to −2.0 rather than −2.5.

The WHO selected −2.5 as the cutoff point for the diagnosis of osteoporosis based on two observations. First, the percentage of postmenopausal Caucasian women whose *T* scores were −2.5 or less at the hip (16%), was approximately the same as the lifetime hip fracture rate in this population (16%). Second, approximately 40% of the postmenopausal women had *T* scores at or below −2.5 at any of the three measured skeletal sites (hip, spine, and wrist), approximating the lifetime *osteoporotic fracture* risk at these same skeletal sites. Hence, the prevalence of osteoporosis using −2.5 as the cutoff was consistent with estimated fracture risk data. The WHO criterion was an important milestone because it provided, for the first time, a BMD level that allowed clinicians to make a diagnosis of osteoporosis before the first fracture occurred. The use of BMD criteria to make a diagnosis before fracture has occurred is analogous to the diagnosis of hypertension before a stroke occurs. This BMD cutoff was especially important since the risk for a second osteoporotic fracture is much greater after the first fracture has occurred (Ross *et al.,* 1998; Nevitt *et al.,* 1999). Prevention of the first fracture is possible only if the population with low bone mass who are at risk can be identified.

Differences in Ethnic- and Gender-Specific Databases among Bone Density Devices

The next step was to determine cutoff points for the male population and different ethnic groups. The prevalence of osteoporosis in the NHANES III study, using *T*-scores and the WHO criteria, was different if males were compared to a female young normal reference database. Prevalence also differed if males or females of one ethnic group were compared to males or females of a different ethnic group reference database (Looker *et al.,* 1995). Likewise, the impact of gender-specific databases on the prevalence of osteoporosis using the WHO criteria was documented in a separate study (Table III) (Melton *et al.,* 1998). *T* scores calculated for elderly men from a female young normal database are different from *T* scores calculated from a male young normal database. Therefore, it is recommended, at the current time, that the *T*-score

Table III Prevalence of Osteoporosis in Men Male vs Female Reference Database

used for the diagnosis of osteoporosis be calculated using a gender-specific young normal database. Hologic, Lunar, and Norland provide gender- and ethnic-specific young normal databases for the calculation of *T*-scores. Since the *T*-score calculation is based on the mean and the standard deviation of the reference population, small differences in these values influence a patient's *T*-score value. Therefore, *T*-score discrepancies are compounded when males are compared to female young normal populations. Therefore, *T*-score discrepancies for males can be reduced by the use of gender-specific young normal databases.

The prevalence of osteoporosis in various ethnic populations is being examined in the NORA (National Osteoporosis Risk Assessment) study. This longitudinal BMD and risk-factor project examines the prevalence of osteoporosis, based on the WHO criteria, in a group of more than 200,000 postmenopausal women of various ethnicities, more than 50 years old in the United States (Siris *et al.,* 1998). *T* scores for the central DXA and peripheral measurements were calculated using a Caucasian young normal database. As expected, African-American women had a higher mean BMD and therefore a higher mean *T* score than Caucasians, Asian-Americans, non-Black Hispanic-Americans, and Native Americans. The rate of bone loss was identical in all the ethnic groups measured. By age 70, the prevalence differences among ethnic groups was very small. Therefore, NORA data suggests that the rate of bone loss in postmenopausal women of various ethnic groups in the United States is similar, and by the age of 70, the prevalence of osteoporosis may be similar in all groups. This appears to be true for U.S. ethnic populations that are three to five generations from their origin, whose gene pools have mixed, and whose diets are all similar. The prevalence of osteoporosis may have been different if the *T* scores had been calculated using ethnic-specific young normal databases. This analysis is in progress. The NORA data, to date, calculating *T* scores from Caucasian young normal women, suggest that this may be an acceptable method of assessing the prevalence of osteoporosis in elderly (over 70 years), using peripheral devices, in U.S. ethnic groups.

In contrast to the prevalence issue, there is little data regarding the effects of gender or ethnicity on the determination of fracture risk using either *T* scores or BMD. The absolute BMD values of the spine by DXA or the heel SXA have shown similar absolute vertebral fracture risk and non-

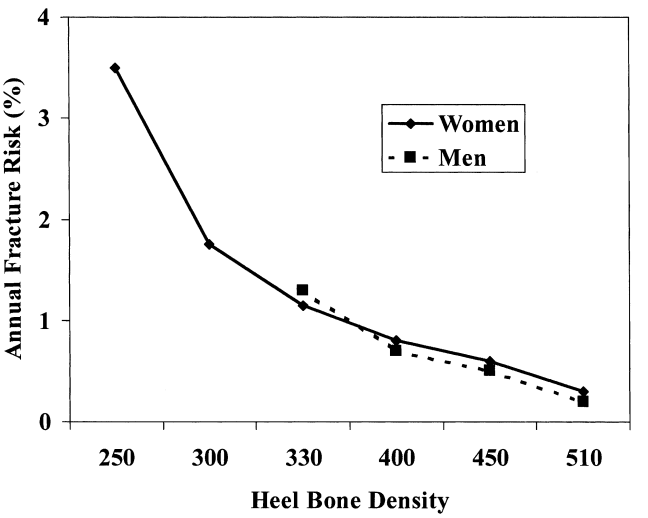

Figure 2 The relationship between heel bone density and annual fracture risk (%) in Caucasian and Japanese-American males and females adjusted for other risk factors.

vertebral, nonhip fracture risk between Caucasian and Japanese-American males and females (adjusted for other risk factors) in a prospective fracture trial (Fig. 2) (Ross *et al.,* 1995). Also, recent data have shown that the 1-year absolute hip fracture risk is identical in elderly age-matched Caucasian Dutch men and women at comparable absolute femoral neck BMD measurements (Fig. 3) (De Laet *et al.,* 1998). Finally, a 10-year prospective hip fracture study in Swedish men and women, using *T* scores calculated from the NHANES III Caucasian female young normal database rather than absolute BMD, showed similar 10-year absolute hip fracture risk in men and women at similar *T* scores (Table IV) (Kanis and Gluer, 2000). In a cross-sectional study, historical fracture risk, relative risk per SD (RR/SD) derived from elderly Caucasian men and women, was calculated using either a male or female young normal database. The RR for fracture per SD reduction in BMD was higher in women than in men (2.0/SD vs 1.4/SD), but the RR for fracture per SD reduction was not different whenever the RR per SD was calculated from the male young normal or female young normal reference population database (Table V) (Melton *et al.,* 1998). Other data suggest that men may fracture at a higher BMD or higher *T* score, calculated from a male young normal reference database, than women (Orwoll, 2000). Though the 5- to 10-year prospective fracture data suggest that men may fracture at similar BMD or *T* score as women, it is well known that lifetime fracture risk (especially hip) is lower in men than in women. The lower lifetime risk of hip fracture in men may be due to fewer falls, greater muscle mass or greater bone size in men (Seeman, 1999; Seeman *et al.,* 2001).

Data on the effects of ethnicity on the determination of fracture risk is scant. Historically calculated fracture data from NORA suggests that the RR for global fracture per SD reduction using *T* scores calculated from a female Caucasian young normal database, is similar in elderly

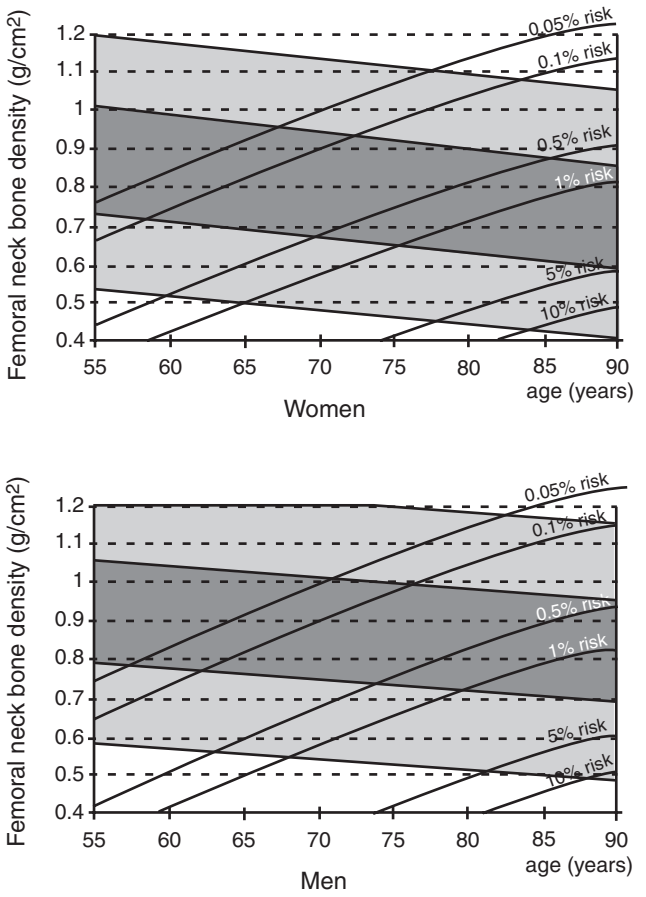

Figure 3 One-year hip fracture risk by age and BMD in women and men. The dark gray area indicates average BMD ± 1 SD, the light gray area indicates average BMD ± 2.5 SD. Reproduced from De Laet *et al.* (1998).

Caucasian, Hispanic, Native American, and Asian women and only slightly less in African-American women (Fig. 4).

Data from China, where the gene pool probably includes no Caucasian genes and the population has not been exposed to U.S. culture and nutrition, suggest that vertebral fracture risk calculated from absolute BMD may be similar to that of American Caucasians. However, hip fracture risk in China, calculated from either absolute BMD or *T* scores related to a Chinese-specific young normal database, is lower than in U.S. Caucasians (Ling *et al.,* 2000), even though the Chinese absolute hip BMD is lower than the absolute BMD of the U.S. Caucasians. The reason for these lower fracture rates in the Chinese is not clear, but shorter hip axis length, lower bone turnover rate, and fewer falls may be contributing factors independent of absolute BMD. Some of these fracture incidence differences are mitigated if the BMD is adjusted for the smaller body mass index (BMI) and smaller bone width observed in the Chinese. At comparable BMI, the absolute BMD to hip fracture risk is comparable to the U.S. Caucasian population.

Therefore, the data suggest that gender and ethnic-specific databases may be needed to determine prevalence, since differences in the mean BMD and SD for the young normal males and different ethnic groups influence the number of patients diagnosed with osteoporosis by the WHO criteria. Absolute 1- to 5-year fracture risk linked to absolute BMD may be similar regardless of gender, although the influence of bone size may alter this risk. Fracture risk data calculated from gender-specific *T* scores is not clear, although the two studies mentioned suggest that risk may be similar between men and women, even when the *T* scores are calculated from a female young normal database. Ethnic-specific global fracture risk (RR/SD) reduction may be similar in women when calculated from a female Caucasian young normal database, at least in the ethnic groups which make up the U.S. population. Ethnic-specific databases or absolute BMD linked to absolute fracture risk may be needed for risk assessments from continent to continent, especially in populations where there is little Caucasian influence on the gene pool. Recent Australian data suggest that hip fracture risk for Caucasian-Australian women is similar when the *T* scores are calculated from the U.S. Caucasian female NHANES III database or from a young normal Australian database.

Absolute risk calculated from absolute BMD may be the best approach for risk assessment regardless of race or gender, yet an sBMD calculated for all central and peripheral devices linked to fracture risk still needs to be completed since different devices give different BMD values. Presently, the sBMD available for central DXA spine and hip measurements is not linked to fracture risk. For now, the best suggestion is to use *T* scores calculated from a Caucasian female young normal database for the diagnosis of osteoporosis in

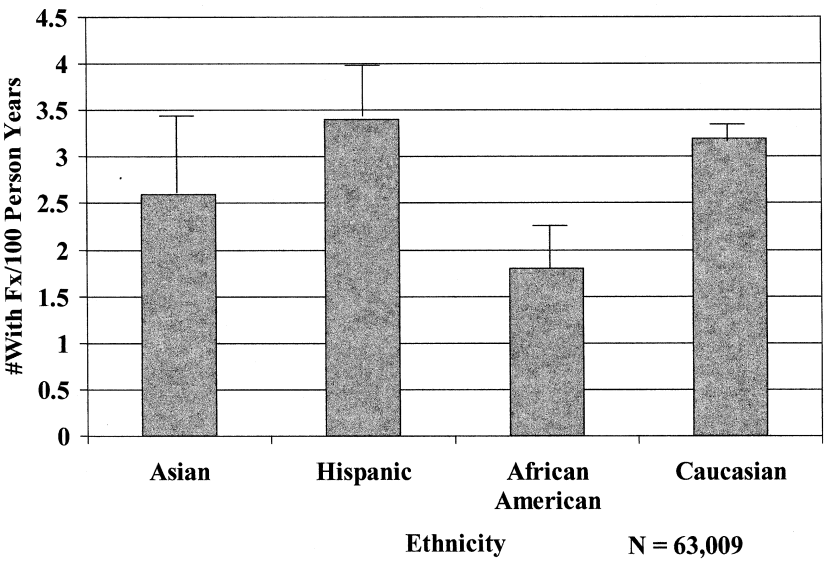

Figure 4 Fracture rates (per 100 person years) by ethnicity.

elderly Caucasian women. For the determination of prevalence, the *T* score calculated from ethnic-specific, young normal databases should be used. Peripheral BMD devices may or may not have gender or ethnic specific young normal databases, which may limit this approach with peripheral technologies, although the NORA data suggest that the Caucasian young normal database may suffice for the assessment of prevalence in U.S. ethnic groups. The diagnosis of osteoporosis in men should be made using *T* scores calculated from a male young normal database. Until more gender- and ethnic-specific fracture data is available using both areal and volumetric BMD measurements, absolute fracture risk (1–10 year) should be calculated using gender-specific absolute BMD for Caucasian men and women. Male and female Caucasian data for hip fracture and global fracture risk has suggested that risk may be the same using *T* scores derived from a young normal female database, although there is no consensus on this issue at this time.

Finally, patients who have already sustained fragility fractures can be diagnosed with established osteoporosis regardless of their absolute BMD or *T* score, assuming secondary causes of fracture, such as Paget's disease or malignancy, are excluded. The diagnosis of osteoporosis was based on the presence of a fragility fracture long before the WHO BMD criteria were established.

Value and Limitations of Serial Bone Mineral Density Measurements

The final controversy in bone density pertains to the use of serial BMD to monitor the effects of aging or disease states, or to monitor the effects of therapeutic agents on BMD.

The best skeletal site for detecting change of BMD, for most disease states that affect bone or pharmacological interventions, is the spine by DXA (Miller *et al.,* 1999; Miller, and Bonnick, 1999). This is due, in part, to the presence of abundant cancellous bone in the spine, a tissue-type which has a much greater surface area and higher metabolic activity than cortical bone. Quantitative computerized tomography (QCT) of the spine measures a larger volume of cancellous bone at the axial skeleton than does DXA, because it is able to isolate cancellous bone. Therefore, larger increases in BMD are observed with therapy. Moreover, QCT measures volumetric density (g/cm3), a parameter believed to be more accurate than the two-dimensional density measured by DXA. However, QCT's ability to monitor longitudinal changes is limited by its relatively poor precision compared to spine DXA. The precision error may be comparable to spine DXA in QCT centers that calibrate their equipment prior to each axial bone density assessment. This process is often unrealistic when the scanner is used for multiple types of scans (chest, head, etc.) rather than being dedicated to bone scans (Grampf *et al.,* 1997).

Other skeletal sites are less useful for monitoring disease states or pharmaceutical effects, with the exception of the distal forearm (1/3 site) which may be profoundly effected by excess parathyroid hormone activity. Patients whose forearm *T* score by DXA is less than that observed at the spine or hip should be assessed for parathyroid abnormalities (Dempster *et al.,* 1999). The hip shows significant serial change in response to pharmacological therapies, although the rate of change per year is less than the rate of change at the spine. The total hip is the best region of interest (ROI) of the hip for monitoring serial change since it is larger than the ROI for the femoral neck. The larger the ROI, the better the precision. However, the femoral neck is the best ROI of the hip for the diagnosis of osteoporosis and the calculation of prevalence, since the total hip BMD may be artifactually elevated in elderly patients by sclerosis below the lesser trochanter, much as osteophytes may artifactually

elevate the PA spine by DXA. None of the peripheral BMD measurements, including ultrasound, have shown significant serial changes in BMD in response to treatment. This is not due to the precision of the technology, which is as good as central devices. It is unclear why the peripheral techniques are not able to show changes in response to therapy. It may be related to the surface area, differences in blood flow, or differences in the bone marrow environment of the peripheral bone measured.

There are three common mistakes made in calculations of serial BMD changes:

1. using BMD values from two different manufacturer's equipment rather than calculating sBMD for both, and then determining serial changes;
2. failure to incorporate the *in vivo* precision error (CV%), determined for each specific device, into the calculation; and
3. using *T* scores rather than absolute BMD for the calculation of serial changes.

As previously discussed, the absolute BMD may vary among manufacturers' equipment, even if the same skeletal site is measured, due to differences in ROI and machine calibration. These differences might be misinterpreted as changes in BMD due to the biology of a disease or the response to a therapeutic intervention. It would be ideal if patients could be monitored on the same DXA machine, or, at the very least, equipment from the same manufacturer, every year. However, this is unrealistic since patients change health insurance, physicians, or move to different locations. In response to this problem, sBMD was developed to equalize the absolute BMD values among the three central DXA manufacturers for the PA spine and the total hip (Hanson *et al.,* 1997; Steiger, 1995). This was achieved by measuring 100 postmenopausal women on each central device and then performing a linear regression to derive an equation to equate the absolute BMD measurements. sBMD provides some degree of equality when it is necessary to compare serial BMD measurements from different manufacturers' central DXA instruments. Most manufacturer software now calculates sBMD as well as their own proprietary absolute BMD. However, sBMD can be calculated using the appropriate equations (Hanson *et al.,* 1997; Steiger, 1995). Even though sBMD provides comparability of measurements from two different devices, there is an additional effect on the precision error. Precision error may be increased as much as 3–5% above the *in vivo* precision error determined for each facility when two machines from different manufacturers are used. Thus, the least significant change (LSC), which is based on the difference of the two sBMD numbers, the precision error of the facility and the precision error between machines, may be increased. The clinician must make the final decision if a particular serial change is significant and thereby warrants a change in patient therapy.

It is incumbent upon each densitometry facility to determine its *in vivo* precision error at all skeletal sites, in addition to the daily *in vitro* phantom calibration that is a routine part of the quality control (QC). Daily phantom scanning for QC detects "drift" of the densitometer, but does not substitute for the additional determination of *in vivo* precision error (CV%) (Miller and Bonnick, 1999). The *in vivo* precision error is affected by changes in patient positioning and absolute BMD, which explains why *in vivo* precision error is higher than *in vitro* precision error. In addition, as Fig. 5 shows, the precision error (CV%) increases with lower BMD values. This is due to the poorer ability of the DXA system to distinguish between soft tissue and bone when there is less bone present. Hence, each densitometry facility must perform *in vivo* QC studies in patients with normal BMD as well as in a group of patients with low BMD to accurately assess their precision error. Precision studies should be

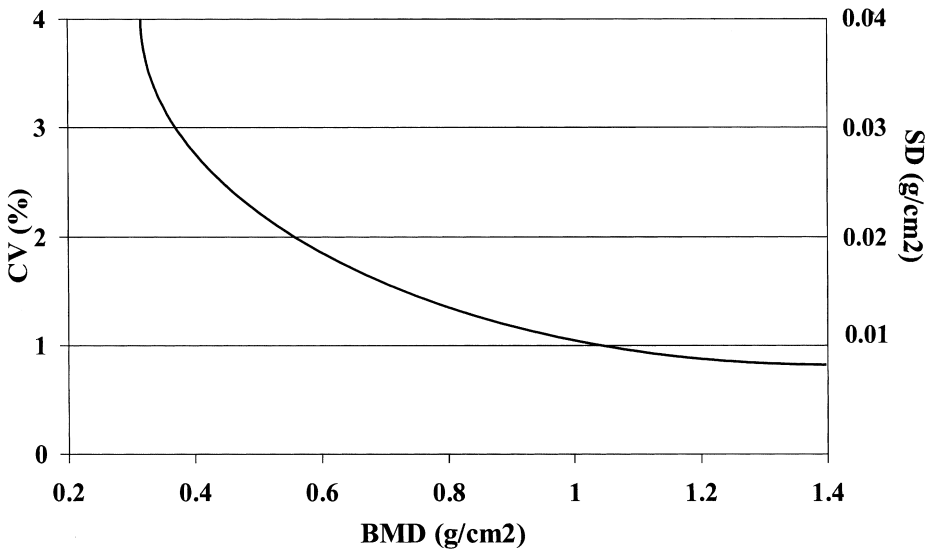

Figure 5 Precision expressed as %CV or SD across a range of bone mineral density. Reproduced from K. Faulkner, personal communication.

repeated whenever a technologist changes, machine location changes, or major software changes are made (Bonnick, 1998).

The least significant change (LSC) for two serial measurements is a function of the precision error. At the 95% confidence level, the difference between two measurements must be at least 2.77 times the precision error to be significant and not simply a measurement error. At the 80% confidence level, which is often acceptable in clinical measurements, the LSC between two BMD measurements must be at least 1.8 times the precision error. Many errors in patient management are made because the densitometry facility does not know their precision error. For example, a patient receiving a bisphosphonate has an increase in BMD of 4% at the PA spine and a decrease of 5% at the total hip and is taken off the bisphosphonate because it is assumed that there has been no response at the hip. In fact, in most instances, these changes at the hip are within the precision error of a hip measurement. The total hip precision error may be 2–3%, especially in patients with a low BMD (<0.60 g/cm^2), which requires a change of 6–9% to be significant at the 95% confidence level. Therefore, the patient had no significant change at the hip, which, if appreciated, may have changed the physician's decision to stop the bisphosphonate therapy.

The calculation of percentage change requires the following steps:

1. 1st BMD − 2nd BMD/1st BMD × 100 = % change
2. 2.77 (for 95% confidence) × precision error = LSC.

If step 1 is greater than step 2, then a LSC has occurred at the 95% confidence level. If step 2 is greater than step 1, then a change which is within the error of the measurement has occurred.

Changes in *T* score values should never be used to monitor patients. *T* scores are dependent on the mean and SD of a young normal reference population. As previously stated, the young normal reference population differs between manufacturers and, in some cases, between models of the same manufacturers' equipment. Over time, manufacturers upgrade their software, which may include changes in the mean and SD of the reference population used to calculate the *T* score.

Recently, the concept of "regression to the mean" has been applied to serial BMD measurements for monitoring the response to pharmacological therapy. In a recent publication, BMD data from 1 and 2 years of treatment with alendronate (5 mg/day) and raloxifene (60 mg/day) were analyzed using the premise of regression to the mean (Cummings *et al.,* 2000). This analysis showed that patients who demonstrate a fall or rise in BMD after the first year of treatment often demonstrate a change in the opposite direction during the second year of treatment. In other words, their BMD changes approach the mean of the group. The paper also stated that patients whose BMD decreased during the first year should not necessarily be taken off treatment, since most will show an increase during the second year. Regression to the mean is a useful concept when applied to groups of patients, however, it cannot be applied to therapeutic decisions for individual patients. This type of analysis is valid only in groups of patients. In addition, regression to the mean occurs in both treated and untreated groups, so in order to determine if the groups are different, regression to the mean in the untreated group must also be assessed (Bonnick, 2000). This has not been presented in the current publication. Finally, if one calculates the LSC range at the 95% confidence level for the total hip BMD in the referenced regression to the mean analysis, nearly all the datapoints fall within this range. The BMD changes at the PA spine were significant in many of the patients in this article (~4.5%), so the medications effectively increased BMD in most patients. Additionally, those patients who had a decline in BMD that was greater than the LSC are nonresponders. Clinic patients are more likely to demonstrate poor adherence, poor absorption, or secondary medical conditions mitigating their response to therapy than their clinical trial counterparts, due to careful selection criteria for participation in a clinical trial (Dowd *et al.,* 2000). Therefore, regression to the mean does not discount the value of serial BMD, but instead enforces the need to perform *in vivo* QC to determine LSC in BMD.

Finally, the relationship between pharmacologically induced increases in BMD and fracture reduction related to improvement in bone strength is presently under investigation. Animal models and *in situ* human studies have shown that 80% of the variance in bone strength is related to bone mineral content (BMC). A linear relationship exists between BMC and bone strength. The issue of fracture reduction has been raised due to observations made comparing changes in BMD versus placebo for calcitonin, alendronate, raloxifene, and risedronate. There are substantial differences in the BMD increases observed but overlap in the 95% confidence limits for relative incident vertebral fracture risk reduction (Faulkner, 2000). This might appear to suggest that changes in BMD are of little importance as an index of changes in bone strength. However, it should be noted that these comparisons are not from head-to-head trials. These different clinical trials recruit from different populations at different times, in contrast to a single head-to-head trial in which patient randomization reduces selection bias and ensures that placebo and treated groups are recruited from the same patient population. Therefore, the conclusions drawn from comparison of BMD changes from separate trial are often incorrect. In contrast, the highest order of evidence-based medicine is a meta-analysis which includes a sensitivity analysis. The data from such analyses suggests that the greater the increase in BMD over the treatment period, the greater the reduction in incident vertebral fractures (Fig. 6) (Wasnich and Miller, 2000). The incident vertebral fracture analysis indicates that there are factors, in addition to increased BMC, which contribute to the increased bone strength produced by the antiresorptive agents. These other factors improve bone strength but cannot presently be measured clinically. Bone architecture, bone size and/or width, and periosteal bone accretion may be altered by antiresorptive agents resulting in increased bone strength which is independent of increased BMC. The mechanism(s)

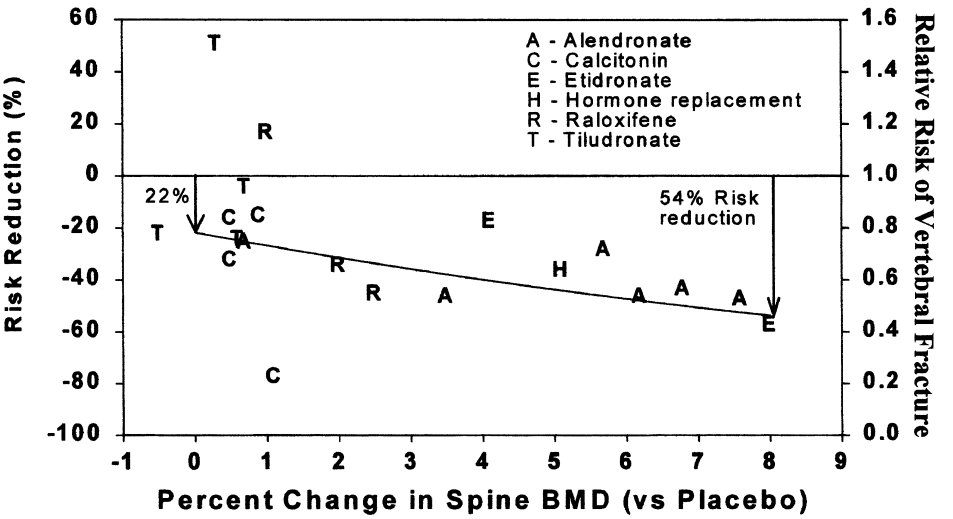

Figure 6 Relative risk of new vertebral fracture vs change in spine BMD (vs placebo) for randomized controlled trials of antiresorptive agents. The solid line represents the Poisson regression results. Reproduced from Wasnich *et al.* (2000).

whereby the various antiresorptive agents increase bone strength are under investigation. It is probable that each antiresorptive agent acts differently to increase bone strength. It is also possible that areal BMD, measured by DXA, underestimates the BMC added by antiresorptive agents, due to the method by which areal BMD is calculated (BMD = BMC/area). In elderly humans, bone size increases with increasing age and it may increase with subperiosteal bone formation induced by various agents. As the bone area increases and the BMC increases, the true increase in BMC may be underestimated by areal BMD measurements. Support for this hypothesis is observations that BMC, assessed by volumetric BMD (QCT), increases more than areal BMC, assessed by DXA with antiresorptive therapy.

In summary, serial BMD measurements should be carefully interpreted to maximize their usefulness. Physicians should never assume that a decline in BMD is not significant as long as the decline exceeds the LSC. It is essential for physicians to monitor the often asymptomatic condition of osteoporosis with BMD measurements. The serial determinations provide feedback and reassurance to ensure patient compliance with treatment regimens. Careful quality control, correct interpretation of serial changes, and proper patient assessment ensures that clinical medicine is not reduced to guess-work.

CHAPTER 93

Macro- and Microimaging of Bone Architecture

Yebin Jiang, Jenny Zhao, and Harry K. Genant
Osteoporosis and Arthritis Research Group, Department of Radiology, University of California, San Francisco, San Francisco, California 94143

Introduction

Bone is a matrix of mineral and organic materials with a certain architecture and texture. The biomechanical competence of bone depends on two variables: its geometric properties and its material properties (Jiang *et al.,* 1999a). In terms of fracture risk, decreasing bone mineral leads to an exponential increase in fracture risk (Geusens, 1992). Yet, other studies have found that bone strength is only partially explained by bone mineral and that bone architecture has great influence on bone strength and the risk of fracture. Bone mineral values in normal and osteoporotic people overlap widely, and the expected correlation between the severity of osteoporosis and the degree of loss in bone mineral has not always been found (Podenphant *et al.,* 1987). The influence of factors other than bone mineral is thought to explain to some extent the overlap in bone mineral measurements between patients with and without osteoporotic fractures. Just as with bridges and buildings, the biomechanical competence or fracture resistance of bone depends not only on the amount of material but also on its spatial distribution, its structure, and its architecture.

Several noninvasive/nondestructive techniques have been developed for measuring bone structure and applied to the study and treatment of osteoporosis. These techniques allow early detection and diagnosis, monitoring of progression and response to therapy, improved estimates of bone strength, and improved prediction of fracture risk (Hassager and Christiansen, 1993; Genant *et al.,* 1996a, 2000). Conventional radiography, microradiography, and radiogrammetry have been used for many years to detect and quantify bone changes. Considerable progress has been made in advanced imaging techniques for noninvasive and/or nondestructive assessment of 2D and 3D bone structure. High-resolution computed tomography (hrCT) and magnetic resonance imaging (MRI) microscopy can be used to examine both cortical and trabecular bone *in vivo.* Much progress has been made in developing micro-CT (μCT) for noninvasive and/or nondestructive assessment of 3D trabecular structure and connectivity. The availability of 3D measuring techniques and 3D image processing methods allows direct quantification of unbiased morphometric parameters, such as direct volume and surface determination (Guilak, 1994), model independent assessment of thickness (Hildebrand *et al.* 1997b), and 3D connectivity estimation (Odgard and Gundersen, 1993).

Assessment of 3D trabecular structural characteristics may further improve our ability to understand the pathophysiology and progression of osteoporosis and other bone disorders. 3D structure is typically inferred indirectly from histomorphometry and stereology on a limited number of 2D sections based on a parallel plate model (Parfitt *et al.,* 1983a,b). With age and disease trabecular plates are perforated and connecting rods are dissolved, with a continuous shift from one structural type to the other. The traditional histomorphometric measurements based on a fixed model type will lead to questionable results (Hildebrand *et al.,* 1999). The introduction of 3D measuring techniques in bone research makes it possible to capture the true trabecular architecture without assumptions of the structure type.

Radiography

Conventional Radiography

Conventional radiography is a widely available, noninvasive means of visualizing bone structure. It also provides qualitative information on bone density. The term osteopenia, "poverty of bone," is used to describe visually decreased bone density—or radiolucency—on radiographs. This decrease in density is a result of a decrease in both mineralized bone volume and total calcium. The amount of calcium per unit of mineralized bone volume remains constant at about 35% (Albright *et al.,* 1941) in osteoporosis and osteopenia, resulting in decreased absorption of the X-ray beam and changes in the bone structure on radiographs. Alone or in conjunction with other advanced imaging techniques, conventional radiography is still widely used to detect osteoporotic fractures and to differentiate various disorders associated with osteoporosis and osteomalacia (Jergas *et al.,* 1999).

Figure 1 General decreased visual bone density results in increased radiolucency of the vertebrae with relative accentuation of the cortical rim, or "picture framing." There is also increased vertical striation due to the proportionally greater loss of horizontal trabeculae and compensatory hypertrophy of the vertical trabeculae.

Figure 2 Multiple fractures in the thoracic spine in advanced involutional osteoporosis, including end plate, wedge, and compression fractures.

Changes in the axial skeleton and the ends of the long tubular bones are most prominent, since these sites have a relatively greater proportion of trabecular bone which has more surface and responds more quickly than cortical bone. As bone mineral is lost, non-weight-bearing connecting trabeculae are resorbed first, while the remaining weight-bearing trabeculae are more widely separated. Some may undergo compensatory thickening in the direction of mechanical stress. Trabecular anisotropy increases, resulting in distinct patterns on radiographs, such as the organized sequential trabecular changes along the compressive and tensile stress in the proximal femur, and an appearance of vertical striation in the lumbar spine in early stages of osteopenia caused by rarefaction of the horizontal trabeculae and a relative reinforcement of the vertical trabeculae (Fig. 1).

On radiographs vertebra may appear as a "picture frame" or as an empty box because of accentuation of the

cortical margins surrounding the lucent trabecular center. Increased bioconcavity of the vertebral endplates due to protrusion of the intervertebral disk into the weakened vertebral body can be seen in osteopenic vertebrae. It has been estimated that as much as 20–40% of bone mass must be lost before a decrease in bone visual density can be seen in lateral spine radiographs (Lachmann *et al.,* 1936).

Vertebral fracture, the hallmark of osteoporosis, has a wide range of morphologic appearances from increased concavity of the end plates, anterior wedging, to a complete destruction of the vertebral anatomy in vertebral crush fractures (Figs. 2–4). Fractures can be graded by radiologists or experienced clinicians and quantified with morphometric methods to reduce the subjectivity inherent in grading (Genant *et al.,* 1996b; Wu *et al.,* 2000; Jiang *et al.,* 1997c). The Genant scoring method (Genant *et al.,* 1993) grades 0 for normal, 1 for mildly deformed (20–25% reduction in anterior, middle, and/or posterior height, and 10–20% reduction in the projected area of the vertebral body), 2 for moderately deformed (25–40% reduction in height, and 20–40% in area), and 3 for severely deformed (40% or greater reduction in height and in area) (Fig. 5). This method offers high reproducibility inter- and intrareader and inter- and intratechnique for multiple experienced bone radiologists who graded both conventional radiographs and laser-digitized images at a 200- μm pixel size in a picture archiving and communication systems (Wu *et al.,* 2000; Jiang *et al.,* 1997c). It has been widely used to evaluate most important end points in epidemiological studies and in various clinical studies investigating the efficacy of osteoporotic drugs (Ettinger *et al.,* 1999; Harris *et al.,* 1999; Chesnut *et al.,* 1999).

Figure 3 Severe osteoporosis. The vertebrae can hardly be distinguished on the lateral lumbar spine radiograph. There are multiple endplate and compression fractures.

Figure 4 Lateral radiograph of the lumbar spine of steroid-induced osteoporosis demonstrates increased radiolucency, moderate wedge deformity of the first lumbar vertebra, and a mild biconcave deformity of the second lumbar vertebra.

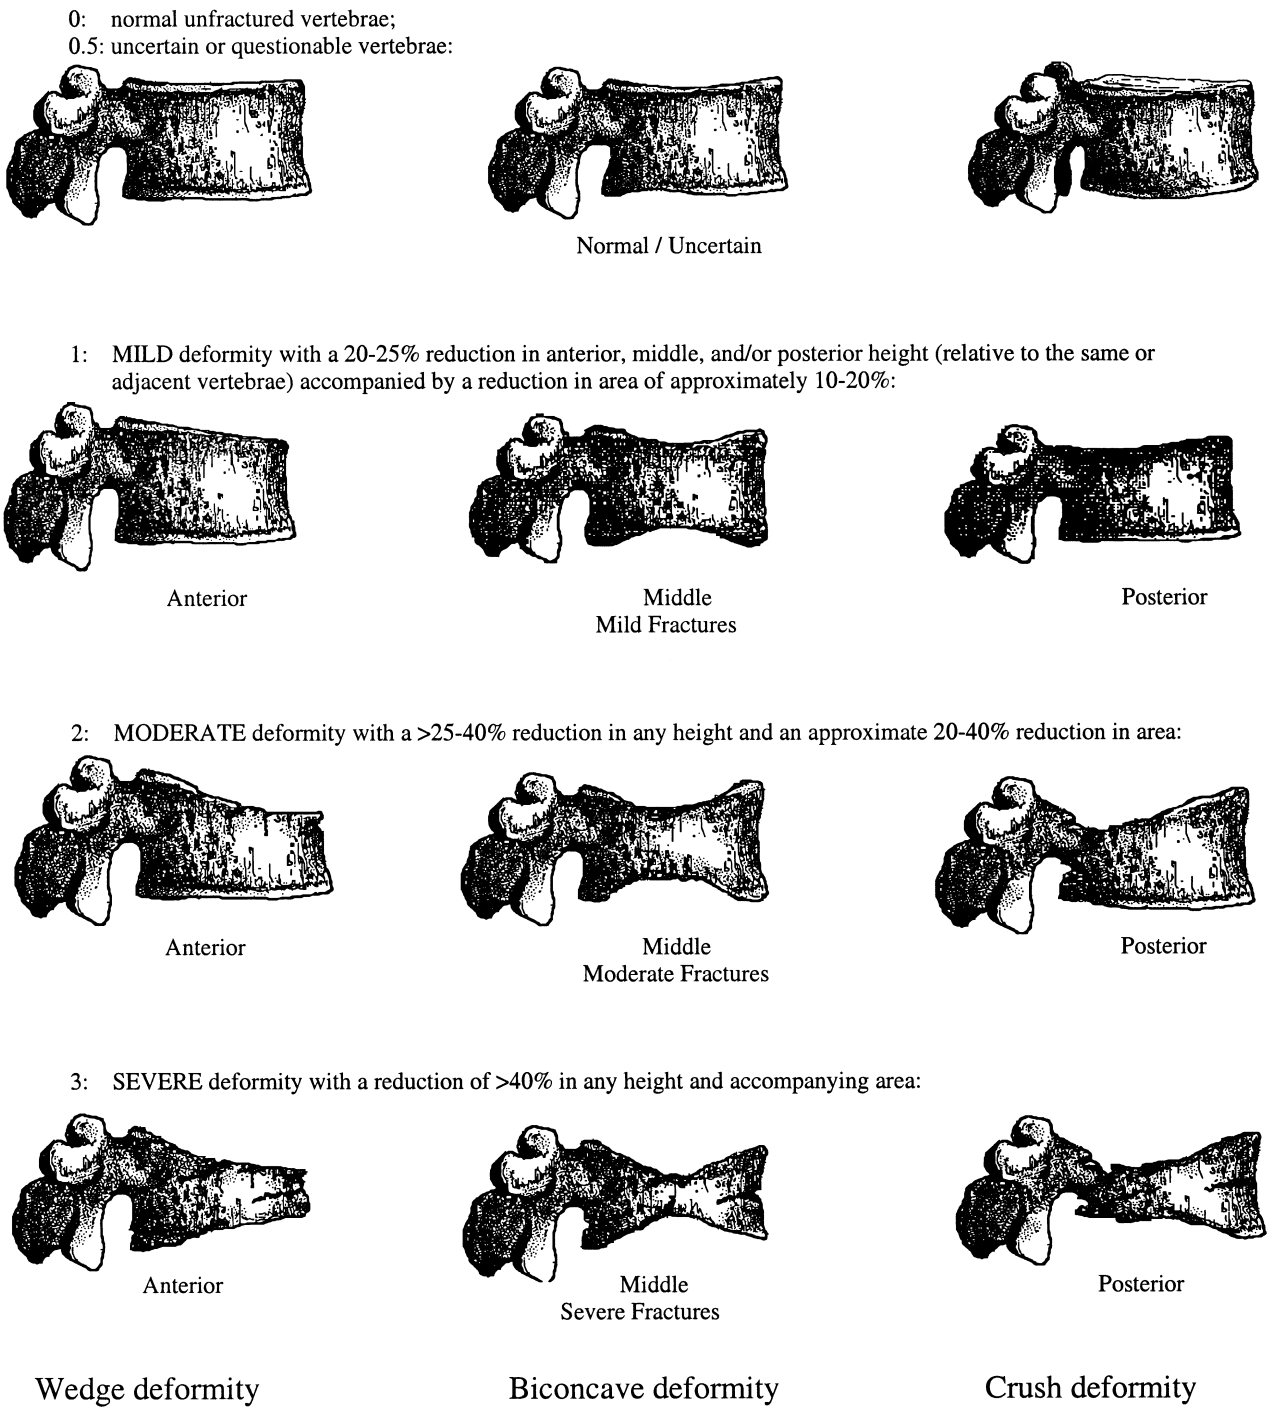

Figure 5 The Genant grading method for a semiquantitative evaluation of osteoporotic vertebral fracture grades fracture severity from normal (grade 0) to severe deformity (grade 3). The scoring scheme illustrates reductions of the anterior height that correspond to the grade of deformity. Reductions of the middle or posterior heights or combinations thereof can be evaluated accordingly.

Of most concern in osteoporosis are fractures of the hips, vertebral bodies, and wrists. Changes in the bone cortex or spongiosa may make such injuries more likely to occur. The shape, size, and structure of bone as well as its mass affect its resistance to these loads. Fractures of the vertebral bodies are a result of predominantly axial compressive loads. The decreased load-bearing capacity of each vertebra is related to the material properties of the bone and changes in the vertebral trabeculae from postmenopausal and age-related bone loss. Absorption and removal of the horizontal trabeculae or lateral support cross-ties change the architectural arrangement and result in a decrease in load-bearing capacity

(Mosekilde *et al.,* 1985). The vertical trabecular bone, therefore, behaves as a column and is prone to critical buckling loads (Townsend, 1975). A 50% decrease in cross-sectional area as a result of absorption of the horizontal trabeculae is associated with a 75% decrease in the load-bearing capacity of the vertebral body (Einhorn, 1992).

In addition to osteoporotic vertebral fracture, loss of horizontal trabeculae increases the likelihood of intertrochanteric hip fractures. Fractures of the wrist and hip usually begin in the metaphyseal–epiphyseal regions of the bone, which depend heavily on the trabeculae to support loads (Brown and Ferguson, 1978; McBroom *et al.,* 1985). Osteoporotic fractures usually do not occur in the mid-shaft of the femur or radius (Smith and Smith 1976), which is mainly cortical bone. Since the diameter of the bone expands with age with an increase in geometrical properties such as cross-sectional moments of inertia, particularly in men, there is more resistance to bending and torsional loads. However, the femoral neck, though also mainly of cortical bone, is not protected in the same way, since the periosteum is arguably absent from the part of the femoral neck within the hip joint for periosteal bone apposition (Pankovich, 1975; Phemister, 1939; Einhorn, 1992). Endosteal bone resorption during the aging process results in cortical bone thinning but is not associated with compensation of periosteal bone apposition to increase geometry such as cross-sectional diameter and moments of inertia. Consequently, the femoral neck with its unique anatomy becomes prone to fracture under deforming forces. A recent study in healthy men and men with hip or spine fractures using DXA shows that advancing age is associated with increased femoral neck width in healthy men, suggesting some capacity for intracapsular periosteal apposition. Bone fragility leading to hip or spine fractures in men may be the result of fracture site-specific deficits in bone size and volumetric BMD that have their origins in growth, aging, or both (Seeman *et al.,* 2001).

The trabecular patterns in the proximal femur have been scored to grade VII (Singh *et al.,* 1972) for individuals with dense trabeculae, even in the Ward's triangle enclosed by compressive and tensile trabeculae, and from grade VI as normal for all compressive and tensile trabeculae visible to grade I for marked reductions in the principal compressive trabeculae (Fig. 6) (Singh *et al.,* 1972). The Singh index has been shown to give different interobserver variation and different results regarding its relationship with bone mass and vertebral fracture (Cooper *et al.,* 1986; Singh *et al.,* 1972, 1970; Dequeker *et al.,* 1974).

In postmenopausal osteoporosis and other high-turnover metabolic bone disorders such as hyperparathyroidism (Fig. 7), renal osteodystrophy, and hypervitaminosis D (Fig. 8, see also color plate). (Jiang *et al.,* 1991), other structural changes in the cortical bone can be observed, such as longitudinal striation and tunneling in the cortical bone,

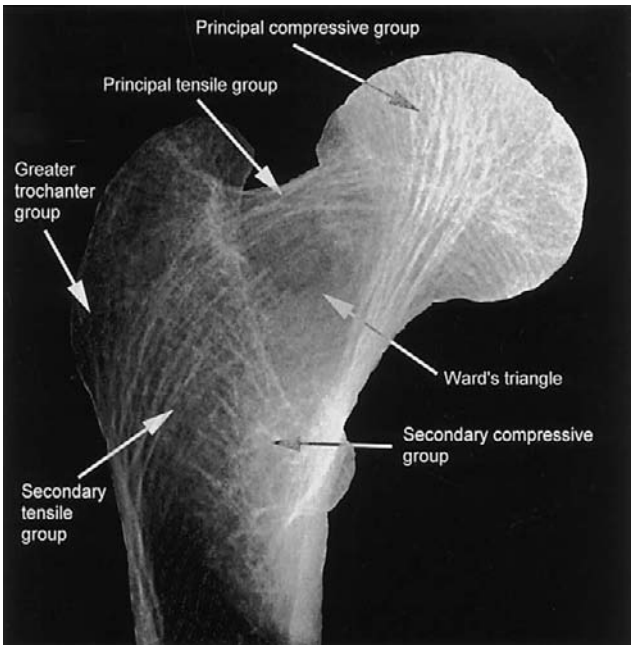

Figure 6 Schematic representation of the five normal groups of trabeculae in the Singh index which is based on the assumption that the trabeculae in the proximal femur disappear in a certain sequence. Ward's triangle is an area enclosed by the principal and secondary compressive as well as principle tensile groups.

Figure 7 Patterns of bone resorption: subperiosteal bone resorption with scalloping and speculation of the outer cortex, acro-osteolyses, and soft tissue calcifications characterizes primary hyperparathyroidism; endosteal resorption and tunneling is prominent in senile osteoporosis; intracortical porosity and trabecular resorption are features of postmenopausal osteoporosis.

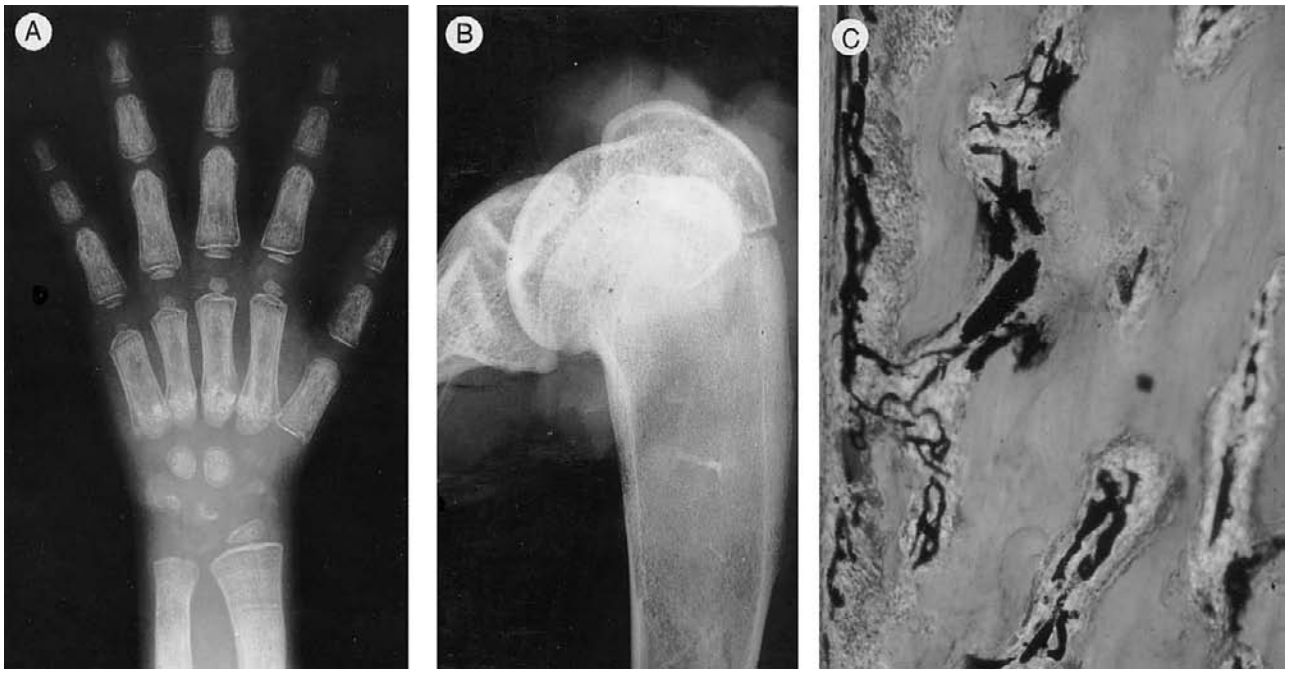

Figure 8 Remarkable increase in intracortical remodeling and aggressive resorption results in "trabeculization" in the metacarpi and phalanges in a child with hypervitaminosis D. There is metastatic calcification in the soft tissues in the wrist (A). Contact radiograph of a rabbit humerus with hypervitaminosis D (B) shows longitudinal striation and tunneling in the cortical bone because of increased intracortical remodeling and resorption, which represent on corresponding histology (C) increased cortical bone porosity, enlargement of the Haversian canals and Volkmann canals, and proliferation of microvasculature in the canals as a result of increased bone resorption by cutting cones (microvascular injection with Chinese ink and HE staining). (See also color plate.)

intracortical porosity, endosteal scalloping, subperiosteal resorption or irregular definition of the outer bone surface, and cortical thinning (Genant, 1983). The increased cortical bone remodeling and aggressive intracortical bone resorption leads to cortical bone "trabeculization."

Radiogrammetry

Radiogrammetry can be performed to measure cortical thickness, vertebral deformity, and bone size. It is simple, inexpensive, and reproducible. Radiogrammetry offers information on bone mass, although long before fractures are manifested radiologically, the patient will have already lost 30–50% of his or her bone mass over the previous 10–20 years (Dequeker, 1976). This technique does not measure cortical porosity or trabecular bone status.

Because of increased endocortical resorption and decreased bone formation with aging and senile osteoporosis, cortical thinning and widening of the medullary space is commonly seen (Fig. 9) and can be quantified using radiogrammetry applied to the metacarpal bones (Dequeker, 1976; Jiang, 1995) or in preclinical studies (Jiang *et al.,* 1996a). Annual decreases in combined cortical width of 0.4% before menopause and of 1.3% after menopause have been reported (Falch and Sandvik, 1990), which is comparable to the 1.45%

Figure 9 Conspicuous general cortical thinning in senile osteoporosis primarily as the result of endosteal bone resorption, decreased visual bone density, and loss in trabecular network.

in untreated women after oophorectomy reported by Genant *et al.* (1982).

The measurements of geometric properties of the proximal femur, including cortical thickness of the femoral shaft and the femoral neck, width of the trochanteric region, and number of tensile trabeculae, have been reported to be associated with the risk of hip fractures (Gluer *et al.,* 1994; Faulkner *et al.,* 1993). DXA can also provide lumbar spine morphometry and femoral neck geometry (Yoshikawa *et al.,* 1994; Seeman *et al.,* 2001) but yields little information on trabecular structure and intracortical changes because of limited resolution. Hip axis length determined from conventional radiographs or DXA can predict hip fracture independently of densitometry, as a longer hip axis length is associated with an increase in femoral neck and trochanteric fracture risk (Faulkner *et al.,* 1993; Gluer *et al.,* 1994). Instead of varying with age after midadolescence, the hip axis length seems to be mainly influenced by genetic factors (Flicker *et al.,* 1996), which supports other reports that differences in the hip axis length may partially explain racial differences in hip fracture (Cummings *et al.,* 1994). Hip axis length adds information to BMD and appears to be useful for cross-sectional studies of risk factors for osteoporosis, but has little value in longitudinal studies.

High-resolution radiographic techniques using high-detail films and small spot X-ray tubes, like the ones used in mammography, are important for depicting changes in bone, since the detection of osteopenia by conventional radiography can be inaccurate and insensitive (Genant *et al.,* 1975). It is influenced by many factors such as soft-tissue thickness, radiographic exposure, the film used, and film processing.

Morphometric radiogrammetry measurements of the long tubular bones on conventional radiographs include bone length (L), the outer diameter or periosteal width (D), and inner diameter or medullary space (d) of the cortical bone at 50% of the length. The cortical thickness can be obtained by simple subtraction ($D - d$). Since the long tubular bones are approximately circular at midshaft and the medullary cavity is nearly centered in the tubular bone cylinder at that point, $D^2 - d^2$ can be regarded as an index of the cortical cross-sectional area after omitting the constant $\pi/4$; $(D - d)/D$ the ratio of cortical thickness to the midshaft width; and $(D^2 - d^2)/D^2$ the ratio of cortical cross-sectional area to the total midshaft cross-sectional area. The reproducibility as coefficient of variation (CV) of six determinations with repositioning of the radiographs at each measurement is *L,* 0.2%; D, 1.2%, *d,* 2.1%; DDM, 1.5%; DPM, 1.8% for conventional radiographs of the radius of baboons and *L,* 0.07%; *D,* 0.65%; *d,* 1% for microradiographs ($\times$100, with focal spot 5 μm) of rat femurs. High correlations are found in both baboons and rats between midshaft periosteal diameter (D) and torsional strength and stiffness ($r = 0.7$); between cortical area index ($D^2 - d^2$) and stiffness ($r = 0.6$); and among D, $D^2 - d^2$, and dual X-ray absorptiometry (DXA) measurements ($0.7 \leq r \leq 0.9$), indicating that radiogrammetric measurements may be useful for estimating bone mineral and strength in preclinical studies (Jiang 1995).

Microradiography

With the expansion of contact radiography, microfocus radiography, and specimen slab radiography, more details of bone structure have been clearly demonstrated (Genant *et al.,* 1973, 1975; Jiang *et al.,* 1990, 1991, 1995; Wevers *et al.,* 1993).

Because trabecular structure can be clearly displayed on radiographs, especially on high-resolution radiographs or microradiographs, sophisticated image processing techniques have been designed to segment and extract trabecular morphometric parameters, such as trabecular bone volume, trabecular thickness, number, separation, and other connectivity information. Fractal analysis and fast Fourier transforms have also been applied to the evaluation of trabecular structure (Benhamou *et al.,* 1994; Ouyang *et al.,* 1998; Jiang *et al.,* 1996b). For structural analysis, gray-scale images with a range of values must be segmented into binary images with only two values, white and black, representing bone and no bone.

Quantitative microradiography using an aluminum calibration step wedge, similar to quantitative backscattered electron imaging and small-angle X-ray scattering imaging, can measure the focal degree of mineralization and secondary mineral apposition. Mineralization of the trabecular bone consists of primary and secondary mineral apposition. Primary mineral apposition is mineralization of osteoid, which can be detected using traditional histomorphometry that measures the amount of bone matrix or bone mass. Secondary mineral apposition is a slow and gradual maturation of the mineral component, including an increase in the amount of crystals and/or an augmentation of crystal size toward their maximum dimensions. Increased bone turnover, as in postmenopausal osteoporosis, results in hypomineralization, because resorption begins prematurely, before mineralization is complete. The least mineralized bone is highly radiotranslucent and is the most recently formed, or has just achieved its primary mineralization, and represents about 75% of the complete mineralization. It contrasts with the adjacent fully mineralized interstitial bone, with low radiotranslucency. Oral administration of alendronate for 2 or 3 years in osteoporotic women increases BMD, but does not increase trabecular bone volume in the iliac crest bone biopsy, which can be explained by an increase in secondary mineralization as a result of reduced bone turnover (Meunier and Boivin, 1997).

Microfocus radiography and specimen slab radiography have been employed in preclinical studies (Jee *et al.,* 1990; Miller and Jee, 1979) and in toxicological and safety studies, e.g., to investigate effects of on/off treatments of high doses of a bisphosphonate, an inhibitor of osteoclastic activities and bone resorption, on bone modeling and bone remodeling in growing nonhuman primates (Fig. 10) and rodents (Fig. 11). Radiological changes are very closely

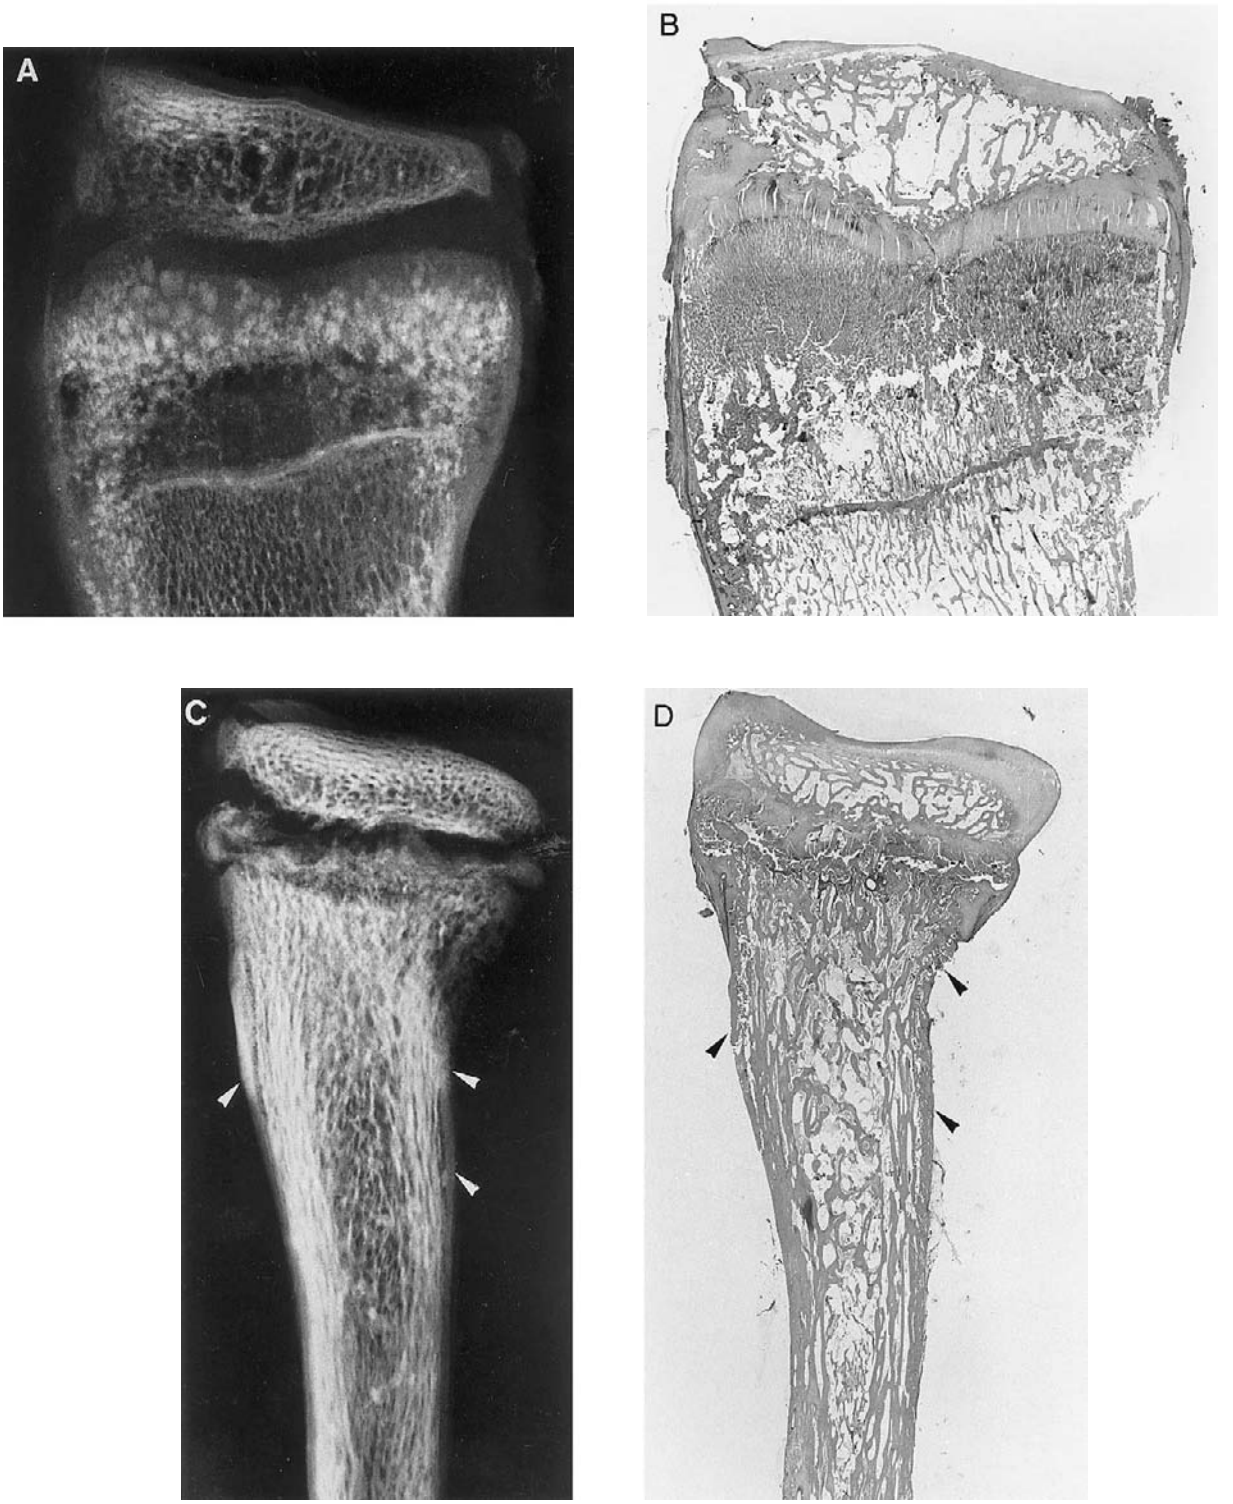

Figure 10 A baboon treated with a high dose of a bisphosphonate. Slab contact radiograph (A) of the distal end of the radius reveals an increase in width of the growth cartilage. The scattered dense amorphous dots on the radiograph represent localized areas of persisting calcified cartilage cores correlative to histological macrosection (B, HE staining). The sharp arrest line, also representing persisting calcified cartilage cores, is the transition between the induced changes and the original normal bone. The periosteal reaction represents woven bone formation. Slab contact radiograph (C) of the proximal end of a baboon treated with a higher dose of a bisphosphonate shows irregularity of the growth plate with dense dots, increased density in the spongiosa, intracortical lucent lines, and periosteal reaction (arrowhead), which correspond in the histologic macrosection (D) to cartilage calcification in the growth plate, increased number of trabeculae in the metaphysis, enlargement of the Haversian canals in the cortical bone, and periosteal woven bone formation (arrowhead).

correlated with corresponding histopathological findings (Jiang, 1995). The radiologic manifestations in baboons are very similar to changes in humans treated with pamidronate (Liens *et al.,* 1994).

CT

There are currently major research initiatives in the areas of high-resolution and microcomputed tomography (hrCT/μCT) for assessment of bone structure. The spatial resolution of clinical CT scanners is inadequate for highly accurate analysis of discrete trabecular morphological parameters and cortical measurements, and newer CT developments address these issues with different approaches: new image acquisition and analysis procedures using state-of-the-art clinical CT scanners; new ultra-high-resolution scanners for *in vivo* investigations of the peripheral skeleton; and new μCT scanners for *in vitro* three-dimensional structural analysis of small bone samples or for preclinical studies. The discrete elements in digital images are called pixels for 2D and voxels for 3D. From a physical perspective, spatial resolution is typically given in line pairs per millimeter or as a 5 or 10% value of the modulation transfer function, requiring measuring the modulation transfer function or the point spread function of the imaging system. For simplicity, pixel or voxel dimensions are used which may result in a "pseudo" resolution that typically overestimates the physically "correct" resolution by a factor of 2–4. Therefore, to image 50-μm-thick structures the "correct" resolution must be at least 50 μm, requiring pixel/voxel size of 25 μm or smaller according to Nyquist's theorem (Engelke *et al.,* 1998a).

High-Resolution CT

High-resolution (hrCT) thin-slice CT, adapted from existing body CT scanners for high-resolution measurements, can be used to assess trabecular and cortical bone structure and cross-sectional geometry of virtually any bone in the body. Volumetric bone mass or density in trabecular and cortical bone can be determined separately using QCT (Genant *et al.,* 1996a). HrCT, using standard body CT scanners, typically has pixel sixes of 300–500 μm and slice thickness of 1–1.5 mm, and can depict the trabecular network of the spine and hip, but requires a higher radiation exposure than standard QCT. As the trabecular thickness is about 100–150 μm and trabecular separation about 500–1000 μm, the depiction of individual trabecula is limited by the spatial resolution and signal to noise ratio as a result of the low radiation dose involved. It is still possible to extract some measures of apparent trabecular structure, though it may not accurately determine trabecular structure. The image processing procedures and threshold used to segment bone structure (Fig. 12) can also influence trabecular structure measurement. Using a textural analysis in osteopenic women with DXA T scores of less than -2.5, with or without vertebral fractures, structural parameters allowed discrimination of fractured from nonfractured women. (Wang *et al.,* 1996)

In CT images of lumbar vertebrae with 1.5-mm slice thickness, trabecular structural analysis can provide differential information, *in vivo,* about the state of trabecular structure, particularly in osteopenic subjects (Chevalier *et al.,* 1992; Gordon *et al.,* 1998). Chevalier *et al.* (1992) used hrCT to measure a feature called the trabecular fragmentation index (length of the trabecular network divided by the number of discontinuities) to separate osteoporotic subjects from normal subjects. In another study using CT images of the vertebral body with 2-mm slice thickness, trabecular separation significantly increased with age in women 50 years of age or older, while women with vertebral fractures had significantly lower BMD and significantly higher trabecular separation (Ito *et al.,* 1995). Gordon *et al.* (1998) reported on an hrCT technique that extracted a texture parameter reflecting trabecular hole area, analogous to star volume (Croucher *et al.,* 1996), which appeared to enhance vertebral fracture discrimination relative to BMD. In other reports, no significant difference was found in pQCT trabecular BMD at the distal radius *in vivo* from premenopausal and postmenopausal women, although the number of trabecular perforations was significantly higher in the postmenopausal women. This suggests that loss of connectivity occurred before a significant reduction of BMD and that trabecular bone connectivity is more sensitive than BMD to the early changes of postmenopausal osteoporosis (Takagi *et al.,* 1995).

Trabecular bone structural parameters derived from *in vitro* CT images correlated moderately with BMD, with r^2 values ranging from 0.37 to 0.64 (Jiang *et al.,* 1998). In CT images of the lumbar vertebrae using 1.5 mm slice thickness, the correlation between trabecular structural parameters and BMD was 0.60 (Chevalier *et al.,* 1992). The same observation has been reported in a study of MRI trabecular structure and CT BMD (Majumdar *et al.,* 1997). This moderate correlation indicates that trabecular structural analysis in CT or MR images — in addition to bone mineral measurement — may provide new information about the state of trabecular bone.

Combining volumetric BMD with trabecular structural parameters provides better prediction of bone biomechanical properties than either parameter alone (Jiang *et al.,* 1998; Mundinger *et al.,* 1993). Osteoporotic fractures are most likely to occur at sites with a considerable amount of trabecular bone such as the distal radius, the vertebral body, and the proximal femur, so the development of diagnostic procedures for detecting individuals at fracture risk has focused on the trabecular compartment at these sites. Low BMD at these sites — hip, spine, and forearm — is significantly associated with the risk of osteoporotic fractures (Hui *et al.,* 1990; Melton *et al.,* 1993; Cummings *et al.,* 1990; Seeley *et al.,* 1991) However, there is often considerable overlap in BMD values between fracture and nonfracture subjects (Cann *et al.,* 1985; Cummings *et al.,* 1993). The overall risk of fracture is determined by the mechanical strength of the bone and other factors such as falls. BMD alone only partially explains the mechanical competence of

Figure 11 Microradiographs of rat femur specimens were taken using a microfocus X-ray system. Compared with a control (A), treatment with a high dose of bisphosphonate for 3 months (B) resulted in an enlarged club-shaped deformity with increased density of the metaphyses and thickening of the growth plates (curved arrows) at both distal and proximal ends, linear intracortical lucencies (arrows) in the diaphysis and femoral neck, and patches of relatively decreased density (open arrows) in middiaphysis. Three months after withdrawal from treatment, the bone in the distal metaphysis normalized so that the originally increased density area progressively moved toward the diaphysis, causing alternate bands of increased and decreased (arrows) density, while the cortical bone and growth plates (curved arrows) became normalized (C). Corresponding μMRI of the same specimens imaged in saggital plane, using a spin echo sequence, in-plane resolution of 78 μm and slice thickness of 150 μm on a Varian Unity 400 NMR instrument at 9.4 T, show normal cortical bone, growth plate, and trabecular network in the metaphysis and epiphysis of a control rat (D), increased bone mass in the metaphysis and epiphysis and increased thickening of the growth plate in the treated rat (E), and normalization of the thickness of the growth plate and trabecular network in the metaphysis and the movement of the increased bone mass toward the diaphysis after withdrawal from treatment (F).

cancellous bone; and trabecular architecture is an important additional factor in assessing bone strength (Vesterby *et al.,* 1991; Dalstra *et al.,* 1993; Chevalier *et al.,* 1992; Wallach *et al.,* 1992).

Analyzing bone strength biomechanically and correlating it to BMD shows correlation coefficients (r) between bone strength and BMD ranging from 0.7 to 0.95 (Linde *et al.,* 1991; Biggemann *et al.,* 1988; Martens *et al.,* 1983; Lang *et al.,* 1988; Lotz *et al.,* 1990; Esses *et al.,* 1989; Jiang *et al.,* 1998). Trabecular structural parameters from *in vitro* CT images of the human vertebral body are significantly correlated with elastic modulus, with r^2 ranging from 0.58 to 0.72 (Jiang *et al.,* 1998). The maximum compressive strength and the shear strength of human L2 vertebral bodies show significant correlations with trabecular architectural parameters determined by hrCT or histomorphometry, with correlation coefficients ranging from 0.88 to 0.55 (Cendre *et al.,* 1999). Consideration of architectural properties by noninvasive imaging techniques seems to increase the predictability of the *in vitro* fracture load beyond BMD measurement alone (Faulkner *et al.,* 1993; Augat *et al.,* 1996).

Because of the resolution and slice thickness used in clinical CT, only the thick plates of the trabeculae are depicted and the dominant structures result in a textural appearance, while the thinner trabecular structure is affected by partial

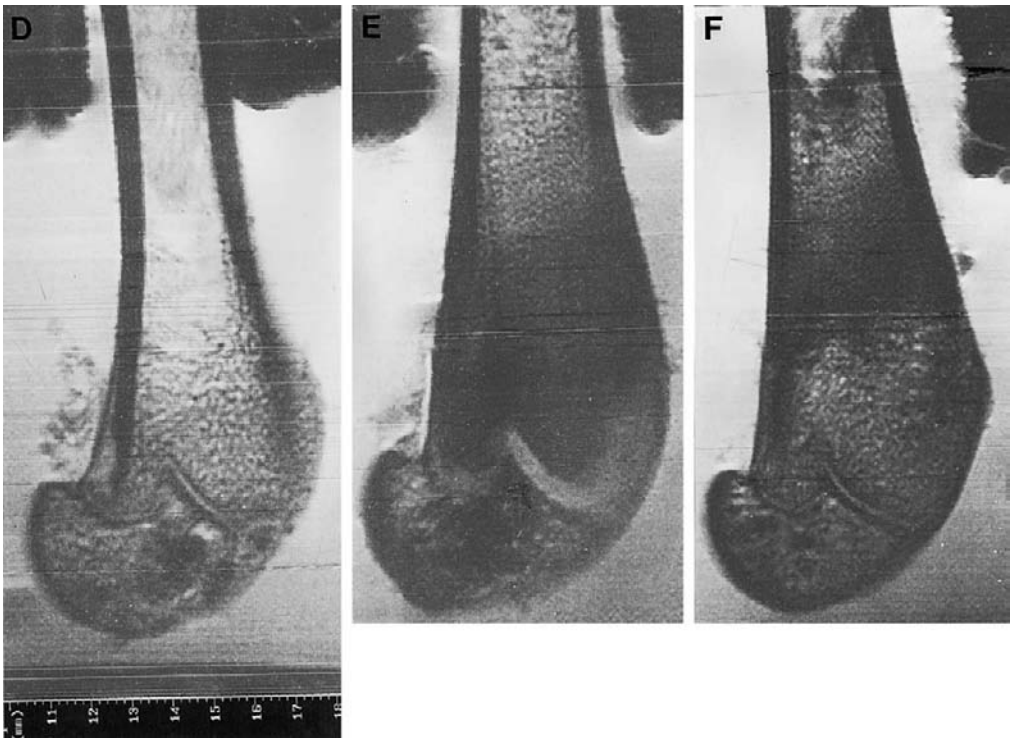

Figure 11 *(Continued)*

volume effects. The segmentation algorithm is important to accurately and reproducibly classify pixels from images in a fast, objective, non-user-specific manner. Segmentation is usually threshold- or edge-based. The threshold depends on the absolute gray value of the pixel, i.e., bone and marrow densities. Global thresholds apply the same threshold to the whole image which works well in high-resolution and high-contrast images, while local thresholds adapt this value to a neighborhood of a selectable size. Edge-based methods apply the first- or second-order derivative and therefore detect changes in gray values (Engelke *et al.,* 1998a). Although some decisions have to be made by the operator, such as placement of the region of interest (ROI), the important advance is that the algorithm is implemented in a uniform manner across all images. An *in vitro* study showed that precision error as coefficient variation (CV) and standardized CV of trabecular structural parameters was $<5\%$ (Jiang *et al.,* 1998). In a validation study, hrCT of a human L2 vertebral body with 150 μm spatial resolution and 330 μm thickness and with edge enhancement to segment bone structure, showed significant correlations with histomorphometry with 7 μm slice thickness, with correlation coefficients ranging from 0.87 to 0.63. Because hrCT has lower spatial resolution and thicker slices, bone volume fraction (bone volume/ total volume, BV/TV) and trabecular thickness determined by hrCT were overestimated by a factor 3.5 and 2.5, respectively, as compared with histomorphometry, while trabecular separatioin was underestimated by a factor of 1.6 (Cendre *et al.,* 1999).

Volumetric CT

Standard CT 2D acquisition is useful for assessing vertebral trabecular bone. Limitations of the single slice standard CT 2D acquisition include a high degree of operator dependence, the need for careful slice positioning, ROI selectioin and placement, and the lack of a technique to assess the proximal femur. Because of the availability of helical CT systems and powerful and relatively inexpensive computer workstations to handle large volumes of image data, new developments in true volumetric acquisition can address some of the limitation of standard 2D CT by providing rapid and highly precise volumetric measurements. The 3D volumetric approaches are optimal for highly complex structures such as the proximal femur and to improve spinal measurements (Fig. 13, see also color plate).

The volumetric acquisition encompasses the entire object of interest either with stacked-slice or spiral CT scans, and uses anatomic landmarks to automatically define coordinate systems for reformatting CT data into anatomically relevant projections. For example, using the vertebral endplates this technique can automatically determine 3D orientation of the vertebral body and does not need an operator for careful slice positioning (Heitz and Kalender, 1994). Measurement accuracy can be improved in patients with scoliotic or lordotic curvature.

With appropriate image processing techniques to reproducibly delineate volumes of interest, spiral CT systems can determine bone mineral content (BMC) or bone mineral

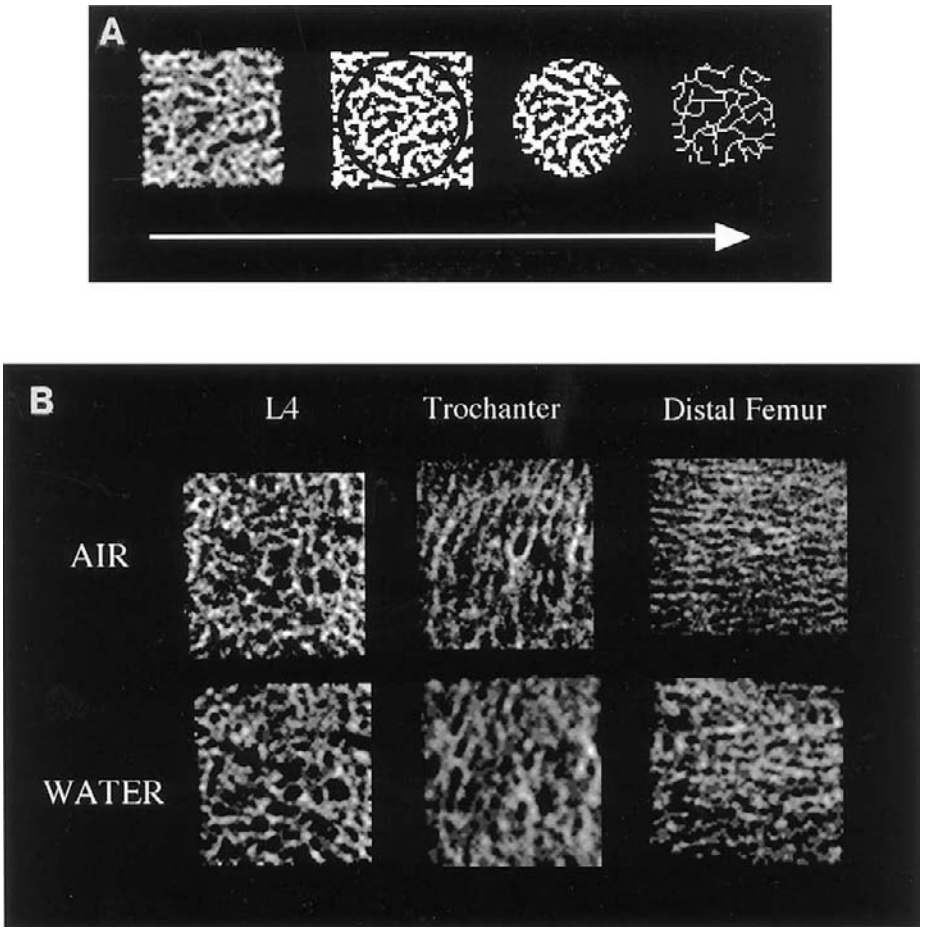

Figure 12 Schematic representation of image processing procedures of trabecular bone structure analysis using AVS, advanced visual system, on a Sun workstation. The analysis procedures are from left to right. This first image on the left is a pQCT image of a bone cube from a vertebral body scanned in water. A threshold is applied to segment the trabecular bone. A region of interest is selected from the binary images to calculate apparent trabecular bone volume, thickness, and separation. Finally, the image is skeletonized to analyze apparent trabecular structure and connectivity (A). Sample images of cubic human specimens from different anatomic locations scanned in air or in water using pQCT (B).

density (BMD) in the trabecular or cortical components separately and of the entire bone or subregion, i.e., the vertebral body, femoral neck, intertrochanteric subregions, etc. In addition, volumetric acquisition can provide highly accurate true volumetric rendering and can calculate important geometrical and other biomechanical measurements, such as cross-sectional area, cross-sectional moments of inertia, and finite element analyses (Faulkner *et al.,* 1990; Heitz and Kalender, 1994; Keyak *et al.,* 1998; Lang *et al.,* 1997; Lotz *et al.,* 1990; McBroom *et al.,* 1985). Such an approach is particularly useful with the proximal femur because of its complex anatomy, dramatic 3D variations in BMD, and biological relevance to osteoporosis, arthritis, and other disorders. Using volumetric acquisition and finite analysis modeling (Lotz *et al.,* 1990; Keyak *et al.,* 1998) can improve estimations of proximal femoral strength over global projectional densitometry. Finite element analysis of bone has shown that bone structure itself rather than density values averaged over a larger volume can be used as a starting point (van Rietbergen *et al.,* 1995), Potentially the interaction of the cortex with the trabecular structure, the transmission of forces inside the bone and the contribution of the cortex to bone strength can be investigated in

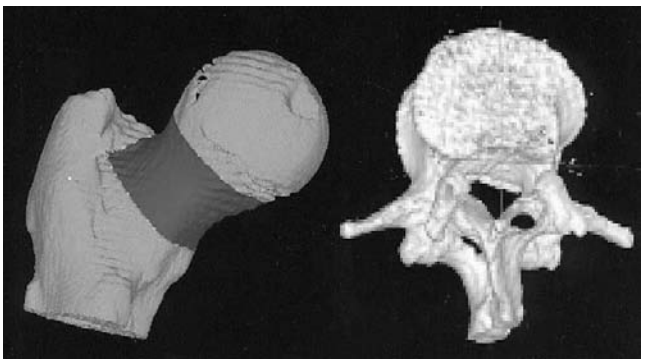

Figure 13 Three-dimensional representation of the lumbar spine and the proximal femur from 3D or volumetric CT acquisition. The lumbar spine and the proximal femur were encompassed with 3-mm contiguous slices, and segmentation was obtained by mapping the bone surface using a contour-tracking algorithm. (See also color plate.)

greater detail. *In vitro* studies using subregions of the hip and volumetric acquisition can enhance prediction of biomechanical strength (Lang *et al.,* 1997; Heitz and Kalender, 1994). It will be of interest to explore the application of these approaches to longitudinal studies, to monitoring response in drug therapies, and to diagnostic measurements.

Ultra-High-Resolution Peripheral CT

Improving spatial resolution by decreasing pixel size and slice thickness improves the accuracy of structural assessment. Several investigators have developed and evaluated special-purpose ultra-high-resolution CT scanners for peripheral skeletal measurements *in vivo* (Müller *et al.,* 1996c). They have achieved resolutions of 0.17 mm isotropic for trabecular structure in the distal radius and obtained morphological data that were comparable to direct histomorphological measurements of bone. The results of the morphometric analysis from the three-dimensional stack of multiple thin CT slices at a resolution of 0.25 mm support the assumption that cancellous bone structures based on noninvasive high-resolution CT measurements are representative for 2D trabecular microstructures assessed from histologic bone sections (Müller *et al.,* 1996a). The images can be used for quantitative trabecular structure analysis and also for a separate assessment of cortical and trabecular BMD. Radiation exposure and acquisition time are the most limiting factors for the *in vivo* system. High quantum detection efficiency is important to reduce radiation exposure. Powerful X-ray tubes and fast readout electronics are essential for minimizing scanning time to avoid motion artifacts (Kapadia *et al.,* 2001).

These state-of-the-art scanners approach the limits of spatial resolution achievable *in vivo* with acceptable radiation exposure (Engelke *et al.,* 1993). The radiation dose can limit spatial resolution and the signal to noise ratio that can be optimized for X-ray-based techniques, as theoretical calculations show that a spatial resolution of 100 μm approaches the limit for human *in vivo* examination (Graeff and Engelke, 1991). An increase in image resolution by a factor of 2 without an increase in noise will result in an increase of dose by a factor of 8, should slice thickness remain unchanged, while dose will be increased by a factor of 16 should slice thickness be further decreased by a factor of 2 (Graeff and Engelke, 1991; Engelke *et al.,* 1991, 1998a), as the applied surface dose (D) is affected by the resolution (w) and slice thickness (h): $D \sim 1/w^3h$ (Graeff and Engelke, 1991; Engelke and Kalender, 1998a). Contrast, noise, and resolution are all important factors for successful detection of trabecular structure. An increase in noise limits the detectibility of finer details of trabeculae. Usually the slice thickness for standard CT is larger than the in-plane pixel size, leading to lower spatial resolution but higher contrast than isotropic resolution, because the pixels representing trabeculae are filled with a larger amount of bone and a smaller amount of marrow as a result of partial volume effect, and because an increase in slice thickness can reduce the noise by a factor of 5 (Engelke and Kalender, 1998a).

Other CT

Peripheral quantitative CT (pQCT) has been explored in clinical and preclinical studies, *in vitro* and *in vivo,* and in the assessment of BMD and cortical bone geometry (Augat *et al.,* 1996; Grampp *et al.,* 1995, 1996; Butz *et al.,* 1994, Neu *et al.,* 2001). In preclinical studies, or *ex vivo* specimen studies, it might be convenient to examine the bones after dissection and exposure to air by densitometry, as pQCT can comparably and reproducibly quantify both volumetric trabecular BMD in either water or in air (Jiang *et al.,* 1998).

pQCT has been used in the study of osteoporotic animal models, such as mice (Turner *et al.,* 2001) but mostly in rats, with osteopenia induced by ovariectomy (Sato *et al.,* 1995, Cointry *et al.,* 1995), orchiectomy (Rosen *et al.,* 1995), immobilization (Ma *et al.,* 1995), and corticosteroid administration (Ferretti 1995). It has also been employed to evaluate effects of pharmaceutical intervention in osteopenic models using antiresorptive (Cointry *et al.,* 1995) or anabolic agents (Ma *et al.,* 1995). pQCT can determine cortical volumetric BMD and geometry (Ma *et al.,* 1995) which significantly contribute to the estimation of cortical bone biomechanical strength (Ferretti *et al.,* 1995, Cointry *et al.,* 1995) and trabecular volumetric BMD (Sato *et al.,* 1995; Rosen *et al.,* 1995; Ma *et al.,* 1995). Longitudinal analysis of the proximal tibia *in vivo* showed a significant reduction of 17% in BMD 31 days after ovariectomy (Sato *et al.,* 1995). It has been reported that pQCT volumetric BMD is more sensitive to bone loss in the rat than DXA (Sato *et al.,* 1995). pQCT was used in a study that found that a low dose of a Chinese herbal preparation containing epimedium leptorhizum was effective in preventing osteoporosis development in weight-bearing proximal femur and tibia but not in the lumbar spine in ovariectomized rats (Qin *et al.,* 2001). pQCT and μCT examinations showed that the distribution of the vertebral mineral into cortical and trabecular compartment is regulated genetically in 12BXH recombinant inbred mice (Turner *et al.,* 2001). It is difficult to determine the trabecular structure in preclinical studies because of limited spatial resolution and increased slice thickness in the pQCT images, though apparent trabecular structural parameters can be derived from pQCT images of human cubic bone specimens using special imaging processing techniques (Jiang *et al.,* 1998).

The scatter or diffraction patterns depend on the molecular structure of scattering tissues and can be used to identify the materials present. Coherent-scatter CT, based on the low-angle X-ray scatter properties of tissues, generates images of scatter intensity from which the scatter patterns corresponding to each pixel are determined. Material-specific tomographic images of mineral, collagen, fat, and water distributions can be obtained, and the gray level in the images provides the volumetric density (g/cm^3) of each material independently. It could be useful for imaging extremities in patients with bone mineralization disorders such as osteomalacia or hypermineralization after certain pharmaceutical intervention, using a radiation exposure about twice that of standard CT (Cunningham and Batchelar, 2001).

μCT

The μCT system was first introduced by Feldkamp and Goldstein (Feldkamp *et al.,* 1989; Kuhn *et al.,* 1990), who used a microfocus X-ray tube as a source, an image intensifier as a 2D detector, and a cone-beam reconstruction to create a 3D object. It was originally designed to detect small structural defects in ceramic materials. Instead of rotating the X-ray source and detectors during data collection as in clinical CT, the specimen is rotated at various angles. X-rays are partially attenuated as the specimen rotates in equal steps in a full circle about a single axis. At each rotational position, the surviving X-ray photons are detected by a planar 2D array. A 3D-reconstruction array is created directly in place of a series of 2D slices. Morphological measures such as the Euler characteristic to quantify connectivity, a measure of the maximum number of branches which can be removed before the structure is divided into multiple pieces, can be determined in the μCT data set without prior skeletonization (Odgaard and Gundersen, 1993; Feldkamp *et al.,* 1989). The connectivity, *c,* of a two-component system such as bone and marrow can be derived directly from the Euler characteristic, *e,* by $c = 1-e$ (Odgaard and Gundersen, 1993), if all the trabeculae and bone marrow cavities are connected without isolated marrow cavities inside the bone. Usually it is normalized by examined tissue volume and reported as connectivity density in $1/mm^3$. Discrepant results of the connectivity measurements, ranging from highly linear to nonlinear relationships with bone volume, have been reported (Odgaard and Gundersen, 1993; Feldkamp *et al.,* 1989; Kinney *et al.,* 1995; Geldstein *et al.,* 1993), which might be due to different specimen and sample sizes studied. Goulet (Goulet *et al.,* 1994) utilized images of bone cubes and related these image-based parameters to Young's modulus, a measure of elasticity of bone. Based on data sets from Feldkamp's μCT, Engelke (Engelke *et al.,* 1996) developed a 3D digital model of trabecular bone that could be used to compare two- and three dimensional structural analysis methods and to investigate the effect of spatial resolution and image processing techniques on the extraction of structural parameters.

The 3D cone-beam μCT imaged the trabecular bone architecture in small samples of human tibias and vertebrae, *ex vivo,* with a spatial resolution of 60 μm (Feldkamp *et al.,* 1989). A resolution of 60 μm, although acceptable for characterizing the connectivity of human trabeculae, may be insufficient for studies in small animals like the rat, where the trabecular widths average about 50 μm and trabecular separations average 150 μm or less (Kinney *et al.,* 1995). Furthermore, Smith and Silver (Smith and Silver, 1994) have reported that 3D images from cone beam scanners are inevitably distorted away from the central slice because the single-orbit cone beam geometry does not provide a complete data set. These distortions and associated loss of spatial resolution have been particularly evident in samples containing plate-like structures, even when the cone beam angle is less than 6.5° (Smith and Silver, 1994). A recent study with direct comparison of fan beam (obtained on the central plane) and cone bone (obtained from a divergent section near the periphery of the volume) techniques over a full cone angle of 9°, using a 100-μm microfocus X-ray tube and isotropic 33-μm voxels, showed that the bone volume fraction based on a gray-scale threshold in the excised lumbar vertebrae from normal adult rats was not adversely affected by cone-beam acquisition geometry for cone angles typically used in μCT (Holdsworth *et al.,* 2000, 2001).

The method was further enhanced by resorting to synchrotron radiation with a spatial resolution of 2 μm (Bonse *et al.,* 1994), or with applications to live rats (Kinney *et al.,* 1995). The X-ray intensity of synchrotron radiation is higher in magnitude than X-ray tubes. When scanning time is important, and for resolution less than 1–5 μm, synchrotron radiation is a better choice than X-ray tubes. Adaptation of the X-ray energy to the sample can be optimized by using monochromatic radiation because of the continuous X-ray spectrum of synchrotron radiation, which can minimize radiation exposure for examining small animals *in vivo.* Synchrotron μCT has spatial resolutions of 2 μm because of high brightness and natural collimation of radiation sources (Bonse *et al.,* 1994). It uses parallel beam-imaging geometry, and avoids the distortions and loss of resolution inherent in cone beam methods and can make distortionless images of human trabecular bone using a CT at a synchrotron electron storage ring (Bonse *et al.,* 1994). Recently, μCT using high-intensity and tight collimation synchrotron radiation that achieves spatial resolution of 1–2 μm has provided the capability to assess additional features such as resorption cavities (Peyrin *et al.,* 1998).

Synchrotron μCT at 23 μm/voxel in the proximal tibial metaphysis of live rats (Lane *et al.,* 1995, 1998, 1999) shows that trabecular connectivity decreased 27% by days 5 and 8 postovariectomy and continued to decrease up to day 50 after ovariectomy. The trabecular BV/TV decreased 25% by 8 days after ovariectomy, and it continued to decrease through day 50. These changes were more rapid than biochemical markers. Estrogen replacement therapy initiated at 5–13 days after ovariectomy can restore BV/TV—but not connectivity—to baseline levels by allowing bone formation to continue in previously activated bone remodeling units while suppressing the production of new remodeling units. Intermittent human parathyroid hormone (1–34) treatment in osteopenic ovariectomized rats increased trabecular BV/TV to control levels or higher by thickening existing trabeculae. Human parathyroid hormone (1–34) did not reestablish connectivity when therapy was started after 50% of the trabecular connectivity was lost. At 120 days after ovariectomy, there was a small but significant decrease in trabecular bone volume, and a significant decrease in trabecular plate thickness. The decrease in trabecular thickness was associated with an increase in connectivity, in contrast to the proximal tibia where connectivity always declines (Kinney *et al.,* 2000).

In addition, synchrotron radiation X-ray microtomography (μT) using new X-ray optic components, has been designed to assess the ultrastructure of individual trabeculae

with a resolution of 1 μm, and to describe microscopic variations in mineral loading within the bone material of an individual trabecular rod. Artifacts from X-ray refraction and diffraction require methods different from those used for other μCT techniques. Delicate and minimal individual trabecular specimen handling and no microtome cutting preserve the specimen geometry and internal microfractures. The histological features of the mineral ultrastructure can be evaluated using volumetric viewing. The volume, shape and orientation of osteocyte lacunae and major cannaliculae can be observed. Quantitative measures of trabecular ultrastructure are now being considered including BMU (basic multicellular unit of bone remodeling with activation → resorption → formation sequence) volume, lamellar thickness, and density gradients (Flynn *et al.,* 2001).

The hardware for synchrotron radiation μCT, however, is not readily accessible. Electron storage rings are stationary and cannot be operated in a small laboratory and only a few synchrotron radiation centers are available worldwide. Rüegsegger *et al.* (1996) developed a μCT device dedicated to the study of bone specimens, without synchrotron radiation. It has been used extensively in laboratory investigations. Image processing algorithms, free from the model assumptions used in 2D histomorphometry, have been developed to segment and directly quantify 3D trabecular bone structure (Hildebrand *et al.,* 1999, 1997ab). Trabecular thickness is determined by filling maximal spheres in the structure with the distance transformation and then calculating the average thickness of all bone voxels. Trabecular separation is calculated with the same procedure, but the voxels representing nonbone parts are filled with maximal spheres. Separation is the thickness of the marrow cavities. Trabecular number is taken as the inverse of the mean distance between the mid-axes of the observed structure. The mid-axes of the structure are assessed from the binary 3D image using the 3D distance transformation and extracting the center points of nonredundant spheres which fill the structure completely. Then the mean distance between the mid-axes is determined similarly to the separation calculation; i.e., the separation between the mid-axes is assessed.

The deterioration of trabecular bone structure is characterized by a change from plate elements to rod elements. Consequently the terms "rod-like" and "plate-like" are frequently used for a subjective classification of cancellous bone. A new morphometric parameter called the structure model index (SMI) makes it possible to quantify the characteristic form of a 3D structure in terms of the amount of plates and rods composing the structure. The SMI is calculated by 3D image analysis based on a differential analysis of the triangulated bone surface. The SMI value is 0 and 3 for an ideal plate structure and a rod structure, respectively, independent of the physical dimensions. For a structure with both plates and rods of equal thickness the value lies between 0 and 3, depending on the volume ratio of rods and plates. The geometrical degree of anisotropy (DA) is defined as the ratio between the maximal and the minimal radius of the mean intercept length (MIL) ellipsoid. The MIL distribution is calculated by superimposing parallel test lines in different directions on the 3D image. The directional MIL is the total length of the test lines in one direction divided by the number of intersections with the bone marrow interface of the test lines in the same direction. The MIL ellipsoid is calculated by fitting the directional MIL to a directed ellipsoid using a least square fit. Also, the relationship of these parameters to *in vitro* measures of strength and their application to microfinite element modeling has been shown (Müller *et al.,* 1996b).

The early uses of 3D μCT focused on the technical and methodological aspects of the systems, but recent developments emphasize the practical aspects of microtomographic imaging. One recent study compared iliac crest bone samples from premenopausal women with iliac crest bone samples taken from the same women after menopause (Fig. 14, see also color plate). The samples were examined using μCT with an isotropic resolution of 20 μm^3. The postmenopause samples showed significant changes in 3D trabecular structural parameters. The annual rate of change from plate-like structure to rod-like structure was 12%, which may have important consequences for bone biomechanical properties.

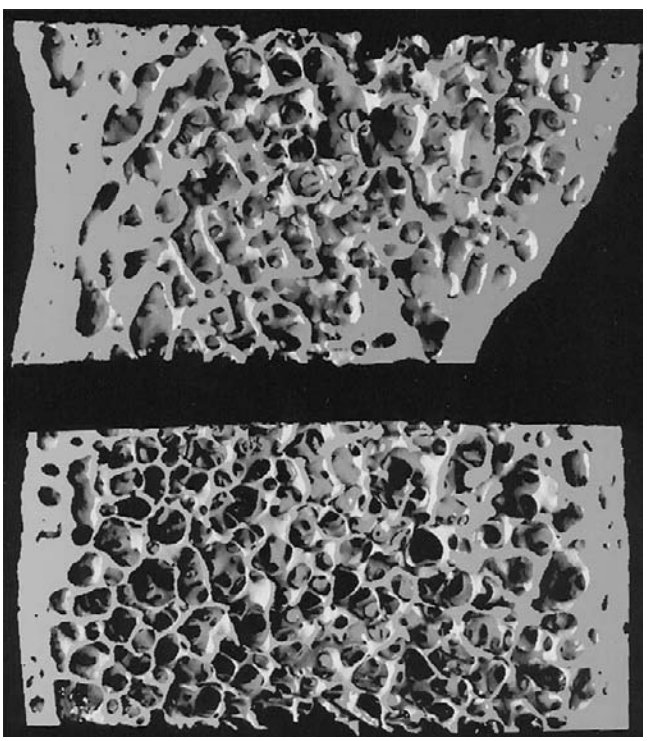

Figure 14 These two images are 3D μCT reconstruction of two paired iliac crest bone biopsy samples from one woman. The first biopsy was taken when she was healthy, premenopausal, and 53 years old. The second biopsy was from the opposite side, 5 years later, after menopause. The samples were examined using μCT with an isotropic resolution of 20 μm^3. The cortical bone of the iliac crest on the sides and trabecular bone between the cortex can be appreciated in both images. The trabecular structure is mainly plate-like and quite anisotropic in general before menopause (A). The changes in 3D trabecular structure after menopause (B) are dramatic: 3D trabecular bone volume has decreased; trabecular separation has increased; the trabeculae have become thinner and more isotropic, and there has been a shift from plate-like to rod-like structure. (See also color plate.)

Trabecular bone became more isotropic after menopause, with an annual decrease rate in DA of 0.7%. Interestingly, annual change in trabecular thickness (−3.5%) is greater than in trabecular number (−1.6%) and separation (+2%) (Jiang *et al.,* 2000a). These findings are quite different from those of traditional 2D histomorphometry. In histomorphometry, it is still a matter of debate whether trabeculae thin or simply disappear after menopause and with aging. It is possible that the loss of entire elements because of trabecular perforation forms the main mechanism of structural changes in osteoporosis. The remaining trabeculae are more widely separated and some may undergo compensatory thickening. Trabecular anisotropy will increase. In another study of paired biopsies taken before and after treatment with human parathyroid hormone, 3D μCT showed increased 3D connectivity density and confirmed the preservation of 2D histomorphometric cancellous bone volume and trabecular number and thickness. Cortical width from 2D histomorphometry increased in osteoporotic men treated with parathyroid hormone PTH and in osteoporotic women treated with parathyroid hormone (PTH) and estrogen (Dempster *et al.,* 2000).

μCT has been used to measure trabecular bone structure in rats. Most studies have focused on the trabecular bone in the proximal tibial metaphysis, but the trabecular bone in rat vertebrae is of interest because of its similarity to the human fracture site and because biomechanical testing is practical (Jiang *et al.,* 1997b). μCT with an isotropic resolution of 11 μm^3 has been used to examine the 3D trabecular bone structure of the vertebral body (Fig. 15, see also color plate) in ovariectomized rats treated with estrogen replacement therapy (Jiang *et al.,* 1999b). μCT 3D determined trabecular parameters show greater percentage changes than those observed with DXA, and they show better correlation with biomechanical properties. Combining trabecular bone volume with trabecular structural parameters provides better prediction of biomechanical properties than either alone. A study of the anabolic effects of low-dose (5 ppm in drinking water) long-term (9 months) sodium fluoride (NaF) treatment in intact and ovariectomized rats shows that NaF treatment increases trabecular bone volume, possibly by increasing trabecular thickness through increasing bone formation on existing trabeculae, rather than by increasing trabecular number. NaF in sham-operated rats increases trabecular structural parameters and bone mineral, but decreases compressive stress in the vertebral body. NaF partially protects against ovariectomy-induced changes in bone mineral and structure but this protection does not translate into a corresponding protection of bone biomechanical properties (Zhao *et al.,* 2000a,b).

The wide availability of genetically altered mice has increased the usefulness of the murine model for investigating osteoporosis and other skeletal disorders. Independent genetic regulation of 3D vertebral trabecular microstructure in 12BXH recombinant inbred mice as measured by μCT contributed information regarding the variation in biomechanical properties among the strains (Turner *et al.,* 2001). Mice homozygous for a null mutation of the PTH-related peptide (PTHrP) gene die at birth with severe skeletal deformities. Heterozygotes survive and by 3 months of age develop osteopenia characterized by decreased trabecular bone volume and increased bone marrow adiposity. PTHrP wild type and heterozygous-null mice were ovariectomized at 4 months of age and sacrificed at 5 weeks. 3D μCT was use to examine the trabecular structure of the mice, with an isotropic resolution of 9 μm^3. Bone specimens from mice heterozygous for the PTHrP null allele demonstrate significant changes as compared to wild-type litter mates in most parameters examined. However, measurements of trabecular number and trabecular thickness were not significantly different between the two groups. These findings support the notion that PTHrP haploinsufficiency leads to abnormal bone formation in the adult mouse skeleton (He *et al.,* 2000).

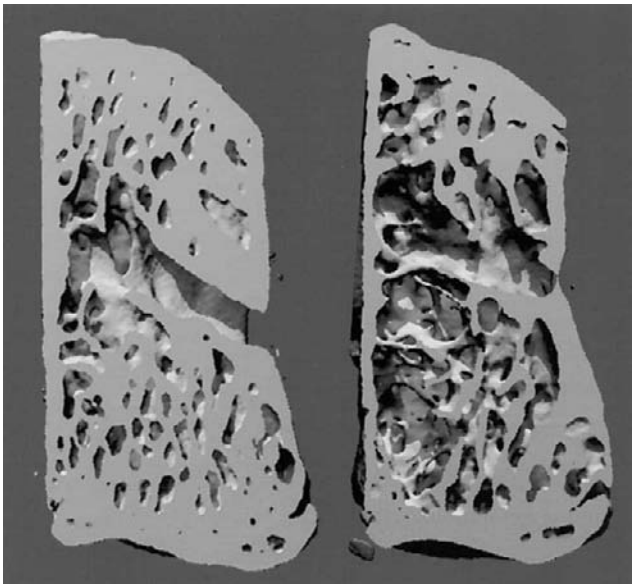

Figure 15 μCT 3D images of rat vertebral body with isotropic resolution of 11 μm^3. Compared with age-matched sham-operated control (left), ovariectomy results in a remarkable decrease in the trabecular bone volume, thickness, number, and a conspicuous increase in trabecular separation. The different trabecular patterns are noticeable, i.e., plate-like trabeculae in the control and rode-like trabeculae in the ovariectomized rat. The cortical thickness is also decreased after ovariectomy. (See also color plate.)

Ovariectomy induces short-term high-turnover accelerated deterioration of 3D trabecular structure in mice (Jiang *et al.,* 2000c). In a study using 3-month-old Swiss Webster mice 5 and 13 weeks after ovariectomy, 3D μCT trabecular structure was measured in the secondary spongiosa of the distal femur with an isotropic resolution of 9 μm^3. The trabeculae become more rod-like and more isotropic, thinner, and more widely separated after ovariectomy (Fig. 16, see also color plate) (Zhao *et al.,* 2000c). HRT prevented ovariectomy-induced bone loss. Percentage changes in pQCT volumetric BMD were similar to the changes measured by μCT but less pronounced (Jiang *et al.,* 2001).

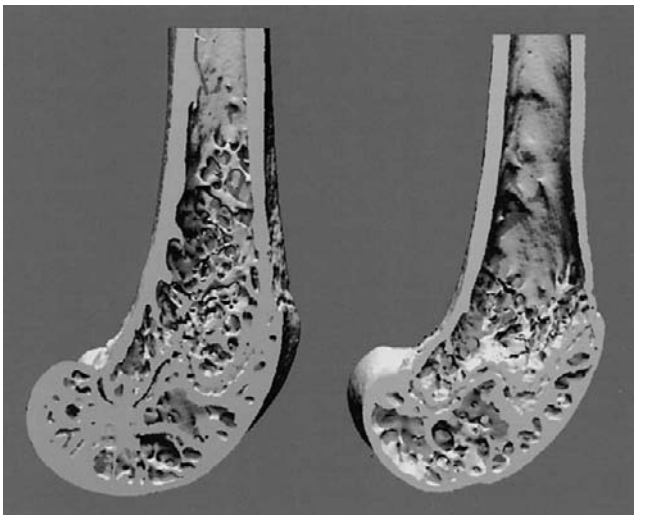

Figure 16 μCT 3D images of trabecular and cortical bone structure of mice with isotropic resolution of 9 μm^3. Compared with age-matched sham-operated control (left), ovariectomy results in a dramatic loss trabecular bone volume and other trabecular bone microstructure (right). (See also color plate.)

Figure 17 Fine trabecular network on μMRI of the femoral neck specimen of an ewe imaged in coronal plane with a spin echo sequence, in-plane resolution of 78 μm and slice thickness of 150 μm on a Varian Unity 400 NMR instrument at 9.4 T.

μCT has other research applications, for example quantifying osteogenesis in mouse Ilizarov leg lengthening procedures and quantifying osteoconduction in a rat cranial defect model (Jiang *et al.,* 2000b,d). In a model of osteoarthritis in dogs, μCT with a nominal resolution of 66 μm was used to examine the subchondral bone changes. 3D μCT and 2D histomorphometry showed a decrease in bone volume fraction and an increase in bone surface fraction in the femur and patella of dogs 3 and 6 months after an anterior cruciate ligament transection. Histomorphometry also shows an increase in bone formation rate. μCT images of the femur showed multiple pits on the bone surface of femoral condyles and femoral trochlear ridges, while the gross inspection of the cartilage showed only a discoloration in the corresponding areas, indicating that the subchondral bone erosions preceded articular cartilage damage in the development of osteoarthritis (Han *et al.,* 2001).

MRI Microscopy

High-resolution MR and μMR, collectively called MR microscopy, have received considerable attention both as research tools and as potential clinical tools for assessment of osteoporosis. As a noninvasive, nonionizing radiation technique, MR can provide 3D images in arbitrary orientations and can clearly depict trabecular bone. MRI is a complex technology based on the application of high magnetic fields, transmission of radiofrequency waves, and detection of radiofrequency signals from excited hydrogen protons. MRI can delineate bone so well (Figs. 11 and 17) because bone mineral lacks free protons and generates no MR signal while adjacent soft tissue and marrow contain abundant free protons and give a strong signal. The great difference in the magnetic properties of trabecular bone and bone marrow produces distortions of the magnetic lines of force which make the local magnetic field within the tissue inhomogeneous and alters the relaxation properties of tissue, e.g., the apparent transverse relaxation time T_2^* in gradient-echo images. This shortening of relaxation time is greater in normal dense trabecular networks than in rarefied osteoporotic trabeculae. T_2^* is directly related to the density of the surrounding trabecular network and its spatial geometry. There is a highly significant correlation between the relaxation rate $1/T_2^*$ by MR and BMD determined by QCT. Measurement of changes in the apparent transverse relaxation time $T2^*$ shortening can discriminate healthy normal dense trabecular networks from rarefied osteoporotic trabeculae (Genant *et al.,* 1996a; Grampp *et al.,* 1996, Chung *et al.,* 1990). $T2^*$ maps of the proximal femur could be used to differentiate between postmenopausal women with and those without osteoporotic hip fractures (Link *et al.,* 1998a). In addition to the indirect measures of the relaxation time, high-resolution images have been obtained to assess bone structure.

Currently, assessment of trabecular structure using MR microscopy is restricted to the peripheral skeleton unlike CT which can be applied to the spine and peripheral bones. The parameters derived from the low-resolution images account for 91% of the variation in Young's modulus, suggesting that noninvasive assessment of the mechanical competence of trabecular bone in osteoporotic patients may be feasible (Hwang *et al.,* 1997). High-field MR spectrometers with imaging possibilities or small-bore MR imaging scanners can be used to obtain ultrahigh spatial resolution. Using a rapid

spin-echo technique and three-dimensional imaging at 9.4 T, an isotropic resolution with 78 μm of human and bovine bone cubes has been reported (Chung *et al.,* 1995a,b; Hwang *et al.,* 1997). Good correlations between MR-derived parameters and standard histomorphometric measures were found. Antich *et al.* (1994) found changes in accordance with histomorphometry measures. Comparison of MR microscopy and the μCT system developed by Feldkamp (Hipp *et al.,* 1996; Kuhn *et al.,* 1990; Simmons and Hipp, 1997) showed that precision for trabecular bone volume is better with μCT (3% vs 6%) but trabecular number is better with MR microscopy (1% vs 2.5%).

In MR the appearance of the image is affected by many factors beyond spatial resolution, including the field strength—since signal is related to the field strength, the specific pulse sequence used, the echo time, and the signal-to-noise achieved. Acquisition, analysis, and interpretation of MR images are more complicated than for X-ray-based images of CT. Both spin-echo (Jara *et al.,* 1993) and gradient-echo sequences (Majumdar *et al.,* 1995) can be used to generate high-resolution MRI or bone structure. Gradient-echo techniques require less sampling time and may be better suited to *in vivo* clinical examinations. A 180° radio frequency (RF) pulse is applied to obtain an echo signal for generating an image in spin-echo sequences, while a reversal of the magnetic field gradient is used for such an echo in gradient-echo sequences. The apparent trabecular size depicted in both spin-echo and gradient-echo images may differ from their true dimensions (Jara and Wehrli, 1994). The overestimation of trabecular dimension is more pronounced in gradient-echo images, especially when TE, echo time, is increased. An increase in TR, the repetition time, leads to an increase in signal to noise ratio, but also an increase in the total scan time. The higher the bandwidth or the total time in which the MR signal is sampled, the shorter the achievable echo time, and the lower the signal to noise ratio. All these parameters need to be carefully weighed and adjusted as they interact in multiple ways and affect resolution and quality of the image (Majumdar *et al.,* 1995).

Segmentation to derive binary images for structural measurement can be challenging, since adaptive threshold- and edge-based methods tend to amplify susceptibility differences in the bone marrow, resulting in misclassification of marrow as bone. Global thresholds based on the histogram of the gray-value distribution (Majumdar *et al.,* 1995), or local thresholds using internal calibration based on fat, air, tendon, and cortical bone (Ouyang *et al.,* 1997) have been used (Fig. 18). The local threshold results in precision of 3–5% for trabecular histomorphometric parameters of the calcaneus, and can discriminate trabecular thickness and separation between pre- and postmenopausal healthy women (Ouyang *et al.,* 1997). Hipp and colleagues (1996) examined bovine cubes in a small bore microimaging spectrometer at 60 μm^3 resolution and found 3D results heavily dependent on the threshold and image processing algorithm. Majumdar *et al.* (1996) examined human cadaver specimens using a standard clinical MR scanner at 1.5 T and a spatial resolution of 117 × 117 × 300 μm and compared these images with μCT images and with serial grindings to determine the impact of in-plane resolution and slice thickness on both 2D and 3D structural and textural parameters. Considerable resolution dependence was observed for traditional stereological parameters, some of which could be modulated by appropriate thresholds and image processing techniques. As results can be affected by operator-adjustable parameters in the threshold-based methods, it is recommended that the same segmentation scheme be used for all patients or specimens in a specific project.

Examination of the distal radius using MRI with a spatial resolution of 156 μm^2, a slice thickness of 0.7 mm, and a modified gradient echo sequence at a 1.5 T clinical imager (Majumdar *et al.,* 1994) clearly depicted the loss of the integrity of the trabecular network with the development of osteoporosis (Fig. 19). Similar images of the calcaneus of normal subjects showed that the orientation of the trabeculae is significantly different in various anatomic regions. Ellipses, representing the mean intercept length, showed a preferred orientation and hence mapped the anisotropy of trabecular structure. Resolutions of 78–150 μm and slice thicknesses of 300 μm have been achieved in the phalanges, a convenient anatomic site that is particularly suitable for obtaining high signal-to-noise and high spatial resolution images *in vivo,* using clinical imagers at 1.5 T with a special RF coil (Jara *et al.,* 1993; Stampa *et al.,* 1998), and quantitative 3D parameters based on an algorithm and model for defining trabecular rods and plates have been derived (Stampa *et al.,* 1998). It has been reported that using trabecular structure or textural parameters from *in vivo* MR images of the radius (Fig. 19) or calcaneus can discriminate spine and/or hip fracture (Link *et al.,* 1998b; Majumdar *et al.,* 1997; Wehrli *et al.,* 1998).

Although high-resolution MR has been used successfully for *in vitro* quantitative evaluation of human trabecular bone, application of this technology to small animal bones is more demanding, as resolution requirements are more stringent because of the considerably smaller trabecular size. The need for higher resolution, dictated by the thinner trabeculae, entails a significant penalty for signal to noise ratio and acquisition time. Recently, the ability of MRI to assess osteoporosis in animal models has been explored in depth. One study demonstrated that using a small high-efficiency coil in a high-field imager, MRI can provide resolutions sufficient to discriminate individual trabeculae. MRI of trabecular structure in the distal radius shows trabecular bone loss after ovariectomy. μMRI of a rat tail showed 3D cortical bone, trabecular network, and other soft tissue. μMRI shows increased bone mass in the distal femoral metaphysis of rats treated with a bisphosphonate, increased cartilage thickness in the growth plate, and corresponding recovery changes after withdrawal of treatment. The trabecular structure in the femoral neck of a ewe can be clearly shown on MRI (Jiang, 1995). In this study, with appropriate choices, it was possible to image trabecular bone in rats *in vivo* and *in vitro.* Segmenting trabecular

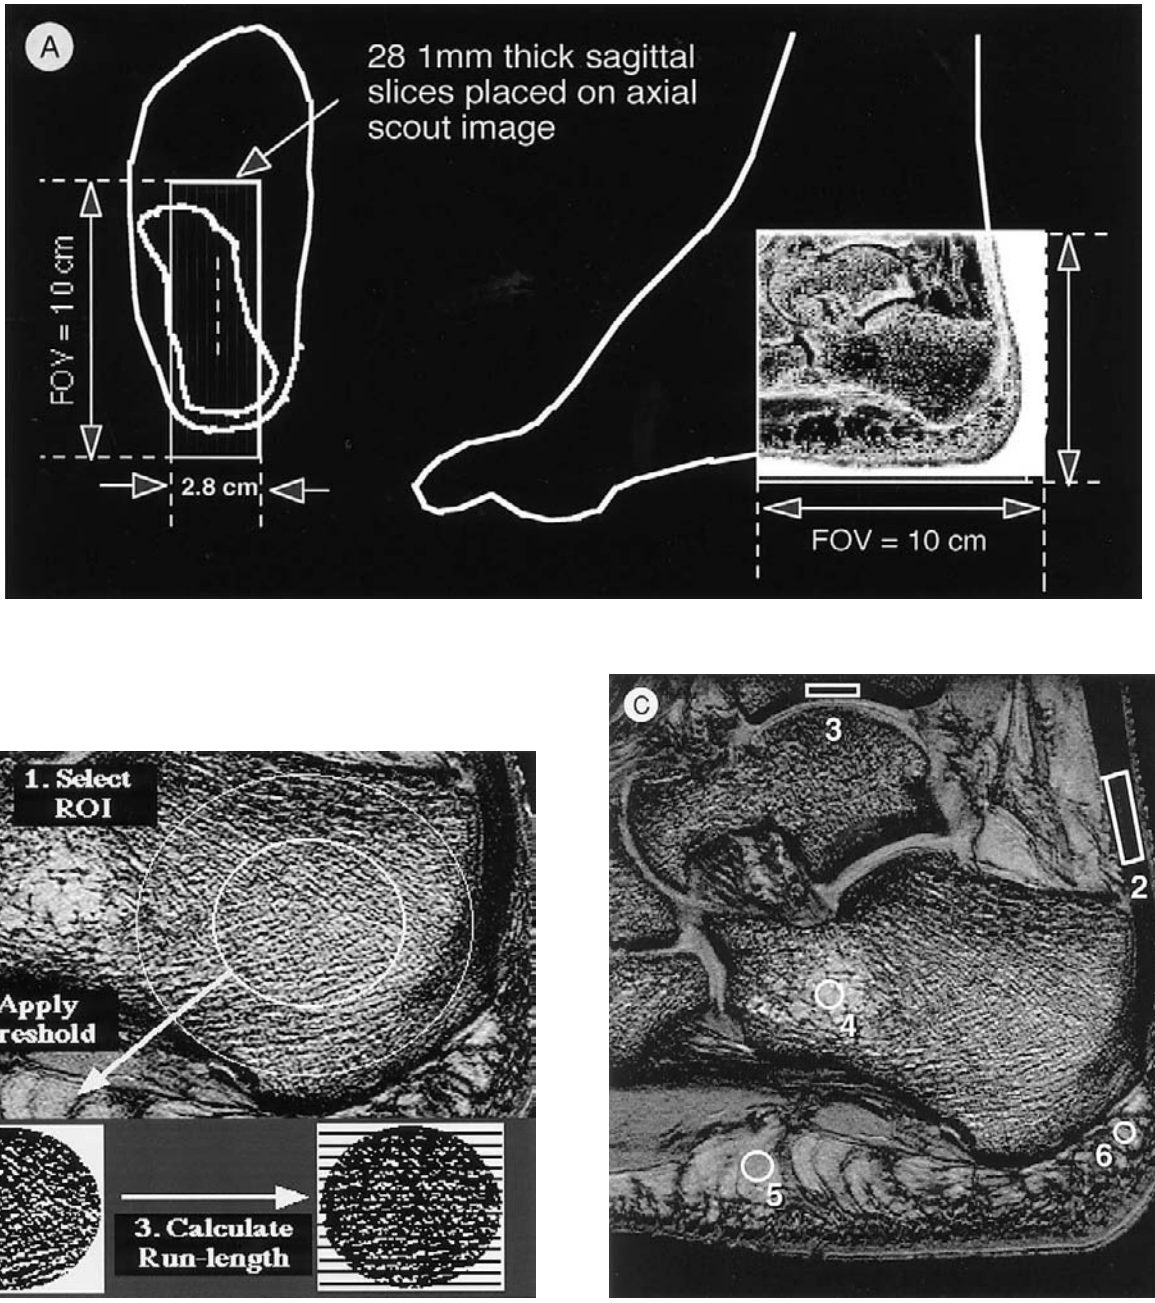

Figure 18 Procedures of trabecular bone structure acquisition and analysis using high resolution MR imaging. (A) Schematic representation of MR imaging acquisition of the calcaneus on a 1.5-T GE Signa imager using a modified 3D GRE pulse sequence (TE/TR/α = 11 msec/35 msec/30°), with in-plane pixel resolution of 195 × 260 μm^2, encompassing the entire central portion of the calcaneus. (B) Illustration of the MR image analysis procedure: (1) selection of the analysis ROI; (2) gray-level thresholding of the ROI to obtain a binary image of bone/marrow; (3) calculation of trabecular structure parameters using run-length analysis. (C) Positioning of ROIs used for internal calibration of the segmentation threshold. Six ROIs are defined in regions of the MR image representing: (1) air, (2) tendon, (3) cortical bone, (4) bone marrow, (5) and (6) subcutaneous fat.

bone from adjacent tissues has been a useful technique in the quantification of trabecular bone in MRI images. In a study of ovariectomy in rats, analysis of MRI demonstrated differences in rat trabecular bone that were not detected by DXA measurements (White *et al.,* 1997).

MRI showed ovariectomy induced losses in trabecular bone volume fraction and structure that ERT prevented (Kapadia *et al.,* 1998). There are excellent correlations between MRI with resolution up to 24 × 24 × 250 μm and histological assessment of intact rat tibiae and vertebrae (Kapadia *et al.,* 1993). It has been reported that rat tibiae were imaged at 9.4 T *in vitro* with isotropic resolution of 46 μm^3. It has also been shown that alendronate maintains trabecular bone volume and structure about midway between intact and ovariectomy, whereas prostaglandin E_2 returned them to intact levels (Takahashi *et al.,* 1999).

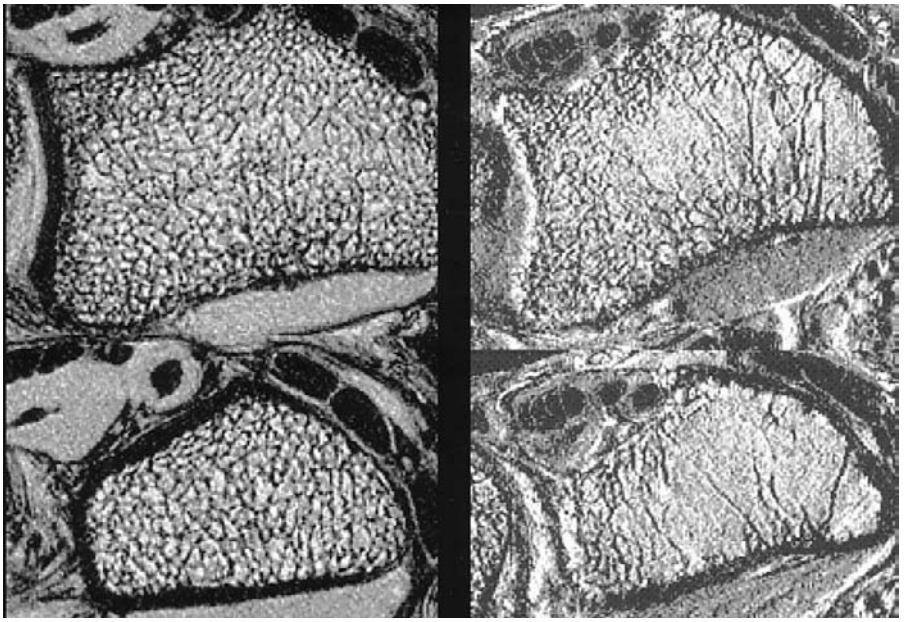

Figure 19 Trabecular network in the distal radius from a healthy, 35-year-old, prememopausal woman (left) and a 76-year-old, osteoporotic postmenopausal woman with vertebral fracture (right), imaged using an 1.5-T Signa SR/230 MR magnet (General Electric) with fast gradient echo imaging sequence at a bandwidth of $\pm$ 8 kHz, in-plane resolution of 156 μm, slice thickness of 700 μm, TE 7.8 msec, TR 31 msec, flip angle 30°. A remarkable decrease in the apparent trabecular bone volume and loss in trabecular connectivity in osteoporotic radius can be appreciated.

MRI shows 3D bone structure and some other tissues at the same time. In the rabbit knee, MRI shows trabecular structure and cartilage. In an osteoarthritis model induced by menisectomy (Jiang *et al.,* 1997a) or anterior cruciate ligament transection (Zhao *et al.,* 1999), MRI shows subchondral osteosclerosis, and decreased cartilage thickness. MRI also shows osteophytes in a rabbit osteoarthritis model. However, radiographs show only subchondral osteosclerosis, while osteophytes could not be found in a rabbit osteoarthritis model.

The usefulness of this powerful tool is balanced by disadvantages: it is expensive to obtain, operate, and maintain, and it is rarely available for routine nonclinical use. Dedicated extremity MR systems, which are low-field and less expensive, can quantify geometry of the cortical bone such as cross-sectional area and cross-sectional moments of inertia (CSMI) in the distal radius and the muscle mass in the forearms, which contribute significantly to the biomechanical strength of the radius (Jiang *et al.,* 1998). The mechanical behavior of a bone reflects the material property within the bones as well as the bone geometry. CSMI describes the geometric configuration or distribution of the bone mass around the central axis. The magnitude of the CSMI depends on both the cross-sectional area and the squared distance of each unit area from the sectional neutral axis that always intersects the centroid, or center of the area of the section. In torsion, deformation would be resisted more efficiently if bone were distributed further away from the neutral torsional axis. Ideally, in bending or torsion, bone should be distributed as far away from the neutral axis of the load as possible (Ruff and Hayes, 1983).

Summary

Many studies have shown that changes in bone quality and structural characteristics lead to changes in bone biomechanical competence or individual risk of fracture independently of BMD. New techniques and imaging modalities have been developed to quantify bone architecture in addition to bone density. Structural measurements using advanced imaging techniques contribute to our understanding of osteoporosis and other bone disorders, and provide insight into their pathomechanisms.

Though progress has been made in the noninvasive and/or nondestructive imaging bone of architecture, there are many issues that require further investigation: the balance between spatial resolution and sampling size; between signal-to-noise and radiation dose/acquisition time; between the complexity/expense of equipment and availability/accessibility of the methods; the potential biological differences between the peripheral appendicular skeleton and the central axial skeleton, and their clinical diagnostic applications that require high accuracy while application of monitoring diseases progress and treatment response that require high precision.

Although they are demanding in terms of equipment and technique, advanced imaging methods have many advantages.

They are unbiased, free from the model assumptions used in 2D histomorphometry. Since a true 3D assessment of the trabecular bone structure is possible, rod or plate model assumptions are no longer necessary. They are able to directly measure 3D structure and connectivity in arbitrary orientations in a highly automated, fast, objective, non-user-specific manner, with little sample preparation, allowing greater numbers of samples for unbiased comparisons between controls and subjects. They can have large sample sizes and therefore less sampling error. They are nondestructive, which allows multiple tests such as biomechanical testing and chemical analysis on the same sample, and noninvasive which permits longitudinal studies. They are noninvasive, allow repeated measurements over time in longitudinal studies, reduce the number of subjects in each study, and may provide a reasonable surrogate for static histomorphometric measurement and a complimentary technique to dynamic histomorphometry. The noninvasive imaging techniques have an advantage over histologic biopsy, in that they allow repeated follow-up measurements, at a number of different skeletal sites. These methods also have weaknesses: they require robust image processing algorithms to segment and quantify bone structure, and may have limitations in spatial resolution for certain structures. They cannot provide information on cellular activities and on dynamic mineralization processes. Rather than replacing bone histomorphometry, these imaging methods provide additional and valuable information and are a useful complement to traditional techniques in the evaluation of osteoporosis and other bone disorders.

CHAPTER 94

Transilial Bone Biopsy

Robert R. Recker and M. Janet Barger-Lux
Osteoporosis Research Center, Creighton University, Omaha, Nebraska 68131

Introduction

Bone biopsy has been widely used as a research tool in clinical studies and animal work for nearly three decades. Fluorochrome tissue-time markers (Frost, 1969) have enhanced the value of the biopsy by giving dynamic information about bone formation in addition to static histologic information. The fluorochrome double label marks the location of mineralization at two nearly instantaneous points in time. The mineral apposition rate (MAR), the key dynamic measurement that opens the door to measurement of bone formation rates, is determined from the two labels. Thus, histologic and dynamic information from bone biopsies can be expressed in numerical terms and evaluated statistically.

Bone biopsy has limited application in clinical diagnosis of common bone disorders such as postmenopausal osteoporosis. However, bone biopsy data are very valuable for studying the etiology and pathogenesis of bone disease, as well as the short- and long-term effects of treatments and interventions, particularly early in the study of new pharmacologic agents.

The transilial biopsy locus has become the predominant one used for histomorphometry in clinical studies. There are shortcomings, to be sure: the tissue sample is small; only bone from the iliac crest is sampled; the morphology of samples varies considerably from core to core within the target area (and even within a single core); analysis of cortical bone is limited; the laboratory procedure is tedious, difficult, and expensive; and few laboratories are available to process and analyze specimens. Patient fear and discomfort, along with perceived risk, have contributed to the reluctance of many investigators to include transilial bone biopsies in their research protocols. However, when properly carried out, the procedure is quite safe, with minimal patient discomfort and minimal risk of morbidity.

In this chapter, we describe the surgical procedure for transilial bone biopsy and the laboratory methods for processing and analyzing the specimens. We then present reference data from both healthy postmenopausal women and patients with postmenopausal osteoporosis. Other chapters in this volume describe the histomorphometric findings in other metabolic bone diseases.

The Procedure

Though few clinicians or clinical investigators will require detailed knowledge of specimen processing and histomorphometric analysis, many of them will be called upon to obtain transilial bone biopsies. We therefore describe the first author's biopsy procedure in some detail and limit our description of laboratory methods to an overview.

Tetracycline Labeling

The tetracycline class of drugs presents the only practical fluorochrome labeling agent for human studies (Frost, 1969). They are safe, available for human use, accumulate at bone-forming sites, and fluoresce brightly when activated with fluorescent light of 350 nm in an epifluorescence microscope system. Although these properties are common to all tetracyclines, tetracycline HCl (250 mg *tid* or *qid*) and demethylchlortetracycline (150 mg *bid* or *tid*) are most commonly used. The drug is deposited at sites of ongoing mineral precipitation. Intensity of the label is dependent on the plasma concentration of the drug, which in turn is dependent on dose. The double-labeling process involves dosing for several days, a longer period off drug, a second dosing period, and biopsy 5 to 14 days after the last dose. The schedule

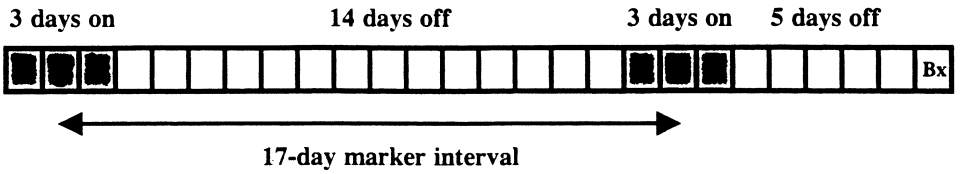

Figure 1 The 3–14–3:5 schedule for double-labeling of bone with oral tetracycline prior to biopsy (Bx). The marker interval is the number of days between the midpoints of the two dosing periods.

abbreviated as 3–14–3:5 (see Fig. 1) produces good results; it involves 3 days on, 14 days off, 3 days on, and 5 days off before biopsy. The number of days that span the midpoints of the first and second labeling periods is called the *marker interval*; this value is used to calculate the mineral apposition rate. As Fig. 1 indicates, the 3–14–3:5 schedule yields a marker interval of 17 days. While other schedules can be used, the marker interval *should not exceed 17 days* in order to minimize the label escape phenomenon (Schwartz and Recker, 1982).

Instructions to Patients

It is essential that patients follow the labeling regimen strictly, and the first and last of dose of each dosing period are the most crucial points of adherence to schedule. Calculations can be altered to accommodate a change in marker interval, *but only if the histomorphometry laboratory has been notified of changes in the dosing regimen.* To reinforce and clarify oral instructions, furnish each patient with a printout of instructions that include tetracycline labeling, preparation for the biopsy procedure, and postbiopsy precautions and wound care. Prior to the actual biopsy, the patient should avoid aspirin for at least 3 days and have nothing by mouth for 4 hr.

Instruments

Suitable specimens can be obtained by use of a trephine with inner diameter of no less than 7.5 mm, e.g., a Rochester bone biopsy trephine (Medical Innovations International, Inc., Rochester, MN). The needle should *always* be very sharp; it should be sharpened (and reconditioned, if necessary) after every three to five procedures. Manual operation of the needle results in better control, although some prefer using a power tool, such as a variable-speed cordless electric drill.

Obtaining the Biopsy

Schedule the transilial bone biopsy as an outpatient minor surgery. The patient wears a hospital gown and lies in the supine position on the surgical table. A folded towel or sheet under the hip will lift the pelvis about 1–2 inches on the side of the biopsy, to provide a better angle for the physician. Use fingertip and cuff *monitoring equipment.* The operator scrubs and uses a cap, mask, gown, and gloves.

Use the transilial approach exclusively. Locate the biopsy site about 2 cm posterior to the anterior–superior spine, which is about 2 cm inferior to the iliac crest. Give a sedative (Versed, 2.5 to 5 mg) through a forearm intravenous catheter. Prep and drape the site. Infiltrate the skin and subcutaneous tissues at the biopsy site with about 30 mL of local anesthetic. Infiltrate the inner wall of the ilium through the abdominal wall. Make a 2-cm skin incision and extend it to the periosteum with blunt dissection. After making the skin incision, use a dissecting scissors for all dissection. Minimal use of the scalpel reduces blood loss, eliminates the need for subcutaneous sutures, and reduces postoperative discomfort. Insert the trephine and remove a core of bone, including both cortices and the intervening trabecular bone. Pack the bony defect with 2 small strips of surgicel (2 by 0.25 inches), secure hemostasis with pressure, close the wound with 5-0 monofilament (3 to 5 stitches), and apply a pressure dressing.

The dressing is to be left in place and kept absolutely dry for 48 hr. The patient can then remove it and shower daily—but not bathe—until the suture is removed. Instruct the patient to keep physical activity to a minimum in the week following the procedure. The patient can expect localized aching for about 2 days, possible itchiness as the wound heals, and a small scar.

If a second biopsy is done, it should always be on the side opposite the first biopsy. Do not attempt more than two biopsies (one on each side) because of potentially confounding effects remaining from the previous biopsy.

Precautions

In order to obtain an intact biopsy, it is vital to use *gentle* pressure to advance the trephine. This is particularly the case in patients whose osteoporotic skeletons are very fragile. Make every effort to obtain an intact specimen, i.e., a core that contains both cortices and the intervening trabecular bone. Anything less is not usable. If the specimen is fractured during the procedure, one or two additional attempts can be made to get a good specimen through the same incision. However, make a new track with blunt dissection for each attempt to obtain an undamaged specimen.

The specimen is sometimes difficult to remove from the trephine; this problem results from wedging of the proximal cortex in the sleeve of the trephine. The specimen can usually be safely dislodged by use of a sharp blow to the handle of the trochar. Immediately transfer the specimen to a 20-mL screw-cap vial containing 70% ethanol.

Complications

PAIN

Pain during and after the biopsy procedure is the most feared complication. It is often reinforced by the stories of family or friends who have had a bone marrow *aspiration,* which typically involves sharp pain as the specimen is withdrawn. However, if generous amounts of local anesthetic are placed periosteally on both sides of the ilium, the bone biopsy procedure described here rarely evokes pain. (Injection of local anesthetic is, of course, associated with some discomfort.) Rarely, a patient will experience acute sharp pain during passage of the trephine through the marrow space, signaling the presence of a pain fiber within the marrow space. If this occurs, a small additional amount of intravenous analgesic can be injected through the indwelling catheter to aid in finishing the procedure. More commonly, patients describe passage of the trephine as feeling "like a cramp."

BLEEDING/HEMATOMA/OTHER

Bleeding during the procedure is minimal. Preoperative tests of the platelet and coagulation systems need not be carried out, unless there is some evidence of risk. Such risks exist in patients on hemodialysis, in those with liver disease, and among those with other conditions or medications that can compromise hemostasis. Prior surgery of any type accomplished without bleeding complications is evidence against an inherited clotting disorder. Aspirin interferes with platelet function (hence the caveat noted earlier). Local hematoma is uncommon, although bruising sometimes occurs around the wound. Occasionally there will be transient neuropathy due to entrapment of a local branch of the femoral nerve by hematoma, or perhaps from transection of a sensory nerve. The resulting paresthesia may take 2 or 3 weeks to resolve. Transient femoral nerve palsy has been reported, as well as postoperative trochanteric bursitis on the side of the biopsy. The first author has encountered two instances in which a sudden episode of severe pain occurred about 10 days after the biopsy in the general area of the biopsy site. These were due to fractures extending from the crest of the ilium to the biopsy site. Healing occurred with analgesics and restriction of activity. Rao surveyed a large number of physicians who performed transilial biopsies, asking them to enumerate the complications (Rao *et al.,* 1980). For 9131 biopsies, they reported 22 with hematomas, 17 with pain for more than 7 days, 11 with transient neuropathy, 6 with wound infection, 2 with fracture, and 1 with osteomyelitis for a total incidence of complications of 0.7%. There were no deaths and no cases of permanent disability among the group.

Specimen Processing

The following overview of laboratory methods associated with transilial bone biopsy includes a number of practical tips derived from the experience of our laboratory. Details of specimen processing can be obtained from the text edited by Recker (1983, though no longer in print) or through one of the laboratories that does this work.

Fixative

As noted earlier, our research unit uses 70% ethanol for fixing transilial bone biopsy specimens. In addition to providing adequate fixation, 70% ethanol is a suitable medium for long-term storage at room temperature, which is particularly important when specimens are shipped to a central biopsy-processing site. Fill specimen containers to capacity (eliminate air) in order to protect the specimen during handling. Biopsies to be stained for tartrate-resistant acid phosphatase require special handling (e.g., specimens in fixative kept on ice until processing). Our laboratory does not recommend use of phosphate-buffered formalin fixative, because it can dissolve bone mineral and distort tetracycline labels. It is possible to dissolve stain (Villanueva *et al.,* 1964) in the fixative so that block staining occurs during fixation. This is valuable for measuring static features at the same remodeling sites where the measurements of interlabel width are made.

Dehydrating, Defatting, and Embedding

Dehydrate and defat specimens slowly, carefully, and completely in order to achieve good quality embedding and avoid creating tissue artifacts. Pass specimens through graded alcohols and acetone, and de-gas to prevent the formation of bubbles during embedding. Embed samples in methyl methacrylate pretreated with appropriate plasticizing agents.

Sectioning and Staining

Trim and face the tissue blocks to provide a plane for sectioning that is parallel to the axis of the biopsy core. Section with a microtome equipped with a tungsten carbide blade. This is the most difficult part of the process, because the sections are very thin and fragile. The technician must grasp them and mount them on slides without creating excessive artifact. Make the first set of sections at 35–40% (about 2.5–3 mm) into the embedded specimen with a minimum side-to-side width of 5 mm. Collect subsequent sets at intervals of 250–300 μm further into the specimen. Obtain at least five 5- to 7-μm sections at each section depth for making Goldner's (Goldner, 1938) stained sections; obtain at least two 8- to 10-μm sections for making unstained slides; and obtain at least two 5- to 7-μm sections for making toluidine blue stained sections. Deplasticize slides with acetone before staining. Use unstained sections to quantitate tetracycline-labeled surfaces and to examine collagen architecture (i.e., lamellar or woven bone). Assess all other variables except for wall thickness with Goldner's stained sections. Use the toluidine blue-stained sections for wall thickness measurements. There are also other methods for measuring wall thickness (e.g., Matrajt and Hioco, 1966).

The Histology

Most of the measurements and calculations of bone histomorphometry reflect concepts about the organization and function of bone cells.

Intermediary Organization

Frost described several discrete bone cell functional activities (Frost, 1986) in what he called the intermediary organization (IO) of the skeleton. These are important in understanding the behavior of bone cells, and the reader is encouraged to consult reviews describing details (Frost, 1986). There are at least four levels of IO: growth, modeling, remodeling, and fracture repair. Growth is responsible for elongation of the skeleton; modeling is responsible for sculpting and shaping the skeleton during growth; remodeling is responsible for removal and replacement of bone tissue without change in volume or mass; and fracture repair is responsible for healing fractures. They all involve the same osteoclasts and osteoblasts, but the coordinated end result is much different in each case. This discussion concerns mainly remodeling, the IO most prominent in adult life.

Basic Multicellular Unit/Basic Structural Unit

Two terms used in histomorphometry need definition. First, the basic multicellular unit (BMU) (Frost, 1973) is the group of osteoclasts, osteoblasts, osteocytes, and lining cells that make up one remodeling unit. Second, the basic structural unit (BSU) is the unit of bone tissue formed by one BMU. It is also referred to as the osteon. These are brought into existence by the remodeling IO and are important because all adult metabolic bone disease occurs through derangement of the remodeling IO and the resulting derangement of BMUs and BSUs.

Osteoblasts and Bone Formation

Osteoblasts are bone-forming cells (Fig. 2). They produce the organic collagen matrix (and noncollagenous proteins) that undergoes mineralization to form both lamellar and woven bone. They originate from marrow stromal cell lineage (Owen, 1978) and appear at bone remodeling sites where osteoclasts previously resorbed bone. They also form bone in other IOs without prior osteoclast resorption. Prominent features are an eccentric nucleus, prominent Golgi apparatus, cell processes, gap junctions, endoplasmic reticulum, and collagen secretory granules. These plump cells appear in microscopic sections lined up at forming sites on the surface of unmineralized osteoid. As the apposition of matrix and its mineralization progresses, the cells become thinner. Some become incorporated into the bone matrix as osteocytes. Others disappear altogether or become thin lining cells on the finished bone surface. In addition to synthesis of osteoid and noncollagenous proteins, osteoblasts also participate in the mineralization process (Marotti *et al.,* 1972). Intensive study over the past decade has described many of the factors that influence osteoblast activity. However, a complete picture (including osteoblast recruitment, attraction to bone-forming sites, regulation of cell numbers, control of the bone formation rate and total amount of bone formed) remains to be pieced together.

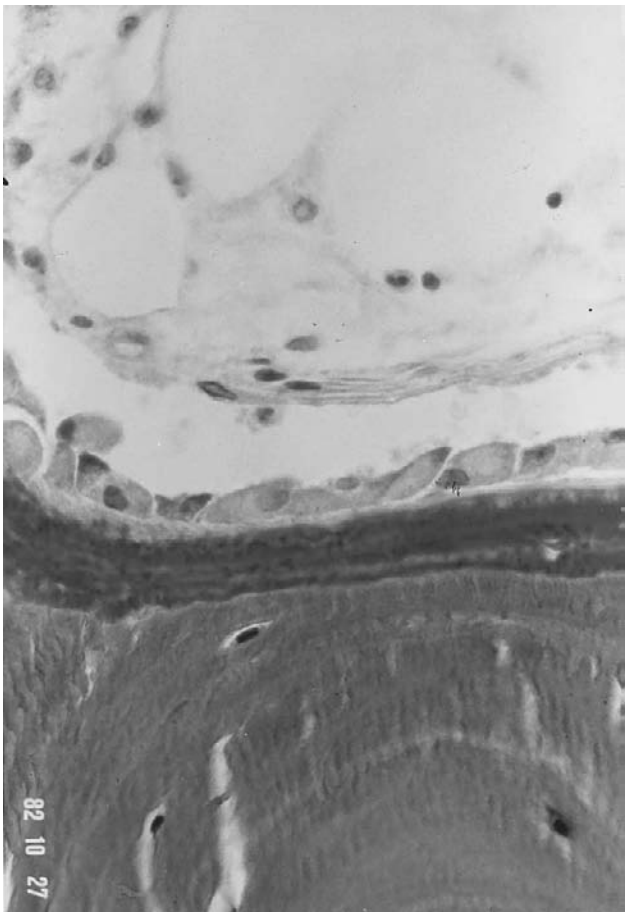

Figure 2 Osteoblasts lined in a palisade along an unmineralized osteoid seam. Goldner's stain; original magnification, ×150.

Osteoclasts and Bone Resorption

Osteoclasts (Fig. 3) are blood-borne multinucleated giant cells that originate from mononuclear hematopoietic stem cells (Jotereau and Le Douarin, 1978). They resorb both the mineral and the organic phases of bone. They contain 1 to 50 nuclei, and range from 20 to over 200 μm in diameter. In trabecular bone, they occupy shallow excavations on the surface, and in Haversian bone, they occupy the leading edge of "cutting cones." Light microscopic features include irregular cell shape, foamy, acidophilic cytoplasm, a striated perimeter zone of attachment to the bone, and positive staining for tartrate-resistant acid phosphatase. Electron microscopic features are numerous mitochondria, rough endoplasmic reticulum, multiple Golgi complexes, pairs of centrioles in a centrosome, vacuoles, and numerous granules.

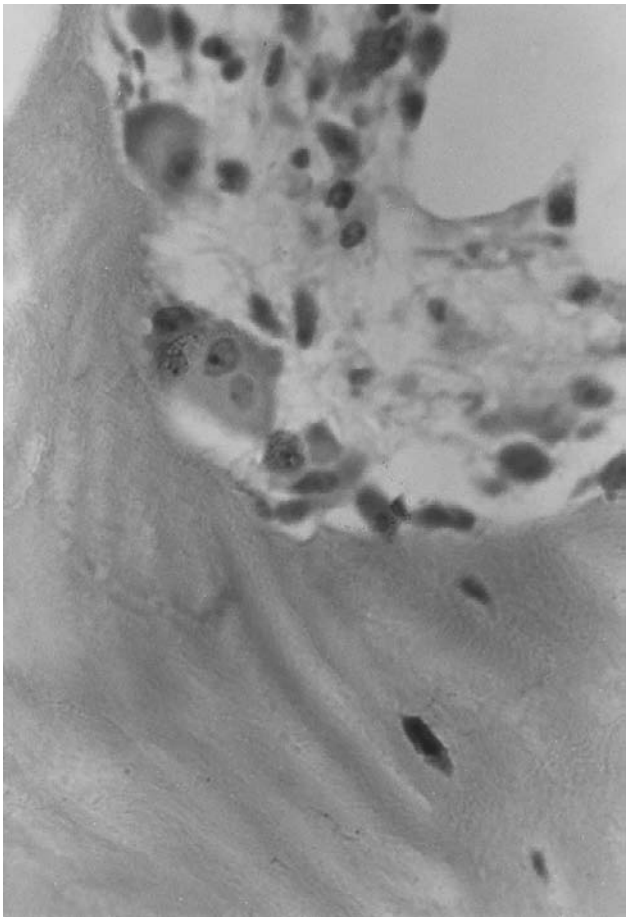

Figure 3 Osteoclast in a Howship's lacuna. Goldner's stain; original magnification, ×150. One multinucleated giant cell is seen, with other cells in the area.

A ruffled border, seen on electron and light microscopy, is located at the interface between resorbing bone surface and the cell surface. Osteoclasts secrete cysteine proteinases, collagenase, and acid phosphatase. Carbonic anhydrase is utilized for production of protons secreted at the ruffled border (Baron, 1985). The life span of osteoclast work at a trabecular resorption site is about 4 weeks on average (Recker *et al.,* 1988).

As noted above for osteoblasts, relatively recent research has described elements of the control mechanisms that influence osteoclast activity, but a fully integrated picture (including cell recruitment, attraction to sites to be resorbed, regulation of cell numbers, and control of the bone resorption rate) remains to be assembled.

Lining Cells

These are members of the osteoblast team (Fig. 4) that remain after bone formation has stopped (Parfitt, 1983). Morphologic features include location on trabecular surfaces; elongated, flattened, thin cytoplasm which cannot ordinarily be seen on light microscopy; and elongated, flattened, darkly stained nuclei. The function of lining cells remains uncertain, although they probably play a key role in the localization and initiation of remodeling (Mundy *et al.,* 1990) and in plasma calcium homeostasis (Parfitt, 1989).

Osteocytes

These, too (Fig. 5), are members of the osteoblast team that remain after bone formation has stopped (Parfitt, 1983), occupying small (10 μm) lacunae within the mineralized matrix of bone. The lacunae are interconnected by a fine network of canaliculi, measuring 1–2 μm in diameter, which contain cytoplasmic processes of osteocytes. Osteocytes can communicate with each other and pass oxygen, cell nutrients, and wastes to and from the canaliculi to the systemic circulation. The network of osteocytes may function to detect strain as mechanical force is applied to bone, and/or to convert changes in the strain environment into organized bone cell work. They may also be important in bone and plasma mineral homeostasis (El Haj *et al.,* 1990), although their function is not well understood.

Fluorochrome Labels

Tetracycline HCl labels are shown in Fig. 6. They were given on a 3–14–3:5 schedule and viewed in an epifluorescence microscope system. The distinction between the first and second labels is clear. The interlabel width measurements are made at several equidistant points at each formation site. The middle of each label is easier to locate than the leading or trailing edges; hence, the width measurements are made from the middle of the first label to the middle of the second label. Tetracycline HCl fluoresces a yellow color, and demethylchlortetracycline fluoresces a slightly orange color in systems activated with fluorescent light at a wavelength of 350 nm. This is helpful when two labelings are given at different points in time.

Regions Evaluated and Morphometric Methods

The area of an undecalcified section selected for histomorphometric analysis is permanently recorded by outline with an indelible mark on the slide. The analysis is restricted to the trabecular area. The distinction between endocortical and trabecular bone is made by pattern recognition by the histomorphometrist.

Few basic data are gathered at the microscope: volumes of bone, osteoid, and marrow; total trabecular perimeter; perimeters bearing the features of formation and resorption; thickness of osteoid and osteon walls; and interlabel width. The reader is encouraged to consult several texts and articles for detailed description of the numerous variables that can be measured or derived from microscopic sections, and for description of the methods of unbiased sampling of microscopic features (Recker, 1983). Several of the more frequently used variables and their abbreviations, as approved by the committee on nomenclature of the American Society

of Bone and Mineral Research (Parfitt *et al.,* 1987), are described in the following paragraphs.

Trabecular bone volume (BV/TV*)* is the ratio of the area of trabecular bone to the total area of marrow (including trabecular bone) expressed as a percentage. It is equivalent to the ratio of the volume of trabecular bone to volume of marrow. It is a "noisy" variable; however, it is important as part of the calculation of a number of other variables. *Osteoid surface* (OS/BS) is the percentage of trabecular perimeter that is occupied by unmineralized osteoid, with or without osteoblasts. *Osteoid thickness* (O.Th) is the average thickness of the osteoid covering trabecular surfaces. *Eroded surface* (ES/BS) is the percentage of trabecular surface that is occupied by Howship's lacunae, with and without osteoclasts. *Osteoblast surface* (Ob.S/BS) is the percentage of trabecular surface that is occupied by osteoblasts. *Osteoclast surface* (Oc.S/BS) is the percentage of trabecular surface that is occupied by osteoclasts.

Mineralizing surface (MS/BS) is the percentage of trabecular surface that is mineralizing and thus labeled. The definition of this surface must be specified; it may include both single and double label, double label only, or double label plus one-half the single label surface. The latter definition is the most accurate expression of mineralizing surface. MS/BS is used in the calculation of bone formation rates, bone formation periods, and the various expressions of mineralization lag time; thus, it is important to define it strictly.

Mineral apposition rate (MAR) is the rate of addition of new layers of mineral at trabecular surfaces. It is obtained by dividing the distance between labels by the time interval between labels. In a 3–14–3 schedule, the time interval is 17 days. The measurements are made from the middle of one label to the middle of the other, and corrected by $\pi/4$ for the randomness of the angle between the section plane and the plane of the trabecular surface. Some authors use an empirically determined refinement (1.199) of this factor, which was introduced because of the known departure from anisotropy of trabecular bone (Schwartz and Recker, 1981). All thickness measurements should be corrected by one of these factors in order to compare histomorphometric expressions of bone remodeling with other methods.

Wall thickness (W.Th) is the average distance between the resting trabecular surface (no osteoid or Howship's lacunae) and the cement lines. It is also corrected for section obliquity by one of the scaling factors. This measurement is used to calculate the formation periods.

Formation period (FP) is the average time required to complete a new trabecular BSU. It is calculated as the MAR divided by the W.Th. It can be used to calculate the resorption period (RP) by multiplying by the ratio of ES/BS to OS/BS.

Mineralization lag time (Mlt) is the lag between the time osteoid is formed and the mineral is added. It is calculated as O.Th/MAR. For a more accurate expression, it can be adjusted downward by the fraction of osteoid surface taking label (MS/OS). Thus, Mlt = O.Th/MAR*MS/OS. The Mlt can be used for detecting a mineralization defect, such as seen in frank vitamin D deficiency.

Bone formation rates (BFR/BV, BFR/BS): The two most useful expressions of bone formation rates are BFR/BV, the annual fractional volume of trabecular bone formed, and BFR/BS, the annual fractional volume of trabecular bone formed per unit trabecular surface area.

Trabecular connectivity: This concept expresses the extent of attachments between trabeculae. Loss of connectivity is a mechanism that might explain excessive (i.e., out of proportion to the deficit in bone mass) bone fragility. Parfitt (Parfitt *et al.,* 1983) described calculations for trabecular thickness (Tb.Th), trabecular number (Tb.N), and trabecular separation (Tb.Sp). These calculations and measurements have become an integral part of the histomorphometric analysis of transilial bone biopsies. Other indices of trabecular connectivity have since been developed and gained a measure of acceptance, i.e., the ratio of nodes to free ends and related measures (Garrahan *et al.,* 1986), star volume (Vesterby *et al.,* 1989 and 1991), and trabecular bone pattern factor (TBPf) (Hahn *et al.,* 1992).

Still another approach involves analysis of superficially stained thick sections ("three-dimensional histomorphometry"), in which artifactual trabecular termini on the surface (created during sectioning) take up the stain, but *real* termini within the section do not. In a study of osteopenic women with and without vertebral fractures, this method disclosed a significant structural difference (Aaron *et al.,* 2000) but conventional histomorphometry did not (Hordon *et al.,* 2000).

Other additions to the list of histomorphometric variables are those associated with total reconstruction of the remodeling site (Agerbaek *et al.,* 1991). This allows calculation of bone balance at the individual BMU. The key maneuver permitting these measurements and calculations is estimating the position of the trabecular surface at the time osteoclasts began their resorption.

Reference Data

Table I contains selected histomorphometric data from a group of 90 untreated patients with postmenopausal osteoporosis compared to 34 healthy postmenopausal women (Kimmel *et al.,* 1990). The table is included here to characterize the findings in normals and in patients with osteoporosis, and to provide data for calculating statistical power and sample size. The patients were selected on the basis of at least one vertebral deformity coupled with low bone mass and no other cause of skeletal fragility. The normals were recruited as a convenience sample of ostensibly healthy postmenopausal women evenly distributed between ages 45 and 75. Careful clinical screening, including spine radiographs, was used to document absence of osteoporosis.

As Table I shows, the patients tended to be older, shorter, and lighter than the normals. It is somewhat surprising that

Table I Reference Data, Normals, and Osteoporosis Patients[a]

Variable			Osteoporosis		Normal		
Abbreviation	Units	Name	Mean ± SD	Median	Mean ± SD	Median	P<
N			90		34

almost all the differences between the normals and osteoporotics are found in the structural variables and not the dynamic ones. This reflects the fact that the remodeling abnormalities in established osteoporosis cause loss of trabecular elements, rather than global thinning of trabeculae. However, wall thickness, a static structural variable that is unrelated to connectivity, is about 13 μm lower in the osteoporotic group. The greatest differences, however, are in trabecular number and trabecular separation (with median values for the osteoporotic group about one-third lower and one-half higher, respectively, than corresponding values for the normal group). Trabecular thickness is modestly affected (with a median value about 1/10th lower in the osteoporotic group). Together, these findings contribute importantly to our understanding of the pathogenesis of osteoporosis: the process leading to postmenopausal osteoporosis removes *entire trabecular elements.* Furthermore, loss of trabecular elements reduces trabecular connectivity, thereby producing bone fragility that is out of proportion to the reduction in mass.

Bone Biopsy in Patient Care

As noted earlier, most patients with osteoporosis can be managed without bone biopsy. However transilial bone biopsy is useful in the clinical setting when there is uncertainty about the nature of a patient's bone disease. A variety of rare metabolic bone diseases are diagnosed without bone biopsy, that is, by clinical, X-ray, and laboratory examinations. However, these diseases have important bone histomorphometric abnormalities, and a bone biopsy before and after starting treatment can be necessary to judge the adequacy of, or adherence to, a treatment intervention. Table II lists situations in which transilial bone biopsy *with tetracycline labeling* can aid in clinical decision making.

Table II Some Clinical Indications for Transilial Bone Biopsy

1. When there is excessive skeletal fragility in unusual circumstances (e.g., the patient younger than age 50)
2. When a mineralizing defect is suspected (e.g., due to occult osteomalacia or treatment with anticonvulsant drugs)
3. To evaluate adherence to treatment in a malabsorption syndrome (e.g., sprue)
4. To characterize the bone lesion in renal osteodystrophy
5. To diagnose and assess response to treatment in vitamin D-resistant osteomalacia and similar disorders
6. When a rare metabolic bone disease is suspected

Bone Biopsy in Clinical Research

Mechanisms, Pathogenesis, and Response to Treatment

The biopsy can give important clues to the pathogenesis of a metabolic bone disease, and the mechanism of a treatment intervention. Further, the information can be obtained rather quickly, at least quickly in the context of clinical bone research. For example, in the first year of a treatment that increases bone mass, the biopsy may be able to distinguish between a mechanism that reduces remodeling and one that is truly anabolic. The increase in bone mass might be similar in both cases. An agent that reduces the activation of new remodeling sites, while leaving the rest of the remodeling IO unaffected, will increase bone mass, sometimes to a striking degree (Heaney, 1994). This occurs by filling part or all of the remodeling space, with increases in bone mass that level off after about the first year or so. On the other hand, a truly *anabolic* agent would increase trabecular thickness, increase connectivity, and/or produce positive bone balance at the BMU. Such an anabolic effect might well continue for a longer period of time, result in a greater net increase in bone mass, and be more effective in preventing fragility fractures.

Prediction of Long-Term Safety

Prediction of long-term safety is perhaps the most valuable information that can be obtained from the bone biopsy in clinical trials. For example, an agent that stops the activation of remodeling completely would be worrisome for long-term safety in the treatment of osteoporosis. In the complete absence of remodeling, one would expect a reduction in the risk of fracture in the first few years of treatment. After several years, as unrepaired microdamage accumulates, the risk would actually increase even though bone mass remained stable. If transilial bone biopsy is part of the research protocol, this problem can be detected in time to adjust the dose or stop treatment.

The biopsy can also be used to identify abnormal bone formation, such as woven bone or osteitis fibrosa, before harm can occur. The histomorphometric evaluation of bone biopsies is particularly important in studying the effects of anabolic agents, where new bone must be normal in histologic appearance to be mechanically useful.

Practical Considerations, Training, Availability, etc.

Few physicians have been trained in the transilial biopsy technique, and few laboratories have the expertise and capacity to process and examine the number of specimens required for large clinical trials. However, not every patient in a large multicenter trial needs to undergo biopsy in order to obtain enough information to understand the mechanism of action or long-term safety of a new drug. Principal investigators or their physician associates can be trained in the biopsy procedure, and central laboratories can process and examine the specimens. Thus, the practical constraints of resources can be overcome to meet the needs of clinical treatment trials.

Timing of the Biopsy

A given patient can undergo no more than two biopsies, one on either side, without danger of confounding effects remaining from a previous biopsy. Thus, the research questions to be answered should be planned around a maximum of two biopsies, preferably one prior to an intervention, followed by another at least 1 year later. The first biopsy can be used to estimate the time required for one remodeling cycle. This is equivalent to the skeletal transient, the time required to reach a new steady state. A second biopsy can be staggered among study patients, at 1 year in some and at longer intervals in others. This requires sufficient numbers of subjects at each time point in order to detect treatment effects. Another strategy is to omit the baseline biopsy, and perform biopsies at time intervals during treatment, comparing controls with those treated. This approach generally requires a larger sample size.

Other strategies have been suggested that are not satisfactory. For example, one might consider multiple periodic labelings at time intervals over several years, followed by a single biopsy. The problem with this is that a profusion of labels appears in microscopic sections. It is impossible to match labels seen on the sections with the times they were given. Little or no useful dynamic information can be obtained under these circumstances.

Another strategy is to give continuous label. Any forming site that was active during administration of the label will contain a broad fluorescent label. The problem with this is that one cannot determine when formation stopped or started at any given forming site, and thus one cannot calculate MAR. Again, little or no useful dynamic information can be obtained under these circumstances.

Conclusion

While transilial bone biopsy has limited value in managing patients in clinical practice, there are a few instances where it can be helpful in making clinical decisions. On the other hand, the biopsy is indispensable in clinical bone research for studying the pathogenesis of bone diseases and the tissue-level mechanisms of treatment effects. It is particularly useful in evaluating and predicting long-term safety of treatment interventions. Finally, it is indispensable for evaluating whether new bone formed by a treatment intervention is histologically normal and likely to be mechanically sound.

CHAPTER 95

Animal Models in Osteoporosis Research

Donald B. Kimmel
Department of Bone Biology and Osteoporosis, Merck Research Laboratories, West Point, Pennsylvania 19486

Introduction

The principal use for animal models of osteoporosis is to provide efficient experimental environments in which bone cells function within their intermediary organizations of modeling and remodeling. This chapter first summarizes important features of human osteoporoses detailed elsewhere in this volume. It then evaluates how a series of animal models provides *in vivo* skeletal behaviors that not only reflect tissue level organizations in humans, but also can be used to improve understanding of the pathogenesis, prevention, and treatment of osteoporosis.

Regulatory Recommendations for Animal Models of Osteoporosis

The most prevalent type of osteoporosis occurs in postmenopausal women. Because of the firm relationship of postmenopausal osteoporosis to estrogen deficiency, the United States Food and Drug Administration (USFDA) guidelines for preclinical testing of anti-osteoporosis agents recommend using animals either losing bone or that have already become osteopenic following ovariectomy (OVX) (USFDA, 1994; Thompson *et al.,* 1995). Before the existence of drugs proven to reduce osteoporotic fracture incidence in humans, the USFDA required data from one small and one large animal species. The guidelines suggest measuring endpoints used in human trials, such as: (a) bone density by densitometry, (b) biochemical markers of bone turnover, (c) bone strength by biomechanical testing (fracture surrogate), and (d) mineralization defect and turnover assessment by histomorphometry.

During the past decade, the de facto requirements for anti-osteoporosis drugs have evolved in several ways. First, because all current osteoporosis treatment drugs reduce fracture in humans, new anti-osteoporosis drugs need to prove anti-fracture efficacy in humans to compete in the marketplace. Experiments in large animals will likely not serve as a substitute for, or informative predecessor to, fracture data in humans. Second, existing guidelines are based principally on testing specific anti-resorptives that treat osteoporosis by slowing bone turnover and correcting the imbalance of bone resorption and formation (e.g., bisphosphonates, estrogen and selective estrogen receptor modulators [SERMs], and calcitonin). Current guidelines thus focus on detecting modest changes in bone mass over long periods of time. When agents that stimulate bone formation are considered, shorter experiments may suffice, due to more rapid changes in measurable endpoints. Improved serum, tissue, and urine bone turnover markers in animals may also shorten the required experimental durations.

A Perspective on *In Vivo* Experimentation

All animal models attempt to bridge the gap between molecular and cell level characterizations of diseases and agents and *in vivo* adult human trials that measure outcomes in afflicted adult humans. Past *in vivo* animal investigations of osteoporosis are a textbook example of how animal models are used to test agents and concepts that improve the understanding and control of human disease. Animal models are the lowest level at which the skeletal tissue level intermediary organizations of modeling and remodeling that govern the output of bone cells and the attendant skeletal

structural adaptations in adult humans can be examined (Frost, 1983).

The principal reason for the success of osteoporosis animal models is that the tissue level features of human osteoporosis are understood adequately to allow recognition of animals with skeletons that satisfactorily mimick those tissue level behaviors. Because of the variety of investigative techniques that can be applied and the extreme time-frame compression, animal studies are the most appropriate way to understand tissue-level mechanisms of drug actions. The combined results from recent Phase III and postapproval trials whose outcomes were accurately predicted by preclinical trials directly document the appropriateness of these animal models. The ongoing examination of human data continues to yield new understanding of human osteoporosis that will lead to further improvements in the animal models (Cummings *et al.,* 1995; Elffors *et al.,* 1994; Blunt *et al.,* 1994; Garnero *et al.,* 1996; Ross *et al.,* 1993).

The most certain way to learn the effects of a safe agent on the human skeleton is to study outcomes in an appropriately selected human population. However, when putative osteoporosis treatment agents need proof-of-concept or early phase efficacy testing prior to safety assessment, *in vivo* animal experimentation is the best choice. In addition, when questions about the effects of agents on turnover and cellular activity in humans in sites prone to osteoporotic fracture (e.g., vertebrae, hip, and wrist) arise, human experiments cannot generate suitable samples. Despite improvements in noninvasive imaging in humans (Link *et al.,* 1999), an appropriate *in vivo* study remains the best approach. The failure of early animal models to predict sodium fluoride effects in humans (Kleerekoper *et al.,* 1991; Riggs *et al.,* 1990, 1994) and failure of fracture reduction to follow bone mineral density (BMD) changes within early reports about etidronate (Chapuy and Meunier, 1995) led the USFDA to require that new classes of anti-osteoporosis agents demonstrate *both* BMD increases and anti-fracture efficacy in clinical trials. Now it is the marketplace that requires such performance.

Criteria for Animal Models in Osteoporosis

Full parallelism of *in vivo* animal models with human symptoms rarely exists. The criteria are flexible, creative, and open to revision as new evidence or needs appear. They place the highest value on animal models that match the tissue level behavior of human osteoporosis, allowing the detailed match of mechanisms to be provided by molecular- and/or enzyme-level characterization.

All bone researchers should participate in optimizing their end points, duration, and physiologic relevance. Clinical investigators can help refine *in vivo* animal models both by revealing new behaviors of the human osteoporotic skeleton, and ranking the importance of various tissue-level end points studied in human osteoporosis. *In vivo* animal investigators can help by developing end points that make the models more closely fit clinical needs. Skeletal research in the ovariectomized (OVX) rat is a critical achievement by bench scientists validating a highly relevant preclinical model (Wronski *et al.,* 1988a,b, 1989a) that led to efficacious treatments for human osteoporosis. That effort, completed in the late 1980s, was made possible by the dynamic characterization of human bone remodeling of the 1960s (Frost, 1969) and the bone mass and metabolic data collected about human osteoporosis during the 1970s (Recker *et al.,* 1978; Nordin *et al.,* 1978; Jensen *et al.,* 1982).

In vivo animal scientists have also done well with model refinement since that time. The introduction of standardized tests of bone strength as surrogates for osteoporotic fracture in the early 1990s is an example of targeted research that further refined the preclinical models (Mosekilde *et al.,* 1991; Toolan *et al.,* 1992; Kasra and Grynpas, 1994). New imaging techniques may further reduce the length of animal experiments by providing extremely precise measurement methods that focus on regions of bone showing the greatest post-OVX change (Kapadia *et al.,* 1998; Kinney *et al.,* 1995; Breen *et al.,* 1998). Relevant physiologic conditions studied in a complete manner should continue to be the hallmark of *in vivo* animal studies. For example, when the goal is to study an *adult* disease process, choosing a growing animal, simply to see quicker changes, makes little sense. Contributions from growth cartilage activity will certainly be absent from the adult human skeleton. Nerve resection experiments (Wakley *et al.,* 1988) best model the motionless, *denervated* limb, not the motionless limb. Combining extreme calcium deprivation with estrogen deficiency to accelerate (or even simply create) bone loss, produces a confused situation that bears limited resemblance to the clinical picture (Geusens *et al.,* 1991; Jerome *et al.,* 1995; Mosekilde *et al.,* 1993b). Though *in vivo* measurements of the animal skeleton are now routinely possible (Ammann *et al.,* 1992; Black *et al.,* 1989), the data often seem incomplete without quantitative histologic characterization of the tissue level events accompanying any bone mass and biochemical changes.

Summary

Using relevant, physiologic methods in an adult animal to produce a consistent, albeit incomplete set of symptoms, is the correct choice during early phases of osteoporosis model development. Additional experimental time, new end points, and more precise analysis tools are clearly preferred during model refinement to introducing irrelevant physiology. Models that give sporadic results across laboratories or require convoluted manipulations do not gain acceptance. Furthermore, today's understanding of animal models in osteoporosis research makes using an irrelevant animal model inexcusable and wasteful. Considering the general regulatory and practical requirement for human anti-fracture efficacy of new osteoporosis treatment agents, the need for studies of a relevant, costly model for terminal studies should be carefully considered. The continuous evaluation of animal models for relevance, need, and cost-effectiveness benefits all.

Postmenopausal Osteoporosis

In vivo animal models for the skeleton have been reviewed elsewhere (Rodgers *et al.,* 1993; Lerome, 1998; Bellino, 2000; Bonjour *et al.,* 1999; Charassieux, 1990; Grynpas *et al.,* 2000; Srinivasan *et al.,* 2000; Hartke, 1999; Grier *et al.,* 1996; Mosekilde, 1995; Newman *et al.,* 1995; Barlet *et al.,* 1994; Miller *et al.,* 1995; Cesnjaj *et al.,* 1991). This chapter not only emphasizes many of their important points, but also widens the perspective by encompassing additional animal models and secondary osteoporoses. Its fundamental approach is to identify animal models that match tissue behaviors that can be assessed *in vivo* in osteoporotic humans.

GROWTH AND ADULT PHASES

An *in vivo* animal model of osteoporosis should exhibit both growing and adult skeletal phases of meaningful duration. Low peak bone mass is an established factor in osteoporosis etiology (Lofman *et al.,* 2000; Baylink, 2000). Its importance is clear because a single BMD measurement at menopause is the best quantitative predictor of future fracture in healthy persons (Hui *et al.,* 1989; Gärdsell *et al.,* 1989a; Ross *et al.,* 1988). That value approximates peak bone mass, because premenopausal bone mass changes are minor (Recker *et al.,* 1992; Rodin *et al.,* 1990).

Growth processes, principally bone modeling under the influence of nutrition, physical activity, and heredity (Johnston *et al.,* 1992; Jones *et al.,* 1977; Liel *et al.,* 1988; Smith *et al.,* 1973; Eisman, 1999; Ralston, 1999; Econs, 2000; Rubin *et al.,* 2000), determine peak bone mass. Adult skeletal processes, predominantly bone remodeling, but some modeling to effect shape changes in response to changing physical activity patterns, determine bone quantity after peak bone mass attainment (Frost, 1983). Accurate animal models of osteoporosis should have both growth and adult phases of sufficient duration to permit useful studies.

ROLE OF ESTROGEN

Menstrual/Estrus Cyclicity Humans not only have a menarche and regular, frequent ovulatory cycles, but also experience bone loss at cessation of ovarian function. The positive linkage of regular menses to bone mass is reinforced by amenorrheic individuals (Drinkwater *et al.,* 1984; Marcus *et al.,* 1985; Klibanski and Green Span, 1986; Dawood *et al.,* 1989) and the bone accumulation that occurs upon resumption of normal menses (Klibanski and Greenspan, 1986; Dawood *et al.,* 1989; Drinkwater *et al.,* 1986). Mammals with regular, frequent ovulatory cycles seem to experience estrogen-deficiency bone loss routinely. Some hold that regularly cycling female mammals integrate an estrogen-related component of bone into the skeleton at puberty (Garn, 1970; Gilsanz *et al.,* 1988) that is lost at menopause (Frost, 1987). Thus, animals with frequent cycles might tend to have the most estrogen deficiency bone loss.

Natural Menopause Women undergo a natural menopause of 2–7 years duration (Treloar, 1981). Only 25–30% of women experience surgical menopause, most with preserved ovarian function or prompt estrogen replacement (McMahon and Worcester, 1966). Though, aside from rate of bone loss, no differences in bone behavior between surgical and natural menopause are known (Cann *et al.,* 1980; Hartwell *et al.,* 1990), naturally postmenopausal women retain widely variant levels of circulating 17-β-estradiol long after their last period (Cummings *et al.,* 1998b; Langcope *et al.,* 1981, 1984; Canley *et al.,* 1999), which affect their fracture and breast cancer risk.

Bone Loss and Rise in Turnover Rate after Estrogen Deficiency Following estrogen deficiency, bone loss accelerates transiently in multiple sites and then decelerates and enters a semiplateau phase (Nordin *et al.,* 1976; Horsman *et al.,* 1977). The loss is most pronounced in cancellous regions and at endocortical surfaces (Nilas *et al.,* 1984; Keshawarz and Recker, 1984). Estrogen status plays a more important role in determining bone quantity in the adult woman than does age (Richelson *et al.,* 1984; Nilas and Christiansen, 1987). Estrogen-deficiency effects on Haversian remodeling in humans are poorly documented. The cancellous and endocortical bone loss is accompanied by kinetically and histomorphometrically increased bone turnover (Recker *et al.,* 1978; Stepan *et al.,* 1987; Coble *et al.,* 1994) and a marked, transient negative calcium balance (Heaney *et al.,* 1978). In an accurate animal model of postmenopausal osteoporosis, these behaviors should be easily monitored by similar methods and end points to those used in humans.

Skeletal Response to Estrogen Replacement Oophorectomized or menopausal women given prompt estrogen replacement experience a smaller rise in turnover (Recker *et al.,* 1978; Steiniche *et al.,* 1989), less bone loss (Jensen *et al.,* 1982; Wasnich *et al.,* 1983; Christiansen and Lindsay, 1990; Christiansen *et al.,* 1980; Ettinger *et al.,* 1985), and fewer fractures (Jensen *et al.,* 1982; Ettinger *et al.,* 1985; Lindsay *et al.,* 1976) than those who receive no estrogen replacement (Christiansen and Lindsay, 1990). This response is demonstrated well by histomorphometric techniques in humans and animals (Wronski *et al.,* 1988b; Coble *et al.,* 1994; Steiniche *et al.,* 1989; Turner *et al.,* 1987). This response is so certain in adult women that an accurate OVX animal model must have an identical response to estrogen replacement.

SKELETAL RESPONSE TO OSTEOPOROSIS TREATMENT AGENTS

The tissue level effects of agents proven to reduce osteoporotic fracture incidence in humans are known. These agents include alendronate (Cummings *et al.,* 1998a; Harris *et al.,* 1993; Liberman *et al.,* 1995), risedronate (Wallach *et al.,* 2000; Eastell *et al.,* 2000), and raloxifene (Ettinger *et al.,* 1999; Meunier *et al.,* 1999). Accurate animal models should yield data predictive of these agents' effects in humans.

Development of Osteoporotic Fractures and Steady-State Osteopenia

Functionally, human osteoporosis is marked by low trauma fractures of the spine and hip (Kanis and McCloskey, 1992; Cummings *et al.,* 1985). An animal model that developed estrogen deficiency fragility fractures could facilitate preclinical anti-fracture efficacy trials. Despite the existence of excellent animal models for detecting estrogen deficiency bone loss, none exhibit low trauma fragility fracture. The lack of fracture in the preclinical models may speak to the importance of low peak bone mass, falls (Tinetti *et al.,* 1994; Gärdsell *et al.,* 1989b), and extended observation periods (often ~5000 patient-years), as factors that contribute positively to the ability to use osteoporotic fracture as an end point in human studies. For example, the one animal model with low peak bone mass, the SAM/P6 mouse, has fragility fractures without estrogen deficiency (Matsushita *et al.,* 1986). Falls and long observation periods are difficult to implement in animal models.

Bone Loss and Decreased Formation after Decreased Mechanical Usage

Older humans experience both loss of cancellous and cortical bone and declines in bone formation unrelated to estrogen deficiency (Schaadt and Bohr, 1988; Riggs and Melton, 1983). These changes come during a life phase when a generalized decline in physical activity also occurs. While extreme physical inactivity, as during bedrest or paraplegia, causes marked bone loss (Donaldson *et al.,* 1970; Minaire *et al.,* 1974; Krolner and Toft, 1983), the impact of long-term, mild inactivity is neither well-understood nor easily assessed. Disuse osteopenia should also be easily demonstrable in an accurate animal model of osteoporosis, but is not crucial to its success.

Remodeling

Remodeling is the principal bone cellular process that influences bone quantity and strength in the adult skeleton (Parfitt, 1983). Osteoclasts, osteoblasts, and their progenitors function in sequence to first remove aged bone tissue and soon after replace it *in situ* with an approximately equal quantity of new bone tissue. Remodeling rate is quantitated in humans by both biomarkers of resorption and formation (Calvo *et al.,* 1996; Garnero *et al.,* 1994; Eyre, 1997; Garnero and Delmas, 1999) and histomorphometric methods in non decalcified sections of iliac crest biopsy specimens obtained after *in vivo* labeling with bone seeking fluorochromes (Parfitt, 1983). Remodeling activity in humans is important in a practical sense, as high remodeling rate tends to be a risk factor for osteoporotic fracture (Garnero *et al.,* 1996; VanDaele *et al.,* 1996). Most current agents that decrease osteoporotic fracture incidence also decrease remodeling rate (Cummings *et al.,* 1998a; Recker *et al.,* 1978, 1996; Steiniche *et al.,* 1989; Harris *et al.,* 1993; Liberman *et al.,* 1995; Wallach *et al.,* 2000; Eastell *et al.,* 2000; Ettinger *et al.,* 1999; Meunier *et al.,* 1999).

Adult humans have both cancellous and Haversian bone remodeling (Frost, 1983). Cancellous and the contiguous endocortical surfaces display relatively high remodeling rates, likely accounting for most remodeling rate variation in the skeleton. While cancellous remodeling plays an important role in renewing bone in the spine, wrist, and greater trochanter, Haversian remodeling is probably more important in the femoral neck. Remodeling rates among cancellous sites are likely to vary by an order of magnitude (Kimmel and Lee, 1982). Though the extent to which estrogen deficiency raises Haversian remodeling in humans has never been defined in quantitative histologic studies, cortical porosity is not a prominent feature of postmenopausal osteoporosis.

In theory, an accurate animal model should display considerable steady-state Haversian remodeling, because of its importance to the maintenance of cortical bone strength. It would be ideal if Haversian remodeling and cortical bone quantity changes caused by agents being considered for osteoporosis treatment were revealed first in animal studies. However, from a practical standpoint, Phase IV followup in humans remains the optimal way to assure long-term cortical bone safety of osteoporosis treatments. Thus, animal models that allow assessing cancellous bone remodeling and bone strength status provide most of the important information available from preclinical studies. Furthermore, it is now likely that anti-fracture efficacy results in Phase III trials will supersede cortical bone data from any preclinical large animal study.

Convenience

Convenience for animal models is denominated as time frame compression, purchase cost, availability, housing requirements, handling difficulties, and the necessity for designing/implementing/validating new analysis procedures.

In adult, estrogen-deplete women, the phase of accelerated estrogen-deficiency bone loss lasts 5–8 years. The time from attainment of peak bone mass until the development of fragility fractures is 30 or more years. An effective animal model known to experience peak bone mass followed by post-OVX bone loss should compress both times by an order of magnitude or more.

Using an animal model with full accuracy can be more difficult than doing a human study. For example, if an intervention requires active subject cooperation, animals may be unable to comply. On the other hand, in animal experiments, clinical research problems like recruitment, lost sampling units, and compliance to pharmaceutical regimens, are generally nonissues. Animals convenient for some researchers because of specialized facilities and expertise, are a poor choice for others lacking those tools. Investigators relying on outdated methods (e.g., whole bone ashing, simple radiography, etc.) will most certainly miss important findings in the name of "convenience."

Glucocorticoid Osteoporosis

The tissue level features of human glucocorticoid osteoporosis are cancellous osteopenia with vertebral and rib fractures (Need, 1987; Reid, 1989, 1997; Lukert and Raisz, 1990). The osteopenia is characterized by a normal number of thinned trabeculae (Bressot *et al.,* 1979; Chappard *et al.,* 1996; Aaron *et al.,* 1989). It occurs most frequently in postmenopausal women and in older persons with underlying gonadal hormone insufficiency (Reid, 1997; Reid *et al.,* 1985), during which both resorption and formation are elevated, though the elevation in resorption is greater (Heaney *et al.,* 1978; Dempster, 1989). Secondary hyperparathyroidism due to decreased intestinal calcium absorption is observed with both bone biomarkers and iliac crest biopsy (Dempster, 1989; Hahn *et al.,* 1979; Klein *et al.,* 1977; Suzuki *et al.,* 1983). Even mild doses of prednisone suppress bone formation. The ongoing rate of bone loss matches or exceeds that in women just after menopause (Heaney *et al.,* 1978; Laan *et al.,* 1993).

Male Osteoporosis

The clinical features, the treatment, and the tissue level mechanisms behind postmenopausal osteoporosis are well-known. Though its molecular mechanisms have not been conclusively identified, the tissue level pathogenesis is reasonably well characterized. Despite the fact that one-third of hip fractures occur in men, male osteoporosis has been less well-studied (Orwoll and Klein, 1995; Swartz and Young, 1988; Ebeling, 1998; Poor *et al.,* 1995; Jones *et al.,* 1994). Probably because of their higher peak BMD, men at comparable ages have a lower fragility fracture incidence than women, making prospective studies of male osteoporotic fracture logistically challenging (Blunt *et al.,* 1994; Jones *et al.,* 1994). Furthermore, gonadal insufficiency is rarely induced surgically and occurs naturally over a more protracted period than female menopause, making detection of its bone consequences more difficult. However, the negative effects of aging and hypogonadism on the adult male skeleton are well-documented (Francis *et al.,* 1986; Murphy *et al.,* 1993).

Animal Models Evaluation

Postmenopausal Osteoporosis

Animals that should receive initial consideration are bird, mouse, rat, rabbit, dog, pig, sheep, and nonhuman primate species. Because the above criteria are directed at tissue-level outcomes in humans, the animal models will be evaluated as to how they duplicate those outcomes. Dissimilarities from the human condition in molecular mechanisms of development of one or more conditions may well exist. The fit of each animal model to the criteria above is summarized in Table I.

Avian

Birds have time-compressed growing and adult skeletal phases when compared to humans. Adult female birds have daily egg-laying cycles that correspond, respectively, to

Table I Summary of *in Vivo* Animal Models for Postmenopausal Osteoporosis

Attribute	Human	Avian	Mouse	Rat	Dog	Pig	Sheep	Primate
Growth/adult phases	Yes	OK	OK	OK	Yes	Yes	Yes	Yes
Role of estrogen								
Cyclicity	28d	Daily	Inducible	4–5d	205d	21d	21d[c]	21–28d

formation and resorption of medullary bone during cyclic oviposition and egg calcification (Bloom *et al.,* 1941). Estrogen status plays a major role in determining medullary bone mass (Wilson and Thorp, 1998). The bone accumulation phase occurs with rising serum 17-β-estradiol, while the removal phase accompanies falling 17-β-estradiol. Estradiol treatment of male birds also stimulates medullary bone formation (Wilson and Thorp, 1998; Miller and Bouman, 1981). Tamoxifen blocks the cyclic formation of medullary bone and the associated loss of cancellous bone, possibly through an indirect action (Wilson and Thorp, 1998).

The bird skeleton experiences localized bone loss during immobilization and increased bone mass during applied mechanical loads (Rubin and Lanyon, 1984, 1985; Matsuda *et al.,* 1986). Though avian models have helped in understanding bone cell origin (Kahn and Simmons, 1975; Jotereau and Ledouarin, 1978), bone loss during immobilization, and bone responses to increased loading (Rubin and Lanyon, 1984, 1985; Matsuda *et al.,* 1986), they are not accurate for studying tissue level aspects of the estrogen/fracture-centered disease of osteoporosis. Furthermore, current data suggest that birds have little cancellous or Haversian remodeling.

The bone response to estrogen in birds provides many opportunities for experiments that bear on bone biology (Miller, 1977), but the estrogen-related bone buildup suggests a fundamental dissimilarity to adult mammalian physiology. While avian hypoestrogenemia is associated with medullary bone *loss,* just as estrogen deficiency in mammals is associated with osteopenia, the course of bone mass following OVX is unknown. The estrogen-related bone accumulation may prove helpful in understanding peak bone mass accumulation in pubertal humans (Garn, 1970; Gilsanz *et al.,* 1988; Attie *et al.,* 1990; Bonjour *et al.,* 1991), but seems likely to hinder the proper interpretation of experiments about osteoporosis.

Avians are convenient, but, at this time, irrelevant for tissue level osteoporosis research, because their skeletal behavior does not mimick tissue-level features associated with adult human osteoporosis.

Mouse

Past success with mice in physiologic aspects of skeletal research is encouraging. Recently, strain-specific post-OVX bone loss and effects of estrogen replacement have begun to appear. It is excellent as a model for osteopetrosis (Walker, 1972; Barnes *et al.,* 1975; Marks and Lane 1976; Felix *et al.,* 1990), osteoclast and stromal cell ontogeny (Lennon and Micklem, 1986), and cytokine and marrow studies (Kyoizums *et al.,* 1992; Most *et al.,* 1995; Passeri *et al.,* 1993; Liu *et al.,* 2000; Masuzawa *et al.,* 1994; Nicola *et al.,* 1985; Takahashi *et al.,* 1994; Jilka *et al.,* 1992; Miyaura *et al.,* 1997; Simonet *et al.,* 1997; Hankenson *et al.,* 2000). The mouse has become even more popular for the ease with which its genome can be systematically manipulated (Cassella *et al.,* 1994; Yoshitake *et al.,* 1999; Lorenzo *et al.,* 1998; Ammann *et al.,* 1997; Ducy *et al.,* 1996; Korach *et al.,* 1996; Windahl *et al.,* 1999; Masuda *et al.,* 1997; Poli *et al.,* 1994). Mice have been used to identify and characterize genes responsible for osteopetrosis (Marks and Lane, 1976; Felix *et al.,* 1990). Mice with respectively low and high peak bone mass (Beamer *et al.,* 1996) lend themselves to genetic investigations using F2 cross and F1 backcross studies of extremes of a continuous phenotype (Lander and Botstein, 1989).

Data validating the mouse as an *in vivo* model for tissue-level osteoporosis research now exist. They suggest that, much like in the rat, cancellous (Jilka *et al.,* 1992; Yoshitake *et al.,* 1999; Lorenzo *et al.,* 1998; Ammann *et al.,* 1997; Masuda *et al.,* 1997; Poli *et al.,* 1994; Broulik, 1991; Onoe *et al.,* 2000; Ishimi *et al.,* 2000; Yamamoto *et al.,* 1998), but not cortical (Edwards *et al.,* 1992), bone loss occurs soon after OVX in popular strains like Swiss-Webster and C57BL. Genetically hypogonadal female mice are osteopenic (Smithson *et al.,* 1994). Estrogen-deficiency bone loss appears to be prevented by 17-β-estradiol (Jilka *et al.,* 1992). Ectopic bone ossicles are preserved by 17-β-estradiol (Hashimoto *et al.,* 1991). Mice also experience age-related cancellous and cortical bone loss in the vertebrae (Bar-Shira-Maymon *et al.,* 1989a,b) and femur (Weiss *et al.,* 1991) during the second year of life.

Estrogen administration increases bone formation with woven bone deposition through an estrogen receptor-mediated mechanism (Edwards *et al.,* 1992; Urist *et al.,* 1950; Liu and Howard, 1991; Bain *et al.,* 1993). However, estrogen-stimulated bone formation in mice occurs at 17-β-estradiol doses above 0.05 mg/kg/day subcutaneously (sc), about an order of magnitude above that which prevents bone loss in the OVX rat. When 17-β-estradiol doses $\sim$0.01 mg/kg/-day 2–3X/week sc have been used in the OVX mouse (Jilka *et al.,* 1992), estrogen replacement has effects like in the rat and human, reducing turnover and stopping bone loss. Additional work at these lower doses of 17-β-estradiol and $\sim$0.5 mpk oral 17-α-ethinyl estradiol is needed to confirm this important parallel of the mouse with rats, nonhuman primates, and adult humans.

Validation of the mouse as a model for tissue level osteoporosis seen in humans needs some targeted experimental work to document the appropriateness of its skeletal response to estrogen. Applications for which rats are not suitable, principally studies of transgenic and knockout animals, are now rapidly driving mouse skeletal experiments. The similar life span of mice to rats and the similar cost for experimentation, suggests that unique applications of the mouse will induce many investigators to choose the mouse in the future. Some mouse strains, including C57BL/6J used to make knockout and transgenic mice, appear to develop estrogen-deficiency bone loss that is prevented by low levels of estrogen replacement. The time course and site specificity for development of estrogen-deficiency osteopenia should be established in representative mouse strains, as it has been for the rat (Wronski *et al.,* 1988a, 1989a). The bone formation response at endocortical surfaces to estrogen seems to be a high dose phenomenon. However, its existence may make studies of bone formation responses in the mouse

questionable, since this formation pathway does not appear to exist in larger animals. Experiments with transgenic and knockout mice are the most likely method to find the molecular pathways by which estrogen influences tissue level behavior of the human skeleton.

Specimens adequate for histomorphometric study of cancellous bone mass, structure, and turnover in mice can best be obtained from the distal femoral metaphysis. Mouse bones contain such small amounts of mineral that conventional dual X-ray absorptiometry (DXA) lacks the necessary precision. Equipment like peripheral quantitative computed tomography (pQCT) is useful (Beamer *et al.,* 1996; Ferretti *et al.,* 1994), but provides a less direct link to human-applicable densitometry measurements than DXA. Specialized (slower speed, smaller collimator) peripheral DXA instruments or μCT (Kapadia *et al.,* 1998; Kinney *et al.,* 1995; Breen *et al.,* 1998) with high resolution and software modifications may hold an answer.

The SAM Mouse

The SAM/P6 (senescence accelerated mouse) mouse not only has low peak bone mass, but also develops fractures in middle and old age (Takahashi *et al.,* 1994; Okamoto *et al.,* 1995; Breen *et al.,* 1998). It is the *only* experimental animal with documented low peak bone mass and fragility fractures of aging. The SAM mouse needs full genetic (Tsuboyama *et al.,* 1993; Benes *et al.,* 2000), hormonal (Takahashi *et al.,* 1994), and biomechanical characterization, including site specificity for fractures. If it does not have collagen defects like those in osteogenesis imperfecta (Cassella *et al.,* 1994; Spotila *et al.,* 1991), it may, when combined with OVX and standard osteopenic prevention approaches like estrogen replacement or bisphosphonates, provide a model for studying the role of low peak bone mass in causing late-life fractures. It may also provide an opportunity to identify genes contributing to peak bone mass.

Rat

The rat has a long history of providing data relevant to the adult human skeleton. It gave the first evidence that osteoclasts ingest bone substance (Arnold and Lee, 1957) and early evidence about the hematogenous origin of osteoclasts (Gothlin and Ericsson, 1973; Andersen and Matthiessen, 1966; Marks and Schneider, 1978). The rat was once held unsuitable as an adult human skeletal model because many epiphyseal growth cartilages in *male* rats remain open past age 30 months (Dawson, 1925). However, bone elongation ceases and effective epiphyseal closure ensues at important sampling sites in *female* rats by age 6–9 months (Acheson *et al.,* 1959; Joss *et al.,* 1963; Spark and Dawson, 1928; Turner *et al.,* 1989; Kimmeh, 1992a). Periosteal expansion continues until about age 10 months in female rat, its age of peak bone mass (Schapira *et al.,* 1992; Li *et al.,* 1992). The healthy life span for intact female rats is 21–24 months. Thus the female rat has an appreciable life span both before and after attainment of peak bone mass. The lengthy bone accumulation period in the female rat presents ample opportunity to study both internal and external determinants of peak bone mass. Even the most vocal critics of the rat as a model of adult human skeletal disease because of its "continuous growth and lack of remodeling" now acknowledge both the inaccuracy of this statement and the presence of cancellous remodeling. They only caution to use female rats of at least 6–9 months age and avoid studying Haversian remodeling (Frost and Lee, 1992).

Adult female rats have a regular estrus cycle during which estrogen levels spike for 18 hr every 4 days (Butcher *et al.,* 1974). During ages 12–24 months, the fraction of rats found in constant diestrus rises gradually (Lu *et al.,* 1979), and cancellous bone loss is frequently observed (Schapira *et al.,* 1992). While this is not true menopause, peaks in estrogen cease as bone loss occurs, making a link of rat "menopause" to cancellous bone loss possible.

Following OVX, loss of cancellous bone mass and strength occurs and then decelerates in a site-specific fashion after 3–4 months, to enter a plateau phase (Wronski *et al.,* 1988a, 1989a,b; Kalu, 1991; Wronski, 1992; Kimmel and Wronski, 1990; Mosekilde *et al.,* 1993a). This bone loss is accompanied by an increase in bone turnover rate (Wronski *et al.,* 1986, 1988a; Black *et al.,* 1989). These events mimick well the bone changes that accompany estrogen deficiency in humans. Not all cancellous bone sites in the rat experience such bone loss (Ito *et al.,* 1993; Li *et al.,* 1996a), further tightening the parallel of the rat and human skeletons, since osteoporotic fragility fractures and osteopenia are limited to a few sites in humans (Wasnich *et al.,* 1983; Cummings, 1991). DXA, the most widely applied method for measuring bone mass in humans, works well in rats (Ammann *et al.,* 1992; Kimmel and Wronski, 1990), providing the best precision on excised specimens obtained at necropsy.

OVX rats given prompt estrogen replacement experience no rise in turnover (Wronski *et al.,* 1988b; Turner *et al.,* 1987; Kalu *et al.,* 1991) and no bone loss (Wronski *et al.,* 1988b; Garner *et al.,* 1992). Agents like bisphosphonates (Toolan *et al.,* 1982; Seedor *et al.,* 1991), SERMs (Evans *et al.,* 1994, 1996), and calcitonin (Nakatsuka *et al.,* 1990; Mazzuoli *et al.,* 1990) also block the rise in turnover and bone loss in both rats and humans (MacIntyre *et al.,* 1988; Szucs *et al.,* 1992). Rats exhibit no dose-related bone formation response to 17-β-estradiol.

The rat, like all other animal models of osteoporosis, has no fragility fractures associated with estrogen deficiency. This shortcoming can be partially overcome by assessments with servohydraulic test systems. Reliable assays now exist for the vertebral body (Mosekilde *et al.,* 1991, 1993a; Toolan *et al.,* 1992) and femoral shaft (Ferretti *et al.,* 1994). Rat vertebral body strength appears to be a reasonable surrogate for human vertebral body fracture risk. Such preclinical testing may avoid the problems revealed during the investigation of sodium fluoride as a treatment for osteoporosis (Kleerekoper *et al.,* 1991; Riggs *et al.,* 1990).

Rats lose bone following immobilization. Multiple methods of permanent and temporary immobilization are available (Wakley *et al.,* 1988; Svesatikoglou and Larsson, 1976; Thomaidis and Lindholm, 1976; Thompson and Rodan 1988; Li *et al.,* 1990; Lindgren and Mattson, 1977). Acute (Thompson and Rodan, 1988), chronic (Li *et al.,* 1990), and recovery phase (Lindgren and Mattson, 1977; Maeda *et al.,* 1993; Lane *et al.,* 1994; Mattson, 1972) bone changes related to disuse are easily studied.

Adult female rats have adequate amounts of cancellous bone remodeling to permit useful experiments (Frost and Lee, 1992; Vignery and Baron, 1980; Baron *et al.,* 1984). The remodeling : modeling ratio rises with age. Reversal lines at the base of cancellous osteons are absent in 4-month-old rats (Erber, 1996), suggesting a predominance of modeling at this age. However, studies of cement line morphology in older rats confirm that bone activity undergoes a transition to remodeling activity during adulthood (Erben, 1996; Wronski *et al.,* 1999). Many cancellous bone regions in intact adult rats maintain stable bone mass for months while showing abundant bone formation and resorption. This neutral balance for resorption and formation (Wronski *et al.,* 1989a,b) suggests the presence of remodeling.

In most cortical bone sites, levels of Haversian remodeling approximate zero in rats. However, processes resembling intracortical remodeling are induced by both anabolic agents (Lee *et al.,* 1990) and stressful metabolic conditions (Ruth, 1953; Baylink *et al.,* 1970; Morey and Baylink, 1978; Wronski *et al.,* 1987; deWinter and Steendijk, 1975). Unfortunately, it is not known whether these agents and conditions accelerate Haversian remodeling in humans. The rat has such low levels of Haversian remodeling that it cannot be used for analysis of Haversian remodeling behavior, especially of agents that suppress such remodeling. These data come from cross sections taken at the tibio–fibula junction or mid-femur (Baylink *et al.,* 1970; Morey and Baylink, 1978). Cortical bone regions surrounding cancellous bone, as in long bone metaphyses, are a reasonable, and currently uninvestigated, site to check to find higher levels of Haversian remodeling.

In 3-month-old OVX rats, the phase of accelerated estrogen deficiency bone loss lasts 3–4 months in the proximal tibial metaphysis (Wronski *et al.,* 1989a), a 20-fold time frame compression when compared with estrogen-deplete women. Experiments with 6- to 9-month-old OVX rats create extremely reliable estrogen deficiency bone loss within 6 weeks. The rat reaches peak bone mass by age 10 months, a 30-fold time frame compression when compared to the adult human. The rat is also among the most convenient of experiment animals to handle and house.

In executing OVX rat experiments, it is wise to restrict food to limit OVX-induced weight gain. This may be either pair-feeding to a sham-group (conservative) or weight-restriction to a sham-group (aggressive). Either type of food restriction speeds cancellous bone loss (Roudebush *et al.,* 1993), and possibly creates more reliable cortical bone loss. Investigators may be tempted to choose "retired breeders" because of their low cost and ready availability. However, the variable skeletal status of retired breeders is likely to influence negatively experimental outcomes. Virgin female rats that are more skeletally mature and not osteopenic in their long bone metaphyses are much more acceptable for prevention studies because they have considerably more cancellous bone in their long bone metaphyses whose loss can be prevented after OVX (Binkley and Kimmel, 1994).

The OVX rat is an excellent model that replicates the most important clinical features of the estrogen-deficient adult human skeleton. Its site-specific development of estrogen-preventable cancellous osteopenia in 6- to 9-month-old female rats is the most widely replicated and easily detected physiologic response in *in vivo* skeletal research. Ample time exists for experimental designs that either prevent estrogen-deficiency bone loss or restore bone lost after estrogen deficiency. The rat's low levels of Haversian remodeling present little problem when testing agents for their ability to prevent the loss of or rebuild lost cancellous bone. The lack of fragility fractures can be compensated by mechanical testing of vertebral bodies. Rats are convenient for most investigators; virgin females ages 6–9 months at the start of an experiment are the optimal choice. Six weeks is the optimal time post-OVX for necropsy sampling in prevention mode studies. Six to eight weeks post-OVX is an appropriate time for beginning treatment mode experiments in the osteopenic OVX rat (Li *et al.,* 1999), but responses in extremely osteopenic bone sites have been studied at up to 15 months post-OVX (Qi *et al.,* 1995). Existing laboratory measurement tools of biochemistry, densitometry, histomorphometry, and mechanical testing are readily applicable. Experimental situations may exist in which the extreme estrogen deficiency of the OVX rat may not be an adequate match to the variable estrogen deficiency seen in naturally postmenopausal women (Cummings *et al.,* 1998b; Langcope *et al.,* 1981, 1984; Cauley *et al.,* 1999).

Guinea Pig, Rabbit, Ferret, and Cat

Though occasional reports using guinea pigs, rabbits, ferrets, and cats in osteoporosis research have appeared (Duncan *et al.,* 1973; Jowsey and Gershan-Cohen, 1964; Vanderschueren *et al.,* 1992; Hirano *et al.,* 2000; Mori *et al.,* 1997; Mackey *et al.,* 1994; Li *et al.,* 1994a,b), few studies of estrogen deficiency bone loss exist. Too few experiments generally exist to properly assess their validity. Seven-month-old guinea pigs do not lose bone by 4 months post-OVX (Vanderschueren *et al.,* 1992). Adult rabbits have abundant Haversian remodeling and an appropriate parathyroid hormone response (Hirano *et al.,* 2000), but their estrus cycle is not like that in humans. Though calcium deficiency bone loss can be induced, estrogen deficiency bone loss does not seem to exist (Mori *et al.,* 1997). The ferret, weighing less than 1 kg, has Haversian remodeling (Mackey *et al.,* 1994). Its normal skeletal physiology, including the accumulation of estrogen-dependent bone that seems to accompany normal cyclicity in other mammals, is dependent on a regular light cycle (Li *et al.,*

1994b). Like the rabbit, it exhibits expected changes in bone remodeling rate and bone volume during treatment with parathyroid hormone (Li *et al.,* 1994a; Parfitt, 1976).

Dog

The adult dog is generally a reliable model for the adult human skeleton. Studies of ^{239}Pu-injected beagles not only identified adult cancellous bone remodeling (Arnold and Jee, 1957), but also pointed to the hematogenous origin of osteoclasts (Lee and Nolan, 1963). The ratio of cortical to cancellous bone is similar to humans (Gong *et al.,* 1964; Johnson, 1964). Both Haversian and cancellous osteons remodel with similar morphology, though more rapidly in dogs (Frost, 1969; Kimmel and Jee, 1982). Skeletal responsiveness parallels the adult human for glucocorticoids (Bressot *et al.,* 1979; Jett *et al.,* 1970), uremia (Ritz *et al.,* 1973; Malluche *et al.,* 1987), bisphosphonates (Delmas *et al.,* 1982; Flora *et al.,* 1981), and disuse (Donaldson *et al.,* 1970; Minaire *et al.,* 1974; Krolner and Toft, 1983; Unthoff *et al.,* 1985; Unthoff and Jaworski, 1978; Jaworski and Unthoff, 1986), and parathyroid hormone excess (Parfitt, 1976; Podbesek *et al.,* 1983).

In contrast to all other uses for the adult beagle as a model of the adult human skeleton, the oophorectomized beagle is controversial, yielding dissimilar results in multiple laboratories. Most studies lack significant findings (Kimmel, 1992b; Cumming, 1990; Drezner and Nesbitt, 1990; Barbier *et al.,* 1991; Shaw *et al.,* 1992; Lynch *et al.,* 1991; McCubbrey *et al.,* 1991; Boyce *et al.,* 1990; Malluche *et al.,* 1986, 1988; Faugere *et al.,* 1990; Nakamura *et al.,* 1992; Dannucci *et al.,* 1987; Karambolova *et al.,* 1985, 1986, 1987; Shen *et al.,* 1992; Snow and Anderson, 1985a,b, 1986; Snow *et al.,* 1984; Koyama *et al.,* 1984a,b). The most complete experiment suggests that annual estrogen-deficiency bone loss of ~6–9% occurs. The bone turnover pattern in one suggests a transient rise after OVX (Boyce *et al.,* 1990). Yet, several publications by one group (Malluche *et al.,* 1986, 1988; Faugere *et al.,* 1990) suggest that formation falls rapidly to 50% of sham, with no increased turnover phase. This suggests a marked dissimilarity to data from transmenopausal humans, where the transient rise in turnover has been well documented (Recker *et al.,* 1978; Stepan *et al.,* 1987; Coble *et al.,* 1994). The data also indicate that estrogen suppresses turnover with uncertain effects on bone mass (Snow and Anderson, 1985a,b, 1986; Snow *et al.,* 1984).

Estrogen exposure and menstrual/estrus cyclicity is much less than in other animals. 17-β-estradiol levels are usually very low in the dog, rising *twice yearly* for several weeks (Concannon *et al.,* 1975; Jones *et al.,* 1973; Bell *et al.,* 1971). In rats, 17-β-estradiol spikes for 18 hr every 4 days (Butcher *et al.,* 1994). Women spike 17-β-estradiol for 1–2 days monthly (Baird and Guevara, 1969; Reed *et al.,* 1986). The estrus cycle in monkeys has a similar frequency to humans (Longcope *et al.,* 1989). Estrogen exposure in dogs, though only marginally less than in rats, is only one-fourth that in humans, but lacks the frequency. It is similar to that in primates, except during the peak periods. This difference could contribute to the dog's developing only a small estrogen-dependent compartment of cancellous bone.

The adult beagle, an excellent model of the adult human skeleton except for estrogen deficiency, has Haversian remodeling. The age of peak bone mass is about 3 years. Though the OVX beagle seems to have estrogen-deficiency osteopenia, poor interlaboratory reproducibility makes it unreliable. A problem has been that most individual studies have inadequate methodology to detect the expected bone loss (Barbier *et al.,* 1991; Shaw *et al.,* 1992; Lynch *et al.,* 1991; McCubbrey *et al.,* 1991; Boyce *et al.,* 1990; Malluche *et al.,* 1986, 1988; Faugere *et al.,* 1990; Nakamura *et al.,* 1992; Dannucci *et al.,* 1987; Karambolova *et al.,* 1985, 1986, 1987; Shen *et al.,* 1992; Snow and Anderson, 1985a,b, 1986; Snow *et al.,* 1984; Koyama *et al.,* 1984a,b). Beagles are less estrogen-replete than women and may have a smaller estrogen-dependent compartment of bone in their skeleton. Despite its unreliable estrogen deficiency bone loss, the dog remains an excellent model for testing the effects on Haversian remodeling of agents that have anabolic effects on cancellous bone. However, using one animal model that combines both Haversian remodeling and consistent estrogen deficiency bone loss is possible and seems a better strategy.

Pig

The pig has both growing and adult skeletal phases and has a regular estrus cycle somewhat shorter than in humans. The OVX pig has been tested a few times (Mosekilde *et al.,* 1993b; Franks *et al.,* 1994). In one study, despite minor structural deterioration, no differences in bone mass, either by densitometry or histomorphometry, were seen. In a second study, minor bone loss in the fourth lumbar vertebra was seen at 3 months post-OVX. Pigs have been used successfully to study fluoride and exercise effects on the skeleton (Kragstrup *et al.,* 1989; Raab *et al.,* 1991). The age of peak bone mass is older than 3 years. Though existing data are limited, they do not encourage further development of this model.

Sheep

The ewe has both growing and adult skeletal phases with an age of peak bone mass of 5–7 years. Ewes have a regular estrus cycle during the short days of fall and winter, but have anestrus in spring and summer (Webb *et al.,* 1992; Malpaux and Karsch, 1990). Fluoride skeletal effects in the adult ewe also seem to parallel histologic changes in humans with frequent signs of increased formation, sluggish mineralization, and toxicity to bone forming cells (Charassieux, 1990; Eriksen *et al.,* 1985; Charassieux *et al.,* 1991a,b). Though early data on post-OVX skeletal behavior were not promising (Hornby *et al.,* 1994; Geusens *et al.,* 1996), recent data are more encouraging (Charassieux *et al.,* 2001). In particular, elevated bone remodeling is seen by

biochemical and histomorphometric measures in cortical and cancellous bone of 8-year-old ewes at 6 months post-OVX. Significant DXA-measured bone loss also occurs in the vertebra and femur. Glucocorticoid data seem consistent with findings in other large animal models and humans (Bressot *et al.,* 1979; Chavassieux *et al.,* 1993). Sheep can be housed readily at most vivariums and pose little problem for handling. Though wider interlaboratory validation is needed, the adult ewe seems to hold promise as an *in vivo* model of osteoporosis.

Nonhuman Primate

The above models focus on traditional skeletal studies that involve a few *in vivo* measurements and primarily post-mortem evaluations. With the nonhuman primate, both terminal and nonterminal studies relevant to the study of osteoporosis are possible.

Terminal Studies

The nonhuman primate has both growing and adult skeletal phases. Peak bone mass occurs at age 10–12 years in cynomolgus and rhesus monkeys and baboons (Jayo *et al.,* 1990, 1991; Pope *et al.,* 1989; Colman *et al.,* 1999a,b; Champ *et al.,* 1996). All non-human primates have a regular menstrual cycle with a duration of ~28 days, an excellent analog of adult women. Nonhuman primates experience a natural menopause early in the third decade of life.

Nonhuman primates show lower bone mass and strength with increased turnover (Binkley *et al.,* 1998; Jerome *et al.,* 1986) after OVX (Binkley *et al.,* 1998; Jerome *et al.,* 1986; Miller and Weaver, 1986; Miller *et al.,* 1986; Balena *et al.,* 1993; Thompson *et al.,* 1992; Lundon and Grynpas, 1993; Lundon *et al.,* 1994; Keller *et al.,* 2000; Jayo *et al.,* 1998; Mann *et al.,* 1992), premature menopause (Shively *et al.,* 1991), or GnRH agonist treatment (Mann *et al.,* 1990). Estrogen or bisphosphonate treatment prevents OVX-induced bone loss (Binkley *et al.,* 1998; Thompson *et al.,* 1992; Keller *et al.,* 2000). Nonhuman primates experience bone loss with age (Jayo *et al.,* 1990, 1991; Pope *et al.,* 1989; Colman *et al.,* 1999a,b; Champ *et al.,* 1996; Aufdemorte *et al.,* 1993; Grynpas *et al.,* 1993), menopause (Colman *et al.,* 1999b), and immobilization of long duration (Young *et al.,* 1983). Histomorphometric studies of primates and humans yield remarkably similar values (Pope *et al.,* 1989; Jerome *et al.,* 1986; Schnitzler *et al.,* 1993; Recker *et al.,* 1988). Though post-OVX bone loss is frequently masked by the use of animals at an age when they are still acquiring peak bone mass (Brommage *et al.,* 1999; Jerome *et al.,* 1997, 1999), when rhesus monkeys age 12 years or greater are used, elevated turnover markers and significant bone loss can be seen at 3 months, with a maximum spinal BMD decrease of 8.5% detected by DXA (Binkley *et al.,* 1998) within 9 months.

Late life spinal pathology in rhesus monkeys (Grynpas *et al.,* 1993; Carlson *et al.,* 1996) and baboons (Kimmel *et al.,* 1993; Hughes *et al.,* 1994) is mostly osteoarthritis. Baboons experience osteopenia (Aufdemorte *et al.,* 1993) with an age-related decline in anterior vertebral height that bears more similarity to that accompanying osteoarthritis than to vertebral crush fractures (Kimmel *et al.,* 1993; Hughes *et al.,* 1994; Degueker, 1985). Thus nonhuman primates are not likely to be a model of fragility fractures, because human osteoarthritis and osteoporosis tend to be mutually exclusive (Dequeke 1985; Ng *et al.,* 1984). Though spinal bone mass measurements in primates may be affected by the osteophytes that occur in osteoarthritis (Hopkins *et al.,* 1989; Drinka *et al.,* 1992), 12-year-old nonhuman primates can easily enter DXA-based studies for 2–3 years.

Nonterminal Studies

Biochemical markers of bone resorption, like urinary deoxypyridinoline show both age and gender effects in rhesus monkeys (Cahoon *et al.,* 1996). Early data suggest that nonhuman primates can be used to test the effects of agents and conditions on bone markers of resorption and formation. $\alpha V\beta 3$ integrin antagonists and cathepsin K antagonists reduce urinary *c*-telopeptide concentrations in GnRH-treated rhesus monkeys, after 5 days of treatment (Stroup *et al.,* 1999, 2000). Though it is not known whether such agents influence bone resorption in estrogen-deficient humans, this model has considerable conceptual relevance.

Summary

The adult nonhuman primate is an excellent model for all aspects of the adult human skeleton. Its extensive Haversian remodeling makes study of cortical bone relevant. The age of peak bone mass is 11–12 years. Its regular estrus cycles are an excellent analog of menstrual cycles in humans. High turnover with cancellous osteopenia develops within 3 to 6 months post-OVX. Requirements for housing and care of nonhuman primates limit their use to a small number of facilities. When handled by experienced staff in an appropriate environment, they present few care problems. In testing new anti-osteoporosis treatment agents that will require human anti-fracture efficacy for successful marketing, the need for terminal nonhuman primate studies must be carefully considered. The use of nonhuman primates in nonterminal studies using bone resorption markers may present an excellent opportunity for future investigations.

Glucocorticoid Osteoporosis

Small animal models generally reproduce important aspects of human glucocorticoid osteopenia poorly (Miller *et al.,* 1995). Most mouse and rat experiments use growing animals and relatively high doses of glucocorticoids (King *et al.,* 1996; Geusens *et al.,* 1990; Simmons and Kunin, 1967;

Turner *et al.,* 1995; Jowell *et al.,* 1987; Li *et al.,* 1996b; Ortoft and Occlude, 1988; Ferretti *et al.,* 1992, 1993; Ortoft *et al.,* 1992, 1999; Aerssens *et al.,* 1994; Altman *et al.,* 1992). They show *increased* metaphyseal cancellous bone mass accompanied by decreased bone elongation rate and lower rates of bone formation and resorption. The increased cancellous bone mass is due to the glucocorticoid influence on endochondral ossification. Glucocorticoids decrease both the disappearance rate of mineralized metaphyseal tissue and the bone elongation rate, thereby increasing cancellous mineralized tissue in a bone of reduced size.

Experiments in small growing animals also show cortical osteopenia and low bone strength with glucocorticoids (Ortoft and Occlude, 1988; Ortoft *et al.,* 1999; Ferretti *et al.,* 1992, 1993), due to inhibition of the rapid bone formation at periosteal surfaces. While the decreased bone formation data are pertinent, the overall picture differs physiologically from adult human glucocorticoid osteopenia, because of the relatively high glucocorticoid doses, the endochondral ossification in growing bones, and the gonadal hormone sufficient state of the rats. Cortical osteopenia and its associated low bone strength are due to reduced periosteal expansion, a minor process in the adult human skeleton. The growing rat is therefore a poor model for adult human glucocorticoid osteopenia.

Recent experiments indicate that mice may be useful for studying glucocorticoid-induced osteoblast apoptosis (Plotkin *et al.,* 1999; Weinstein *et al.,* 1998). Glucocorticoid experiments in older rats tend to show either a trend to or a significant, minor decrease in metaphyseal cancellous bone mass and cortical area (Nakamura *et al.,* 1996; Sjoden *et al.,* 1984; Larsson and Seuastikoglou, 1972; Goulding and Gold, 1988; Lindgren and DeLuca, 1983; Ortoft *et al.,* 1995; Wimalawansa *et al.,* 1997; Wimalawansa and Simmons, 1998). The usual dose and treatment time is subcutaneous 0.5–2.5 mg/kg/day prednisolone for 6–8 weeks. Metaphyseal bone density by Archimedes' principle or defatted bone weight was ~6% lower (Sjoden *et al.,* 1984; Larsson and Sevastikoglou, 1972; Goulding and Gold, 1988; Lindgre and DeLuca, 1983). Lumbar spine BMD by DXA was ~9–10% lower after 6 weeks (Wimalawansa *et al.,* 1997; Wimalawansa and Simmons, 1998). In 3-month-old female rats, total body calcium was ~12–15% lower after 12 weeks (Goulding and Gold, 1988). However, no glucocorticoid data in older rats have been uniformly reproduced in multiple laboratories.

Glucocorticoids in large animals cause increased remodeling activity and development of osteopenia (Duncan *et al.,* 1973; Charassieux *et al.,* 1993). Consistent with the small animal, the formation phase that follows remodeling's resorption phase proceeds slowly (Duncan *et al.,* 1973; Jett *et al.,* 1970). Studies in rabbits suggest that bones are weaker and BMD is lower after glucocorticoid treatment (Lindgren *et al.,* 1984; Waters *et al.,* 1995; Grardel *et al.,* 1994). In dogs, a 13% loss of lumbar spine BMD occurs over 12 months (Lyles *et al.,* 1993; Jett *et al.,* 1970). Bone formation is suppressed in sheep (Charassieux *et al.,* 1993, 1997; O'Connell *et al.,* 1993). Though these large animal results are consistent with data from humans and aged small animal models of glucocorticoid osteopenia, these large animals are poor models of the estrogen deficient skeleton (Kimmel, 1996). Given that glucocorticoid osteopenia has a hypogonadal component and frequently develops in the backdrop of postmenopausal estrogen deficiency, these large animals offer no possibility for studying this important interaction.

Summary

The clinical picture of glucocorticoid-induced osteopenia in humans is one of low bone mass accompanied by negative bone balance. The young, growing rat is a poor model for human glucocorticoid osteopenia. A relative shortage of data on adult small animals treated with glucocorticoids exists. Additional experiments documenting the influence of: (a) decreased food intake and (b) gonadal hormone status on the glucocorticoid effects on BMD, bone cell status, and bone strength are needed. The large animals showing glucocorticoid bone loss are poor models of the estrogen-deficient skeleton, limiting the degree to which they can mimick humans. At this time, there is no accepted small animal model for glucocorticoid osteopenia. The rabbit is the animal model of choice.

Male Osteoporosis

Small animal models of male osteoporosis are now sufficiently reliable to be employed in studies of male osteoporosis (Feldmann *et al.,* 1989; Wink and Felts, 1980; Gurkan *et al.,* 1986; Vanderschueren *et al.,* 1993, 1994, 1996, 2000a,b; Ke *et al.,* 2000; Erben *et al.,* 2000; Kapitola *et al.,* 1995). For instance, like female rats, male rats gonadectomized as young adults (age 4–6 months) soon become relatively osteopenic (Wink and Felts, 1980; Gurkan *et al.,* 1986). Though significant cancellous bone *loss* occurs in female rats OVX at this age, the osteopenia of young adult orchidectomized (ORX) male rats represents failure to achieve normal peak bone mass, rather than hypogonadism-induced bone loss in the adult skeleton.

The female and male rat skeletons age at different rates. The female skeleton stops growing and reaches peak bone mass by age 6–9 months, some 6 months before that of male rats. Considering their later age of peak bone mass, male rats should be at least age 12–15 months to demonstrate the prevention and treatment of osteopenia intended to mimic that in adult human males.

Orchidectomy induces high turnover and bone loss in cancellous regions (Wink and Felts, 1980; Garkan *et al.,* 1986; Vanderschueren *et al.,* 1993, 1994, 2000a,b; Ke *et al.,* 2000; Erben *et al.,* 2000). These changes are reversed by androgen replacement (Vanderschueren *et al.,* 1994). At longer times,

cortical osteopenia occurs. Age-related bone loss also occurs in male rats between 1 and 2 years of age. The 12- to 15-month-old male rat is an accurate model of the adult male human skeleton. In order to use rats of this age in studies of sufficient length, consideration should be given to restrict feeding to extend healthy life span (Weindruch, 1996).

Summary

When an *in vivo* osteoporosis research project cannot be done in humans, the 6- to 9-month-old female rat is the animal model of choice to mimick tissue level findings in humans. It is near peak bone mass and can be manipulated to simulate accurately most clinical findings of osteoporosis in the adult female skeleton. Serum biochemistry, histomorphometry, and densitometry, routinely used in humans, can be used. Like all animal models, the rat develops no fragility fractures. However, mechanical testing of rat bones is a reasonably accurate predictor of bone fragility.

The OVX mouse is an accurate model for tissue-level bone changes when low doses of 17-β-estradiol ($<$0.01 mg/kg sc) are used for replacement. Appropriately prepared transgenic and knockout mice will be the most direct route to identifying molecular mechanisms behind estrogen deficiency bone loss.

The rat's low levels of Haversian remodeling do not permit accurate evaluation of cortical bone behavior, making additional studies of cortical bone, either in large animals or in humans, a necessity. Though the adult dog is an accurate model of the adult human skeleton, its hormonal dissimilarity seems to cause it to yield inconsistent results in the acutely estrogen-deficient state that differ from those in humans. Estrogen deficient nonhuman primates are currently the large animal of choice for quantitative histologic evaluation of Haversian remodeling.

Small animals are poor models of glucocorticoid-induced osteopenia. Larger animals like rabbits and dogs are acceptable, but do not replicate well the usually coexistent condition of estrogen deficiency. Aged male rats model all aspects of male osteoporosis well except for aspects connected with cortical bone remodeling.

CHAPTER 96

Defining the Genetics of Osteoporosis

Using the Mouse to Understand Man

C. J. Rosen, L. R. Donahue, and W. G. Beamer
The Jackson Laboratory, Bar Harbor, Maine 04609

Introduction—Historical Perspective

Low bone mineral density (BMD) has become the most established and identifiable risk factor for osteoporotic fractures. The proliferation of newer tools for measuring bone mass has resulted in widespread testing and has also led to the realization that BMD is a complex trait normally distributed across various populations. In addition, the data produced by these tools also provided the first clues that a syndrome once characterized as an age-related disorder associated with back pain and fractures is, in fact, a heritable disease. More recently, BMD studies of mother–daughter pairs, twins, and large sib cohorts estimated the heritability of this trait to be between 50 and 70% (Eisman, 1999). This finding led most investigators somewhat hastily to conclude that the genetic influences on BMD were "oligogenic"; i.e., the phenotypic variation in BMD was caused by the actions of a limited number of genes with discrete effects. Fueled by this concept, the past 10 years have been characterized by a flood of candidate-gene association studies in both small and large unrelated cohorts (Eisman, 1999). Although data from these papers were conflicted, and failed to yield major genes that defined osteoporotic risk, such studies, combined with genome-wide scanning of multigenerational families, served to reinforce the complex and polygenic nature of the genetic influence on bone acquisition. Having entered a new millenium, we are now left with the daunting task of defining the role of multiple genes that individually, or in concert, moderate the acquisition and maintenance of peak bone mass.

In addition to the complex multifactorial nature of genetic influences, three other factors have emerged that further complicate our search for osteoporosis genes. First, it is now clear that individual genetic determinants of BMD are strongly influenced by other genes that do not have direct effect themselves on BMD; i.e., epistasis (Eisman, 1999; Frankel, 1995). Second, there are numerous environmental factors that may modulate expression of one or more genes (Eisman, 1999). Sorting these genetic and environmental interactions will require complex modeling that must control for nutritional, hormonal, mechanical, and lifestyle factors. Third, most investigators have come to recognize that the BMD phenotype is only a surrogate for fracture. Defining "bone density genes" provides limited information with respect to prediction of future fractures, in part because there are other contributing factors that affect the eventual health of any given bone. The emergence of measurement tools with superb resolution of bone microstructure has further heightened this awareness. Such technology has resulted in a better understanding of what bone "quality" represents, and how this is related to skeletal frailty. Finally, and probably most importantly, there is now a growing realization that BMD represents the sum of several temporally related processes beginning with skeletal development and including modeling, remodeling, and consolidation. Decomposition of bone mass into intermediate phenotypes, such as BMD, cross-sectional area, shape, or a biochemical marker such as insulin-like growth factor (IGF)-I, is likely to yield more mechanistic insights not only into the overall processes of peak acquisition, but also into the

determinants of skeletal strength. Most certainly, finding genes that predict the risk of fractures in humans is going to require novel strategies and will remain a challenging endeavor for the foreseeable future.

Enter the mouse! Rodent models for testing hypotheses related to skeletal disorders are not new. The ovariectomized rat is a well-established tool for testing new therapies for osteoporosis, as well as for understanding how estrogen deprivation affects the bone remodeling unit. Adding to data from the rat are new models of laboratory mice that carry specific gene deletions (knockouts), gene additions (transgenic), or spontaneous mutation. These mice are currently at a frontier of basic research, specifically to test how a known gene may regulate diverse skeletal actions For example, targeted overexpression of IGF-I in transgenic mice using the osteocalcin promoter is characterized by a marked increased in both cortical and trabecular bone density at 6 weeks of age (Zhao *et al.,* 2000). Similarly, mice globally lacking expression of the *Cbfa1* gene (i.e., null mutation) are characterized by the absence of osteoblast differentiation, failure to mineralize bone, and lethality at birth (Komori *et al.,* 1997). Finally, spontaneous mutants such as the osteopetrotic mouse (gene symbol, *op*) which lacks a functional *mcsf* gene and its product, fail to exhibit differentiated osteoclasts which are required for normal bone resorption (Suda *et al.,* 1999). Such gene mutations, induced or spontaneous, help to elucidate the potential rule of single gene action in bone biology.

An entirely different approach utilizes the power of the mouse as a genetic tool to uncover genes whose normal allelic variation regulates BMD. Over the past 30 years, inbred strains of mice have helped identify genetic determinants of various disease states with both single and polygenic bases (Silver and Nadeau, 1997). Although investigators in the bone field have been a little late in recognizing these models, several factors have hastened their utilization. First, technology was developed to measure BMD accurately, easily, and relatively inexpensively in mice. Use of peripheral quantitative computed tomography (pQCT), peripheral dual X-ray absorptiometry (DXA), and full body DXA, by both *ex vivo* and *in vivo* methods, now allow investigators to measure BMD and appreciate large differences among knockouts, transgenics, mutants, and healthy inbred strains (Beamer *et al.,* 1996). Micro-CT has, for the first time, provided an opportunity to define three-dimensional microstructural aspects of bone, and in conjunction with newer methods of measuring bone strength, have opened the door for identifying determinants of bone quality (Turner *et al.,* 2000). Finally, the power of breeding strategies to isolate quantitative trait loci (QTL), and to test their effects either singly or in combination with other genetic determinants, has permitted hypothesis testing for individual or clusters of genetic loci (Zeng, 1994).

There are several confounding factors that have plagued human genetics studies in the past two decades, making gene identification exceedingly difficult. These have included the complex nature of the phenotype regulated by numerous genes, significant gene × gene and environment × gene interaction, and the multifactorial nature of bone quality (Eisman, 1999; Kelley *et al.,* 1990). Mouse studies have made these much more amenable to resolution. Furthermore, the homology between human and mouse genomes, as well as the intense efforts to map every gene in both species, provides more impetus to use this animal as a tool for defining the heritable determinants of osteoporotic risk. In this paper, we will describe the role of several mouse model systems for determining the polygenic basis of osteoporosis. In addition, we will define their relevance for subsequent human studies. We will not examine mutant, transgenic or knockout models, in part because we want to deemphasize the role of single genes in producing extreme pathology. Rather this review will focus on normal allelic variation in inbred strains of mice, an animal model more directly applicable to understanding the BMD trait in humans.

Inbred Strains of Mice

There are many types of mice available for genetic and biologic studies. In general, mice have become the workhorses of biomedical research because of their ease of breeding and reproductive capacity, their short life span, and the availability of large numbers of genetic markers in the mouse genome. Probably more importantly, though, and unlike the rat, dozens of different inbred mouse strains have been available since the early decades of the 20th century. These inbred strains of mice were developed by repeated matings between siblings for at least 20 consecutive generations (Silver and Nadeau, 1997). This resulted in nearly 100% homozygosity at all alleles across the mouse genome. By continuing the process until the 60th generation, inbred mice eventually became 100% homozygous at all loci (except for any spontaneous mutations which arise), thereby providing researchers with a plethora of genomically identical mice. More than 700 pure inbred strains are currently available at The Jackson Laboratory alone, including C57BL/6J (B6), the standard strain for many laboratories doing genetic as well as biologic analyses.

The second feature of inbred strains that makes them powerful genetic and physiologic tools is that an individual inbred strain differs from all other strains. Each strain has its own set of phenotypic characteristics that make it unique and allow innumerable differences in physiologic behavior. One such difference is in the wide variation in BMD among inbred strains. Thus, by choosing two inbred strains that differ in a trait of interest, a cross can be made to enumerate, locate, and define heritability of the genes that contribute to that trait.

Crossing two inbred strains of mice results in hybrid F1 mice that are genetically identical with each other and heterozygous at all loci. As illustrated in Fig. 1, intercrossing F1 mice results in F2 progeny in which genetic alleles for BMD have randomly reassorted into new combinations, such that at any given locus an F2 mouse will be homozygous for either progenitor strain alleles (i.e., *b6*/*b6* or *c3*/*c3*)

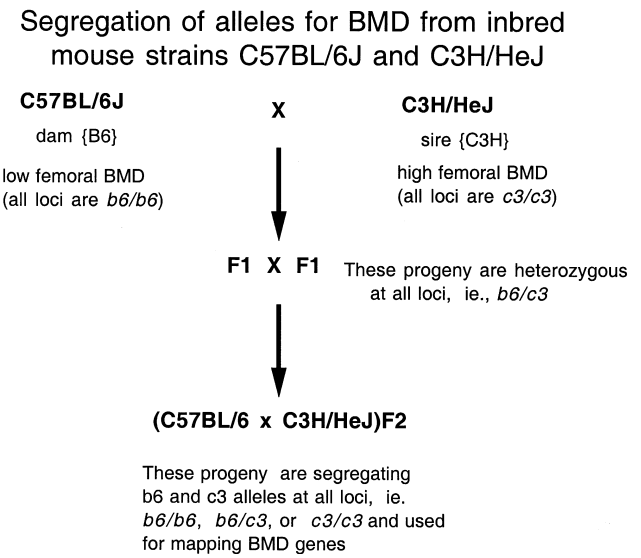

Figure 1 The use of two inbred mouse strains for analysis of a genetically regulated phenotypic trait. The C57BL/6J and C3H/HeJ strains characterized by low and high volumetric bone mineral density (BMD) are depicted. F2 progeny analyses are equally effective for mapping single gene traits and polygenic traits that are either quantitative or qualitative in nature.

or heterozygous (i.e., *b6/c3*). BMD regulatory loci that are not genetically linked to each other will independently segregate in these F2. The net effect of alleles at all BMD regulatory loci yields the BMD for each mouse.

Since there are now more than 8000 genotypic markers that are variably polymorphic across inbred strains, investigators can identify QTLs by genotyping and phenotyping the F2 progeny (Lander and Botstein, 1989). Analyses of the F2 progeny in the extremes of the phenotypic distribution allows rapid identification of major effect loci, whereas analyses of all F2 progeny yields major and minor effect loci, as well as opportunity to assess trait variance accounted for by each locus and gene × gene interactions. Genetic linkage is established by testing for association of progenitor alleles with high or low expression of a particular phenotype using various computer software programs (Lander and Kruglyak, 1995; Lander and Botstein, 1989). The initial QTLs may reside in chromosomal regions up to 40 centiMorgans (cM, recombination distances between specific markers), areas of the chromosome with hundreds of potential candidate genes. Fine mapping and congenic construction (see below) define narrower regions of the chromosome and allow for positional cloning and gene sequencing to be undertaken. This type of QTL strategy has been successful in identifying genes associated with obesity, atherosclerosis, epilepsy, and cancer susceptibility in the mouse.

Beamer *et al.,* in 1996 first described large differences in femoral and vertebral BMD, as measured by pQCT, among various inbred strains of mice (Beamer *et al.,* 1996). Subsequently, other investigators reported similar findings using planar radiography, whole-body BMD by DXA, and site-specific regions of interest (i.e., vertebrae, femur, and tibia) by peripheral DXA technology (Benes *et al.,* 2000; Klein *et al.,* 1998; Shimizu *et al.,* 1999). More recently, micro-CT has been utilized to detect differences in trabecular bone structural parameters in vertebrae, femorae, and tibia among nbred strains (Turner *et al.,* 2000). For each pair of strains differing in a bone phenotype, the strategy has been to map QTLs by crossing the progenitor strains and then intercrossing their F1 hybrids to produce large numbers of F2 progeny (range 250–1000 males and females). Data from several sets of such F2 progeny have now been reported for the BMD phenotype and include C3H/HeJ (C3H:) vs C57BL/6J (B6: low BMD), Castaneus/EiJ (CAST: high BMD) vs B6 (low BMD), SAMR1(high BMD) vs SAMP6 (low BMD), AKR/J (high) vs SAMP6 (low BMD), and B6 (high BMD) vs DBA/2J (D2 low BMD) (Beamer *et al.,* 1999, 2001; Benes *et al.,* 2000; Klein *et al.,* 1998; Shimizu *et al.,* 1999).

As noted earlier, bone mass is a complex phenotype that includes mineral content, size (length, width, cross-sectional area), trabecular connectivity, and shape. Bone strength is determined by these dimensions as well as other variables affecting overall bone quality. Depending on the exact measurement, and the instrument used to define it, a bone density phenotype varies within a given strain as well as between inbred strains. For example, B6 is a low bone density strain compared to C3H, when defined by volumetric measurements of the femur such as pQCT, but B6 is a high density strain in comparison to D2 when whole body BMD using DXA technology is the bone density phenotype of choice (14,17). In part, this can be related to the shape as well as the size of bone and its individual components. The B6 femurs have thinner cortices, a more elliptical shape, and lower volumetric BMD than C3H animals. However, in comparison to D2 mice, the periosteal circumference of B6 is greater, hence areal measurement of the femur by DXA can actually show relatively greater apparent BMD for this strain. Since size, shape and mineral are all critical components of strength, the phenotype under study becomes critical not only for assigning QTLs, but also for attempting to understand the biomechanical mechanisms that ultimately define both bone morphology and strength.

Mapping "bone density genes" can be extremely productive in F2 mice because there is independent segregation of unlinked genes for this polygenic phenotype. Surprisingly, progenitor differences are not mandatory before performing genetic analyses of polygenic traits, as the F2 population, with its independent assortment of loci, will reveal genetic determinants whose actions might not to be evident in the progenitor inbred strains or may be hidden by actions of epistatic loci (Soller *et al.,* 1976). Moreover, QTLs in the F2s can display alleles with actions that appear contrary to expectations based on the pprogenitor strains' phenotype. For example, the high BMD C3H inbred strain has been found in one QTL analysis to be carrying two genes yielding a "low density" in F2 progeny (Beamer *et al.,* 2001). Similarly, Benes *et al.* found that two AKR QTLs (i.e., Chr 7, 11) were associated with low areal BMD when these alleles were homozygous in F2 mice from an AKR (high density) × SAMP6 (low density) cross (Benes *et al.,* 2000).

Thus, F2 mice provide an invaluable tool for locating and enumerating QTLs, as well as delineating allelic effects. Moreover, the phenomena of transgenesis (gene recombinations in the F2s resulting in phenotypic values that are greater or lesser than the progenitor strain phenotype) can offer critical insight into the complex genetic influence on a specific phenotype (Benes *et al.,* 2000).

Another exciting aspect of gene mapping in mice is the evolving story surrounding trabecular structure and strength. Newer technology with micro-CT has provided investigators with the opportunity to study trabecular spacing, number, connectivity, and three-dimensional structure, in the vertebrae and femorae of mice. These determinants are likely to produce even more phenotypes for QTL analyses, especially in respect to understanding "bone quality." Recent work by Turner *et al.,* suggest that data on vertebral and femoral neck breaking strength in one inbred strain can differ considerably from that at the mid-diaphysis of the femur in the same strain (Turner *et al.,* 2000). For example, C3H femurs have a high BMD and thick cortex and therefore are stronger than B6 femurs by three-point bending in the mid-diaphysis. However, vertebral strength by compression testing is reduced in C3H compared to B6. Micro-CT analyses has revealed a markedly reduced number of trabeculae in C3H vertebrae (Turner *et al.,* 2000). These data are consistent with the fact that although C3H has higher apparent BMD (even in the vertebrae!) by projectional methodology, trabecular BMD, when quantitated properly, is actually reduced. This would suggest that there are distinct genetic determinants within a given strain that define cortical vs trabecular BMD. Moreover, these findings support long-standing clinical observations that different bone compartments acquire peak bone mass at different times, and that there can be very disparate BMD values between the spine and hip in an individual. Furthermore, response to both anti-resorptive and anabolic treatment clearly differs from one skeletal site to another. Hence, there has to be a multitude of osteoporosis genes, some of which regulate both trabecular and cortical components, some which must determine distinct skeletal compartments, and some which must be temporally activated or suppressed during the acquisition and consolidation phase of acquiring bone mass.

Finally, it should be noted that the search for mouse "bone density" genes permits a more in-depth analysis of the biology related to acquisition and maintenance of BMD. For example, C3H mice have high cortical bone density, in part because, their bone marrow stromal cells proliferate more rapidly, their osteoblasts are programmed to synthesize more IGF-I and alkaline phosphatase than B6 bone cells, and their rate of bone formation is much higher than B6 mice. By histomorphometry, C3H bone shows high rates of bone formation and modest bone resorption rates compared to B6 mice (Rosen *et al.,* 1997, 2000). These data combined with biochemical markers of bone turnover reflecting similar alterations in bone remodeling, demonstrate that the genetic determinants of bone density affect the basic cellular processes of bone. Intermediate skeletal phenotypes, such as IGF-I, N-telopeptides, or alkaline phosphatase, can also be examined in F2 mice for QTL analysis, thereby providing additional approaches to understanding the cellular mechanisms responsible for acquisition of peak bone mass.

Recombinant Inbred Strains

Recombinant inbred (RI) strains are generated by outcrossing two progenitor strains and then intercrossing these F1 hybrids to produce F2 progeny, as illustrated in Fig. 2. Then, pairs of sister–brother F2 mice are selected at random to serve as founders for each RI strain. These F2 mice are mated to produce F3 generation mice and this process of sibling mating within each RI line is repeated 20 generations. The result is new inbred strains nearly 100% homozygous at all loci, yet of which has a different combination of genes from the same original progenitor strains (Silver and Nadeau, 1997). This constitution can be maintained indefinitely by continual brother-sister matings. Since the original founders were selected at random, many distinct RI strains can be generated from the original progenitors (more than 12 such sets of RI strains exist at The Jackson Laboratory). These RI strain sets are named by the capital letter of each strain separated by "X" (e.g., B6 and D2 gave rise to BXD) plus a number for the particular strain (e.g., BXD-16) (Silver and Nadeau, 1997). Unlike classic inbred strains, the genotype of a RI strain is somewhat limited by the fact that there are only two possible alleles (e.g., B6 or D2) at each locus. More importantly, there is limited recombination because homozygosity sets in relatively quickly during the intercrosses. In addition, because both D2 and B6 inbred strains were originally derived from the same founder animals more than 70 years ago, a significant number of loci are not polymorphic. However, the strength of the RI strategy is that hundreds of genomic markers for each strain are identified, and publicly available databases can be utilized for rapid linkage studies and for determining map distances, with as few as one to two mice phenotyped from each RI strain. To establish genetic linkage, the investigator simply phenotypes each of the strains in a RI set (e.g., 12 BXD strains) to obtain a strain distribution pattern for the phenotype. The strain distribution pattern for the new phenotype is compared with strain distribution patterns of known polymorphic loci previously established in that RI set. When congruence between strain distribution patterns is found, linkage of the phenotype to a specific chromosomal region is established. By using known recombination sites in the mouse RI stains, one can mate RIs to parental strains (e.g., BXD-8 to DBA/2 and B6) to obtain new F1 progeny. Then by linkage between the genotype and phenotype, the QTL can be placed either above or below the recombination break point. This approach is called the recombinant inbred segregation test strategy (RIST) and has been successfully used by one group (see below) to help refine QTLs locations for bone density genes (Darvasi, 1998).

Klein *et al.,* was the first group to employ RI strains to define BMD QTLs. Their group utilized 19 BXD RI strains to show that: (1) whole-body areal BMD is heritable

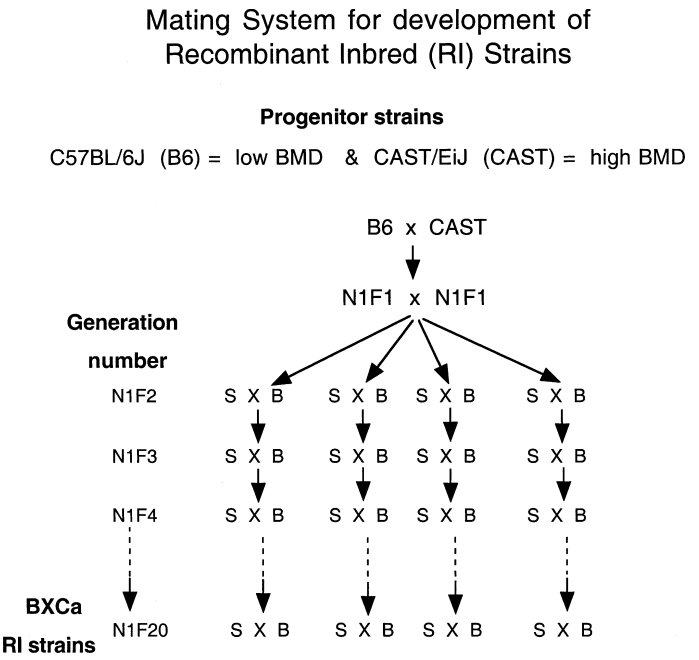

Figure 2 The method for developing a set of recombinant inbred (RI) strains. The C5&BL/6J and CAST/EiJ inbred strains are presented as the progenitors. Randomly selected sister (S) and brother (B) sibling N1F2 pairs are mated to produced N1F3 progeny, which in turn are mated to produce N1F4 progeny, etc. At the N1F20 generation, the mice within a strain will be inbred, with better than 99% of all loci homozygous for either B6 or CAST alleles. Each RI strain will have inherited on average one half its genes for each of the progenitor strains.

($h2 = 0.50$); (2) gender- and strain-specific effects are present, and (3) BMD differed by 30% among individual RI strains, suggesting that combinations of genes played a big part in overall peak bone acquisition (Klein *et al.,* 1998). Using published data bases containing more than 1500 genetic markers, Klein *et al.* (2001) identified QTLs on Chrs 2, 7, and 11 (see Table I) with major effects. Interestingly, some QTLs were present only in males, while others only in females, and three QTLs (Chrs 1, 18, 19) appeared to be gender independent (Orwoll *et al.,* 2001). Moreover, several of these QTLs were found to be similar to those identified independently by other groups using different strategies (i.e., F2 matings). Finally, from this same group, Klein *et al.,* recently reported that RIST allowed them to narrow the QTLs on Chrs 2 and 11 by more than 10 cM (Klein *et al.,* 2001). Hence, RI strains have provided a tool for rapidly establishing linkage of whole-body areal BMD QTLs, as well as for further resolution of large QTL regions into smaller segments.

Congenic Strains

Congenic strains are generated to test the effect of individual or multiple linked loci from a donor strain placed on the genetic background of a recipient strain (Silver, 1995). As illustrated in Fig. 3, the strategy is based on repetitive backcrossing to the recipient strain while genotyping for the donor strain's alleles in the subsequent backcross generations. Procedurally, the donor and recipient inbred strains are mated; the F1 progeny are then backcrossed to the recipient successively for 10 generations (N10). With each generation, the homozygosity of the recipient background increases from 50% at N1F1 to 99.9% at N10F1. The residual heterozygosity resides at the region of interest carrying the donor alleles. Hence, the genetic background of the chromosomal region of interest has been switched from donor to recipient. Congenic strains are particularly useful for confirming the QTL existence, fine mapping of the QTL, and for testing the quantitative effect of individual QTLs. For example, if there is a strong BMD QTL on Chr 1 from C3H mice, as found by F2 analysis, congenic strain mice in which the Chr 1 QTL is now placed on a B6 background, allows the investigator to test the effect of this single genetic locus on a low-bone-density background. The congenic strain would be named B6.C3H-1 (recipient, donor, and chromosome). Multiple QTLs can be combined to test for gene $\times$ gene interactions. Congenic strain construction takes about 18 months and may be labor intensive, but it provides an essential means of evaluating the biology regulated by the QTL, as well as refining the map position of individual loci. However, there are two caveats to this approach: (1) "passenger" loci adjacent to the QTL of interest travel with the donor QTL may affect the phenotype and affect mapping precision; (2) the QTL phenotype may be

Table I Summary of QTLs for BMD in Mice from Four Different Laboratories

the net result of linked genes with different effects within the QTL region. In each case, fine mapping and generation of nested congenics can overcome these problems (Silver and Nadeau, 1997).

Congenics have recently become extremely valuable tools for bone biologists, not only for studying the quantitative effect of individual QTLs, but also for more completely understanding the phenotype and its underlying physiology. Thus, one moves from breeding strategies and QTL analysis to individual congenic construction in order to define the locus of interest, as well as to test precisely how that locus could affect the phenotype. Two groups have reported generation of congenics using their most promising QTLs for either whole-body BMD or femoral BMD. These loci include Chrs 1, 2, 4, 5, 6, 11, 13, 14, and 18 (see Table I (Beamer *et al.,* 2001; Klein *et al.,* 2001)). In addition, one group has developed congenic strains for the serum IGF-I phenotype on Chrs 6 and 15. The power of this strategy is illustrated by some very recent studies (Rosen *et al.,* 2000).

Klein and colleagues constructed congenic mice for the Chr 2 areal BMD QTL and reported that after the fourth generation, D2.B6-2 mice (i.e., mice carrying a B6 QTL) on a nearly 93% homozygous D2 background had a difference of nearly one standard deviation in whole-body BMD compared to inbred D2 mice (Klein *et al.,* 2001). Moreover, this effect occurred only in female mice. Beamer *et al.,* reported

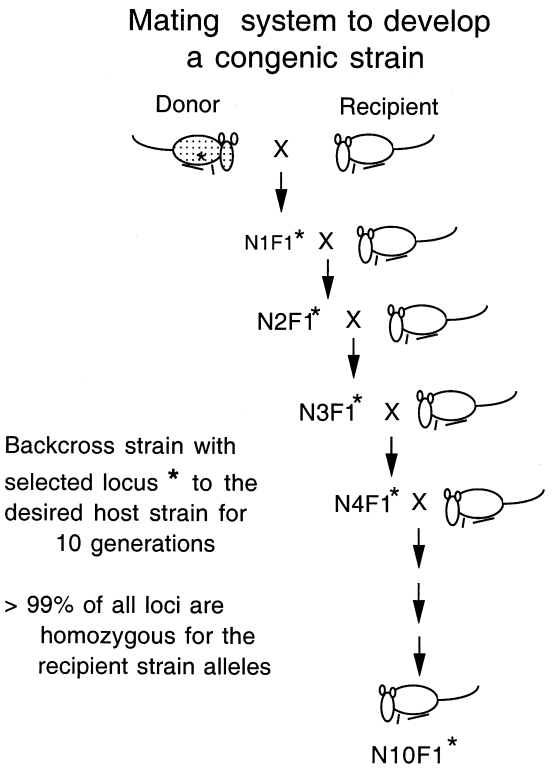

Figure 3 The method for producing a congenic strain that carries a segment of a chromosome transferred from a donor strain to a recipient strain. The transfer is accomplished by at least 10 cycles of backcrossing and F1 to a recipient strain. The region containing the gene or QTL of interest is found by genotyping each generation of progeny and mating the identified carrier of the donor segment to the recipient strain.

that the Chr 1 QTL from C3H mice had an approximately 8% increase in femoral BMD when placed on a B6 background in N6 congenics (Beamer *et al.,* 2000). Similar findings were also noted for the Chr 4 QTL. On the other hand, a "low bone density QTL" from C3H in Chr 6 was associated with a 3.5% reduction in BMD, when donated to a B6 background. Not unlike the studies from Orwoll *et al.,* this effect was noted only in female mice (Orwoll *et al.,* 2001). Hence, congenic strains can provide insight into the effect of individual QTLs in respect to bone and to the mechanism of such action.

The power of the congenics extends beyond simple tests for QTL effects. For example, Beamer *et al.,* reported that although the congenic on Chr 1 had a statistically significant effect on femur BMD, micro-CT analysis revealed a much greater effect on vertebral trabecular bone (Beamer *et al.,* 2000). In fact, vertebral bone density (measured as BV/TV) was nearly 35% greater in the Chr 1 congenic compared to progenitor B6 mice at 16 weeks. These findings, also noted for the Chr 4 QTL congenic, support the thesis that bone microstructure may be altered dramatically while BMD may change only modestly. If confirmed these data provide more impetus for defining aspects of bone quality and their relationship to skeletal fragility, an issue very relevant when considering the skeletal response to long-term anti-resorptive therapy. Finally, Rosen *et al.,* have noted that one of the strongest QTLs for serum IGF-I in B6C3F2 mice is likely to be the Chr 6 QTL noted for BMD (Rosen *et al.,* 2000). Moreover, the congenic B6.C3H-6 mice at N10 generated from this QTL, show not only reduced femoral and vertebral BMD, but also markedly lower serum IGF-I concentrations. This model provides further proof that the congenics can offer insight into the mechanisms whereby peak bone mass is acquired.

Recombinant Congenic Strains

A fourth system available for genetic and biological studies of polygenic traits, such as BMD, is illustrated in Fig. 4. Recombinant congenic (RC) Strains represent a combination of the attributes found in RI strains and congenic strains of mice. As can be discerned from Fig. 4, two backcrosses are made to a recipient strain to achieve progeny that carry 12.5% of genes from the donor strain. Sibling progeny from the N3F1 cross are then incrossed to inbred status as shown. The intent of this system is to isolate small subsets of genes that regulate a complex trait within distinct inbred strains. Demant and colleagues have successfully used RC strains to genetically analyze both colon and lung cancer in mice (Fijneman *et al.,* 1996; Moen *et al.,* 1991). In addition, in preliminary studies, Blank *et al.* (1999) has reported that

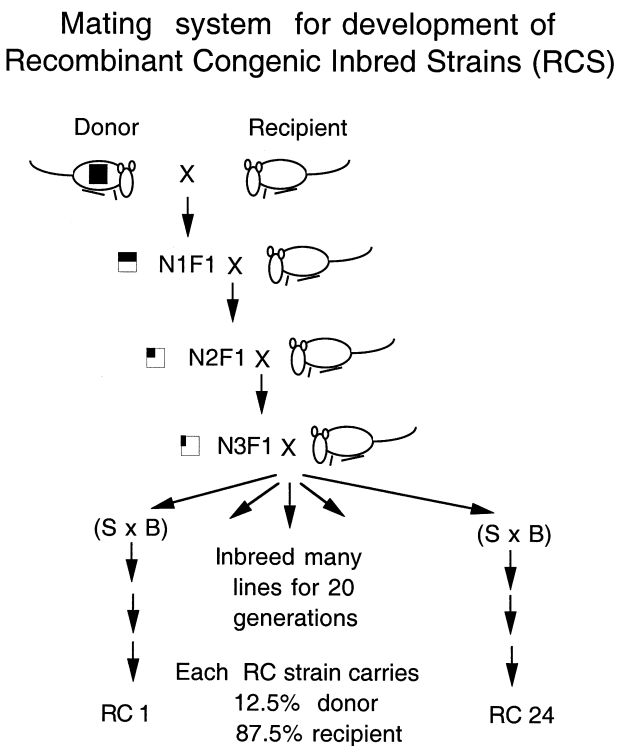

Figure 4 The method for development of a set of recombinant congenic strains, each of which carries 12.5% of it genes from the donor strain and 87.5% of the genes from the recipient strain. The desire is to capture subset of genes that regulate a complex trait in a series of related but distinct inbred strains. This method is particularly useful for analyses of phenotypes that depend on modifier genes for expression.

genetic linkage to regions on 11 different chromosomes could be demonstrated for bone strength, ash percentage, and morphological parameters using the set of 27 HcB/Dem RC strains. These strains were derived from donor C57BL/10Sc-SnA and recipient C3H/DiSnA strains. Thus, RC strains are very suitable for analyses of complex traits and may be most valuable for assessment of gene that interact in subtle ways not easily identified by standard statistical means.

Mouse to Man—The Present and Future

This review has pointed out some of the models investigators have used to define the genetic determinants of bone density in mice. However, it is quite obvious that despite major efforts by several groups, no mouse "bone density" gene has yet been cloned. Still, inbred, recombinant inbred and congenic strains, as model systems, offer a wealth of information related to acquisition and maintenance of peak bone mass. With the advent of more rapid genotyping and congenic generation techniques, it seems certain that these putative QTLs will yield numerous genes that contribute to the variance in bone density within a mouse strain. Moving from mouse genes to human genes using published maps, as well as with the ongoing genome sequencing projects, may actually turn out to be easier than once thought (Blake *et al.,* 1997). More of a challenge, however, will be to understand the full effects of a particular gene on bone cell function, the interactions with environmental factors, and perhaps even more importantly, the regulators of such genes. Notwithstanding those tasks it has become clear that the power of the mouse for bone biologists lies in several relevant factors:

(1) the strong homology (60–70%) between human and mouse genomes (see Table I);
(2) the ongoing efforts to completely map the mouse genome, thereby permitting more rapid identification of putative bone density genes;
(3) the ease and rapidity of conducting crosses among various strains of mice;
(4) the relative control that investigators have over environmental factors that modulate genetic determinants of bone density; and
(5) the rapid acceleration in knockout and transgenic technology permiting functional testing of putative bone density "genes."

Clearly, the last two factors are the most appealing and compelling. In contrast to human studies, strict regulation of dietary factors, physical activity, life style, and environment, is relatively straightforward in the mouse. Moreover, except for the sex chromosomes, each of the mice in an inbred is an identical twin to the next, carrying the same genome as all others within that strain. This makes it considerably easier to refine the search for various bone density genes, and more importantly, to be able to test their responsiveness to various perturbations, all within a defined life cycle. Finding "osteoporosis" genes in mice provides an unmatched opportunity to test their role in all aspects of bone biology, and indeed, such findings can then be used to further our understanding of the pathophysiology of this debilitating disease.

Reporter genes, types, 1511–1512
Reproductive system
effects of
calcitonin, 627
raloxifene, 684–685
SERMs, 682
tamoxifen, 685–686
VDR in, 594–595
Resorption, bone
associated cell-matrix interactions, 266
biopsy, 1628–1629
coupling to formation, 1277
critical functions rule, 12
cycle, osteoclast role
cytoskeletal changes, 132–133
degradation product removal, 135–136
life span, 128–129
membrane domains, 130–132
polarization, 130–132
sealing zone formation, 129–130
surface attachment, 129–130
effects of
androgens, 764–766
FGF, 838–839
glucocorticoids, 727–729
IL-4, 965
IL-7, 966
INF-γ, 964
OPN, 243–244
PTH/PTHrP, 499–500
TGFβ, 905
thyroid hormones, 711–712
TNF, 963–964
effects on prostaglandin receptors, 986
factors effecting, 1550–1551
IL-1 stimulation, 961–962
inhibition by bisphosphonates
mechanisms of action level, 1366–1367
models, 1362–1365
relative potency, 1365–1366
markers, 218–220, 1547–1549
in osteoporosis, 1276–1277
phases, 307–309
PTH-induced, role of OPN, 244–245
role of
brandykinin receptors, 778
cathepsin K, 216
integrins, 270–271
kinin receptors, 778–779
septoclasts, 127–128
tumor-induced, effects of bisphosphonates, 1365
Respiratory system, effects of calcitonin, 626–627
RET protooncogene
characterization, 1024, 1067
mutations
role in MEN2 syndrome
correlations, 1070–1071
mechanism, 1071–1072
role in neural development, 1072
Rheumatoid arthritis, 156, 894–895
Rickets
clinical features, 1196–1197
diagnosis, 1204
hereditary hypophosphatemic, 329–331
therapy, 1204–1205, 1411
vitamin D-dependent
type I, description, 1197–1198
type II
biochemical features, 1198–1200
cellular defects, 1200–1204
clinical features, 1198–1200
mode of inheritance, 1199–1200
molecular defects, 1200–1204

Rickets (*continued*)
occurrence, 1197–1198
X-linked hypophosphatemic, 326–329
X-linked recessive hypophosphatemic, 333
RNA, messenger
PTH degradation, 414
splicing, CTR proteins, 607–609
stability, transcriptional control *vs.,* 1507–1508
Rod conversion, 311–313
ROS 17/2.8 cells, 1504
Ruffled border, 130–132

S

Saos-2 cells, 1506
Sclerotome differentiation, 37
SEAP. *see* Secreted alkaline phosphatase
Seasonal variability, effects on bone turnover, 1551
Secreted alkaline phosphatase, 1512
Selectins
characterization, 269
role in osteoblast functions, 278
Selective estrogen receptor modulators
function, 666–667
mechanism of action, 677–681
physiologic effects on
bone, 681
breast, 682
cardiovascular system, 681–682
reproductive tract, 682
Sepsis, calcitonin-associated, 630–631, 633
Septoclasts, 127–128
Serine kinase
activation, 932–933
characterization, 929–932
intracellular signaling
in cytoplasm, 935–936
in nucleus, 936
regulation, 937–938
structure, 933–935
target genes, 936–937
SERMs. *see* Selective estrogen receptor modulators
Serotonin
receptors, effects on bone, 789
transporter, effects on bone, 789
Serum proteins, description, 232–233
Sheep models, 1643–1644
SIBLING. *see* Small integrin-binding ligand with N-linked glycosylation
Signal transduction
adhesion-dependent, in osteoclasts, 143–144
androgen receptors, 758–760
BMP, SMAD
in cytoplasm, 935–936
in nucleus, 936
regulation, 937–938
structure, 933–935
target genes, 936–937
CSF-1, 949
$\alpha_v\beta_3$-mediated, 274
mechanical, electric fields in, 1483
microdomains, 539
NO, 966–968
protein binding, 889–890
PTH-PTHrP
downstream activities, 428–429
dual intracellular, 427–428
function, 1137–1140
selective ligands, 429–430
PTHR in
Ca excretion, 487–488
Mg excretion, 487–488
Na/H excretion, 491–492
Ph excretion, 490–491
renal cells, 484
RANK, 118–121
$1\alpha,25(OH)_2$ vitamin D_3, 549–551
Silicon-bone, interaction, 365
Skeleton
adaptation
belief in, 1477
cellular basis, 1482–1483
effects of age, 1483–1484
effects of exercise, 1480–1483
exercise constraints, 1484–1485
role of electric fields, 1483
androgen mode of action, 1462
biology, endogenous gene disruption, 1498–1499
development
cellular divisions, 5–6
effects of connexins, 293
embryonic
axial, 34–38
chondrogenesis, coupling, 52–53
intramembranous bone, 42–52
limb initiation, 38–40
mesenchymal condensation, 40–42
morphology, 33–34
osteogenesis, coupling, 52–53
patterning, 40–42
role of BMP, 922–923
formation, 8–11
genes affecting, analysis, 1494–1496
molecular regulation, 11–12
role of cadherins, 288–289
studying, 12–13
effects of estrogens, 655–656, 658
growth, effects of IDDM, 741–743
hypophosphatasia, 1236
intercellular Ca signaling, 297–298
male
interventional studies, 1474–1475
observational studies, 1472–1473
malignancy (*see specific diseases)*
osteoporosis treatment response to, 1637–1638
response
curvilinear nature of, 1481–1482
to HRT, animal models, 1637
role of androgens, 1456–1457
thyroid hormones
animal studies *in vivo,* 712–713
cell phenotypic responses, 711–712

gene products, 709–711
membrane actions, 709
nuclear receptors, 707–709
tissues, role of CaR, 1355
Skin
effects of PTH/PTHrP, 515–517
lipoma, *MEN1* gene and, 1059–1060
previtamin D_3 photosynthesis in, 587
Small integrin-binding ligand with N-linked glycosylation, 231
Sodium
effects of CaR, 381
excretion, role of PTH/PTHR, 491–492
-phosphate cotransporter, 413
Somatic cells therapy, 74–76
Somatostatin
characterization, 787
MEN1 syndrome treatment, 1051
Somitogenesis, 34–37
Southwestern blot, 1515–1516
SPARC, description, 228–229
SRC. *see* Steroid receptor coactivators
Stem cells. *see* Meschymal stem cells
Steroid receptor coactivators, 580–581
Sterol synthesis, blocking, role of FFP, 1369–1371
Strain
curve, 21–22
minimum effective, 1480
rate of, 1481
-stress, relationship, 18–20
Strength, tensile, 22
Stress
definition, 18
fractures
fluoride-induced, 1389–1390
occurence, 28
mediating, role of OPN, 246–248
patterns, 19
relaxation, 23
standard unit, 18
-strain
curve, 21–22
relationship, 18–20
Stroke-fracture association, 791–792
Stromal cells
-osteoblasts
M-CSF production by, 111–112
role in
OPG expression, 116–118
osteoclast differentiation, 109–111
osteoclast regulation, 111–112
RANKL regulation, 116–118
Stromelysin, 252
Strontium-bone interaction, 365–366
Substance P, 786
Sunscreens, 588
Surgery, orthopedic, 920
Syndecans
characterization, 269
expression in
cartilage, 281
syndecans, 279

T

Tamoxifen
effects on
bone, 685
breast, 685–686
cardiovascular system, 685–686
reproductive tract, 682, 685–686
thrombeoembolism association, 687
Tartrate-resistant acid phosphatase
assays, 1536
expression, 109–110, 1495
levels in Paget's disease, 1554
levels in PHPT, 1557
as resorption marker, 1549
T cells, role in RANKL regulation, 118
Telopeptides, cross-linked, 1548–1549
Tensile strength, 22
Tension, definition, 18–19
Testosterone. *see* Androgens
Tetracycline labeling, 1615–1616
Tetranectin, 229
Thiazide, effects on bone turnover, 1550
Threonine kinase
activation, 932–933
characterization, 929–932
intracellular signaling
in cytoplasm, 935–936
in nucleus, 936
regulation, 937–938
structure, 933–935
target genes, 936–937
Thrombospondin, description, 230–231
Thymus, PTH gene expression, 408
Thyroid gland
medullary cancer, 629–630
PTH gene expression, 408
Thyroid hormones
bone loss and, 714–715
effects on
chondrocytes, 46
skeleton
animal studies *in vivo,* 712–713
cell phenotypic responses, 711–712
gene products, 709–711
in humans, 713–714
membrane actions, 709
nuclear receptors, 707–709
osteoporosis pathophysiology and, 1280
phosphate transport regulation, 324–326
role in collagen synthesis, 199–200
Tissue-nonspecific alkaline phosphatase
biology, 1231–1232
circulating, 1242
deficiency, 1237
description, 1231
discovery, 1229
function, hypophosphatasia as model, 1243
history, 1229–1231
physiological role, 1229–1231
structural defects, 1238

Tissues
cultures
current techniques, 1530–1531
in vitro systems, 1529–1530
engineering, 74
TNALP. *see* Tissue-nonspecific alkaline phosphatase
TNF-related activation-induced cytokine, 113
Toremifene, 687
Torsion effects, 19–20
Trabecular bone
connectivity, 1631
strength of, 23
volume, 1631
TRAF. *see* Tumor necrosis factor receptor-associated factors
TRANCE. *see* TNF-related activation-induced cytokine
Transcription factors
collagen genes
mode of action, 203
proximal promoter binding, 200–201
function, 69–71
in osteoblast differentiation, 85–88
PTH, 495
regulatory complexes
analysis, 1507–1508
cloned or purified, characterization, 1518–1519
cloning, 1515–1518
DNA-protein interaction analysis, 1512–1515
initiation by nuclear run-on assays, 1508
multiprotein, purification/sequencing, 1516–1517
osteoblast cell culture models, 1504, 1506–1507
promoter analysis
assay selection, 1509–1510
reporter genes, 1511–1512
transfection methods, 1510–1511
Transcytosis, 274–275
Transfection
biolistic, description, 1511
methods, 1510–1511
stable, assay selection, 1509–1510
transient, assay selection, 1509
Transforming growth factor α
effects on osteoclasts, 121
osteoporosis pathophysiology and, 1279
phosphate transport regulation, 323–326
Transforming growth factor β
binding protein, 911–912
in bone
effects of FGF, 837
effects of PTH/PTHrP, 495
characterization, 904–905
connexin regulation by, 293
effects on
bone cells *in vitro,* 905–906
chondrocytes, 47
osteoclast formation, 948–949
VEGF-A expression, 891–892
gene expression in bone
effects of glucocorticoids, 732–733
targeted disruption of, 904
isoforms, 903–904
latency, 909–911
-RANKL, cross-communication between, 121
receptors, 906–907
role in
BMD, 1266–1267
bone cancer metastasis, 911–912
collagen synthesis, 194–196
osteoblast apoptosis, 160
osteoblast development, 71–73, 72
signaling pathways, 908–909
superfamily, 903
Transgenes, tissue-directed, 1494–1496
Transilial bone biopsy
in clinical research, 1633
complications, 1617
histology, 1628–1629
morphometric methods, 1629, 1631
in patient care, 1632
practical considerations, 1633
procedure, 1615–1616
reference data, 1631–1632
regions evaluated, 1629, 1631
specimen processing, 1617
timing, 1633
Transmission disequilibrium test, 1262
Transplantation
heart, associated bone loss, 1561–1562
kidney, associated bone loss, 1562
as osteopetrosis therapy, 1224–1225
TRAP. *see* Tartrate-resistant acid phosphatase
T scores. *see* Desitometry
Tumor necrosis factors
effects on bone, 963–964
expression, 109
α
effects on VEGF-A expression, 891
osteoporosis pathophysiology and, 1278–1279
role in collagen synthesis, 197–198
in osteoblasts, effects of estrogen, 662–663
receptor-associated, 118–119
role in
HHM, 1094–1095
MAH, 1087–1088
osteoclast
apoptosis, 158–159
formation, 693–695
ovariectomy-induced bone loss, 699–702
β, in cancer cells, 1098
Tumors
bone disease, 1376–1377
extrathyroidal neuroendocrine, 630
nonneuroendocrine, 630
suppressor genes, 1022, 1024
Turnover, bone
effects of
GH, 1443–1446
IGF-I, 1447–1448
Mg, 350
raloxifene, 682–683
as fracture risk marker, 1296–1298
postmenopausal rate, animal model, 1637
Tyrosine kinase, 889

U

Ultrasound, BMD, 1292–1293
Urokinase-type plasminogen activator, 257
Uterus, effects of PTH/PTHrP, 523–524

V

Vascular endothelial growth factor
  in bone formation, effects of FGF, 837
  effects on
    bone, 893–896
    cartilage, 893–896
    osteoclast formation, 948–949
  ligand family
    alternative splicing, 884–885
    postranslation processing, 885
    structure, 885–886
    viral, 886
  receptors
    activation, 889–890
    expression, 891–892
    structure, 886
    types, 887–888
  type A
    activities, 889–891
    expression, 891–892
    mechanisms, 889–891
Vasculature
  cells, uniquness, 883
  PTH in, 473–475
  PTHrP in
    effects on
      anatomy, 532–533
      contractile mechanisms, 532–533
      smooth muscles, 534
    expression, 533–534
    mode of action, 535–536
  role in remodeling, 311
Vasoactive intestinal peptide
  characterization, 781–783
  clinical observations, 791–792
Vasodilation, VEGF-A-induced, 891
VEGF. *see* Vascular endothelial growth factor
Versican (PG-100), 226
Viral vectors, description, 1510–1511
Viscoelasticity, 23–24
Vitamin D
  absorption, genetic determinants, 1269
  binding proteins, receptor interactions, 1413–1415
  compounds
    activating enzymes, 1412–1413
    analogs, 1409, 1411, 1416
    binding proteins, 1413
    clinical applications, 1411–1412
    genomic mechanisms, unraveling, 1417–1418
    hepatic clearance, 1416
    modeling, 1418
    molecular mechanisms of action, 1416–1417
    prodrugs, 1408
    target cell catabolic enzymes, 1415–1416
  deficiency, animal models, 1205
  effects of osteocytes, 98–99
  effects on chondrocytes, 47
  endocrine system, 548–549
  enhancer domain, 178
  function, 1195–1196
  hereditary deficiencies (*see* Osteomalacia; Rickets)
  metabolism
    effects of
      glucocorticoids, 725–726
      Mg depletion, 348–349
      PTH, 492–493
      sunlight, 573–574, 590–591
    in type II rickets, 1199
  osteoporosis pathophysiology and, 1280–1281
  production, hereditary deficiency, 1197–1198
  pseudohypoparathyroidism therapy, 1154–1156
  related genes
    response elements, 577–579
    transcriptional regulation, 579–581
  role in
    collagen synthesis, 199
    FBHH, 1036
    MAH, 1087
Vitamin D_3
  analogs, 561–565
  as arthritis treatment, 598
  conformational flexibility, 545–548
  effects on
    bone, 574–575
    calcitriol levels, 1204
    differentiation, 576–577
    hormone secretion, 577
    immune system, 577
    intestine, 575
    kidney, 575–576
    parathyroid glands, 576
    proliferation, 576–577
  genomic mechanism of action, 574
  nuclear receptor
    characterization, 551–552
    dimerization, 552–553
    evidence for, 558–559
    hormone response element, 553–554
    knockout model, 556–558
    ligand binding, 554–555
    ligand shape, 559–561
    mutations, 556
    receptor structure, 555–556
  photosynthesis, 587–590
  posttranscritpional effects *in vitro,* 1202–1203
  role in
    malignancy-associated hypercalcemia, 1081
    PTH gene regulation, 409–412
    PTHrP repression, 1086–1087
  signal transduction pathways, 549–551
  as skin disease treatment, 595–597
  structure, 545
  transcriptional regulation by, 577–579
  transcritpional effects *in vitro,* 1202–1203

Vitamin D receptors
in cancer cells, 591–592
characterization, 551–552
compound interactions, 1413–1415
deficient
DNA binding, 1201
hormone binding, 1201
nuclear uptake, 1201
dimerization, 552–553
evidence for, 558–559
function, 1195
genes, role in BMD, 1264–1265
heterodimerization, 580
homodimerization, 580
hormone response element, 553–554
in immune system, 592–594
interacting proteins complex, 581
knockout model, 556–558
ligand binding, 554–555
ligand shape for, 559–561
mutations, 556
phamacologic actions, 595
phosphorylation, 579–580
physiolgic actions, 595
receptor structure, 555–556
regulation, 579
reproductive system, 594–595
-transcription machinery
interaction, 580–581
Vitamin K, role in osteoclast apoptosis, 159
Vitronectin, 231

W

Water metabolism, 379–381
WHO. *see* World Health Organization
Wolff's law, 17, 99, 1477
World Health Organization
osteopenia definition, 1582
osteoporosis classification, 1573–1574
Wounding healing, 821
Woven bone, 315

X

X-linked hypophosphatemic rickets, 326–329
X-linked recessive hypophosphatemic rickets, 333
X-ray energy, 1612–1613

Y

Yield point, 21–22
Young's modulus, 21

Z

Zone of polar activity, 38, 40
ZPA. *see* Zone of polar activity
