CHAPTER 40

Thyroid Hormone and Bone

Paula H. Stern

Department of Molecular Pharmacology and Biological Chemistry, Northwestern University Medical School, Chicago, Illinois 60611

Thyroid hormone has profound effects on skeletal development and differentiation and also modulates the activities of mature bone. Both beneficial and deleterious effects of thyroid hormone on the skeleton are seen, depending on the stage of development and the concentration of hormone presented to the cells. The roles of specific thyroid hormone receptor (TR) isoforms and of other factors present in the bone microenvironment in determining thyroid hormone effects are only beginning to be understood. This chapter focuses on the relationship of the *in vitro* effects of thyroid hormone on bone cells to the observed effects of the hormone on the skeleton *in vivo* in both experimental animals and clinical studies.

Mechanism of Thyroid Hormone Action on the Skeleton

Nuclear Receptors

Structural and Genetic Studies

Thyroid hormone receptors are members of the steroid receptor superfamily (Evans, 1988). All of these receptors share a common modular structure with a centrally located DNA-binding domain composed of two zinc fingers and a carboxy-terminal ligand-binding domain that is also involved in receptor dimerization and interactions with coactivators and corepressors. The receptors are nuclear proteins capable of binding to cognate DNA elements in the absence of their ligands. Binding of the ligand to the receptor alters the receptor conformation and subsequently enables the activation or repression of specific genes. Most commonly, the unliganded thyroid hormone receptor represses gene transcription. Interaction of the unliganded receptor with a corepressor complex, including histone deacetylases, results in the condensation of chromatin structure and repression of transcription through decreased access of transcription factors (Koenig, 1998; Wu and Koenig, 2000). Interaction of the receptor with the active thyroid hormone triiodothyronine (T_3) results in a conformational change that leads to dissociation from the repressor complex and interaction with an activation complex containing histone acetylase. Other mechanisms of transcriptional regulation, independent of histone acetylation, have also been described (Fondell *et al.,* 1996).

Thyroid hormone receptors are encoded by two genes: one found on chromosome 17 encoding TRα and one on chromosome 3 encoding TRβ. Alternative splicing of TRα transcripts results in the generation of several carboxy-terminal products (Izumo and Mahdavi, 1988; Chassande *et al.,* 1997). The TRα1 isoform is a commonly expressed active isoform of the receptor. TRα2, which is homologous to the v-erb A oncogene, is a nonbinding isoform resulting from alternative splicing of the TRα primary transcript. TRα2 fails to heterodimerize with retinoic acid receptors (RXR) (Reginato *et al.,* 1996) and may act as a dominant-negative repressor (Koenig *et al.,* 1989; Sap *et al.,* 1986). The TRβ1 and the amino-terminal splice variant, TRβ2, are both active. Tissue expression of TRβ2 is limited, and this isoform is expressed most significantly in the hypothalamus and pituitary (Lazar, 1993), although TRβ2 mRNA has been found in osteoblasts (Abu, 2000). Differential cell and tissue expression of the α1 and β1 isoforms could lead to different responses to thyroid hormone. It could also allow for the development of thyroid hormone analogs that have tissue specificity due to their preferential interaction with one receptor isoform. An example of such an analog is the TRβ-selective agonist GC-1, which had greater effects on lipid metabolism and less on cardiac activity (Trost *et al.,* 2000). The effects of this compound on the skeleton have not been reported, although another agonist, tiratricol (3,5,3′-triiodothyroacetic acid), showed enhanced effects on hepatic lipids and skeletal metabolism (Sherman *et al.,* 1997).

TR isoforms have been found in skeletal tissues. mRNAs for TRα1, TRα2 and TRβ have been detected in MG63, ROS 17/2.8, and UMR-106 cell lines (Williams *et al.,* 1994; Allain *et al.,* 1996). Immunohistochemical staining with antibodies recognizing a TRα epitope or specific TRα2 and TRβ revealed the presence of receptor protein in osteoblast cell lines and in osteoclasts in tissue smears from a human osteoclastoma (Allain *et al.,* 1996). TRα1, TRα2, TRβ1 and TRβ2 mRNAs were expressed in chondrocytes at all stages of differentiation; TRα1, TRα2, and TRβ1 mRNAs were highly expressed in osteoblasts at bone-remodeling sites; and mRNA for all of the isoforms was present and highly expressed in multinucleated osteoclastic cells from an osteoclastoma (Abu *et al.,* 1997). In contrast to mRNA expression, TRα1 protein expression was not seen in the osteoclastoma cells and was limited to osteoblasts at sites of remodeling and undifferentiated chondrocytes (Abu *et al.,* 2000). TRα1, TRα2, and TRβ1 mRNA have also been detected in rat femurs and vertebrae (Milne *et al.,* 1999).

To determine the role(s) of specific TR isoforms, TR-deficient mouse strains have been generated by homologous recombination. TR$\alpha1^{-/-}$ mice did not show bone defects (Wikstrom *et al.,* 1998), whereas mice in which both TRα isoforms were deleted showed growth retardation and impaired development of epiphyseal bone, with disorganization of chondrocyte columns, decreased hypertrophic chondrocytes, and low ossification (Fraichard *et al.,* 1997). The animals died shortly after weaning. TRβ knockout mice failed to show bone defects (Gauthier *et al.,* 1999; Gothe *et al.,* 1999), suggesting that the TRβ isoform is not essential for bone development in the mice. The TR$\alpha1^{-/-}$ TR$\beta^{-/-}$ double knockout produced viable mice, the majority of which survived at least through 12 months, although there was increased mortality compared to wild-type mice (Gothe *et al.,* 1999). TR$\alpha1^{-/-}$ TR$\beta^{-/-}$ double knockout mice exhibited retarded growth and significantly reduced levels of growth hormone (GH) and insulin-like growth factor I (IGF-I). Bone length was decreased significantly in limbs and vertebrae, with the effect being most marked in the femur. Growth plates were disorganized and epiphyseal ossification was delayed. Dual X-ray absorptiometry showed decreased bone area and bone mineral content but no significant effect on bone mineral density. Middiaphyseal peripheral quantitative computed tomography (pQCT) scans of the femurs revealed decreased cortical density, cortical area, bone mineral content, and periosteal circumference. Cross-sectional moment of inertia and moment of resistance were decreased significantly. It was noted that the phenotype was less severe than that resulting from thyroidectomy, and this was postulated to be a reflection of the fact that in the case of thyroidectomy, T_3 would not be available to alleviate the transcriptional repression effected by the TRs (Gothe *et al.,* 1999). It is also possible that novel, previously unrecognized thyroid hormone receptor isoforms may be present that could compensate for the loss of the deleted receptors.

Skeletal alterations associated with mutations in the TRβ1 gene have been described in patients with resistance to thyroid hormones (RTH). In most reported cases, the defect shows an autosomal dominant pattern of inheritance. The mutations are clustered and largely located within domains in the carboxy-terminal region. They are mainly nucleotide substitutions that result in single amino acid changes (Refetoff, 1993). The mutant alleles may act by a dominant-negative mechanism to inhibit the ability of the normal allele to elicit normal receptor function (Chatterjee *et al.,* 1991; Sakurai *et al.,* 1990). The dominant-negative action appears to be at the level of DNA binding (Kopp *et al.,* 1996). The mutant phenotypes are heterogeneous, but some patients have shown evidence of retarded bone age and stippled epiphyses, similar to characteristics of hypothyroidism, with resulting short stature. In other patients there is accelerated bone age, accelerated chondrocyte maturation, and early epiphyseal closure, again resulting in short stature (Behr *et al.,* 1997). The target sites at which resistance occurs (pituitary or peripheral) may determine the phenotype. It is possible that mutations in TRα may be lethal and thus are not seen.

Similar to the pattern for retinoid and vitamin D receptors, DNA-binding sites for thyroid hormone receptors include monomeric, palindromic, inverted repeat, and direct repeat response elements derived from a common AGGTCA motif. Multiple functional forms exist for thyroid hormone receptors, including monomers, homodimers, heterodimers between thyroid hormone isoforms, and heterodimers with retinoid and vitamin D receptors. In bone (Williams *et al.,* 1994; Williams *et al.,* 1995), as in other tissues (Glass, 1994; Brent *et al.,* 1991), DNA binding and transcriptional activation are enhanced when the thyroid hormone receptor isoforms are present as heterodimers with retinoid or vitamin D receptors. In osteoblast cell lines, interactions among the retinoid, vitamin D, and thyroid hormone ligands appeared to mediate specific responses (Williams *et al.,* 1994, 1995). Studies on the effects of treatment combinations on the expression of osteoblast phenotypic genes in the cell lines revealed complex responses that indicated the importance of dose, treatment duration, and degree of confluence in dictating the magnitude of the response (Williams *et al.,* 1995). However, in primary rat osteoblastic cells, alteration of the ligand combinations did not influence the responses (Bland *et al.,* 1997).

Competitive Binding Studies

Two studies of T_3 binding to nuclei from ROS 17/2.8 cells gave the following parameters: K_d 5 n*M*, B_{max} 0.13 ng/mg DNA, with incubation for 60 min at 37°C (Rizzoli *et al.,* 1986) and K_d 150 p*M*, B_{max} 24 fmol/100 μg DNA, with incubation for 2.5 hr at 37°C (Sato *et al.,* 1987). In UMR-106 cells, two nuclear-binding sites were identified: one with K_d 260 p*M*, B_{max} 7.7 pg/mg DNA, and one of lower affinity, K_d 1.8 n*M* (LeBron *et al.,* 1989). In MC3T3-E1 cells, K_d for T_3 binding was 120 p*M* (Kasono *et al.,* 1988). T_3 receptors were also found in cell lines (ROS 25/1, ROS 17/2.8-3) that did not show an alkaline phosphatase response to T_3, suggesting that there is a postreceptor defect in these cell lines (Sato *et al.,* 1987). There was good agreement between the relative affinity of different ligands [T_3 = 1, thyroxin (T_4) = 0.1, 3,3′-

diiodothyronine = 0.013, reverse T_3 (rT_3) = 0.002, monoiodotyrosine = 0, diiodotyrosine = 0] and their ability to increase alkaline phosphatase in ROS 17/2.8 cells (Sato *et al.,* 1987). In another study, T_4 had a 20-fold lower and rT_3 a 400-fold lower affinity compared with T_3 in ROS 17/2.8 cells (Rizzoli *et al.,* 1986). In binding studies with a nuclear fraction from neonatal mouse calvaria, carried out for 60 min at 22°C, K_d for T_3 was 3 n*M* and the B_{max} 1.9 pmol/mg DNA (Krieger *et al.,* 1988). The cardiotonic agent milrinone, which has structural homology to T_4 (Mylotte *et al.,* 1985), did not compete for binding to the calvarial receptors. Both time and temperature dependence were observed in the binding studies, with binding being more rapid at 37°C than at 22°C (Krieger *et al.,* 1988; Sato *et al.,* 1987). Kinetic analysis of normal nuclear receptors gave K_a of $9 \times 10^8\ M^{-1}\ min^{-1}$ and K_d of 0.016 min^{-1} with a $t_{1/2}$ of approximately 36 min (Krieger *et al.,* 1988). For binding studies in the cell lines, the method of Samuels *et al.* (1979) was used to remove thyroid hormones from serum used in the growth medium. The procedure involves treatment of the serum with AG1-X8 resin and removes more than 90% of the T_4 and 95% of the T_3.

Relevance of *in Vitro* Concentrations and *in Vivo* Dosages of Thyroid Hormone to Physiological and Pathophysiological Concentrations

It has been reported that the normal range for serum-free T_3 is similar in rats and humans, and is 3.3–8.2 p*M* (Jurney *et al.,* 1983). Wide concentration ranges of thyroid hormones have been used in experimental studies, especially *in vitro,* and often markedly different dosages are required to obtain the same response in a different cell line, model system, or laboratory. The differentiation state and the production of modulating factors are potential variables that can affect the response in a given system. In addition, the presence of thyroid hormone in the added sera or the presence of binding sites in stripped sera can dramatically influence the free hormone available to the cells or tissue. Several studies have estimated the amount of free hormone available under the experimental conditions used (Sato *et al.,* 1987; Allain *et al.,* 1992). In one study, an equilibrium dialysis method was used to determine free T_4 and T_3 after treating fetal calf serum with AG1-X8 resin (Sato *et al.,* 1987).T_4 and T_3 concentrations in the fetal calf serum prior to extraction were 11.1 μg/dl and 157 ng/dl, respectively. It was determined that addition of 10 n*M* T_4 to the stripped serum provided 80 p*M* free T_4 and that addition of 1 n*M* T_3 provided 40 p*M* free T_3. In the other study, in which 10% neonatal calf serum was used, the free T_3 was measured by radioimmunoassay (Allain *et al.,* 1992). It was determined that the addition of 10 p*M* T_3 yielded a free T_3 concentration of 2.1 p*M,* that 0.1 n*M* yielded 4 p*M,* that 1 n*M* yielded 11.8 p*M* and that 10 n*M* yielded >39 p*M* (Allain *et al.,* 1992). Although the type and percentage of serum would influence the final values, these measurements and calculations are of value in comparing studies and in relating *in vitro* concentrations to the concentrations of thyroid hormones in normal serum.

Membrane Actions

Signal Transduction Pathways

Thyroid hormones interact with several signal transduction pathways in bone cells. These results suggest that extranuclear actions could initiate some of the thyroid hormone effects on bone. Rapid (within 30 sec) increases in inositol mono-, bis-, and trisphosphates are elicited by treatment of fetal rat limb bones with 100 n*M* and 1 μM T_3 (Lakatos and Stern, 1991). The inactive analogs diiodothyronine and rT_3 did not increase inositol phosphates. This effect of T_3 was inhibited by indomethacin and could represent an initiation pathway for the prostaglandin-dependent effects of thyroid hormones on bone resorption, discussed later. Thyroid hormones at high doses inhibit cyclic AMP phosphodiesterase (Marcus, 1975). T_3 at 0.1 and 1 n*M* increased ornithine decarboxylase and potentiated the responses of this enzyme to parathyroid hormone (PTH) (Schmid *et al.,* 1986). Specific cellular functions associated with membrane receptors have not been identified, although it has been proposed that nongenomic actions of thyroid hormones serve homeostatic functions for membrane transport and may modulate genomic actions of the hormones (Davis and Davis, 1996).

Gene Products

Thyroid hormone promotes the proliferation and differentiation of osteoblastic cells (Ohishi *et al.,* 1994; Ishida *et al.,* 1995). This is reflected in the increased expression of a number of markers.

Osteoblast Phenotypic Markers

Alkaline Phosphatase T_4 (10 n*M*) and 1 n*M* T_3 increased alkaline phosphatase in ROS 17/2.8 cells (Sato *et al.,* 1987). The effect was seen within 4 days of culture. Responses were more robust in subconfluent cells and were inhibited by 1 μg/ml cycloheximide or 0.1 μg/ml actinomycin D. T_3 modulated the stimulatory effect of hydrocortisone on alkaline phosphatase. At low hydrocortisone concentrations (1 n*M,* 10 n*M*), 1 μ*M* T_4 resulted in an additive effect, whereas at higher hydrocortisone concentrations (0.1 μ*M,* 1 μ*M*), coincubation with T_4 decreased the stimulatory effect (Sato *et al.,* 1987). T_3 also increased alkaline phosphatase in MC3T3-E1 cells (Kasono *et al.,* 1988; Klaushofer *et al.,* 1995). In one study, significant responses were elicited with 0.1 n*M* T_3 and 10 n*M* T_4; the effect of T_4 was further increased by concentrations up to 1 μ*M* and was less at 10 μ*M*; the effect of T_3, however, was maximal at 1 n*M,* and no increase was observed at 100 n*M* (Kasono *et al.,* 1988). T_3 failed to affect alkaline phosphatase in UMR-106 cells (LeBron *et al.,* 1989; Huang *et al.,* 2000), possibly due to the high basal expression of the enzyme in this cell line. T_3 had biphasic effects on alkaline phosphatase in normal rat osteoblastic cells (Ernst and Froesch, 1987), stimulating at concentrations of 0.01 and 0.1 n*M* and inhibiting at a concentration of 10 n*M.* In neonatal rat calvarial cells, mRNA for alkaline phosphatase was

decreased by 1 or 4 days exposure to 1 n*M* T_3 (Schmid *et al.,* 1992). In cells derived from human trabecular bone explants and cultured in medium containing charcoal-stripped serum, alkaline phosphatase in the cell layer was increased by T_3 at concentrations up to 200 n*M* (Kassem *et al.,* 1993). Alkaline phosphatase was also increased by thyroid hormone in isolated tibiae (Stracke *et al.,* 1986) and in primary human (Kassem *et al.,* 1993) and rodent (Egrise *et al.,* 1990) osteoblasts. Thus, most but not all osteoblastic cells respond to thyroid hormones with an increase in alkaline phosphatase. Effects are seen at concentrations in the physiologic range; however, the dose dependence of the effect is quite variable and may be dependent on cell type and culture conditions.

Osteocalcin T_3 increased osteocalcin in a dose-dependent manner in ROS 17/2.8 cells (Rizzoli *et al.,* 1986; Sato *et al.,* 1987). In medium containing 2% T_3-depleted serum, a significant effect was seen at 1 n*M,* with a half-maximal effect at 2.5 n*M*; the osteocalcin concentration in the control medium was 9 ng/10^6 cells and was increased to 12.3 ng/10^6 cells by 1 n*M* T_3 (Rizzoli *et al.,* 1986). A striking difference in the response of osteocalcin mRNA to T_3 was observed between cells derived from femoral and vertebral bone marrow, cultured under conditions leading to osteogenic differentiation (Milne *et al.,* 1998). In cultures from femoral marrow, T_3 supplementation (10 or 100 n*M*) prevented the time-dependent decrease in osteocalcin mRNA observed in untreated cells. In cultures from the vertebral marrow, osteocalcin mRNA expression was maintained over time in untreated cells, and T_3 failed to augment the response.

Collagen In cultured rat osteoblastic cells, decreases in collagen and noncollagenous protein synthesis were noted with 0.01 and 0.1 n*M* T_3, but not with higher concentrations (Ernst and Froesch, 1987). Thyroid hormones did not inhibit collagen synthesis in rat calvaria (Canalis, 1980). In neonatal mouse calvaria precultured with indomethacin to inhibit prostaglandin synthesis, both collagen and noncollagenous protein synthesis were stimulated by T_3 and by triiodothyroacetic acid at concentrations in the 0.01 – 10 n*M* range (Kawaguchi *et al.,* 1994a). Cells from human trabecular bone explants showed decreased type I procollagen carboxy-terminal propeptide production when treated with T_3 (Kassem *et al.,* 1993). The synthesis of collagen thus appears to be regulated by T_3 in a complex manner and may be influenced by T_3 stimulation of other cellular products, such as prostaglandins. Collagen type I gene expression was regulated differentially by T_3 in marrow cultures from femoral and vertebral bones, with a more marked stimulatory effect in the femoral bones (Milne *et al.,* 1998).

Other Phenotypic Responses A series of studies has characterized other changes elicited by T_3 in MC3T3-E1 osteoblastic cells (Luegmayr *et al.,* 1996; Franzl-Zelman *et al.,* 1997; Varga *et al.,* 1997, 1999; Luegmayer *et al.,* 1998, 2000). In addition to alkaline phosphatase, expression of c-fos, c-jun, and an osteocalcin-related protein were increased in T_3-treated cells. Morphological changes were also observed. T_3-treated cells ceased proliferation and became flattened, enlarged, and polygonal. The amount of F-actin increased and the patterns of actin expression were altered. Pancadherin/β catenin immunoprecipitation was increased by T_3, which could reflect the organization of adherens junctions. Apoptosis was also accelerated. In ROS 17/2.8 cells, treatment with T_3 increased expression of receptors for PTH: conversely, PTH increased binding of T_3 (Gu *et al.,* 2001).

Insulin-like Growth Factors and IGF-Binding Proteins

IGF-I has significant anabolic effects on bone, increasing cell replication and both collagen and noncollagen protein synthesis (Canalis, 1980; Hock *et al.,* 1986; McCarthy *et al.,* 1989; Centrella *et al.,* 1990; Pirskanen *et al.,* 1993). IGF-I is increased in fetal rat bones treated with thyroid hormone (Schmid *et al.,* 1992; Lakatos *et al.,* 1993; Varga *et al.,* 1994; Klaushofer *et al.,* 1995). At 1 n*M,* T_3 stimulates IGF-I production in neonatal rat calvarial osteoblasts (Schmid *et al.,* 1992). There is a dose-dependent, biphasic effect of T_3 and T_4 on IGF-I production in UMR-106 cells and fetal rat bone organ cultures (Lakatos *et al.,* 1993). IGF-I mRNA is increased by T_3 treatment in MC3T3-E1 cells (Varga *et al.,* 1994; Klaushofer *et al.,* 1995). T_3 increased IGF-I expression more markedly in cells from vertebral marrow than in cells from femoral marrow (Milne *et al.,* 1998). Interference with IGF-I action by decreasing expression or function of the IGF-I receptor by the use of antisense oligonucleotides, antibodies, and antagonist peptide decreased the anabolic effects of T_3 on MC3T3-E1 cells and primary mouse calvarial osteoblasts, including effects on alkaline phosphatase, osteocalcin, and collagen synthesis (Huang *et al.,* 2000). The effects of thyroid hormones on IGFs may be modulated by changes in IGF-binding proteins (IGFBPs). The physiological role of the binding proteins is not fully understood; however, they can influence the cellular uptake and turnover of IGF-I. The binding proteins may represent a mechanism for retention of IGFs in the bone matrix (Bautista *et al.,* 1991). IGFBPs can also modulate IGF action in osteoblastic cells. IGFBP-2 and IGFBP-4 can inhibit IGF-I actions (Mohan *et al.,* 1989; Feyen *et al.,* 1991). Both enhancing and inhibitory (Schmid *et al.,* 1995) effects are produced by IGFBP-3 (Ernst and Rodan, 1990; Schmid *et al.,* 1991). In rat osteoblasts, T_3 stimulates the production of IGFBP-2 and IGFBP-3 (Schmid *et al.,* 1992). T_3 increases IGFBP-4 expression in MC3T3-E1 cells (Glantschnig *et al.,* 1996), which could regulate the response to T_3 and contribute to the decreased anabolic effects observed at higher concentrations. Alterations in thyroid status *in vivo* influence the expression of IGFBPs in a complex manner. In hyperthyroid rats, IGFBP-3 gene expression in liver is decreased; however, in hypothyroid (propylthiouracil-treated) animals, IGFBP-1 and IGFBP-2 gene expression are increased and IGFBP-3 mRNA is decreased (Rodriguezarnao *et al.,* 1993). In hyperthyroid patients, serum IGFBP-3 and IGFBP-4, but not IGFBP-5, are increased (Lakatos *et al.,* 2000).

Cell and Tissue Phenotypic Responses

Osteoblast Proliferation

T_3 can increase proliferation of rodent and human osteoblastic cells (Ernst and Froesch, 1987; Kassem *et al.,* 1993). In the rodent cell cultures, 0.01 and 1 n*M* were stimulatory, and 10 n*M* was inhibitory in longer term cultures (Ernst and Froesch, 1987). Cell number was decreased after 8 days of incubation with T_4 in MC3T3-E1 cells; inhibition was observed with 10 n*M* T_3 and was maximal at 1 μM (Kasono *et al.,* 1988). In other investigations, T_3 did not significantly affect growth of ROS 25/1, UMR-106, or ROS 17/2.8 cells (Sato *et al.,* 1987; LeBron *et al.,* 1989; Williams *et al.,* 1994). The diversity of the responses obtained suggests that in addition to thyroid hormone dose, the cell type, passage number, degree of confluence, and the presence or production of other factors can determine the particular outcome that is observed. In explanted neonatal mouse calvaria, T_3 stimulated thymidine incorporation in a dose-dependent manner and was significant at 10 p*M* (Kawaguchi *et al.,* 1994a). A preculture period was required to demonstrate the effect, as high levels of prostaglandin production from untreated tissues appeared to mask treatment effects.

Nodule Formation

Bone nodule formation has been used as a parameter of bone cell differentiation, presumably representing the capability of the cell to generate a mineralized matrix. T_3 or T_4, at concentrations of 1 n*M*–0.1 μM, decreased nodule formation by 21-day fetal rat calvarial cells cultured in medium containing 15% heat-inactivated fetal bovine serum, and lower concentrations, starting at 1 p*M,* had no effect (Ishida *et al.,* 1995). When serum was depleted of T_3 with AG-1X-10 resin (Samuels *et al.,* 1979), basal bone nodule formation was increased (Ishida *et al.,* 1995). Dexamethasone (10 n*M*), enhanced bone nodule formation markedly. This was promoted by low concentrations of T_3 (1 and 10 p*M* and inhibited by higher concentrations (10 and 100 n*M*). Although the results suggest that high concentrations of thyroid hormones can inhibit mineralization, the authors point out that the procedure to strip serum of thyroid hormone could remove other inhibitory factors as well.

Osteoclast Activation

Two studies indicate that the resorptive effects of thyroid hormones on bone are mediated indirectly through the stimulation of osteoblasts or other cell types present in bone. T_3 failed to activate isolated osteoclasts; however, when mixed bone cells were added to the cultures, a significant response was observed with 1 μM T_3, although not with lower concentrations (Allain *et al.,* 1992). UMR-106 cells failed to activate the osteoclasts in the presence of T_3, suggesting that a different cell type or a different osteoclast stage might be responsible for the activation observed with the mixed bone cells. In another study, either UMR-106-01 cells or rat calvarial cells were able to activate the osteoclasts (Britto *et al.,* 1994). Responses were detected at lower T_3 concentrations in the latter study, perhaps due to the use of stripped serum.

Resorption

T_3 stimulates resorption in bone organ cultures. Fetal rat limb bones (Mundy *et al.,* 1979; Hoffmann *et al.,* 1986; Lakatos and Stern, 1992) and neonatal mouse calvaria (Krieger *et al.,* 1988; Klaushofer *et al.,* 1989; Kawaguchi *et al.,* 1994) are the models that have been studied most extensively. In both the limb bones and calvaria, responses to T_3 are slower to develop than the effects of PTH (Mundy *et al.,* 1979; Klaushofer *et al.,* 1989; Kawaguchi *et al.,* 1994b) and the dose–response curves are generally shallow (Mundy *et al.,* 1979; Hoffmann *et al.,* 1986; Krieger *et al.,* 1988). Higher doses of thyroid hormones *in vitro* can have inhibitory effects on resorption (Orbai and Gazariu, 1982). One of the most striking differences from the effects of PTH is that the maximal responses to thyroid hormones are lower (Mundy *et al.,* 1979; Lakatos and Stern, 1992; Kawaguchi *et al.,* 1994b), sometimes only about 50% of those elicited with maximal concentrations of PTH. The slower responses and lower efficacy of thyroid hormones compared with PTH may be the basis for the observation that thyroxin does not exhibit "escape" from the inhibitory effects of calcitonin (Krieger *et al.,* 1987; Klaushofer *et al.,* 1989). Alternatively, this may reflect a different mechanism for the direct effect of thyroid hormones compared with PTH. Further evidence for such a difference between the mechanism of T_3 and PTH responses is the contrast in their interaction with TGFβ (Lakatos and Stern,1992). TGFβ enhanced the early responses to PTH and inhibited the later effects, whereas the interaction with T_3 displayed a somewhat reverse time course. A range of threshold concentrations was observed for both T_3 and T_4 in the different studies, with no clear basis in terms of the composition of the medium. 3,5,3′-Triiodothyroacetic acid, an analog that binds to nuclear receptors, especially β forms, with higher affinity than T_3, was a more potent stimulator of resorption than T_3 (Kawaguchi *et al.,*1994). In cultured fetal bones, T_3 increases collagen degradation (Halme *et al.,* 1972). T_3 increased mRNA for the metalloproteinases collagenase-3 and gelatinase B in cultures of osteoblastic cells, effects that were not inhibited by indomethacin (Pereira *et al.,* 1999).

Several mechanisms may mediate thyroid hormone-stimulated resorption. In neonatal mouse calvaria, resorption was inhibited by indomethacin, implicating a prostaglandin-dependent pathway (Krieger *et al.,* 1988; Klaushofer *et al.,* 1989; Kawaguchi *et al.,* 1994b). Other studies have shown prostaglandin-independent effects on the calvaria (Conaway *et al.,* 1998). In fetal rat limb bones, the T_3 effect is not affected by indomethacin. However, in limb bone cultures, T_3 potentiates the bone-resorbing effect of IL-1 (Tarjan and Stern, 1995), and the effect of IL-1 and the IL-1/T_3 combination is sensitive to indomethacin. T_3 also potentiates the IL-1-

mediated production of IL-6 in this model (Tarjan and Stern, 1995), as well as in MC3T3-E1 osteoblastic cells (Tokuda *et al.,* 1998) and in bone marrow stromal cells (Kim *et al.,* 1999). In contrast, in MC3T3-E1 cells, T_3 reduced the IL-6 production elicited by prostaglandin, cholera toxin, and forskolin, possibly reflecting cross-talk through effects on a cAMP pathway (Tokuda *et al.,* 1998). In mouse bone marrow cultures, T_3 promoted calcitriol-induced osteoclast formation through an IL-6-dependent pathway (Schiller *et al.,*1998). T_3 also increased IL-6 production in MG-63 cells and human bone marrow stromal cells (Siddiqi *et al.,* 1998). These findings suggest that the indirect stimulation of osteoclast differentiation by IL-6 may be a component of the resorptive effect of thyroid hormone. The IL-1 receptor antagonist protein did not prevent the resorptive effect of thyroid hormones in limb bone cultures (Kawaguchi *et al.,* 1994b). Thyroid hormone effects on resorption were blocked by aphidicolin or cortisol (Kawaguchi *et al.,* 1994b) and by hydroxyurea (Conaway *et al.,* 1998), indicating the involvement of cell replication. Immunosuppressive cyclosporins blocked the thyroid hormone effects in limb bone cultures (Lakatos and Stern, 1992), and interferon-γ (Klaushofer *et al.,* 1989) and the antibody to TGFβ (Klaushofer *et al.,* 1995) blocked the thyroid hormone effects in calvaria, consistent with the participation of other local factors in the resorptive response to thyroid hormone.

Remodeling

Most *in vitro* studies have focused on either anabolic or catabolic effects of thyroid hormone, under conditions designed to optimize the study of the particular response. However, because there are dose-dependent biphasic effects on formation parameters and delayed (Klaushofer *et al.,* 1989) and submaximal (Mundy *et al.,* 1979; Krieger *et al.,* 1988; Lakatos and Stern, 1992) effects on resorption, it may be that neither effect can be studied to the exclusion of the other, and the net effects on bone remodeling may be accessible to *in vitro* investigation. A model system designed to study growth, mineralization, and resorption in radii and ulnae of 16-day fetal mice (Soskolne *et al.,* 1990) revealed interesting differences between effects of T_3 and PTH. Effects of T_3 were studied over a $0.1\ nM - 10\ \mu M$ dose range. T_3 concentrations in the $10\ nM - 0.3\ \mu M$ range resulted in increases in diaphyseal length, in calcium, phosphate, and hydroxyproline content, and in decreases in ^{45}Ca release. At higher concentrations (1 and 10 μM), T_3 stimulated ^{45}Ca release. In contrast, when PTH was studied over a $1\ pM - 0.1\ \mu M$ range, only resorptive effects were observed, these being at concentrations of 1 n*M* and higher.

Chondrocyte Responses

Thyroid hormones block clonal expansion of the proliferative cell layer of the epiphyseal growth plate and promote chondrocyte maturation (Nilsson *et al.,* 1994). In earlier studies on isolated cells, T_3 was found to inhibit chondrocyte proliferation (Burch *et al.,* 1987). T_3 suppressed the synthesis of DNA, protein, and type II collagen when added to rapidly proliferating chicken growth plate chondrocytes cultured in serum-free media (Ishikawa *et al.,* 1998). When T_4 was added to chemically defined medium containing insulin and growth hormone, there were dose-dependent increases in type X collagen and in alkaline phosphatase (Ballock and Reddi, 1994). T_3 was approximately 50 times more potent than T_4 in promoting expression of the hypertrophic markers in prehypertrophic chondrocytes in cells cultured with insulin/transferrin/selenium (Alini *et al.,* 1996). There was a biphasic dose dependency of the effects of T_3 and T_4 to stimulate the synthesis of type II collagen and chondroitin sulfate-rich proteoglycans in cultured rabbit articular chondrocytes (Glade *et al.,* 1994). In an *in vitro* model of cartilage formation from a chondrocyte pellet, the developing cartilage assumed the structural architecture of the normal epiphysis if thyroid hormones were present, whereas the structure was random in their absence (Ballock and Reddi, 1994). Findings from cocultures of vascular endothelial cells and chondrocytes suggest that vascular endothelial cells may also produce factors that act synergistically with thyroid hormone to derepress the late differentiation of resting chrondrocytes and permit them to become hypertrophic and express type X collagen and alkaline phosphatase (Bittner *et al.,* 1998), leading to mineralization.

In Vivo Responses of the Skeleton to Thyroid Hormones: Animal Studies

When thyroid hormones are administered to young rats, bone growth is enhanced (Glasscock and Nicoll, 1981). This response is not seen in older rats, suggesting that the stage of cellular differentiation or the environment in terms of other hormones and local factors can influence the manifestation of thyroid hormone responses. T_3 treatment of neonatal rats elicited a narrowing of the sagittal suture and increased mineral apposition rates at the osseous edges of the sutures (Akita *et al.,* 1994). Histomorphometric analysis was consistent with the conclusion that T_3 is critical for bone remodeling (Allain *et al.,* 1995).

Hypothyroidism

Animal models of hypothyroidism include the use of the antithyroid agents propylthiouracil or methimazole to block the synthesis of thyroid hormones. Treatment of young rats with methimazole for 7 weeks resulted in a marked increase in trabecular bone volume of the subchondral spongiosa of the mandibular condyles and a decrease in cartilage cellularity (Lewinson *et al.,* 1994). IGF-I was present in the condyles of control rats, but lacking in hypothyroid rats. Replacement of T_4 during the last 2 weeks of treatment restored the parameters to normal (Lewinson *et al.,* 1994).

Histomorphometric studies in iliac crest biopsies of young rats made hypothyroid by a 12-week treatment with propylthiouracil showed that both osteoid surfaces and eroded surfaces were reduced and cancellous bone volume was increased (Allain *et al.,* 1995). In a study in which 21-day rats were made hypothyroid by administration of methimazole, T_4 given daily at doses of 2 to 64 μg/kg/day for 21 days elicited biphasic effects on epiphyseal growth plate width and logitudinal growth rate (Ren *et al.,* 1990). The dose–response curve paralleled that of serum IGF-I concentrations, which were postulated to contribute to the growth responses (Ren *et al.,* 1990).

An interesting animal model for hypothyroidism utilizes transgenic mice (line TG66-19) in which the bovine thyroglobulin promoter drives the expression of the herpes simplex type I virus thymidine kinase gene in thyrocytes. This enzyme converts ganciclovir to ganciclovir-5′-phosphate, which inhibits DNA replication, resulting in loss of thyrocytes, loss of follicles, and undetectable T_3 and T_4; levels of PTH and CT are unaffected (Wallace *et al.,* 1991, 1995). In this transgenic mouse model, administration of 15 or 50 μg of ganciclovir to mouse dams during days 14–18 of gestation resulted in growth delay in pups carrying the transgene (Wallace *et al.,* 1995). The authors point out that the reason their effects were more dramatic than those obtained with the *hyt/hyt* mouse, a strain that has an inactivating mutation in the TSH receptor, is that in the latter model, circulating T_4 is still 10–20% of normal (Adams *et al.,* 1989). Effects of mutations in thyroid hormone receptors in mouse models were discussed earlier.

Hyperthyroidism

A range of T_4 regimens has been used to elicit hyperthyroidism in animal models. The duration of treatment is generally at least 3 weeks and dosages range from 200 μg to 1 g/day. Lower concentrations have been used in animals previously made hypothyroid with antithyroid drugs (Lewinson *et al.,* 1994). When the animals were rendered hyperthyroid by treatment with T_4 (200 μg/day for 12 weeks), the mineral apposition rate and the mineral formation rate were increased markedly, with a smaller increase in eroded surfaces (Allain *et al.,* 1995). A greater sensitivity of cortical bone (femur) than trabecular bone (spine) to thyroid hormone-induced bone loss has been noted in animal models of hyperthyroidism (Ongphiphadhanakul *et al.,* 1993; Suwanwalaikorn *et al.,* 1996, 1997; Gouveia *et al.,* 1997; Zeni *et al.,* 2000). Tooth movement was greater in T_3-treated rats undergoing orthodontic procedures than in control untreated animals, probably reflecting greater root resorption (Shirazi *et al.,* 1999). Ten-day-old rats treated with 100 μg/kg/day for up to 60 days displayed altered parameters of cranial width, narrowing of the suture gap of the sagittal suture, and intense immunohistochemical staining for IGF-I along the suture margins, consistent with the possibility that local IGF-I is involved in the effect of thyroid hormone to cause premature suture closure (Akita *et al.,* 1996).

Ovariectomized rats treated with a low dose of T_4 (30 μg/kg/day for 12 weeks) showed increased bone turnover and decreased bone density compared with controls; however, in the presence of 17β-estradiol, their bone mass and mineral apposition rate were greater than those of controls (Yamaura *et al.,* 1994). T_4, (250 μg/kg/day for 5 weeks) increased serum osteocalcin and urinary pyridinolines and produced a greater loss of bone mineral compared with either ovariectomy alone or T_4 alone (Zeni *et al.,* 2000). In contrast to the effects of these high doses of T_4, administration of a more physiological concentration (10 μg/kg/day) to ovariectomized rats resulted in a generalized increase in bone mineral density at both lumbar and vertebral sites (Gouveia *et al.,* 1997). Estradiol prevented T_3-stimulated decreases in bone mineral density in ovariectomized thyroidectomized rats, but had no effect in animals that were not treated with T_3 (DiPippo *et al.,* 1995). These results raise the possibility of cross-talk at the level of binding of estradiol and T_3 receptors to DNA target sites.

Pathophysiological Effects of Altered Thyroid Hormone Status in Humans

Hypothyroidism

Bone turnover is decreased in hypothyroidism (Mosekilde and Melson, 1978). In juvenile hypothyroidism, there is delayed skeletal maturation and epiphysial dysgenesis. In a study of children with congenital hypothyroidism treated with T_4, the bone age at 1.5 years was correlated positively with the dose of T_4 administered during the first year and with the concentrations of serum T_4 (Heyerdahl *et al.,* 1994). As discussed previously, multiple skeletal abnormalities have been described in syndromes of RTH, including short stature, delayed skeletal maturation, and stippled epiphyses (Refetoff *et al.,* 1993). Serum IGF-I is lower in hypothyroid patients (Lakatos *et al.,* 2000). Bone resorption is decreased in patients with hypothyroidism, as indicated by reduced urinary pyridinium cross-links (Nakamura *et al.,* 1996).

Hyperthyroidism

Since the initial description of bone loss in thyrotoxicosis by von Recklinghausen more than a century ago (von Recklinghausen, 1891), substantial additional evidence has shown that excessive thyroid hormone production can lead to bone loss. In patients with hyperthyroidism, markers of bone turnover are increased. Pyridinoline and hydroxypyridinoline cross-link excretion are elevated (Harvey *et al.,* 1991; Garnero *et al.,* 1994; Nagasaka *et al.,* 1997; Engler *et al.,* 1999), as are urinary N-terminal telopeptide of type I collagen (NTX) (Mora *et al.,*1999; Pantazi *et al.,* 2000) and serum carboxy-terminal-1-telopeptide (ICTP) (Loviselli *et al.,* 1997; Miyakawa *et al.,* 1996; Nagasaka *et al.,* 1997). Evidence of activation of osteoblasts in hyperthyroidism is the elevation of alkaline phosphatase (Mosekilde and Christesen,

1977; Cooper *et al.,* 1979; Martinez *et al.,* 1986; Nagasaka *et al.,* 1997; Pantazi *et al.* 2000), osteocalcin (Martinez *et al.,* 1986; Lee *et al.,* 1990; Mosekilde *et al.,* 1990; Nagasaka *et al.,* 1997; Loviselli *et al.,* 1997; Pantazi *et al.,* 2000), and carboxy-terminal propeptide of type I procollagen (PICP) (Nagasaka *et al.,* 1997). Osteocalcin showed a better correlation than alkaline phosphatase with thyroid hormone concentrations (Martinez *et al.,* 1986; Garnero *et al.,* 1994). Greater increases in the resorption markers than the formation markers suggest an imbalance between resorption and formation, leading to bone loss (Garnero *et al.,* 1994; Miyakawa *et al.,* 1996). Histomorphometric analyses show increased osteoclast numbers and resorbing surfaces, with loss of trabecular bone volume (Meunier *et al.,* 1972; Mosekilde and Melsen, 1978). Histomorphometric data yield a kinetic model demonstrating accelerated bone remodeling, with a disproportionately greater increase in resorption and a net loss of bone with each cycle of remodeling (Eriksen, 1986). Decreased bone mineral content in hyperthyroidism is well documented (Fraser *et al.,* 1971; Krolner *et al.,* 1983; Toh *et al.,* 1985), and fracture risk is increased in hyperthyroidism (Fraser *et al.,* 1971; Cummings *et al.,* 1995; Wejda *et al.,* 1995; Vestergaard *et al.,* 2000a). Mild hyperthyroidism may increase bone loss in postmenopausal women (Lakatos *et al.,* 1986). In children, however, thyrotoxicosis can lead to acceleration of growth and skeletal development (Schlesinger and Fisher, 1951; Saggese *et al.,* 1990).

T_4 Therapy and Bone Loss

A particularly critical issue regarding the effects of thyroid hormone on the skeleton is the question of what amounts of exogenously administered thyroid hormones increase the risk of bone loss, especially among individuals already at risk for osteoporotic fractures from other causes. Thyroid hormones are given as replacement therapy for hypothyroidism after thyroidectomy, as well as in other states where patients may have inadequate thyroid hormone secretion and goiter, such as autoimmune thyroiditis. Thyroid hormones are also used as suppressive therapy for toxic nodular goiter or for thyroid cancer. There may be patients who used excess thyroid hormones in the past for weight loss or as a tonic. Decreased bone density, accelerated bone turnover, and increased risk of fracture in patients treated with T_4 have been documented extensively (Fallon *et al.,* 1983; Coindre *et al.,* 1986; Ross *et al.,* 1987; Paul *et al.,* 1988; Stall *et al.,* 1990; Taelman *et al.,* 1990; Adlin *et al.,* 1991; Diamond *et al.,* 1991; Greenspan *et al.,* 1991; Lehmke *et al.,* 1992; Frevert *et al.,* 1994; Garton *et al.,* 1994; Grant *et al.,* 1995; McDermott *et al.,* 1995; Campbell *et al.,* 1996; Affinito *et al.* 1996; Jodar *et al.,* 1998; Hadji *et al.,* 2000). Several studies and a meta-analysis (Marcocci *et al.,* 1994; Uzzan *et al.,* 1996; Greenspan and Greenspan, 1999; Campbell *et al.,* 1996; Affinito *et al.,* 1996) concluded that the dose of T_4 and duration of treatment are major determinants of the occurrence of bone loss. Other factors that appear to amplify the risk include a previous history of hyperthyroidism (Grant *et al.,* 1995), age (Duncan *et al.,* 1994), and postmenopausal status (Greenspan *et al.,* 1991; Stepan and Limanova, 1992; Franklyn *et al.,* 1994; Garton *et al.,* 1994; Affinito *et al.,* 1996; Jodar *et al.,* 1998). It has been suggested that a low dietary calcium intake can contribute to the risk of T_4-induced bone loss (Kung *et al.,* 1983). Estrogen and HRT protected against the bone loss associated with T_4 treatment (Schneider *et al.,* 1994; Franklyn *et al.,* 1995). Consistent with the importance of dose and duration, TSH has been a useful predictive marker for bone loss (Wartofsky, 1991). A meta-analysis of 13 publications in which TSH was suppressed by thyroid hormone treatment projected that a premenopausal woman at an average age of 39.6 years, treated with L-T_4, (164 μg/day for 8.5 years), would have an excess annual bone loss of 0.31% and 2.67% less bone mass than a control (Faber and Galloe, 1994).

In contrast with these findings, a number of studies report that T_4 treatment failed to produce bone loss (Toh and Brown, 1990; Ribot *et al.,* 1990; Franklyn and Sheppard, 1992; Grant *et al.,* 1993; Fujiyama *et al.,* 1995; Hawkins *et al.,* 1994; Schneider *et al.,* 1995; DeRosa *et al.,* 1995; Saggase *et al.,* 1996, 1997; Marcocci *et al.,* 1997; Gurlek and Gedik, 1999; Rachedi *et al.,* 1999; Nuzzo *et al.,* 1998; Knudsen *et al.,* 1998; Hanna *et al.* 1998; Langdahl *et al.,* 1996a). One explanation for this apparent disparity, in the case of patients receiving T_4 replacement therapy, is that their cortical bone density was initially higher due to their hypothyroidism and that T_4 replacement resulted in a normalization (Ross, 2000). A longitudinal study would indicate bone loss, whereas a cross-sectional study would not reveal a significant difference from the control group. Another possible basis for some of the diversity of findings is that the accelerated bone turnover and increased fracture risk with T_4 treatment can be a transient phenomenon. In one report, correlations between serum-free T_4 and serum procollagen III peptide, which had been noted after 6 months of T_4 treatment, were not found in patients treated chronically (Nystrom *et al.,* 1989). There may be an initial increase in cortical width and bone porosity that results in increased fracture risk until a new steady-state condition is established (Coindre *et al.,* 1986). Another study found a temporary increase in fracture risk in previously hypothyroid patients, which was most prevalent in patients over 50 years of age and limited to forearm fractures (Vestergaard *et al.,* 2000b)

Stimulation of the production of local factors by thyroid hormone, which was observed *in vitro* and animal studies, is also seen in humans. Thyroid hormone increases circulating IL-6 (Lakatos *et al.,* 1997; Siddiqi *et al.,* 1999) and IGF-I (Brixen *et al.,* 1995; Kassem *et al.,* 1998; Foldes *et al.,* 1999; Lakatos *et al.,* 2000). One can speculate that the greater rate of production of IGF-I in children could explain the findings of studies in which large doses of thyroid hormone were not deleterious to bone in children (Kooh *et al.,* 1996; Verrotti *et al.,* 1998; Dickerman *et al.,* 1997; Leger *et al.,* 1997; Van Vleit *et al.,* 1999; Tumer *et al.,* 1999). The anabolic effect of the increased IGF-I could compensate for or override the bone breakdown.

Reversibility/Treatment/Prevention of Thyroid Hormone-Stimulated Bone Loss

Recovery of bone loss in hyperthyroid patients following antithyroid treatment has been inconsistent (Fraser *et al.,* 1971; Toh *et al.,* 1985; Saggese *et al.,* 1990; Diamond *et al.,* 1994; Mudde *et al.,* 1994), but may be achieved more readily in younger individuals (Fraser *et al.,* 1971; Saggese *et al.,* 1990). Studies have documented protective effects of methimazole (Langdahl *et al.,* 1996b; Nagasaka *et al.,* 1997; Mora *et al.,* 1999). Surgery and radioactive iodine also prevented bone loss in hyperthyroid patients (Langdahl *et al.,* 1996c; Arata *et al.* 1997), but were less protective than methimazole (Vestergaard *et al.,* 2000a). The protective effects of estrogen during treatment with T_4 were noted earlier, and androgen may also be beneficial (Lakatos *et al.,* 1989). Bisphosphonates may also protect against thyroid hormone-induced bone loss. Both animal (Ongphiphadhanakul *et al.,* 1993; Rosen *et al.,* 1993a; Yamamoto *et al.,* 1993; Kung and Ng, 1994) and human (Rosen *et al.,* 1993b; Lupoli *et al.,* 1996) studies have demonstrated that bisphosphonates are effective in preventing thyroid hormone-stimulated bone loss. Etidronate (0.5 mg/100 g administered twice weekly) prevented decreased bone mineral density and increased mRNA for alkaline phosphatase, tartrate-resistant acid phosphatase, and histone H4 in femurs of rats treated with L-T_4 for 20 days (Ongphiphadhanakul *et al.,* 1993). The combination of L-T_4 and etidronate resulted in lower expression of mRNA for type I collagen, osteocalcin, and osteopontin, which was lower than that of controls, although neither L-T_4 nor etidronate alone affected these parameters. Alendronate (1.75 mg/kg orally twice weekly) prevented increased bone turnover resulting from the administration of excess T_4 for 3 weeks (Lupoli *et al.,* 1996). The preventive effect was assessed by histomorphometry and measurement of osteocalcin. Bone volume was above control in all alendronate-treated groups in the study. Pretreatment of rats with pamidronate (5 μmol/kg/day subcutaneously for 1 week prior to T_3) prevented increases in alkaline phosphatase and osteocalcin at 1 week and losses of bone mineral density at 3 weeks in the femur and spine (Rosen *et al.,* 1993b). Pamidronate pretreatement (30 mg iv, daily for 2 days) prevented increases in urinary calcium/creatinine ratio, urinary hydroxyproline, and urinary pyridinoline cross-links in normal male subjects treated with T_3 (Rosen *et al.,* 1993a). Calcium and calcitonin were also found to offer some protective benefit (Kung and Yeung, 1996).

Overview, Speculations, and Future Directions

Thyroid hormones interact with both nuclear receptors and membrane-binding sites in bone and influence many of the phenotypic responses of bone cells. In intact organisms, deficiency or excess thyroid hormone can alter skeletal development and maintenance, indicating the importance of physiological concentrations of the hormones for normal skeletal physiology. Effects of thyroid hormones to amplify bone turnover are evident from clinical studies, *in vivo* investigations in animals, and *in vitro* models. There is a dose dependence to the effects, with anabolic effects declining and catabolic effects becoming more prominent with the higher concentrations of thyroid hormone present in hyperthyroidism and with the higher doses that are used for suppressive therapy. Determination of TSH to guide thyroid hormone dosage can decrease the occurrence of bone loss resulting from the therapeutic use of thyroid hormone. However, factors other than dosage can influence the response to thyroid hormone. The anabolic effects of thyroid hormone on bone are more apparent in younger animals and children, consistent with the possibility that growth factors can have significant mediating or modulating effects. Thyroid hormones increase IGF-I in osteoblasts and experimental animals; elevated circulating thyroid hormones are associated with increases in IGF-I and IGFBPs in patients. Other physiological factors modulate the skeletal effects of thyroid hormones; e.g., estrogens can decrease the deleterious effects of excess thyroid hormone. The pharmacological inhibition of bone resorption with bisphosphonates can also diminish thyroid hormone-stimulated bone loss. The biphasic effects of thyroid hormones observed *in vivo* are also seen in *in vitro* models at physiologically and pathophysiologically relevant concentrations. Thyroid hormones stimulate osteoblast proliferation, promote the differentiation of this cell type, and stimulate differentiated functions, as shown by increases in alkaline phosphatase activity, osteocalcin expression, and stimulation of collagen synthesis. The variation in the responses when different model systems are used indicates that there are additional modulating factors that are not yet understood. The osteoblast is the target cell for thyroid hormone activation of mature osteoclasts. The promotion of resorption by thyroid hormones may be mediated through the activation of cytokine pathways that lead to osteoclast differentiation. Thus, thyroid hormones act at receptor, cellular, and organismal levels to modulate or interact with many of the other factors and pathways that determine the status of the skeleton. The elucidation of thyroid hormone receptor diversity and its consequences for the skeleton is clearly an important goal for the near future.

CHAPTER 41

Clinical and Basic Aspects of Glucocorticoid Action in Bone

Barbara E. Kream
Department of Medicine, Division of Endocrinology and Metabolism, University of Connecticut Health Center, Farmington, Connecticut 06030

Barbara P. Lukert
Division of Endocrinology, Metabolism, and Genetics, University of Kansas Medical Center, Kansas City, Kansas 66103

General Introduction

Glucocorticoid-induced osteoporosis was first reported by Cushing (1932) when he described osteoporosis in patients with high levels of cortisol due to an adrenocorticotrophin-producing tumor of the pituitary gland. The problem became clinically significant in 1949 when pharmacological doses of glucocorticoids were introduced for therapeutic use because of their potent anti-inflammatory and immunosuppressive effects. It became clear that treatment with glucocorticoids causes a loss of bone mass and pathologic fractures. Since then, efforts have been made to elucidate the cause of steroid-induced bone loss.

Cortisol, the glucocorticoid secreted by the adrenal gland, is essential in physiologic doses for the differentiation and function of osteoblasts and osteoclasts, and modulates the effects of other hormones and mediators of cell function, whereas supraphysiologic doses inhibit bone formation. These direct effects on bone, combined with effects on other systems that indirectly regulate bone metabolism, cause rapid bone loss in patients treated with glucocorticoids. The mechanisms involved and the resulting clinical picture are the subjects of this chapter.

Pharmacology of Glucocorticoids

Synthetic derivatives of cortisol with less mineralocorticoid effect have been developed. The compounds prescribed most frequently are prednisone, prednisolone, methylprednisolone, betamethasone, dexamethasone, and triamcinolone. Prednisone is metabolized to prednisolone. The 4,5 double bond and the 3-ketone structures are both necessary for typical adrenocorticoid activity. Introduction of the 1,2 double bond, as in prednisone or prednisolone, enhances the ratio of carbohydrate regulating potency to sodium-retaining potency. 6α-methylation of the B ring (6α-methylprednisolone) increases anti-inflammatory potency while reducing electrolyte-retaining properties. 9α-fluorination enhances all biologic activities, whereas 16-methylation eliminates the sodium-retaining effect, but only slightly alters other effects on metabolism or inflammation. Substitution in the 17α-ester position produces a group of extremely potent steroids, beclomethasone diproprionate and budesonide, which are effective when applied topically to skin or administered by inhalation (Gilman *et al.,* 1990). The absorption of inhaled steroids is virtually equivalent to that of oral administration, and absorption from skin is significant if applied over a large surface or under plastic film. Despite this, inhaled or topical steroids reduce side effects because the drugs are targeted to the site of the disease and lower doses can be used. Deflazacort, an oxazoline derivative of prednisone, has been developed with the hope of reducing the catabolic effects of glucocorticoids while maintaining anti-inflammatory effects (Gennari *et al.,* 1984), but the results have been disappointing. The development of synthetic glucocorticoids that dissociate transactivation and AP-1 transrepression and yet exhibit anti-inflammatory activity holds

promise for the development of glucocorticoid-based drugs that separate beneficial from deleterious effects.

Glucocorticoids are widely used in the treatment of asthma, collagen-vascular disease, inflammatory bowel disease, granulomatous, and skin diseases. The skeletal response to glucocorticoids is not disease specific, and accelerated bone loss has been described in patients with each of these diseases when they are treated with steroids (de Deuxchaisnes *et al.,* 1984; Reid *et al.,* 1986a; Rizzato *et al.,* 1988).

Characteristics of Bone Loss

Bone loss, measured by dual-energy X-ray absorptiometry in patients receiving glucocorticoids for more than a year, has been reported to average 0.6–6% per year (Sambrook *et al.,* 1990; Lukert *et al.,* 1992; Laan *et al.,* 1993). Trabecular bone and the cortical rim of the vertebral body are more susceptible to the effects of glucocorticoids than the cortical bone of the extremities year (Seeman *et al.,* 1982; Laan *et al.,* 1993). Consequently, compression fractures of the spine are frequently the first sign of glucocorticoid-induced bone loss, and the proximal femur becomes more fragile. Although bone loss appears to be most rapid during the first 6–12 months of treatment, loss remains above average for the duration of treatment (Gennari, 1985; Lukert *et al.,* 1992). Approximately 30–50% of patients taking glucocorticoids long term and 50% of patients with Cushing's disease (excessive endogenous production of steroids) have at least one atraumatic fracture (Ross *et al.,* 1982; Adinoff *et al.,* 1983). The risk for hip fracture is doubled and the risk for vertebral fracture is increased five-fold by oral doses of prednisone exceeding 7.5 mg/day (Van Staa *et al.,* 2000). The risk for fracture increases within the first 3 months after the initiation of glucocorticoid therapy and decreases within 3 months after discontinuation.

One study showed that the fracture threshold for vertebral fractures may be higher for patients taking steroids than for those with involutional osteoporosis (Luengo *et al.,* 1990); i.e., fractures occur at a higher bone density in steroid-treated patients. However, a more recent study found no increase in risk of clinical fracture in corticosteroid-treated patients whose bone densities were matched to controls; i.e., patients on steroids tended to fracture at bone densities similar to patients with involutional osteoporosis.

Glucocorticoid-induced bone loss is partially reversible after cessation of prednisone administration or removal of the cause of excessive endogenous production of cortisol (Manning *et al.,* 1992; Laan *et al.,* 1993; Rizzato *et al.,* 1993; Van Staa *et al.,* 2000). Bone loss is also partially reversible during treatment with estrogen/progesterone therapy, bisphosphonates, calcitonin, parathyroid hormone (PTH), or sodium fluoride while prednisone is continued (Meunier *et al.,* 1987; Luengo *et al.,* 1990; Lukert *et al.,* 1992; Struys *et al.,* 1995; Saag *et al.,* 1998; Lane *et al.,* 2000; Reid *et al.,* 2000).

Histomorphometric studies on bone from glucocorticoid-treated patients show that glucocorticoids cause apoptosis of osteoblasts and osteocytes and depress osteoblastic function, while simultaneously, the frequency of activation of bone remodeling units is increased. Thus, there is an increase in the number of sites at which bone is being resorbed, and the ability of osteoblasts to replace bone at each site is decreased. This results in a reduced wall thickness of cancellous bone packets and, eventually, to perforation and removal of trabecular plates (Bressot *et al.,* 1979; Meunier *et al.,* 1982; Dempster, 1989; Weinstein *et al.,* 1998; Plotkin *et al.,* 1999).

Serum levels of osteocalcin, the most abundant noncollagen bone matrix protein and a biochemical marker of bone formation, are suppressed in patients receiving either oral or inhaled glucocorticoids (Lukert *et al.,* 1986; Puolijoki *et al.,* 1992). Surprisingly, urinary hydroxyproline and pyridinium cross-links, markers of bone resorption, are not increased by glucocorticoids (Cosman *et al.,* 1994; Lukert *et al.,* 1995). Conversely, serum tartrate-resistant acid phosphatase was elevated during short-term steroid therapy. It was felt that the high doses used in this study could have been toxic to osteoclasts, causing cell death and liberation of cytoplasmic TRAP into serum in the absence of increased bone resorption (Cosman *et al.,* 1994). The finding of a 96% increase in osteoclast perimeter observed in vertebrae taken from mice receiving prednisolone for 7 days makes it more likely that osteoclastic bone resorption is indeed increased early in the course of glucocorticoid administration (Weinstein *et al.,* 1998).

Risk Factors for Glucocorticoid-Induced Bone Loss

The usual risk factors for involutional osteoporosis (age, race, sex, weight, and parity) do not apply to the same extent to glucocorticoid-induced bone loss (Dykman *et al.,* 1985). Everyone taking high doses (greater than 10 mg/day of prednisone) loses significant amounts of bone (Garton *et al.,* 1993). Postmenopausal women receiving equivalent doses of steroids are more at risk for fractures than premenopausal women or men, presumably because they also have age and menopause-related bone loss. It is unlikely that there is a threshold dose of glucocorticoid below which bone loss does not occur. A retrospective cohort study showed that the risk for fracture is increased even for doses below 7.5 mg/day and increases further with increasing daily and cumulative doses (Van Staa *et al.,* 2000). Even high doses of some inhaled steroids (Ip *et al.,* 1994), but not others (Medici *et al.,* 2000), cause bone loss.

Indirect Mechanisms for the Pathogenesis of Glucocorticoid-Induced Bone Loss

Glucocorticoids affect nearly every system in the body. We will first discuss the effects of glucocorticoids on systems that modulate bone metabolism indirectly (Table I) to set the stage for a discussion of the direct effects of glucocorticoids on bone.

Table I Effect of Glucocorticoids on Systems That Modulate Bone Remodeling

Pituitary
Inhibition of secretion of growth hormone, FSH/LH and ACTH
Cellular transport
Decrease in transport of calcium and phosphorus
Parathyroid hormone
Increased secretion
Increased peripheral sensitivity of PTH
Gonads
Inhibition of synthesis of estrogen by ovary and testosterone by testes
Adrenal
Decrease in secretion (due to ACTH) of dehydroepiandrosterone and androstenedione

Effects on Pituitary Function

GROWTH HORMONE

The secretion of growth hormone is partially controlled by glucocorticoids. Prednisone inhibits pituitary secretion of growth hormone in response to GH-releasing hormone in normal men (Kaufmann *et al.,* 1988). Nevertheless, serum concentrations of growth hormone and insulin-like growth factor-1 (IGF-1) are normal in patients receiving glucocorticoids (Morris *et al.,* 1968; Gourmelen *et al.,* 1982; Kaufmann *et al.,* 1988). Despite normal levels, IGF-1 activity measured by bioassay is decreased in patients with glucocorticoid excess, perhaps because of an IGF-1 inhibitor that has been found in the serum of children receiving glucocorticoids (Unteman *et al.,* 1985). This inhibitory factor may be one of the IGF-binding proteins (IGFBP).

A clearer understanding of the role of IGF-binding proteins on IGF activity is emerging and shedding light on the mechanisms through which glucocorticoids may exert their effect. As discussed later, glucocorticoids may affect IGFBP, which inhibit or enhance IGF activity. Glucocorticoids increase circulating levels of IGFBP-1, which may limit the activity of IGF-1; this effect has been associated with glucocorticoid-induced fetal growth retardation (Prince *et al.,* 1992). The importance of serum levels of growth factors or their binding proteins is unknown, as growth factors are produced locally by bone cells. Growth hormone and PTH are trophic hormones (Ernst *et al.,* 1988; McCarthy *et al.,* 1989) for growth factors produced in bone, and the increase in bone density observed with the administration of PTH may be due to stimulation of the production of growth factors in bone (Lane *et al.,* 2000).

HYPOTHALAMIC–PITUITARY–GONADAL AXIS

Glucocorticoids blunt pituitary secretion of luteinizing hormone (Sakakura *et al.,* 1975). A subset of gonadotropin-releasing-hormone (GnRH)-containing neurons in the rat hypothalamus possesses glucocorticoid receptors that bind dexamethasone *in vitro* with high affinity. Glucocorticoids repress transcription in a hypothalamic cell line, and glucocorticoid receptors acting directly within GnRH neurons could be at least partly responsible for negative regulation of the hypothalamic–pituitary–gonadal axis. Glucocorticoids also have direct effects on gonads inhibiting follicle-stimulating hormone (FSH)-induced estrogen production by ovarian granulosa cells and testosterone production by the testes (Hsueh *et al.,* 1978). The adrenal secretion of androgens is also decreased due to suppression of ACTH secretion. Inhaled beclomethasone in doses of 1 mg/day or greater lower mean serum levels of dehydroepiandrosterone sulfate (DHEA) by 35% in postmenopausal women (Smith *et al.,* 1994). As a result of these combined effects, serum concentrations of estradiol, estrone, DHEA, androstenedione, and progesterone are decreased in women, whereas DHEA and testosterone are decreased in men receiving glucocorticoids (MacAdams *et al.,* 1986). It is very likely that deficiencies in these anabolic hormones accelerate bone loss. There is a direct correlation between bone mineral density and plasma estradiol levels in glucocorticoid-treated women (Montecucco *et al.,* 1992); furthermore, women receiving estrogen/progesterone replacement therapy and men given medroxyprogesterone acetate while taking glucocorticoids were protected against bone loss (Grecu *et al.,* 1990; Lukert *et al.,* 1992).

Calcium and Phosphorus Transport, Parathyroid Function, and Vitamin D Metabolism

Patients taking pharmacological doses of glucocorticoids have impaired gastrointestinal absorption of calcium, hypercalciuria, and phosphaturia and higher levels of serum PTH and $1,25(OH)_2D$ when compared to patients not taking steroid. (Favus *et al.,* 1973; Adams *et al.,* 1981; Bikle *et al.,* 1993; Shrivastava *et al.,* 2000). Even very small oral doses of beclomethasone, similar to doses that may be swallowed by patients using the drug in inhaled form, decrease calcium absorption for the intestine (Smith *et al.,* 1993). High PTH levels have traditionally been attributed to prolonged negative calcium balance, and the rise in $1,25(OH)_2D$ is due to the trophic effect of PTH. However, acute longitudinal studies have shown that serum $1,25(OH)_2D$ levels increase and serum phosphorus levels decrease within 2 hr after intravenous administration of methylprednisolone, before PTH had risen significantly. PTH levels increased progressively during the first 2 weeks of high-dose treatment. All of these parameters returned to baseline at 3 weeks when methylprednisolone was given orally but still at a high dose (Cosman *et al.,* 1994). These findings suggest that glucocorticoids alter transport across a number of biologic membranes. Whether these effects on transport are due to changes in calcium receptor or other proteins or enzymes involved in transport (a genomic effect) or to direct effects on membrane permeability remain unknown at this time.

Although acute studies showed that the changes in PTH and $1,25(OH)_2D$ were transient, it is important to note that others have found high PTH and $1,25(OH)_2D$ levels and higher levels of urinary cAMP and reduced tubular reabsorption of phosphate in patients taking glucocorticoids for more

than a year and in those with Cushing's disease (Lukert *et al.,* 1976; Findling *et al.,* 1982; Bikle *et al.,* 1993). This suggests that glucocorticoids have an acute effect on transport, which inhibits gastrointestinal absorption of calcium, decreases renal tubular reabsorption of calcium and phosphorus, and may decrease intracellular calcium and phosphorus. This in turn promotes synthesis of $1,25(OH)_2D$. Long-term glucocorticoid administration causes negative calcium balance, which perpetuates secondary hyperparathyroidism with its accompanying hypophosphatemia and elevated serum $1,25(OH)_2D$ levels. The high levels of cAMP and decreased TRP indicate that the increase in PTH (even though in the normal range) is of physiologic significance, as both of these changes are known effects of PTH on the kidney.

In addition to the effects of glucocorticoid-induced elevation of PTH levels on phosphate transport, glucocorticoids have direct effects on renal tubular reabsorption of phosphate acting through the Na^+-H^+ exchange activity in the proximal tubule, thus decreasing Na^+ gradient-dependent phosphate uptake (Frieberg *et al.,* 1982). Likewise, although glucocorticoids induce changes in vitamin D metabolism, which could affect calcium transport, non-vitamin D-dependent alterations in calcium transport have been observed in the gastrointestinal tract in the presence of glucocorticoids (Charney *et al.,* 1975; Adams *et al.,* 1980). The role of vitamin D metabolites and vitamin D-dependent mechanisms in the malabsorption of calcium in patients taking glucocorticoids is unclear. Active transport of calcium is inhibited by glucocorticoids in the presence of elevated levels of $1,25(OH)_2D$ and is only partially corrected by pharmacological levels of $1,25(OH)_2D$. Calbindin synthesis is stimulated by glucocorticoids (Corradino *et al.,* 1991), and the brush border uptake of calcium is not altered (Shultz *et al.,* 1982). These findings suggest that glucocorticoid-induced inhibition of calcium absorption is caused by alterations in posttranscriptional events, alterations in basolateral membrane transport, or other toxic mechanisms. Possible mechanisms include depletion of mitochondrial adenosine triphosphate (Krawitt, 1972) or pericellular back flux due to stimulation of the sodium–potassium–ATPase pump by glucocorticoids (Charney *et al.,* 1975; Adams *et al.,* 1980).

The sensitivity of osteoblasts to PTH is increased by glucocorticoids. Glucocorticoids probably act on or near the stimulatory guanine nucleotide-binding regulatory protein complex. The potentiation of PTH-induced increases in cAMP response appears to be due to increases in cAMP activity and inhibition of phosphodiesterase (Chen *et al.,* 1978). Whether renal tubules are more sensitive to PTH in the presence of glucocorticoids remains unclear.

Osteonecrosis

Osteonecrosis (avascular necrosis or aseptic necrosis) is a well-recognized complication of glucocorticoid excess. Glucocorticoid-induced osteonecrosis was first recognized in 1957. Previous administration of glucocorticoids can be implicated in 16–34% of patients presenting with "idiopathic" osteonecrosis (Fisher *et al.,* 1971). The femoral head is affected most frequently, followed by the head of the humerus and distal femur, but osteonecrosis may occur in other long bones and the bones of the feet. A similar lesion characterized by a transverse radiolucent cleft running under an end plate is seen in the vertebra and resembles subchondral fracture seen in long bones. The risk for osteonecrosis increases with both the dose of glucocorticoids and the duration of treatment (Zizic *et al.,* 1985). However, osteonecrosis may develop in patients who receive steroids in very high doses for a short period of time (Taylor, 1984), moderate doses over a long period of time (Metselaar *et al.,* 1985), or by intraarticular or epidural injection.

The mechanisms responsible for glucocorticoid-induced osteonecrosis remain obscure. Etiologic considerations invoke several theories. One is a mechanical theory that attributes ischemic collapse of the epiphysis to osteoporosis and the accumulation of unhealed trabecular microcracks resulting in fatigue fractures. Others include a vascular theory proposing that ischemia is caused by microscopic fat emboli and a theory that increased intraosseous pressure due to fat accumulation as part of the Cushing syndrome leads to mechanical impingement on the sinusoidal vascular bed and decreased blood flow (Mankin, 1992). The number of apoptotic osteoblasts and osteocytes is increased in femoral necks removed from patients developing avascular necrosis while taking steroids, whereas this phenomenon was not observed in patients with avascular necrosis due to other causes (Weinstein *et al.,* 1998). The induction of early cell death may play a pivotal role in the etiology of steroid-induced avascular necrosis.

Clinically, pain is the usual presenting symptom and may be mild or vague in chronic forms of the disease, but it is usually acute and severe. Osteonecrosis may remain silent as long as it is not associated with epiphyseal collapse, which appears to initiate symptoms (Maldague *et al.,* 1984). Early osteonecrosis of the hip may be managed by prolonged avoidance of weight bearing, but prosthetic replacement of the joint is frequently necessary. Surgical decompression may be attempted but the results are not encouraging (Mankin, 1992).

Summary of Cumulative Effects of Glucocorticoid-Induced Metabolic Changes on Bone

The overall effect of glucocorticoids is catabolic. Inhibition of pituitary secretion of growth hormone and alterations in IGF-binding proteins lead to a fall in the biologic activity of growth factors with loss of their anabolic effect on bone and other tissues. Gonadotrophin secretion is inhibited and, along with direct inhibitory effects of glucocorticoids on gonadal secretion of estrogen/testosterone, leads to a fall in circulating gonadal hormone concentrations. Deficiency in gonadal hormones causes an increase in bone resorption (Fig. 1).

Membrane transport systems are altered by glucocorticoids, resulting in inhibition of gastrointestinal absorption of calcium and decreased renal tubular absorption of calcium and phosphorus. Lowered intracellular phosphorus

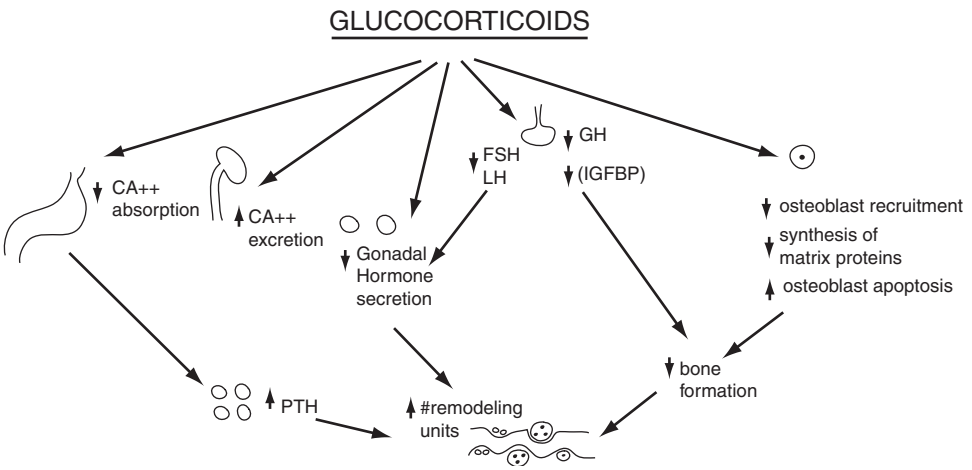

Figure 1 Effect of steroids on bone and calcium metabolism. Glucocorticoids (GC) inhibit gastrointestinal absorption and increase renal excretion of calcium. A negative calcium balance and perhaps failure to transport calcium into the parathyroid cell cause an increase in the secretion of parathyroid hormone (PTH). PTH increases the number of sites undergoing bone remodeling. Decreased levels of gonadal hormones caused by GC inhibition of their secretion further augment bone resorption. Glucocorticoids decrease recruitment of osteoblasts from osteoprogenitor cells, accelerate apoptosis of osteoblasts and osteocytes, and inhibit bone formation at each site. Combination of an increase in the number of sites undergoing remodeling and a decrease in bone formation at each site causes rapid bone loss.

causes an acute rise in $1,25(OH)_2D$ synthesis. PTH secretion is increased, despite elevated serum levels of calcium and $1,25(OH)_2D$. Chronically, increased PTH secretion and the resultant elevation in $1,25(OH)_2D$ production are perpetuated by a negative calcium balance. The elevated levels of PTH and $1,25(OH)_2D$, along with deficiency of gonadal hormones, increase the number of sites undergoing bone resorption. The direct inhibition of osteoblastic bone formation at each bone remodeling site further augments the rate of bone loss.

Glucocorticoid-induced bone loss can be prevented by bisphosphonates, hormone replacement, PTH, and perhaps calcitonin (Luengo *et al.,* 1990; Lukert *et al.,* 1992; Reid *et al.,* 1996; Lane *et al.,* 1998; Saag *et al.,* 1998; Cohen *et al.,* 1999). Fracture risk is reduced by bisphosphonates but fracture data are not available for the other modalities. In addition to inhibiting bone resorption, bisphosphonates and calcitonin appear to decrease the number of apoptotic osteocytes and osteoblasts observed in bone biopsies from patients treated with prednisolone (Plotkin *et al.,* 1999). Estrogen has a similar effect in estrogen-deficient states but it is not known whether estrogen prevents apoptosis in the presence of glucocorticoids. Protection from glucocorticoid-induced apoptosis may play a major role in the prevention of early bone loss in patients taking glucocorticoids.

Direct Actions of Glucocorticoids on Bone

Introduction

Glucocorticoids have a myriad of effects on osteoblastic cells, resulting in profound changes in bone remodeling (Delany *et al.,* 1994; Canalis, 1996; Ishida *et al.,* 1998; Cooper *et al.,* 1999; Manolagas *et al.,* 1999). A hallmark of glucocorticoid-induced osteoporosis in humans is decreased mean wall thickness of trabecular bone, reflecting a reduction in the amount of new bone replaced in each remodeling cycle (Dempster *et al.,* 1983). Cells of the osteoblast lineage contain glucocorticoid receptors (Chen *et al.,* 1977; Manolagas *et al.,* 1978; Haussler *et al.,* 1980; Abu *et al.,* 2000), and supraphysiological concentrations of glucocorticoids decrease protein, RNA, and DNA synthesis in primary bone cell cultures (Peck *et al.,* 1967; Chen *et al.,* 1977; Choe *et al.,* 1978; Wong, 1979). Teleologically, these studies are consistent with the catabolic effects of high levels of glucocorticoids on human bone. Likewise, glucocorticoid treatment also decreases bone formation in dogs, rats, and mice (Altman *et al.,* 1992; Quarles, 1992; Ortoft *et al.,* 1995; Turner *et al.,* 1995; Weinstein *et al.,* 1998). In some rat studies, glucocorticoid treatment decreases bone formation but does not induce osteopenia. This is due to an inhibition of turnover, as both bone resorption and formation are reduced, and bone mass does not decrease (Li *et al.,* 1996; Shen *et al.,* 1997). In mice, however, there is an increase in osteoclast surface shortly after glucocorticoid treatment, which is followed by a decrease in the rate of bone formation and a reduction in bone mass (Weinstein *et al.,* 1998). Thus, mice, compared to rats, may be more like humans in the response of bone to pharmacological doses of glucocorticoids (Manolagas *et al.,* 1999).

Bone Formation and Osteoblast Differentiation

In contrast to the marked inhibitory effect of pharmacological doses of glucocorticoids on bone formation *in vivo*, glucocorticoids cause both catabolic and anabolic effects

on bone formation and osteoblast differentiation *in vitro.* Although the relevance of the *in vitro* anabolic effect is not completely understood, it may reflect a permissive role in the maintenance of the osteoblast phenotype during bone remodeling. Analysis of data from *in vitro* studies is complicated by a plethora of experimental variables, including the concentration of hormone, the molecular form of the glucocorticoid used, the timing of hormone addition, the presence of serum, and the species, cellular heterogeneity, and developmental stage of the model system. However, some generalizations can be made. *In vitro,* physiological concentrations of glucocorticoids enhance the differentiation of early osteoprogenitors and stimulate the formation of bone in "developmental" models of bone formation. In contrast, pharmacological concentrations of glucocorticoids inhibit cell proliferation, impair the function of more mature osteoblasts, and increase osteoblast and osteocyte apoptosis. These effects ultimately lead to a decrease in bone mass.

Organ cultures reflect both anabolic and catabolic effects of glucocorticoids on bone formation. Organ explants of folded periostea from embryonic chick calvariae form new bone during culture (Tenenbaum *et al.,* 1985). When dexamethasone is added at the onset of culture, there is enhanced osteoid formation, alkaline phosphatase activity, and a transient increase in the replication of cells adjacent to the newly formed bone surface. However, when dexamethasone is added late in the culture period after bone has formed, there is a decrease in alkaline phosphatase activity (Tenenbaum *et al.,* 1985). Thus, it appears that glucocorticoids initially cause the proliferation and differentiation of a distinct population of osteoprogenitor cells that participate in bone formation, but then limit further cell proliferation in the cultures (McCulloch *et al.,* 1986).

Glucocorticoids both stimulate and inhibit type I collagen synthesis in serum-free organ cultures of fetal rat calvariae depending on the dose of hormone and duration of hormone treatment (Dietrich *et al.,* 1978; Canalis, 1983; Kream *et al.,* 1990b). In fetal rat calvariae, physiological concentrations of cortisol (30–100 n*M*) stimulate collagen synthesis after 24 hr, whereas pharmacological concentrations (1000 n*M*) are inhibitory at 48–96 hr (Dietrich *et al.,* 1978). Likewise, there is a rapid stimulatory effect of cortisol on collagen synthesis in newborn rat calvariae (Hahn, 1984). In fetal rat calvariae, the early stimulation of collagen synthesis is blocked by the addition of IGFBP-2, which binds and inactivates secreted IGFs (Kream *et al.,* 1997). These data suggest that the initial stimulation of collagen synthesis by glucocorticoids depends on the activity of endogenous IGF-1 and may be due to increased osteoblastic differentiation.

Many studies show that gluococorticoids enhance osteogenic differentiation in long-term primary calvarial cell cultures that form mineralized bone nodules in the presence of serum, ascorbic acid, and β-glycerolphosphate. These cultures are defined by the stages of cell proliferation, extracellular matrix maturation, and matrix mineralization, each characterized by the expression of cell growth and tissue-specific genes (Gerstenfeld *et al.,* 1987; Owen *et al.,* 1990; Stein *et al.,* 1990). Glucocorticoids increase the formation of bone nodules and the expression of genes associated with the osteoblast phenotype in primary rat osteoblastic cell cultures (Bellows *et al.,* 1987, 1989, 1990; Shalhoub *et al.,* 1992). The effect of glucocorticoids is biphasic: low concentrations of dexamethasone and hydrocortisone increase nodule formation, whereas pharmacological concentrations are less effective or not stimulatory (Bellows *et al.,* 1987). In this model, the anabolic effect of glucocorticoids has been attributed to the enhanced proliferation and differentiation of glucocorticoid-dependent osteoprogenitors (Bellows *et al.,* 1989, 1990). High concentrations of glucocorticoids inhibit osteogenic differentiation in MC3T3-E1 (Lian *et al.,* 1997) and primary murine osteoblast cultures (Bellows *et al.,* 1998).

Bone marrow stromal cell cultures grown in the presence of serum, ascorbic acid, and β-glycerolphosphate have been used extensively as a model system to study the stages of osteoblast differentiation. Osteoprogenitor cells within the bone marrow stromal network, when activated to differentiate, provide a renewable source of osteoblasts for endosteal and trabecular bone surfaces. Glucocorticoids enhance the expression of osteoblastic phenotypic traits such as alkaline phosphatase activity, osteocalcin, type I collagen, osteopontin, and bone sialoprotein and the formation of mineralized bone nodules in cultures of chick, rat, and human bone marrow stromal cells (Kasugai *et al.,* 1991; McCulloch *et al.,* 1991; Kamalia *et al.,* 1992; Cheng *et al.,* 1994, 1996; Malaval *et al.,* 1994; Rickard *et al.,* 1994; Herbertson *et al.,* 1995; Aubin, 1999). Bone stromal cell cultures contain glucocorticoid-dependent osteoprogenitor cells that gives rise to mineralized bone nodules (Aubin, 1999).

The pathway by which glucocorticoids enhance osteogenic differentiation *in vitro* is thought to involve members of the bone morphogenetic protein (BMP) family of proteins. BMP-2 and glucocorticoids exert a synergistic enhancement of the osteogenesis in rat bone marrow stromal cells (Rickard *et al.,* 1994) and fetal rat calvarial cells (Boden *et al.,* 1996). In the calvarial model, BMP-4 and BMP-6 are synergistic with glucocorticoids in promoting osteogenesis (Boden *et al.,* 1996). Moreover, glucocorticoid-dependent differentiation of fetal rat calvarial cells is blocked by antisense oligonucleotides to BMP-6 (Boden *et al.,* 1997).

High concentrations of glucocorticoids regulate preosteoblast replication and function. Glucocorticoids inhibit collagen synthesis in organ cultures of fetal rat (Dietrich *et al.,* 1978; Canalis, 1983) and mouse calvariae (Woitge *et al.,* 2000). In subclones of osteoblastic ROS 17/2 osteosarcoma cells, glucocorticoids either stimulate or inhibit collagen synthesis depending on the state of maturation of the cells; in less mature osteoblasts, glucocorticoids stimulate collagen synthesis, whereas in more mature osteoblasts they inhibit collagen synthesis (Hodge *et al.,* 1988). In confluent cultures of primary osteoblastic cells, glucocorticoids generally inhibit

collagen synthesis (Chen *et al.,* 1978; Kim *et al.,* 1989; Ng *et al.,* 1989). The inhibitory effect of glucocorticoids on collagen synthesis in fetal rat calvariae is accompanied by a decrease in periosteal cell content (Dietrich *et al.,* 1978; Canalis, 1984; Chyun *et al.,* 1984). Glucocorticoids also decrease the number of cells in the osteoblastic and periosteal layers of fetal rat parietal bone organ cultures (Gronowicz *et al.,* 1994). These effects in organ culture reflect at least in part the antiproliferative effect of glucocorticoids seen in osteoblastic cell cultures (Chen *et al.,* 1977; Hodge *et al.,* 1988; Hughes-Fulford *et al.,* 1992). Glucocorticoids decrease osteocyte formation in these cultures, which may reflect an inhibition of osteoblast renewal (Gohel *et al.,* 1995) and/or oseoblast apoptosis (Gohel *et al.,* 1999). High concentrations of glucocorticoids inhibit proliferation in primary human bone marrow stromal cell cultures (Silvestrini *et al.,* 2000; Walsh *et al.,* 2001). However, not all the effects of glucocorticoids on osteoblast function can be ascribed to an inhibition of cell replication. For example, the inhibitory effect of glucocorticoids on collagen synthesis, although blunted, still persists in the presence of DNA synthesis inhibitors, suggesting that glucocorticoids also inhibit the function of differentiated osteoblasts (Lukert *et al.,* 1991). In cultured bone marrow stromal cells, it was shown that a physiologically relevant concentration of dexamethasone (10 n*M*) promotes osteogenic differentiation, whereas a higher concentration (100 n*M*) was also osteogenic but decreased cell number. These data suggest that glucocorticoids enhance osteoblastic differentiation but that a decrease in the proliferation of osteogenic precursors ultimately limits the extent of bone formation (Walsh *et al.,* 2001).

Glucocorticoids increase the apoptosis of osteoblasts (Weinstein *et al.,* 1998; Gohel *et al.,* 1999; Silvestrini *et al.,* 2000) and osteocytes (Weinstein *et al.,* 1998; Plotkin *et al.,* 1999). In primary fetal rat calvariae cell cultures, the increase in osteoblast apoptosis is associated with a decrease in the Bcl-2/Bax protein ratio (Gohel *et al.,* 1999). Chronic treatment of adult mice with prednisolone increases apoptosis of osteoblasts in vertebrae and osteocytes in metaphyseal cortical bone and decreases bone mass (Weinstein *et al.,* 1998), which is reduced by bisphosphonate treatment (Plotkin *et al.,* 1999). Acute treatment of neonatal mice with dexamethasone increases apoptosis of osteoblasts in calvariae (Gohel *et al.,* 1999), and this effect was reversed by cotreatment with 17β-estradiol. Apoptotic osteocytes and cancellous-lining cells were seen in femoral heads from patients with glucocorticoid-induced osteonecrosis (Weinstein *et al.,* 2000).

Chronic glucocorticoid administration decreases osteoblast formation *in vivo.* When mice are treated with pharmacological levels of glucocorticoids *in vivo,* the generation of fibroblast colony forming units in *ex vivo* bone marrow cultures is decreased, suggesting that glucocorticoids deplete the bone marrow of osteogenic precursors (Simmons *et al.,* 1990). Likewise, glucocorticoids treatment of adult mice for 1 month suppresses osteogenic differentiation in *ex vivo* bone marrow cultures (Weinstein *et al.,* 1998).

Collectively, these data suggest that pharmacological doses of glucocorticoids induce osteoporosis due to a decrease in bone formation that results from an impairment of osteoblast function, inhibition of osteoblast renewal, and increased osteoblast apoptosis. However, physiological concentrations of glucocorticoids may be important for maintaining osteoblast differentiation.

Bone Resorption

Although the primary defect in glucocorticoid-induced osteoporosis is an inhibition of bone formation, glucocorticoids have direct effects on bone resorption. Glucocorticoids inhibit basal and agonist-stimulated resorption of fetal rat long bones (Raisz *et al.,* 1972) but increase resorption of fetal rat parietal bones (Gronowicz *et al.,* 1990) and mouse calvariae (Reid *et al.,* 1986b; Conaway *et al.,* 1996). Glucocorticoids decrease the activity and increase the apoptosis of rat osteoclasts (Tobias *et al.,* 1989; Dempster *et al.,* 1997). Dexamethasone increases osteoclastogenesis in mouse bone and spleen cell cocultures (Kaji *et al.,* 1997). In human stomal cell and osteoblastic cell cultures, glucocorticoids stimulate expression of the receptor activator of NF-κB (RANKL), the key stimulator of osteoclast formation, and decreases expression of osteoprotegerin (OPG), an inhibitor of osteoclast formation (Hofbauer *et al.,* 1999). This increase in the RANKL/OPG ratio is consistent with a stimulation of osteoclast formation and may explain the early stimulation of resorption in humans and mice.

Permissive Effects of Glucocorticoids on Osteoblasts

Some of the physiological effects of glucocorticoids on bone may be due in part to their ability to act as permissive hormones, thereby allowing other hormones to function optimally. Low doses of glucocorticoids enhance PTH-stimulated adenylate cyclase in rat, mouse, and human bone cells (Chen *et al.,* 1978; Wong, 1980; Rodan *et al.,* 1984; Wong *et al.,* 1990) and PTH-mediated bioactivities (Wong, 1979). The enhancement of the PTH-dependent cAMP response may be due to an increase in cAMP activity and a decrease in phosphodiesterase activity (Chen *et al.,* 1978). Glucocorticoids also increase the number of PTH receptors and levels of PTH/PTHrP receptor mRNA (Yamamoto *et al.,* 1988; Urena *et al.,* 1994).

The effect of glucocorticoids on 1,25$(OH)_2$D receptors and biological activity, however, is not as clear. In rat bone cytosol and primary rat osteoblastic cells, glucocorticoids maintain or increase 1,25$(OH)_2$D receptor number (Manolagas *et al.,* 1979; Chen *et al.,* 1983) and enhance the biological actions of 1,25$(OH)_2$D (Chen *et al.,* 1986). However, in one study using primary mouse osteoblastic cells, the effect of glucocorticoids on 1,25$(OH)_2$D receptor number was dependent on the stage of growth of the cells; receptor number was decreased at early log phase growth and at confluence and increased at late log phase growth (Chen *et al.,* 1982). In another study, glucocorticoids were shown to

increase 1,25$(OH)_2$D biological activities in primary mouse osteoblastic cells (Wong, 1980). In human MG-63 cells, glucocorticoids decrease the expression of 1,25$(OH)_2$D receptor mRNA (Godschalk *et al.,* 1992). Taken together, these findings indicate that glucocorticoids can increase or decrease 1,25$(OH)_2$D receptor levels depending on the experimental model.

Glucocorticoids alter the IGF-1 pathway. They inhibit IGF-1 mRNA and protein expression by osteoblasts (as discussed later) but increase IGF-1 receptor number (Bennett *et al.,* 1984). Physiological concentrations of cortisol enhance the stimulatory effects of IGF-1 on collagen synthesis, producing a larger anabolic effect than with IGF-1 alone (Kream *et al.,* 1990a). The ability of glucocorticoids to augment IGF-1 activity may represent a compensatory response that helps maintain bone mass and growth during periods of diminished IGF-1 supply, such as starvation. A similar enhancing effect of glucocorticoids on IGF-1 action occurs in fibroblast cultures (Conover *et al.,* 1986; Bird *et al.,* 1994). Cortisol enhances the anabolic effects of exogenous prostaglandins on collagen and DNA synthesis in organ cultures of rat calvariae, which may be dependent partly on the IGF-1 pathway (Raisz *et al.,* 1993). Physiological concentrations of glucocorticoids may amplify the stimulatory effect of PGE_2 on the IGF-1 promoter through the induction of C/EBP family transcription factors (McCarthy *et al.,* 2000b).

Target Cell Metabolism of Glucocorticoids

Target cell metabolism has emerged as an important mechanism for regulating the sensitivity of cells to glucocorticoids (Eyre *et al.,* 2001). Glucocorticoids can be modified by two 11β-hydroxysteroid dehydrogenases (Krozowski, 1999; Krozowski *et al.,* 1999; Stewart *et al.,* 1999). The NAD-dependent enzyme 11β-HSD type 2 (11β-HSD2) catalyzes the unidirectional conversion of biologically active glucocorticoids to inactive metabolites and the bidirectional interconversion of dexamethasone to 11-dehydrodexamethasone. The NADP-dependent 11β-HSD type 1 (11β-HSD1) has oxidoreductase activity and catalyzes the bidirectional conversion of inactive glucocorticoids to active metabolites. 11β-HSD2 is highly expressed in kidney where it protects the mineralocorticoid receptor from activation by glucocorticoids and is abundant in placenta where it protects the fetus from maternal glucocorticoids. Mice with a targeted deletion of 11β-HSD2 develop hypertension because glucocorticoids, which fail to be metabolized in kidney cells, evoke mineralocorticoid effects via the mineralocorticoid receptor (Kotelevtsev *et al.,* 1999). Both 11β-HSD1 and 11β-HSD2 are expressed in osteoblasts of rat and human osteoblasts (Cooper *et al.,* 2000). Rat and human osteoblastic osteosarcoma cell lines express 11β-HSD2 (Bland *et al.,* 1999; Eyre *et al.,* 2001). Both rat and mouse calvarial osteoblast cultures can convert inactive glucocorticoids to active metabolites (Bellows *et al.,* 1998). Primary human osteoblasts and adult human bone explants express both 11β-HSD1 and 11β-HSD2 (Bland *et al.,* 1999). The glucocorticoid sensitivity of osteosarcoma cell lines with equivalent numbers of glucocorticoid receptors is directly correlated with the level of 11β-HSD2 expression (Eyre *et al.,* 2001). Moreover, ROS 17/2.8 and MC3T3-E1 cells transfected with 11β-HSD2 show reduced responsiveness to natural glucocorticoids but maintain responsiveness to the synthetic glucocorticoid dexamethasone (Woitge *et al.,* 2001). Thus, 11β-HSD enzymes may regulate the sensitivity of osteoblasts to glucocorticoids.

Glucocorticoid-Regulated Gene Expression in Bone

Molecular Mechanisms of Glucocorticoid Action

At the molecular level, glucocorticoids alter the expression of a wide variety of genes in osteoblastic cells, including those for structural proteins, growth factors, receptors, and enzymes. Glucocorticoids elicit biological responses in their target cells by binding to and activating the intracellular glucocorticoid receptor. The structure and function of the glucocorticoid receptor, its intracellular trafficking, and glucocorticoid receptor-dependent transcription are discussed in detail in many excellent reviews (Beato *et al.,* 1995, 1996; McKay *et al.,* 1999; Webster *et al.,* 1999; Defranco, 2000). The glucocorticoid receptor is a modular protein containing an amino-terminal domain that encodes a transactivation function and a carboxyl-terminal domain that specifies ligand binding, dimerization, heat shock protein (HSP) binding, and transactivation functions. The most highly conserved region is the 66 amino acid DNA-binding domain consisting of two zinc finger motifs with cysteine residues that are coordinated with zinc atoms (Freedman *et al.,* 1988). Unligated glucocorticoid receptors are found in the cytoplasm in association with a variety of molecular chaperone proteins, including hsp90, an FK506-binding immunophilin protein, and p23 (Cheung *et al.,* 2000; Defranco, 2000). Upon hormone binding, a conformational change enables the receptor to translocate to the nucleus, dimerize, and bind to DNA. Transcriptional activation by a glucocorticoid receptor homodimer occurs when the DNA-binding domains interact with a glucocorticoid response element (GRE). The GRE consensus sequence is GGTACAnnnTGTTCT (Beato, 1989). Transcriptional activation involves protein–protein interactions between the receptor dimer and basal transcription factors and RNA polymerase II (Mitchell and Tijan, 1989). Glucocorticoid-dependent inhibition of gene expression has become a molecular paradigm for understanding mechanisms of transcriptional repression by steroid hormone receptors (Webster *et al.,* 1999). Transcriptional repression by glucocorticoid receptors occurs by direct interaction with DNA through negative GREs (Sakai *et al.,* 1988), by blocking the access of positive transcription factors to DNA sequences (Akerblom *et al.,* 1988), and by protein–protein interaction with transcription factors (Chatterjee *et al.,* 1991). An example of the latter mechanism is glucocorticoid

inhibition of collagenase expression, which is thought to occur by interaction of the glucocorticoid receptor with the AP-1 transcription factor complex (Jonat *et al.,* 1990; Schule *et al.,* 1990; Yang-Yen *et al.,* 1990).

Effects on Gene Expression

PROTOONCOGENES AND TRANSCRIPTION FACTORS

Glucocorticoids cause a rapid and transient increase in the mRNA levels of c-fos (Birek *et al.,* 1991; Shalhoub *et al.,* 1992; Subramaniam *et al.,* 1992) and c-myc (Subramaniam *et al.,* 1992) in human and rodent osteoblastic cells and chick periosteal cultures. The rat c-fos promoter contains a putative GRE that may mediate glucocorticoid-dependent induction (Wang *et al.,* 1994). Cell lines prepared from tumors of c-fos transgenic mice show changes in osteoblast phenotypic markers but have unaltered glucocorticoid responsiveness (Grigoriadis *et al.,* 1993). The role that protooncogene induction plays in glucocorticoid-mediated gene expression is unknown, although it may represent an example of cross-talk between signal transduction pathways. The induction of protooncogenes may be a primary event in the regulation of downstream genes such as those that encode growth factors and matrix proteins. Id (inhibitor of differentiation) is a member of the helix-loop-helix (HLH) family of transcription factors that binds to other HLH factors and suppresses differentiation (Benezea *et al.,* 1990). Id mRNA is detectable in early cultures of MC3T3-E1 cells and then decreases as the cells differentiate (Ogata *et al.,* 1993). Dexamethasone maintains the high levels of Id mRNA in confluent MC3T3-E1 cells (Ogata *et al.,* 1993).

TYPE I COLLAGEN

Type I collagen is the most abundant protein in the bone matrix and its expression is regulated by a wide variety of hormones, growth factors, and cytokines (Raisz, 1988). Glucocorticoids decrease α1(I) collagen (Col1a1) mRNA levels in osteoblastic cells and calvarial organ cultures (Kim *et al.,* 1989; Kream *et al.,* 1990a; Lukert *et al.,* 1991; Delany *et al.,* 1995a) and in calvariae of neonatal mice given *in vivo* dexa-methasone (Advani *et al.,* 1997). Glucocorticoid down-regulation of Col1a1 mRNA occurs by an inhibition of Col1a1 transcription and a decrease in the stability of Col1a1 mRNA (Delany *et al.,* 1995a). Dexamethasone decreases the activity of transfected Col1a1 mRNA promoter–reporter constructs in stably transfected osteoblastic cells, indicating a transcriptional effect (Petersen *et al.,* 1991). The precise molecular mechanisms by which glucocorticoids inhibit Col1a1 transcription in osteoblastic cells have not been elucidated. However, studies performed in fibroblasts provide mechanistic clues. Glucocorticoids decrease type I collagen mRNA levels in fibroblasts by decreasing the transcription of collagen genes and the stability of collagen mRNA (Hamalainen *et al.,* 1985; Cockayne *et al.,* 1986; Raghow *et al.,* 1986). Glucocorticoids also decrease Col1a1 mRNA stability by affecting protein binding to 3′ UTRs (Määttä *et al.,* 1993). Glucocorticoids decrease the activity of transfected mouse α2(I) collagen (Col1a2) promoter–reporter constructs in fibroblasts through sequences from −2048 to −981 bp and from −506 to −351 bp (Perez *et al.,* 1992). In stably transfected fetal skin fibroblasts, the inhibitory effect of dexamethasone on rat Col1a1 promoter activity is maintained when the promoter is deleted to −900 bp. This region contains a putative GRE half-site; however, a mutation of this site does not block glucocorticoid-dependent inhibition of Col1a1 promoter activity (Meisler *et al.,* 1995). In this study, it was suggested that glucocorticoids decrease Col1a1 transcription in fibroblasts by acting at a TGFβ responsive site (Meisler *et al.,* 1995).

NONCOLLAGEN PROTEINS OF BONE

Glucocorticoids alter the expression of a variety of noncollagenous structural proteins in bone. *In vivo* glucocorticoid treatment of rats and mice decreases osteocalcin mRNA levels in bone (Ikeda *et al.,* 1992; Advani *et al.,* 1997). Acute treatment of osteoblastic cell cultures with glucocorticoids inhibits basal and agonist-induced osteocalcin production and mRNA levels (Wong *et al.,* 1990; Schepmoes *et al.,* 1991). Glucocorticoids inhibit $1,25(OH)_2D$-mediated osteocalcin transcription (Morrison *et al.,* 1989). It has been proposed that this occurs by binding of the glucocorticoid receptor the TATA box in the proximal promoter region of the osteocalcin gene (Stromstedt *et al.,* 1991; Meyer *et al.,* 1997). Glucocorticoids may also modulate other cell-specific factors that control osteocalcin transcription (Morrison *et al.,* 1993).

Glucocorticoids increase alkaline phosphatase activity and mRNA levels in human osteoblastic cells (Subramaniam *et al.,* 1992), SaOS-2 osteosarcoma cells (Murray *et al.,* 1987), and ROS 17/2.8 cells (Majeska *et al.,* 1985). Glucocorticoids increase alkaline phosphatase mRNA levels in ROS 17/2.8 cells; the increase in mRNA occurred after a lag period of 12 hr and is blocked by cycloheximide, indicating the requirement for new protein synthesis (Green *et al.,* 1990). Actinomycin D does not block the stimulatory effect of glucocorticoids on alkaline phosphatase mRNA levels, indicating transcriptional regulation (Green *et al.,* 1990). Osteoblasts synthesize the bone/liver/kidney/placenta form of alkaline phosphatase; this gene contains two alternative promoters spaced 25 kb apart; baseline and glucocorticoid-stimulated alkaline phosphatase mRNA in calvariae and ROS 17/2.8 cells is transcribed from the upstream promoter (Zernick *et al.,* 1991).

Bone sialoprotein is a glycoprotein containing an arginine-glycine-aspartic acid (RGD) sequence that mediates the attachment of cells to extracellular matrix proteins. Glucocorticoids increase bone sialoprotein mRNA levels in fetal rat calvarial, bone marrow, ROS 17/2.8, and UMR-106–06 cells in part by a transcriptional mechanism (Ogata *et al.,* 1995). The bone sialoprotein promoter contains a GRE between −906 and −931 bp that may mediate this transcriptional effect of glucocorticoids (Ogata *et al.,* 1995). There have been few studies examining the direct effect of

glucocorticoids on the expression of osteonectin, an abundant noncollagenous glycoprotein that may have a role in mineralization. In one study, dexamethasone increased osteonectin mRNA levels and the activity of an osteonectin promoter–reporter construct in preosteoblastic UMR 201 cells (Ng *et al.,* 1989).

Gluococorticoids decrease fibronectin (Gronowicz *et al.,* 1991) and β1 integrin (Doherty *et al.,* 1995) mRNA levels in fetal rat parietal bone organ cultures. The inhibitory effect on β1 integrin expression is accompanied by a disruption of osteoblast organization on the bone surface and a decrease in calcification of the bone (DiPersio *et al.,* 1991). In primary rat osteoblastic cells and ROS 17/2.8 cells, glucocorticoids decrease plasma membrane β1-integrin staining, adhesion of the cells to bone matrix proteins, and β1 integrin mRNA levels (Gronowicz *et al.,* 1995). Glucocorticoids decrease the expression of cells containing the α2 and α4 integrin subunits in bone marrow stromal cultures (Walsh *et al.,* 2001).

Glucocorticoids decrease interstitial collagenase mRNA levels in human skin fibroblasts by reducing the half-life of collagenase mRNA (Delany *et al.,* 1992). In contrast, glucocorticoids increase the expression of collagenase mRNA in rat osteoblastic cells (Shalhoub *et al.,* 1992; Delany *et al.,* 1995b) by a mechanism that involves increased collagenase mRNA stability (Delany *et al.,* 1995b). In addition, cortisol antagonized the phorbol ester-mediated increase in activity of a transiently transfected rat collagenase promoter–reporter construct (Delany *et al.,* 1995b). Glucocorticoid induction of interstitial collagenase expression in osteoblasts may be related to biological activities, such as growth factor activation, or the activation of osteoclastic bone resorption (Delany *et al.,* 1995b).

Growth Factor Systems

IGF-1 is an important anabolic growth factor for bone (Rosen *et al.,* 1999). It has been suggested that the inhibitory effects of glucocorticoids on bone formation may be due in part to a decrease in the production of IGF-1 (McCarthy *et al.,* 1990). Glucocorticoids decrease IGF-1 mRNA expression in rat tibia, organ cultures of fetal rat calvariae, and primary osteoblastic cell cultures (Luo *et al.,* 1989; McCarthy *et al.,* 1990; Chen *et al.,* 1991). However, glucocorticoids do not regulate IGF-II mRNA levels in primary rat osteoblastic cells (McCarthy *et al.,* 1992), but they decrease IGF-II peptide production in fetal rat calvarial cultures (Canalis *et al.,* 1991). Inhibitory effects of glucocorticoids on bone formation persist when IGFBP-2 is added to cultures of fetal rat calvariae to inactivate IGFs (Kream *et al.,* 1997). Moreover, calvariae from mice with a complete ablation of the Igf1 gene maintain responsiveness to glucocorticoids (Woitge *et al.,* 2000). These studies suggest that inhibitory effects of glucocorticoids are partly independent of the IGF-1 pathway.

IGFBPs regulate the storage, transport, and bioactivities of IGFs (Clemmons *et al.,* 1993). Six IGFBPs, termed IGFBP-1 through -6, have been identified in a variety of tissues (Shimasaki *et al.,* 1991). The expression of IGFBPs in osteoblastic cells of different origins is cell line specific (Hassager *et al.,* 1992). IGFBPs generally inhibit IGF-1 action *in vitro* (Mohan *et al.,* 1989; Feyen *et al.,* 1991), except for IGFBP-5, which may act as an anabolic growth factor (Andress *et al.,* 1992; Miyakoshi *et al.,* 2001). Glucocorticoids decrease IGFBP-3, -4, and -5 production in normal human osteoblastic cells (Okazaki *et al.,* 1994) and decrease IGFBP-3 production in transformed osteoblastic cell lines (Nakao *et al.,* 1994). Glucocorticoids decrease IGFBP-5 transcription in rat osteoblasts (Gabbitas *et al.,* 1996b) and decrease IGFBP-2 production in rat calvarial osteoblastic cells (Chen *et al.,* 1991) and immortalized rat osteoblastic PyMS cells (Schmid *et al.,* 1988). However, glucocorticoids increase the expression of IGFBP-6 in fetal rat calvarial cell cultures (Gabbitas *et al.,* 1996a). Because IGFBP-6 has higher affinity for IGF-2 than IGF-1, glucocorticoid stimulation of IGFBP-6 may limit the availability of IGF-2 as an anabolic agent (Gabbitas *et al.,* 1996a). Because glucocorticoids decrease IGF-1 production in bone, the inhibitory effect of glucocorticoids on IGFBP expression may provide a mechanism by which osteoblastic cells are more responsive to the residual pool of IGF-1. Alternatively, downregulation of IGFBP-5 production could represent the removal of an anabolic factor and result in part in the inhibitory effects of glucocorticoids. Glucocorticoids alter the expression of other growth factor systems in cultured fetal rat calvarial osteoblasts, such as mac25 (IGFBP-related peptide), connective tissues growth factor, and hepatocyte growth factor and its receptor c-met (Pereira *et al.,* 1999, 2000; Blanquaert *et al.,* 2000). As of yet, the role of these factors in mediating glucocorticoid responses in bone is not known.

TGFβ is anabolic for bone formation and is either stimulatory or inhibitory for bone resorption depending on the experimental model and the culture conditions (Centrella *et al.,* 1994). TGFβ binds to three cell surface receptors, termed TGFβRI, II, and III, which are expressed in osteoblastic cells (Centrella *et al.,* 1991). Type I and II receptors are thought to mediate TGFβ signaling (Massague, 1992); the type III receptor, β-glycan, is a cell surface proteoglycan that is more abundant than type I and II receptors but has lower affinity for TGFβ1 (Lopez-Casillas *et al.,* 1993). Glucocorticoids modify the expression of molecules in the TGFβ pathway (McCarthy *et al.,* 2000a). Glucocorticoids decrease the stimulatory effects of TGFβ1 on DNA synthesis and collagen synthesis in fetal rat osteoblastic cells and increase the binding of TGFβ1 to β-glycan in primary cultures of fetal rat osteoblastic cells (Centrella *et al.,* 1991). Dexamethasone increases β-glycan mRNA levels in immortalized MC3T3-E1 and RCT1 osteoblastic cells (Nakayama *et al.,* 1994). If the function of β-glycan were to decrease the amount of TGFβ available for signaling, these effects of glucocorticoids would reduce the anabolic effects of TGFβ1 on osteoblastic cells. In fetal rat osteoblasts, glucocorticoids suppress Cbfa1 expression, which is associated with a decrease in the expression and activity of the TGFβRI (Chang *et al.,* 1998).

Plasminogen activator is a serine protease that activates plasminogen to the serine protease plasmin. The plasminogen activator–plasmin system may have a role in bone resorption by activating latent collagenase or TGFβ (Hamilton *et al.,* 1985). Glucocorticoids decrease plasminogen activator activity in normal rodent osteoblasts and UMR-106–01 cells (Hamilton *et al.,* 1985); this is due primarily to an increase in plasminogen activator inhibitor-1 mRNA and protein level (Fukumoto *et al.,* 1992). Glucocorticoid inhibition of plasminogen activator activity, therefore, might limit the activation of locally produced TGFβ, leading to a decrease in bone formation (Fukumoto *et al.,* 1992). However, glucocorticoids enhance the activation of latent TGFβ1 in normal human osteoblastic cells without an alteration of TGFβ1 mRNA levels (Oursler *et al.,* 1993). Such an effect of glucocorticoids might be expected to increase the availability of TGFβ as an anabolic bone growth factor; alternatively, enhanced TGFβ activation might lead to increased bone resorption. Taken together, the effect of glucocorticoids on TGFβ activity in bone may result from a combination of the actions described previously.

PROSTAGLANDINS

Prostaglandins are produced by bone cells and can affect both bone formation and resorption. Prostaglandins directly inhibit the activity of isolated osteoclasts (Fuller *et al.,* 1989) but increase bone resorption by increasing the formation of new osteoclasts (Dietrich *et al.,* 1975). Prostaglandins have both stimulatory and inhibitory effects on bone formation in organ cultures of rodent calvariae, depending on the dose and hormonal milieu that is used (Raisz *et al.,* 1990). Glucocorticoids decrease baseline and agonist-induced prostaglandin production in bone (Klein-Nulend *et al.,* 1991; Marusic *et al.,* 1991; Hughes-Fulford *et al.,* 1992). The mechanisms for this inhibition likely include both a decrease in arachidonic release from membranes and a decrease in the expression of the cyclooxygenases that convert arachidonic acid to prostaglandins. Osteoblasts express two cyclooxygenases, the constitutive prostaglandin synthase-1 (PGHS-1) and the inducible prostaglandin synthase-2 (PGHS-2) (Pilbeam *et al.,* 1993; Kawaguchi *et al.,* 1995). Endogenous glucocorticoids tonically suppress PGHS-2 in mice, and this suppression is relieved when the animals are adrenalectomized (Masferrer *et al.,* 1992). The induction of PGHS-2 by interleukin-1 and PTH in mouse calvariae and by serum in MC3T3-E1 cells is antagonized by glucocorticoids (Kawaguchi *et al.,* 1994). In summary, glucocorticoid inhibition of prostaglandin production in bone occurs primarily by a decrease in agonist-induced PGHS-2 expression.

Summary and Conclusions

A variety of *in vitro* models have been developed to examine the direct effects of glucocorticoids on bone formation and resorption. These experiments show that glucocorticoids have diverse and complex direct effects on bone and can modify the expression of a wide variety of genes in osteoblastic cells. It is likely that the experimental outcomes in different models are affected by the concentration of glucocorticoid used, the timing of glucocorticoid addition, the presence of serum and growth factors, the developmental stage of the model, and species differences. However, several general principles can be drawn from these studies. Glucocorticoids can either stimulate or inhibit bone formation *in vitro* and these effects depend on the developmental stage of the model. Low concentrations of glucocorticoids are permissive for hormone action in bone (allowing other hormones to have optimal activity) and are associated with increased osteoblastic differentiation and bone formation. The daily secretion of physiologic concentrations of cortisol may render osteoblasts and/or osteoprogenitor cells highly responsive to the effects of systemic and locally produced hormones. The ability of glucocorticoids to enhance the activity of some anabolic hormones may represent a compensatory response, which helps maintain bone mass during periods of diminished growth factor supply. A challenge will be to develop models that test the hypothesis that physiological glucocorticoids are required for bone formation and maintenance of the osteoblast phenotype *in vivo*. Pharmacological doses of glucocorticoids suppress bone formation by inhibiting osteoprogenitor proliferation, osteoblast renewal, and osteoblast function and by increasing osteoblast apoptosis. Understanding the molecular events that lead to the suppression of bone formation will enable the development of effective therapeutic modalities for glucocorticoid-induced osteoporosis.

CHAPTER 42

Effects of Diabetes and Insulin on Bone Physiology

Johan Verhaeghe[*,†] **and Roger Bouillon**[*]

[*]*Laboratorium voor Experimentele Geneeskunde en Endocrinologie and* [†]*Department of Obstetrics and Gynaecology, Katholieke Universiteit Leuven, 3000 Leuvren, Belgium*

Introduction

The liver, the skeletal muscles, and the adipose tissue are the main insulin-responsive tissues, yet insulin also influences the physiology of other tissues, including cartilage and bone. In conditions of hypoinsulinemia (e.g., type 1 diabetes) or hyperinsulinemia with or without glucose intolerance or fasting hyperglycemia (type 2 diabetes), endochondral bone growth and bone (re)modeling show significant alterations.

Type 1 diabetes is caused by pancreatic β-cell destruction (mostly immune mediated, or otherwise idiopathic), usually leading to absolute insulin deficiency. Type 2 diabetes is the most prevalent form of diabetes; its pathophysiology is heterogeneous, ranging from predominantly insulin resistance (i.e., at any of the main insulin-responsive tissues) with relative insulin deficiency to a predominantly insulin secretory defect with variable insulin resistance. Hence, insulin levels in type 2 diabetes vary widely, anywhere between hyper- and hypoinsulinemia. Most patients with type 2 diabetes are obese, and obesity itself causes some degree of insulin resistance. Other types of diabetes will not be considered herein.

Effect of Diabetes and Insulin on Endochondral Bone Growth

Type 1 Diabetes and Skeletal Growth and Maturation in Humans

At onset of type 1 diabetes, there is no difference in height compared with nondiabetic children; in fact, some, but not all, studies have documented that children are slightly taller at the onset of diabetes compared with reference values (Pond, 1970; Holl *et al.,* 1998).

However, growth is affected after the diagnosis of diabetes. In the preinsulin era, growth virtually stopped after the onset of diabetes in prepubertal or pubertal children, and stunted growth remained common in later decades of irregular insulin treatment (Pond, 1970). Even in the 1990s, the majority of studies document a slight reduction in growth velocity on the basis of height SDS or *Z* scores. This effect is more marked in type 1 diabetes with prepubertal than with pubertal onset (Holl *et al.,* 1998). The main predictor of reduction in growth velocity is the level of glycemic control, and glycohemoglobin levels—a reflection of glycemic control in the previous 2–3 months—correlate inversely with height velocity (Danne *et al.,* 1997; Holl *et al.,* 1998). In one recent cohort, final height was found to be reduced by a median of 0.5 SDS (2–3 cm) (Danne *et al.,* 1997).

At diagnosis, bone age—determined by radiographs of hand and wrist—is not different in diabetic and nondiabetic children (Holl *et al.,* 1994; Danne *et al.,* 1997). However, there is a small, but significant, retardation of bone age with increasing diabetes duration: the difference between chronological and bone age equals 1 year after a mean diabetes duration of 11 years (Holl *et al.,* 1994).

Skeletal Growth in Diabetic Experimental Animals

The effect of diabetes on bone growth has been examined in BB (Bio-Breeding) rats with spontaneous immune-mediated diabetes and in rats that received an injection of a diabetogenic drug such as alloxan or, more commonly,

Table I Histomorphometric Data from Proximal Tibial Metaphysis in Untreated and Insulin-Treated Male Spontaneously Diabetic BB Rats[a]

[a]From Verhaeghe *et al.* (1992), with permission of the Journal of Endocrinology Ltd. Measurements were performed about 4 weeks after onset of diabetes in diabetic rats and in nondiabetic littermates. Insulin-treated rats were treated with 3 U/day of insulin, infused sc with a miniosmotic pump for 14 days. Data are expressed as means (SEM). Statistical analysis:*, versus nondiabetic rats ($^{*}P < 0.05$, $^{**}P < 0.01$, $^{***}P < 0.001$);†, versus diabetic rats ($^{\dagger}P < 0.05$, $^{\ddagger}P < 0.001$).

streptozotocin (SZ). Spontaneously diabetic BB rats in our colony develop diabetes at a mean age of 13 weeks (Verhaeghe *et al.,* 2000), which is past the peak growth rate (week 7) in rats (Locatto *et al.,* 1993). Insulin levels in BB rats are very low or undetectable.

In rats in which diabetes is drug-induced at an early age, long bones such as the femur are shorter after 4 weeks of diabetes (Lucas, 1987). Growth plate width as well as endochondral bone growth—assessed by double fluorochrome labeling of the calcifying cartilage—of the proximal tibia are markedly lower in untreated diabetic rats, which is corrected by insulin treatment (Bain *et al.,* 1997; Epstein *et al.,* 1994; Scheiwiller *et al.,* 1986; Verhaeghe *et al.,* 1992) (Table I). Cartilage activity, assessed by the incorporation of [^{35}S]sulfate ($^{35}SO_4$) into proteoglycans, is reduced robustly in growth plate explants from diabetic rats as well as in demineralized bone particles implanted into diabetic rats, which again is reversed by insulin treatment (Axelsson *et al.,* 1983).

The effect of insulin on bone growth could be direct or indirect; the latter could be the result of normalizing hepatic production and circulating levels of insulin-like growth factor-I (IGF-I). Although one study reported that recombinant human IGF-I partly normalized growth plate width in diabetic rats (Scheiwiller *et al.,* 1986), this finding was not confirmed in other studies (Verhaeghe *et al.,* 1992). Kelley *et al.* (1993) confirmed that the low $^{35}SO_4$ uptake by rib cartilage explants from diabetic rats is unresponsive to recombinant bovine IGF-I administration; however, this unresponsiveness is restored by hypophysectomy, implying that a pituitary hormone-dependent factor induces IGF-I resistance in diabetic cartilage.

Effects of Insulin on Cartilage in Nondiabetic Animal Models and *in Vitro*

The classic experiments of Salter and Best (1953) demonstrated that insulin treatment increases growth plate width in hypophysectomized rats. Subsequent data by Heinze *et al.* (1989) confirmed that the administration of insulin to hypophysectomized rats increases body length, growth plate width of the proximal tibia, and $^{35}SO_4$ incorporation into rib cartilage. This is a local effect of insulin because insulin injection into the proximal tibia growth plate (Heinze *et al.,* 1989) or insulin infusion into one hindlimb (Alarid *et al.,* 1992) produces exclusive widening of the treated growth plates. The direct effect of insulin on the growth plate appears to be mediated by the *in situ* production of IGF-I: IGF-I is present on immunohistochemistry in hypertrophic chondrocytes of the insulin-treated growth plates only, and the effect of insulin on the growth plate is abolished by coinfusion of an IGF-I antibody (Alarid *et al.,* 1992).

In vitro studies have documented the presence of insulin receptors in a chondrosarcoma cell line (Foley *et al.,* 1982). Chondrocyte proliferation and $^{35}SO_4$ incorporation have been shown to be stimulated by insulin in a number of *in vitro* systems: organ and tissue cultures of neonatal mouse mandibular condyles (Maor *et al.,* 1993) and chondrocyte cultures from rat chondrosarcoma, rat rib cartilage, or fetal lamb growth plate cartilage (Foley *et al.,* 1982; Heinze *et al.,* 1989; Hill and De Sousa, 1990). These effects are obtained at physiological levels of insulin, as low as 1 n*M* (Hill and De Sousa, 1990). Proinsulin is only 3% as potent as insulin (Foley *et al.,* 1982), but equimolar IGF-I is more potent than insulin (Hill and De Sousa, 1990). Several data suggest that insulin stimulates chondrocyte proliferation and activity through its own receptor, not through the type 1 IGF receptor: (1) the effects of insulin and IGF-I on chondrocyte proliferation are additive (Maor *et al.,* 1993; Hill and De Sousa, 1990); (2) the stimulation of $^{35}SO_4$ incorporation by insulin is blocked by an insulin receptor antibody (Foley *et al.,* 1982); and (3) the stimulation of $^{35}SO_4$ is not affected by cotreatment with an antiserum against the type 1 IGF receptor (Maor *et al.,* 1993).

Conclusions on Effects of Diabetes and Insulin on Bone Growth

Insulin-deficient states are accompanied by stunted growth. Insulin stimulates the proliferation and metabolic activity of chondrocytes *in vitro,* as well as in insulin-deficient

and pituitary hormone-deficient conditions *in vivo.* This effect occurs at physiological insulin levels, presumably through interaction with the insulin receptor. The effect of insulin appears to be mediated by the local production of IGF-I in growth cartilage.

Effects of Diabetes and Insulin on Bone Remodeling, Bone Mass, and Bone Strength in Humans

Introductory Remarks

Published data on bone markers, bone mass, and bone strength in diabetic subjects are not infrequently difficult to interpret, for several reasons. The first problem pertains to the study subjects: (1) series often consist of a "mixed bag" of diabetic subjects (female and male, type 1 and type 2), with widely different diabetes duration and degree of long-term glycemic control; (2) the study population may include a variable proportion of subjects with diabetes complications such as retinopathy, neuropathy, or atherosclerotic disease, conditions that may limit physical activity and capabilities; and (3) diabetic subjects frequently take multiple medications, which may influence bone density and fracture risk, as has been shown for statins (Chung *et al.,* 2000). Second, diabetes may alter the reliability of bone and mineral measurements: (1) because diabetes affects bone size, areal bone mineral density (BMD) measurements may need to be adjusted; (2) the measurement of serum total alkaline phosphatase is meaningless in diabetic subjects because of overproduction of the intestinal and possibly the hepatic isoenzyme (Tibi *et al.,* 1988; Bouillon *et al.,* 1995); and (3) changes in collagen metabolism in tissues other than bone may interfere with the measurement of the excretion of collagen breakdown products, particularly hydroxyproline or pyridinoline cross-links, and reduce their usefulness as markers of bone resorption.

Type 1 Diabetes and Bone Remodeling

Formal bone histomorphometry data are lacking, but the measurement of biochemical markers of bone formation produces unequivocal evidence that bone formation is decreased. We found that serum osteocalcin concentrations are 24–28% lower in diabetic children, adolescents, and adults compared to age- and gender-matched nondiabetic subjects (Fig. 1) (Bouillon *et al.,* 1995). In the same study, serum levels of bone-specific alkaline phosphatase were decreased by 24% in diabetic adolescents, but there was no change in diabetic adults. Serum levels of PICP (procollagen carboxy-terminal extension peptide) were unchanged, however. Interestingly, serum osteocalcin levels were found to be below the control range at diagnosis of diabetes in 31 children aged 2–13 years and subsequently reverted to within the control range after 15 days of intensive insulin treatment; osteocalcin levels were correlated negatively with glycohemoglobin levels (Guarneri *et al.,* 1993). Again, PICP levels were unchanged at diagnosis of type 1 diabetes in prepubertal children (Bonfanti *et al.,* 1997).

Regarding bone resorption, plasma ICTP (collagen type I C-terminal telopeptide) levels were found to be normal at onset of diabetes (Bonfanti *et al.,* 1997). Urinary-free deoxypyridinoline cross-links (D-PYR) were measured by a commercial ELISA kit in 18 diabetic adolescents aged 12–17 years and compared with 69 nondiabetic adolescents of the same age group: D-PYR/creatinine levels were

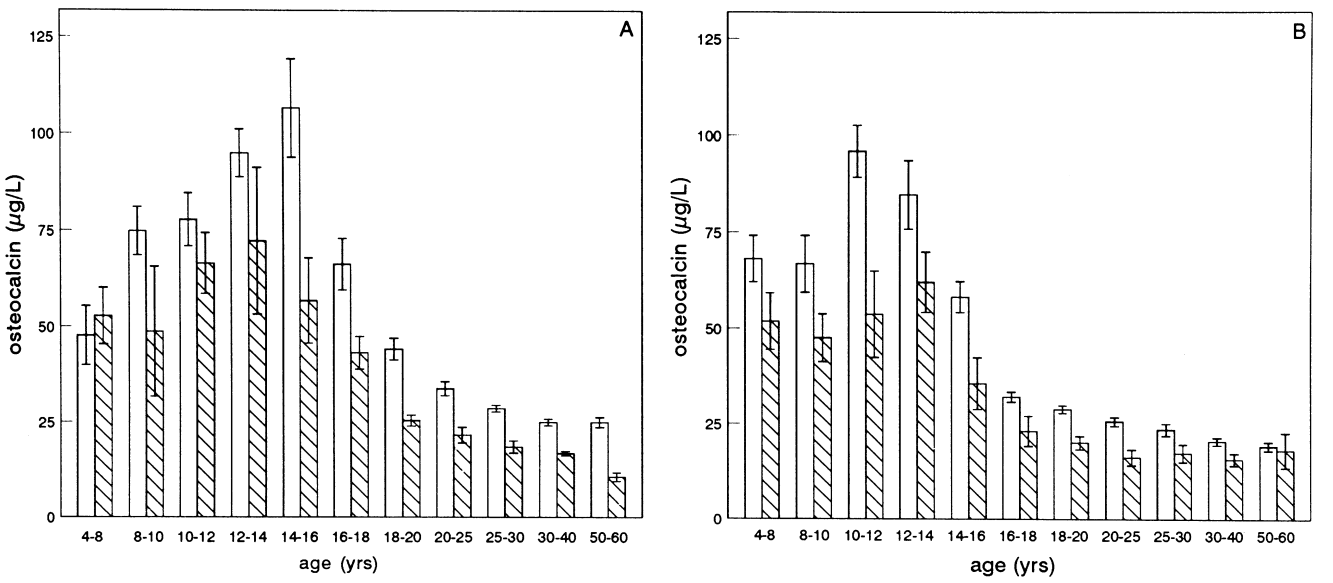

Figure 1 Serum osteocalcin concentrations in normal individuals (open bars) and individuals with type 1 diabetes (hatched bars): (A) male and (B) female. Data are presented as means ±SEM. Multiple regression analysis showed a positive correlation between age and serum osteocalcin levels below 16 and 12 years for boys and girls, respectively, and a negative correlation above those ages ($p < 0.001$). A significant ($p < 0.005$) decreasing effect of diabetes on serum osteocalcin was observed for both genders. From Bouillon *et al.* (1995), with permission. ©The Endocrine Society.

slightly ($p < 0.05$) higher in the diabetic group (Bjorgaas *et al.,* 1999). In contrast, total and free D-PYR excretion, measured by high-performance liquid chromatography (HPLC), were reported to be lower in a rather unspecified group of 84 adult type 1 diabetics compared with 99 adult controls, and the decrease was proportional to the level of glycosuria (Cloos *et al.,* 1998).

Type 2 Diabetes and Bone Remodeling

Bone formation is also dampened in type 2 diabetes. In a small series of 8 diabetic subjects (aged 37–67 years, diabetic for 2–36 years), 6 of whom had type 2 diabetes, a bone biopsy was carried out because of a low BMD *Z* score at the radius; histomorphometry showed a significant decrease in the osteoid thickness and in the dynamic bone formation rate (Krakauer *et al.,* 1995). Measurement of biochemical markers indicates lower serum osteocalcin levels, even in the presence of fasting hyperinsulinemia (Montecucco *et al.,* 1990). In a group of 37 Pima Indians, 22 of whom had impaired glucose tolerance or type 2 diabetes, osteocalcin levels correlated inversely with the 2-hr glucose value during an oral glucose tolerance test (OGTT) (Bouillon *et al.,* 1995). Poor glycemic control in subjects with type 2 diabetes impairs the response of osteocalcin to administration of $1,25(OH)_2D_3$ (Inaba *et al.,* 1999), whereas improvement in glycemic control augments serum osteocalcin levels (Okazaki *et al.,* 1997; Rosato *et al.,* 1998).

Measurement of D-PYR by HPLC showed that urinary D-PYR is decreased comparably in a group of 58 type 2 diabetics as in type 1 diabetics (Cloos *et al.,* 1998). Improvement in glycemic control increased D-PYR excretion measured by HPLC in one study (Rosato *et al.,* 1997), but not in another study in which urinary D-PYR and the type I collagen carboxy-terminal telopeptide (CTx) were measured with commercial kits (Okazaki *et al.,* 1997).

In conclusion, type 1 and type 2 diabetes are characterized by decreased bone formation and mineralization, as was shown in histomorphometrical and biochemical studies. Methodological issues obscure the interpretation of bone resorption markers, and more work is needed in this regard, perhaps focusing on other markers of bone resorption than collagen breakdown products, such as the measurement of the osteoclast-specific tartrate-resistant acid phosphatase (TRAP) isoform.

Type 1 Diabetes and Bone Mass

The effect of type 1 diabetes on axial bone density has been investigated in several relatively small studies. Ponder *et al.* (1992) studied 25 girls and 31 boys with diabetes, aged between 5 and 18 years, and compared their lumbar spine BMD (assessed by dual-photon absorptiometry) with those of 221 nondiabetic children/adolescents of the same age group. The BMD *Z* score was not significantly different from controls in diabetic subjects, regardless of diabetes duration. In the same age group, Roe *et al.* (1991) measured BMD by quantitative computed tomography (QCT) at the lumbar vertebrae in 23 girls and 25 boys with type 1 diabetes (aged 5–19 years) and in a similar number of age- and gender-matched controls: they found a small decrease ($p < 0.02$) in cortical bone density in the diabetic group, but no difference in trabecular bone density. Gallacher *et al.* (1993) reported on 20 type 1 diabetic women (aged 23–42 years, diabetic for 2–22 years): compared with an age-matched control group of 27 women, lumbar spine BMD (assessed by dual-energy X-ray absorptiometry, DXA) was higher ($p = 0.02$) in the diabetic group. Olmos *et al.* (1994) found no difference in lumbar spine BMD, measured by DXA, between 94 type 1 diabetic subjects (of whom 50 women; aged 18–62 years, diabetic for 1–42 years) and an age-matched control group of 34 women and 30 men. More recent studies present BMD data as *Z* scores compared with reference values provided by the manufacturer or validated in a local population. The conclusion from these studies would be that type 1 diabetic subjects have a mean *Z* score below, but generally within 1 SD, reference values at the lumbar spine (Lunt *et al.,* 1998; Miazgowski and Czekalski, 1998; Rix *et al.,* 1999). In addition, this BMD deficit does not appear to deteriorate, as the BMD did not change over 2 years in 54 subjects with long-term diabetes (Miazgowski and Czekalsi, 1998); in another study, BMD actually increased ($p = 0.002$) over 2 years in a group of 15 subjects with type 1 diabetes aged <30 years at the first evaluation (Kayath *et al.,* 1998), suggesting that type 1 diabetes does not impede the attainment of peak axial bone density.

At the femoral neck, results are comparable with those found at the lumbar spine. Some studies found no difference between diabetic subjects and controls (Gallacher *et al.,* 1993), whereas others reported a small decrease compared with controls or reference values, with a mean *Z* score between 0 and −1.0 SD (Lunt *et al.,* 1998; Rix *et al.,* 1999). Again, there is no reduction of femoral neck BMD 2 years after the initial evaluation (Kayath *et al.,* 1998).

Bone density at the appendicular skeleton was assessed in earlier studies. The control population is not well described or validated in many of these studies. With this caveat in mind, some studies conclude that BMC and BMC/width on single-photon absorptiometry (SPA) of the forearm (midshaft or distal one-third) are about 10% lower in diabetic children, adolescents, and adults than in control populations; the same is true for the cortical area measured by radiogrammetry of the metacarpal bones (McNair *et al.,* 1978; Wiske *et al.,* 1982). There is no correlation between diabetes duration and BMC deficit, and BMC deficit can be measured within a few years after diagnosis (McNair *et al.,* 1978).

Sixteen subjects with type 1 diabetes were studied by SPA at the radius at age 51 ± 13 years (mean ± SD) and again 12.5 ± 0.5 years later: BMC/width *Z* score had not changed significantly (Krakauer *et al.,* 1995). QCT of the ultradistal radius in 21 diabetic children/adolescents (of whom 8 girls; aged 6–19 years; diabetes duration 0.8–18 years) showed that cortical bone density was not different from age- and gender-matched controls, but trabecular bone density was 19% lower ($p < 0.01$) in the diabetic group.

The effect of diabetic neuropathy was investigated by Rix *et al.* (1999), who compared 21 male type 1 diabetics [aged 57 ± 6 (mean ± SEM) years; mean diabetes duration 28 (range 9–59) years] with severe neuropathy with 21 gender-, age-, and diabetes duration-matched diabetics with mild or no neuropathy and 21 age-matched controls. Subjects with neuropathy had a lower BMD than reference values (*Z* score around −1.0 SD) and a lower BMD at the proximal femur than controls, as well as lower broadband attenuation on quantitative ultrasound (QUS) of the calcaneus compared with diabetics without neuropathy and with controls. Whether this is caused by reduced physical activity is unknown.

In conclusion, a mild decrease in the BMD at the lumbar spine, proximal femur, and distal forearm has been found in some, but not all, studies in type 1 diabetics. The difference is maximally 10% or 1 SD compared with age-matched control groups. This effect can be seen within a few years after diagnosis and is not progressive. We speculate that this mild decrease is due to decreased appositional growth during the early hypoinsulinemic phase of the disease. Neuropathy appears to aggravate the BMD deficit.

Hyperinsulinemia and Bone Mass

Hyperinsulinemia is a marker of insulin resistance, the central mechanism in the pathogenesis of type 2 diabetes. Two population-based studies have addressed the relationship between insulin levels and BMD: the large Rotterdam study (5931 individuals, aged at least 55 years, including 578 diabetics) and the smaller Rancho Bernardo study (970 individuals, aged 50–89 years, diabetics excluded). It was shown that age-adjusted BMD at the lumbar spine, proximal femur, and radius correlated with fasting or post-OGTT insulin levels and with serum glucose levels. Excluding subjects with diabetes does not change this conclusion, but adjusting for body mass index (BMI) and other potentially confounding factors does reduce the correlation, and significance is lost in subgroups of individuals (Barrett-Connor and Kritz-Silverstein, 1996; Stolk *et al.,* 1996). Further studies should disentangle the respective effects of body weight and insulin levels on BMD in elderly individuals without type 2 diabetes.

Type 2 Diabetes and Bone Mass

Meema and Meema (1967) measured the cortical thickness at the radius in aged (65–101 years) Caucasian women and found that women with type 2 diabetes (average duration: 9 years) had higher cortical thickness compared with nondiabetics. In the Study of Osteoporotic Fractures, a population-based study of 7664–9704 nonblack women aged 65 years or older, type 2 diabetes (prevalence: 6%) was a significant predictor of BMD at the radius and the femoral neck, but not at the lumbar spine: in multivariate analyses, type 2 diabetes was associated with a 4.8% [95% confidence intervals (CI), 2.2–7.3] increase in BMD at the radius and a 3.4% (CI, 1.3–5.6) increase in BMD at the femoral neck (Bauer *et al.,* 1993; Orwoll *et al.,* 1996). In the Rotterdam study, the BMD of 578 subjects with type 2 diabetes was significantly (3–4%) higher at the lumbar spine and the femoral neck than in 5353 nondiabetic subjects, even after multivariate adjustment (van Daele *et al.,* 1995). The BMD of type 2 diabetics was found to be correlated with fasting insulin levels and urinary C-peptide levels (Rishaug *et al.,* 1995; Wakasugi *et al.,* 1993), again suggesting a link between hyperinsulinemia and an increase in BMD. In line with this contention, the BMD of insulin-treated type 2 diabetics (presumably with impaired β-cell function) was not different from controls (van Daele *et al.,* 1995; Tuominen *et al.,* 1999). While it has been reported that the BMD at the lumbar spine correlates inversely with the duration of type 2 diabetes (Wakasugi *et al.,* 1993), others found a significant increase in BMD (increase in *Z* score of 0.09 ± 0.01 per year, mean ± SD) at the radius in 19 type 2 diabetics (mean age: 63 years) 12.5 years after the initial evaluation (Krakauer *et al.,* 1995). Future studies should link changes in BMD in type 2 diabetics with circulating insulin levels.

The different effect of type 1 and type 2 diabetes on BMD was confirmed by Tuominen *et al.* (1999), who studied subjects (aged 52–72 years) who developed diabetes after 30 years of age (i.e., after achievement of peak bone mass) and were insulin treated, but differed in their insulin secretory response (C-peptide levels after glucagon). Subjects with deficient insulin secretion (classified as type 1 diabetes) had a lower BMD at the proximal femur than subjects with normal insulin secretion (type 2 diabetes) or controls. After adjusting for age, BMI, and other factors, the difference was less significant but still demonstrable.

In conclusion, type 2 diabetes is associated with a small but significant increase in areal BMD as measured by DXA, even after adjustment for BMI and other variables. Hence, low bone turnover in type 2 diabetes does not cause bone loss (Krakauer *et al.,* 1995). There is inconclusive evidence at this time that hyperinsulinemia is a causal factor.

Type 1 and Type 2 Diabetes and Fractures

Several cohort studies have shown that diabetes is a risk factor for fractures. In a study from Norway, 35 to 49-year-old women and men (24,000 each) were followed for at least 10 years: a self-reported diagnosis of diabetes (prevalence: 0.49% of women and 0.74% of men) was a strong predictor of hip fractures. Indeed, multivariate analysis showed a relative risk (RR) of 9.2 (CI, 3.4–24.9) in women with diabetes and 9.4 (2.9–30.5) in men with diabetes (Meyer *et al.,* 1993). In another Norwegian cohort study, 27,986 individuals aged 50–74 years were followed for 9 years. The age-, BMI-, and smoking-adjusted RR of hip fracture was 6.9 (CI, 2.2–21.6) in women with type 1 diabetes (prevalence: 0.17%) and 4.5 (CI, 0.6–31.9) in men (prevalence: 0.21%). However, the significantly increased RR in diabetic women was lost after adjusting for impaired vision, physical inactivity, impaired motor abilities, and a history of stroke. Type 2 diabetes for more than 5 years was associated with a slightly increased RR

of hip fracture in women only (1.8, CI, 1.1–2.9), which again was lost after adjusting for the factors mentioned earlier (Forsén *et al.,* 1999).

In the Study of Osteoporotic Fractures, insulin-treated diabetes (presumably type 2 diabetes in most women) was a strong predictor for fractures of the proximal humerus in multivariate analysis with a RR of 3.8 (CI, 1.2–12.4), during 2.2 years of follow-up (Kelsey *et al.,* 1992); there was no effect on distal forearm fractures, however. In the lower limbs, insulin-treated diabetes was an independent predictor of foot fractures, with a RR of 2.9 (CI, 1.2–7.2), during 5.9 years of follow-up; there was no significant effect on ankle fractures (Seeley *et al.,* 1996). In a subsequent analysis specifically studying the effect of type 2 diabetes on fractures, the risk of any nonspine fracture was found to be increased in diabetic women, particularly in diabetic women treated with insulin: the RR of nonspine fractures was 1.3 (CI, 1.1–1.6) in women not treated with insulin and 1.9 (CI, 1.3–2.8) in insulin-treated women (Schwartz *et al.,* 1999).

In the Rotterdam study, however, type 2 diabetes was not associated with an increased self-reported risk of nonspine fractures in the preceding 5 years; in fact, the RR was decreased (0.63, CI, 0.44–0.90) in women with type 2 diabetes (van Daele *et al.,* 1995).

Neuropathy is a predisposing factor for fractures: in a series of diabetic individuals (both type 1 and type 2, aged 50–73 years), foot fractures were detected radiographically in 12 of 54 (22%) subjects with a history of foot ulcers, but only in 3/83 subjects either without neuropathy or with neuropathy but no history of foot ulcers (Cavanagh *et al.,* 1994).

It is well known that diabetes can delay the healing of fractures (Loder, 1988). By analogy, it has been postulated that diabetes may impair the healing of fatigue microfractures (also called microdamage or microcracks) in load-bearing bones because of low bone formation and may thereby ultimately lead to overt fractures (Krakauer *et al.,* 1995). This interesting hypothesis has yet to be tested.

In conclusion, diabetes is an independent risk factor for the occurrence of nonspine fractures in the majority of studies. Type 1 diabetes appears to be associated with a stronger risk than type 2 diabetes, and neuropathy is an additional risk factor. Whether this is due to decreased intrinsic bone strength and/or an increased propensity to fall is uncertain at this time.

Diabetic Nephropathy and Bone

Several histomorphometric studies show that parameters of bone formation and resorption are lower in diabetic than in nondiabetic patients with chronic renal failure, and thus that mild or aplastic renal osteodystrophy is more prevalent in diabetics whereas high-turnover osteodystrophy is rare (Pei *et al.,* 1993, and references therein). Bone formation parameters were also found to be lower in 5/6 nephrectomized rats with SZ-induced diabetes compared with nondiabetic rats (Jara *et al.,* 1995).

Diabetic patients with chronic renal failure also have less Tc-99m methylenediphosphonate uptake on bone scintigraphy, confirming reduced osteoblastic activity; bone scans are, therefore, unreliable as a diagnostic method for renal osteodystrophy in diabetic subjects (So *et al.,* 1998). Importantly, diabetes was found to be the most significant predictor of fracture after renal transplantation; in a series of 193 transplant patients (of whom 35 had diabetes), followed for 6 months to 23 years, 40% of diabetics sustained at least one fracture, predominantly in ankles and feet, compared with 11% in nondiabetics (Nisbeth *et al.,* 1999). In another series of 35 kidney–pancreas transplant recipients, the 5-year fracture-free rate was only 48%; the cumulative steroid, but not cyclosporine, exposure was a significant predictor of fractures in this group (Chiu *et al.,* 1998). This confirms data in SZ diabetic rats that bone volume and bone remodeling parameters are unaffected by cyclosporine treatment (Epstein *et al.,* 1994).

The Effect of Diabetes and Insulin on Bone (Re)modeling, Bone Mass, and Bone Strength in Experimental Animals *in Vivo*

Effect of Insulin on Bone in Nondiabetic Animal Models

Significant *in vivo* insulin binding has been detected by autoradiography in osteoblasts, but not in osteocytes (Martineau-Doizé *et al.,* 1986). Cornish *et al.* (1996) injected human insulin over the periosteum of one hemicalvarium of normal adult mice for 5 days. In the insulin-injected hemicalvaria, histomorphometric parameters indicated a stimulation of bone formation (osteoblast number/perimeter, osteoid area), but no change in the osteoclast number/perimeter.

Bone (Re)modeling in Animal Models of Type 1 Diabetes

There is consensus that untreated severe diabetes is associated with low to virtually absent bone formation. First, this has been shown by biochemical markers, in particular plasma osteocalcin levels. Plasma osteocalcin levels drop exponentially after onset of diabetes in BB rats to about 25% of the levels in nondiabetic animals after 5 weeks (Verhaeghe *et al.,* 1997b) (Fig. 2); this was confirmed in SZ-induced diabetes (Epstein *et al.,* 1994). Interestingly, plasma osteocalcin levels are lower than in nondiabetic littermates on the first day of glycosuria (Verhaeghe *et al.,* 1997b), confirming data obtained in humans by Guarneri *et al.* (1993) that diabetes depresses bone formation parameters rapidly. Osteocalcin levels respond poorly, if at all, to exogenous $1,25(OH)_2D_3$ administration in diabetic rats (Verhaeghe *et al.,* 1989, 1993). The half-life of plasma osteocalcin is similar in diabetic and nondiabetic BB rats, indicating that circulating osteocalcin levels are not decreased because of faster clearance (Verhaeghe *et al.,* 1989). Osteocalcin levels gradually return to within the normal range with increasing insulin dose in

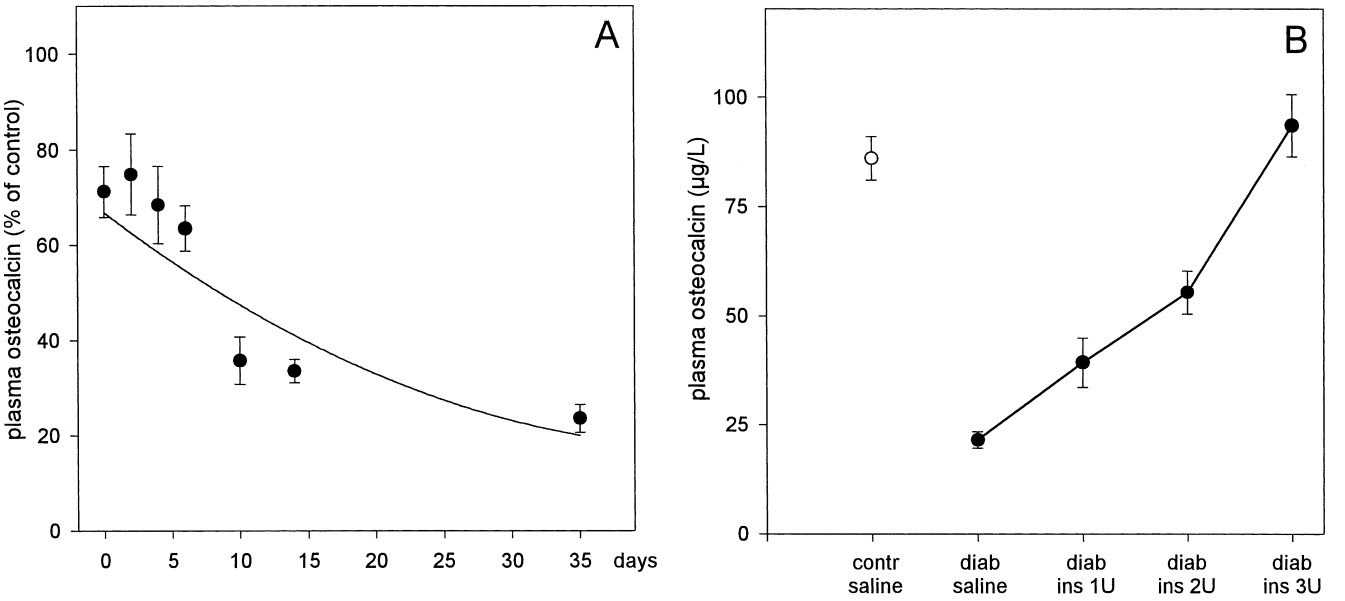

Figure 2 (A) Plasma osteocalcin concentrations after onset of diabetes in male spontaneously diabetic BB rats presented as the percentage (mean ±SEM) of values measured in nondiabetic (control) littermates. Osteocalcin levels were significantly different at the first day of glycosuria (71 ± 5% of paired controls) and decreased exponentially thereafter ($y = 67.e^{-0.0346}x$ (%); $R^2 = 0.62$; $p < 0.0001$). (B) Effect of sc-infused insulin, via miniosmotic pump, during 14 days on plasma osteocalcin concentrations in male spontaneously diabetic BB rats (diabetes duration about 5 weeks). Data are means ±SEM. Statistical analysis: significantly different compared with saline-infused control rats ($^{*}p < 0.001$); significantly different compared with saline-infused diabetic rats ($^{+}p < 0.001$). Modified from Verhaeghe *et al.* (1997b), with permission of Humana Press, Inc.

BB rats (Verhaeghe *et al.,* 1997b) (Fig. 2) and are also normalized by pancreas transplantation in SZ-diabetic rats (Ishida *et al.,* 1992).

Second, low to virtually absent bone formation has been shown by histomorphometry in many studies in SZ-diabetic and BB rats. This applies to all bone surfaces: trabecular-endosteal, endocortical, and periosteal (Bain *et al.,* 1997; Epstein *et al.,* 1994; Glajchen *et al.,* 1988; Shires *et al.,* 1981; Verhaeghe *et al.,* 1992). Static morphometry demonstrates a marked decline in osteoblast and osteoid surface/volume (Table I). Dynamic morphometry shows a decrease in both mineralizing surface (or labeled perimeter) and mineral apposition rate; however, the maturation and mineralization of osteoid remain normal when adjusted for the decrease in osteoid production rate (Goodman and Hori, 1984), indicating that the basic defect is in the number of active osteoblasts producing osteoid. Insulin treatment reverses these effects (Goodman and Hori, 1984; Verhaeghe *et al.,* 1992).

Electron microscopy of the endocortical surface in diabetic rats shows that active, cuboidal osteoblasts are virtually absent and are replaced by bone-lining cells with flattened nuclei, little or no rough endoplasmic reticulum, and no detectable alkaline phosphatase activity or uptake of [^{3}H]proline for collagen synthesis (Sasaki *et al.,* 1991).

Regarding bone resorption, the measurement of urinary D-PYR shows decreased total and creatinine-corrected D-PYR excretion in diabetic BB rats (Verhaeghe *et al.,* 2000). Most histomorphometric data confirm that the osteoclast surface/number is decreased moderately to severely in diabetic rats, which is reversed by insulin treatment (Glajchen *et al.,* 1988; Shires *et al.,* 1981; Verhaeghe *et al.,* 1992). Electron microscopy shows that most osteoclasts in diabetic rats lack a ruffled border–clear zone complex and that acid phosphatase activity is rarely detected (Kaneko *et al.,* 1990).

In conclusion, there is strong evidence from *in vivo* studies in animal models that diabetes is associated with a marked dampening of both resorption and formation. The bone surface engaged in remodeling is scant, whereas most of the bone surface is in a quiescent state.

Bone Mass in Animal Models of Type 1 Diabetes

Physicochemical measurements in rats in which diabetes was drug-induced at an early age show a gradual decline in both body weight and skeletal weight (Locatto *et al.,* 1993). Thus, femoral (wet and dry) weight, length, and diaphyseal width are lower in diabetic than in nondiabetic rats, and this decrease in bone size is more apparent with longer diabetes duration and with higher average glycemia (Dixit and Ekstrom, 1980; Einhorn *et al.,* 1988; Locatto *et al.,* 1993; Lucas, 1987). This corresponds with a decrease in bone blood flow, as measured using radiolabeled microspheres (Lucas, 1987). In diabetic BB rats, which develop diabetes at an average age of 13 weeks, femur weight and diaphyseal width, but not femur length, are decreased after 8–12 weeks of diabetes (Verhaeghe *et al.,* 1994, 2000). However, the ash percentage and calcium/phosphate concentration of long bones remain within the normal range in SZ-diabetic and BB-diabetic rats (Bain *et al.,* 1997; Dixit and Ekstrom, 1980; Shires *et al.,* 1981; Verhaeghe *et al.,* 1989, 1990, 1994). After 1 year of SZ diabetes, Einhorn *et al.* (1988) found a small decrease in bone ash percentage at the femoral metaphyseal level, but an increase at the diaphyseal

level; Bain *et al.* (1997) also reported an increase in tibial cortical bone density in SZ-diabetic rats.

Using DXA technology, we confirmed that diabetes (for 6–12 weeks) affects bone size, as reflected by the measurement of bone area, in BB rats; consequently, BMC is decreased, particularly at the diaphysis (Verhaeghe *et al.,* 1997a, 2000). However, the BMD (BMC/area) at the distal metaphysis and the BMD or the BMAD (bone mineral apparent density, BMC/area^2) at the diaphysis are not significantly different from values in nondiabetic rats (Verhaeghe *et al.,* 1994, 1997a, 2000).

Histomorphometry, again, shows a decrease in total and cortical area at the tibial diaphysis, whereas the cortical area as a percentage of total area remains unchanged (Epstein *et al.,* 1994). Thus, physiochemical, DXA, and histomorphometry consistently show a decrease in bone size, and consequently in the total amount of bone (mineral), whereas bone density (mineral per unit bone) is normal.

There is some inconsistency in the reported effect of diabetes on trabecular (cancellous) bone volume at the proximal tibial metaphysis, as measured by histomorphometry. In SZ- or alloxan-diabetic rats, trabecular bone volume was found to be decreased in most studies, and this reduction correlates with the average glycemia (Bain *et al.,* 1997; Epstein *et al.,* 1994; Glajchen *et al.,* 1988; Locatto *et al.,* 1993); further analysis showed a decrease in trabecular thickness, but not in the number of trabeculae (Epstein *et al.,* 1994). In diabetic BB rats, we found a normal trabecular bone volume at the secondary spongiosa in most (Verhaeghe *et al.,* 1989, 1992, 1993, 1994, 2000), but not all (Verhaeghe *et al.,* 1990), experiments. The discrepancy in results may be explained by the differences in age at onset or induction of diabetes and the method of measuring trabecular volume (i.e., the distance from the distal growth plate). Ovariectomy (6–12 weeks) results in trabecular bone loss at the proximal tibial metaphysis in adult diabetic BB rats, but not in diabetic ovariectomized rats treated with 17β-estradiol (Verhaeghe *et al.,* 1994, 1997a). In contrast, we found no trabecular bone loss in diabetic BB rats after 8 weeks of skeletal disuse induced by unilateral sciatic neurectomy, in contrast to what was observed in paralyzed limbs of nondiabetic rats (Verhaeghe *et al.,* 2000); urinary D-PYR excretion was increased in nondiabetic rats only, suggesting that bone resorption is not stimulated by immobilization in diabetic rats.

Bone Remodeling and Bone Mass in Animal Models of Type 2 Diabetes

Data are scarce. Takeshita *et al.* (1993) examined the effects on bone in genetic Wistar fatty rats and in rats treated neonatally with SZ, a frequently used animal model for type 2 diabetes. Wistar fatty rats are markedly obese, hyperinsulinemic, and hyperglycemic. Despite this, femur size (length and weight) is decreased and femur calcium content is decreased, as well as plasma osteocalcin levels. Rats with neonatal SZ treatment have a normal weight and are hypoinsulinemic and hyperglycemic. Their bone size and calcium content are normal, but plasma osteocalcin levels are again lower than in controls. These effects are reminiscent of those found in animal models of type 1 diabetes and indicate that the effect of diabetes on bone size and bone formation parameters is, at least to some extent, independent of plasma insulin levels and body weight.

Bone Strength in Animal Models of Type 1 and Type 2 Diabetes

The breaking strength of the femur—assessed by torsion or by pressure with a knife edge—has been shown to be lower after 8 weeks of diabetes or more in SZ-diabetic and diabetic BB rats (Dixit and Ekstrom, 1980; Einhorn *et al.,* 1988; Verhaeghe *et al.,* 1990, 1994), but not after 4 weeks (Funk *et al.,* 2000). Decreased torsional strength in rats diabetic for 1 year persisted after correcting for smaller bone size (Einhorn *et al.,* 1988). Similarly, decreased breaking strength was found at the femoral neck of SZ-diabetic rats, which was partly restored by insulin treatment (Hou *et al.,* 1993). Femoral breaking strength was also found to be decreased in models of type 2 diabetes (Takeshita *et al.,* 1993).

We carried out a detailed analysis of bone strength in BB rats at the fifth lumbar vertebra and at the femoral neck, diaphysis, and distal metaphysis; diabetic rats were poorly controlled, and the rats had received either no intervention or had received running exercise for 8 weeks (starting within 4 days of diagnosis in diabetic rats). Using two-factor ANOVA, diabetes had no effect on biomechanical competence at the lumbar vertebra, femoral neck, and diaphysis. At the femoral metaphysis, however, load/density was reduced in diabetic rats; moreover, biomechanical competence at the femoral metaphysis improved after a running exercise program in nondiabetic rats only so that the biomechanical differences between diabetic and nondiabetic rats were more marked in the exercise group (Verhaeghe *et al.,* 2000).

As in human diabetics, fracture repair is delayed in diabetic rats: callus volume and BMC after fracture of the fibula were found to be lower in SZ-diabetic than in nondiabetic rats (Kawaguchi *et al.,* 1994), as well as biomechanical properties after fracture of the femur (Funk *et al.,* 2000). The postfracture expression of basic fibroblast growth factor (FGF-2) in the soft callus and periosteum is impaired in diabetic rats and is restored by insulin treatment. Administration of FGF-2 dose dependently facilitates callus volume in both nondiabetic and diabetic rats (Kawaguchi *et al.,* 1994).

Insulin and Bone Cells *in Vitro*

High-affinity insulin receptors have been documented in several mature osteoblastic cell lines: in UMR-106, a clonal rat osteogenic osteosarcoma cell line (De Luise and Harker, 1988; Hickman and McElduff, 1989; Ituarte *et al.,* 1989; Pun *et al.,* 1989; Thomas *et al.,* 1996), and in ROS-17/2.8, a

rat osteogenic osteosarcoma cell line (Levy *et al.,* 1986). However, there is no insulin binding in UMR-201, a rat calvaria-derived preosteoblastic clonal cell line (Thomas *et al.,* 1996). Half-maximal displacement of ^{125}I-labeled insulin is attained at physiological concentrations of unlabeled insulin (between 0.5 and 1.0 n*M*) (Fig. 3) (Ituarte *et al.,* 1989; Pun *et al.,* 1989). In cultures from neonatal rat calvaria, positive immunostaining was observed within the cytoplasm of mature cuboidal osteoblasts, and insulin binding was found to be higher in osteoblast-enriched populations of cells with high alkaline phosphatase activity than in less mature cell populations (Thomas *et al.,* 1996). In UMR-106, the number of high-affinity receptors is estimated to be around 80,000 per cell (Ituarte *et al.,* 1989; Pun *et al.,* 1989); insulin binding and the number of insulin receptors are downregulated by supraphysiological levels of insulin (10^{-7} *M*) but are stimulated by dexamethasone (from 10^{-8} *M*) (De Luise and Harker, 1988; Ituarte *et al.,* 1989; Pun *et al.,* 1989).

Osteoblast proliferation, assessed by [^{3}H]thymidine incorporation, is stimulated by physiological concentrations of insulin (0.5–1.0 n*M*) in UMR-106 cells (Hickman and McElduff, 1989). In other cell culture systems, osteoblast proliferation can be achieved only at supraphysiological or pharmacological doses of insulin (10^{-7}–10^{-6} *M*), e.g., in osteoblastic cells obtained from fetal rat calvariae or from human femoral trabecular bone (Hock *et al.,* 1988; Wergedal *et al.,* 1990). Physiological concentrations of insulin (0.5–1.0 n*M*) stimulate glucose uptake in UMR-106 osteoblastic cells (Ituarte *et al.,* 1989; Thomas *et al.,* 1996). Glucose uptake is generally examined using radiolabeled 2-deoxyglucose (2-DG), which cannot be metabolized beyond 2-DG-6-phosphate. Ituarte *et al.* (1989) found that the half-maximal concentration of insulin needed for displacement of radiolabeled insulin corresponds with the half-maximal concentration needed to stimulate 2-DG (Fig. 3). Insulin at 10^{-8} *M* also increases the mRNA level of the glucose transporter GLUT1 by threefold in UMR-106 cells (Thomas *et al.,* 1996). Insulin, even at 10^{-6} *M,* does not stimulate glucose uptake in preosteoblastic UMR-201 cells, as expected in the absence of insulin binding (Thomas *et al.,* 1996); surprisingly, insulin is also ineffective in stimulating glucose uptake in ROS 17/2.8 osteoblastic cells, which contain insulin receptors (Levy *et al.,* 1986). Insulin also affects ion fluxes across the osteoblast membrane in UMR-106: there is stimulation of the Na^+-K^+ pump-mediated K^+ uptake with half-maximal stimulation at 0.25 n*M* (De Luise and Harker, 1988) and a stimulation of the Na^+-dependent PO_4^{2-} uptake by 10^{-9}–10^{-7} *M* insulin (Kunkler *et al.,* 1991).

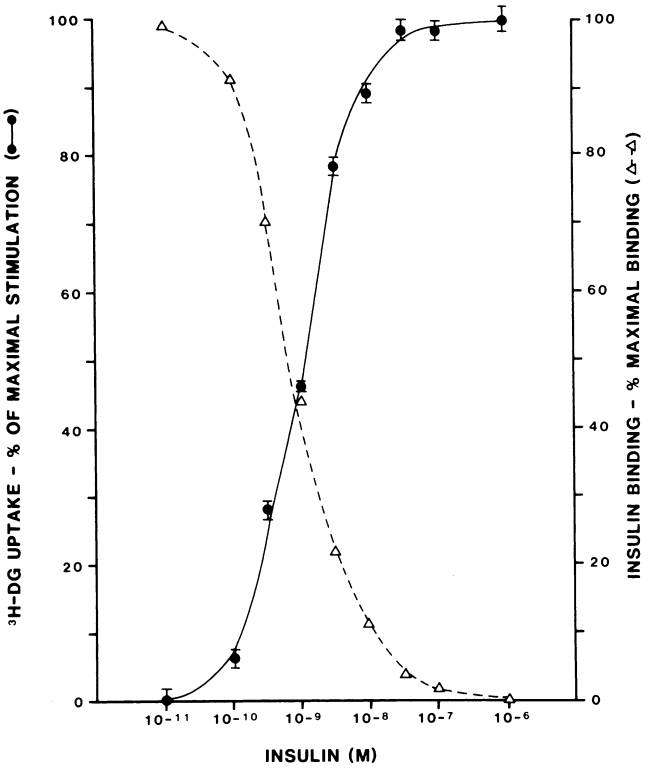

Figure 3 Relationship between insulin receptor occupancy and stimulation of 2-deoxyglucose (2-DG) uptake in UMR-106 (rat osteosarcoma) cells. Insulin displacement of [^{125}I]insulin binding and stimulation of 2-DG were performed in parallel cultures. The half-maximal insulin concentration for both processes was 0.8 n*M*. Each point represents the mean ±SEM of 12 determinations. From Ituarte *et al.* (1989b), with permission.

Furthermore, insulin at 1 n*M* stimulates the incorporation of collagen synthesis—measured by the uptake of [^{3}H]proline into collagen—in UMR-106 cells (Pun *et al.,* 1989), but also in fetal rat calvariae, especially in its osteoblast-rich central bone area (Kream *et al.,* 1985); at the latter site, insulin at 3 n*M* stimulates the level of α-1(I)-procollagen mRNA, possibly by modulating the stability of the procollagen mRNA (Craig *et al.,* 1989). Thus, in fetal rat calvariae, there is a discrepancy between the effect of insulin on collagen synthesis and matrix apposition, assessed by histomorphometry (effective from 10^{-9} *M*) versus its effect on osteoblast replication (from 10^{-7}–10^{-6} *M*), indicating that the stimulating effect of insulin on collagenous matrix production is not explained by its effect on osteoblast replication (Hock *et al.,* 1988). Proinsulin is only 0.1–1% as effective as insulin in stimulating collagen synthesis in UMR-106 and fetal rat calvariae (Kream *et al.,* 1985; Pun *et al.,* 1989).

Thomas *et al.* (1998) produced evidence that there is insulin binding in primary mouse and rat osteoclasts and in cultured osteoclast-like cells; the receptor density was higher in purified osteoclast-like cells than in primary osteoblast cultures. Insulin dose dependently inhibited pit formation in a dentine slice assay. These results would indicate that insulin inhibits bone resorption, but further studies are needed to corroborate this conclusion.

In conclusion, high-affinity insulin receptors are present in mature osteoblastic cells but not in preosteoblastic cell lines. Insulin at physiological concentrations (1 n*M* or lower) stimulates osteoblastic cell function, including glucose and phosphate uptake, and collagenous matrix synthesis. In mature osteoblastic cell lines, insulin at the same concentration also stimulates osteoblast replication; however, experiments in fetal rat calvariae indicate that the effect of insulin on osteoblastic function is not fully explained by its effect on cell proliferation. Osteoclasts also appear to contain insulin receptors.

Causative Factors and Mechanisms of Diabetic Bone Disease

The *in vivo* repression of bone growth and remodeling in diabetic subjects and animal models can be replicated *in vitro* using diabetic serum. Indeed, diabetic rat serum inhibits collagen production in rib cartilage from hypophysectomized rats (Spanheimer, 1992, and references therein), and sera from diabetic individuals with poor glycemic control inhibit the proliferation of human osteoblastic cells and osteoblastic collagen production (Brenner *et al.,* 1992). Hence, diabetic bone disease appears to be induced by one or several circulating factors. These factors almost certainly include insulin, but may also include glucose, IGF-I, the IGF-binding proteins (IGFBPs), and glucocorticoids. Indeed, insulin-deficiency *per se* does not appear to explain all clinical and experimental data: (1) low osteocalcin levels have been measured in subjects and animal models with type 2 diabetes and hyperinsulinemia (Montecucco *et al.,* 1990; Takeshita *et al.,* 1993) and (2) the addition of insulin to diabetic sera *in vitro* does not reverse defective collagen synthesis, whereas prior *in vivo* treatment of the animals does (Spanheimer, 1992).

A very high glucose environment has been shown to inhibit basal and IGF-I-induced osteoblastic cell proliferation and $1,25(OH)_2D_3$-induced osteocalcin secretion in human MG-63 cells *in vitro;* this was not replicated in mannitol cultures (Terada *et al.,* 1998). However, in another study, the effect of high extracellular glucose concentrations on osteocalcin gene expression in mouse osteoblasts was mimicked by mannitol so that the effects of hyperglycemia versus osmotic stress must be further delineated (Zayzafoon *et al.,* 2000). In addition, we found no *in vivo* effect of hyperglycemia on plasma osteocalcin levels in chronically catheterized nondiabetic BB rats (Verhaeghe *et al.,* 1997b).

IGF-I is well known to promote osteoblast proliferation and bone matrix formation (Hock *et al.,* 1988). Numerous reports have shown that circulating IGF-I levels are decreased in subjects with type 1 diabetes; in addition, we found a correlation between IGF-I levels and biochemical markers of bone formation in subjects with type 1 diabetes (Bouillon *et al.,* 1995). We confirmed this correlation between plasma IGF-I and osteocalcin levels in several studies in diabetic BB rats (Verhaeghe *et al.,* 1997b). Insulin-deficient diabetic subjects also have increased serum IGFBP1 concentrations (Bereket *et al.,* 1995) due to increased hepatic IGFBP1 gene expression; IGFBP1 has been shown to inhibit IGF-I-induced DNA synthesis in human osteosarcoma cells (Campbell and Novak, 1991). Moreover, the osteoblastic expression of IGFBP1 is potently inhibited by insulin in human osteoblasts *in vitro* (Conover *et al.,* 1996) and would thus be expected to be increased in type 1 diabetes.

Glucocorticoid excess also appears to play a role in the development of diabetic bone disease. Children with newly onset type 1 diabetes have increased cortisol levels (Bereket *et al.,* 1995), and higher corticosterone levels were found in some, but not all, studies in animal models of severe type 1 diabetes (Verhaeghe *et al.,* 1997b). We showed that osteocalcin levels consistently rose to within the control range 4 days after adrenalectomy in severely diabetic BB rats, but not in corticosterone-treated adrenalectomized diabetic rats (Verhaeghe *et al.,* 1997b) (Fig. 4). The effect of glucocorticoid excess on bone is mediated, in part, by altered IGF and IGFBP gene expression in hepatocytes (affecting circulating levels) and in osteoblasts, i.e., decreased IGF-I but increased IGFBP1 gene

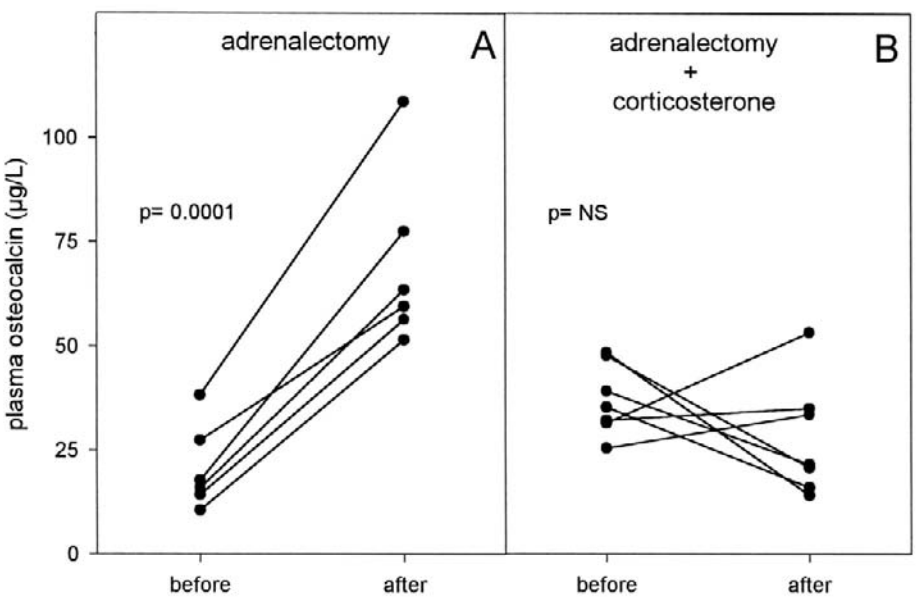

Figure 4 Effect of adrenalectomy (A) and adrenalectomy with corticosterone treatment (15 mg/day, sc) (B) on plasma osteocalcin concentrations in male spontaneously diabetic BB rats. Individual data are shown before adrenalectomy and 96 hr after adrenalectomy. Modified from Verhaeghe *et al.* (1997b), with permission of Humana Press, Inc.

expression (reviewed by Verhaeghe *et al.,* 1997b). Glucocorticoid excess is well known to decrease osteoblastogenesis and stimulate osteoblast apoptosis. However, in contrast to diabetic bone disease, corticosteroid excess is associated with an early increase in bone resorption (reviewed by Manolagas, 2000).

Diabetes is associated with changes in the circulating levels of the calciotropic hormones PTH and (total) $1,25(OH)_2D_3$, which were found to be decreased in some, but not all, studies in type 1 diabetic subjects and in animal models of type 1 diabetes (reviewed by Verhaeghe *et al.,* 1999). However, we found that $1,25(OH)_2D_3$ injections, even at doses that cause hypercalcemia, do not increase bone formation in diabetic BB rats (Verhaeghe *et al.,* 1993). Intermittent administration of PTH_{1-34} was found to normalize trabecular bone formation rate in SZ-injected diabetic rats (Tsuchida *et al.,* 2000); however, intermittent PTH is effective in increasing trabecular bone formation and bone volume in rats with various osteopenic conditions not necessarily associated with hypoparathyroidism (e.g., after ovariectomy, glucocorticoid administration).

In diabetic rats treated with tetracycline or a nonmicrobial tetracycline analog, there is normalization of both growth plate width and bone formation rate at the trabecular-endosteal bone surface, as well as an unequivocal increase in bone formation rate at the periosteal surface (Bain *et al.,* 1997). On electron microscopy, inactive bone-lining cells are reverted into active osteoblasts, and osteoclasts are structurally normal (i.e., containing a ruffled border) in tetracycline-treated diabetic rats (Kaneko *et al.,* 1990; Sasaki *et al.,* 1991). Tetracycline is known to inhibit collagenase (matrix metalloproteinase) activity in osteoblastic cells. Collagenase activity is increased in the skin and periodontium of diabetic rats and presumably in bone as well (Bain *et al.,* 1997, and references therein). Low IGF-I levels and glucocorticoid excess in diabetic serum may be involved, as collagenase expression in osteoblastic cells is known to be repressed by IGF-I but stimulated by glucocorticoids. An interesting preliminary report also showed that femoral neck BMD is determined by type 1 collagen gene polymorphism in women with (type 1 or type 2) diabetes (Hampson *et al.,* 1998).

Although there is evidence from electron microscopic studies that (some) osteoblasts revert to an inactive state as bone-lining cells in severe diabetes (Sasaki *et al.,* 1991), the possibility that low bone formation would also result from reduced osteoblastogenesis from marrow stromal cells and/or increased osteoblast apoptosis has not been studied to date. Osteoblast survival *in vitro* has been found to be promoted by insulin and IGF-I (Hill *et al.,* 1997), and glucocorticoid excess stimulates osteoblast apoptosis *in vivo* (Manolagas, 2000). Further studies are needed in this regard. Insulin and IGF-I bind to insulin and type 1 IGF receptors, which are both tyrosine kinase receptors. The subsequent intracellular signaling involves the phosphorylation of insulin receptor substrate (IRS)-1 and -2. Mice deficient for the IRS-1 gene have been generated: interestingly, the bone changes in these animals are virtually identical to those observed in severely diabetic rats, with a dramatic decline in bone-remodeling parameters. Osteoblastic cells from IRS −/− mice show decreased proliferation and differentiation *in vitro,* but increased apoptosis, which is unaffected by insulin or IGF-I administration (Ogata *et al.,* 2000). These experiments underscore the potent *in vivo* effects of insulin and/or IGF-I on bone.

Postfracture periosteal FGF-2 expression has been shown to be decreased in insulin-deficient rats, which is restored by insulin administration (Kawaguchi *et al.,* 1994). Mice with a disruption of the FGF-2 gene show decreased trabecular bone formation and bone volume, although to a lesser extent than is observed in severely diabetic rats or IRS-1-gene null mice (Montero *et al.,* 2000). The effect of diabetes on the expression of growth factors in bone needs to be studied further.

The collagenous matrix is not only scant in diabetic rats, but type 1 collagen is glycated to a larger extent as well, which increases with longer diabetes duration. *In vitro,* osteoblastic cells cultured on glycated collagen show decreased proliferation and differentiation (Katayama *et al.,* 1996). Thus, glycosylation of collagen may constitute yet another mechanism for low bone formation in diabetic rats, although it is unlikely to be the initiating pathogenetic mechanism of diabetic bone disease.

In conclusion, the pathogenesis of diabetic bone disease is complex: a serum factor(s) is believed to inititate low bone formation, but the role of insulin and IGF-I deficiency, hypercortisolism, and changes in the IGFBP concentrations must be delineated further. At the bone level, there is evidence of a reversible swap of active osteoblasts into inactive bone-lining cells and increased collagenase (metalloproteinase) activity. Clearly, more research is needed as understanding of the mechanisms involved in osteoblast generation might be important for all metabolic bone diseases.

General Conclusions

Insulin stimulates endochondral bone growth and osteoblast proliferation and function *in vitro* and *in vivo* at physiological concentrations. Severe diabetes in animal models typically induces a "freeze" effect on bones, with robust reductions in bone blood flow, bone growth, periosteal bone apposition, and bone remodeling (both resorption and formation). Consequently, when diabetes is present in fast-growing animals or/and is long-standing, bone size and bone mass (BMC) are reduced. However, when adjusted for bone size, there is no effect of diabetes on bone mineral density. These changes are less apparent in (insulin-treated) human type 1 diabetes, although many studies report (1) a mild reduction in growth velocity in prepubertal children with type 1 diabetes, (2) a mild deficit in areal BMD (maximum 10% or *Z* score between 0 and −1.0 SD), which does not deteriorate with longer diabetes duration, and (3) significantly reduced bone remodeling parameters. Individuals with hyperinsulinemia and/or type 2 diabetes, however, have a mild increase (3–5%) in areal BMD.

Whereas the effect of diabetes in humans on bone density is mild, diabetes increases the risk of nonspine fractures, particularly of the lower extremities. Peripheral neuropathy and steroid exposure after kidney (pancreas) transplantation aggravate the risk of nonspine fractures. However, the effect of diabetes on intrinsic bone strength in animal models remains controversial, and diabetes-related factors that predispose to falls may be important to explain increased fracture risk.

Apart from insulin deficiency, there are likely to be other causative factors in the development of diabetic bone disease, including alterations in the IGF-IGFBP system and hypercortisolism. The cellular and molecular mechanisms by which diabetes affects chondrocyte, (pre)osteoblast and (pre)osteoclast proliferation, and function still need to be elucidated.

CHAPTER 43

Androgens

Receptor Expression and Steroid Action in Bone

Kristine M. Wiren and Eric S. Orwoll

Portland Veterans Affairs Medical Center and the Oregon Health Sciences University, Portland, Oregon 97201

Introduction

The obvious impact of menopause on skeletal health has focused much of the research on the general action of gonadal steroids on the specific effects of estrogen. However, androgens, independently, have important beneficial effects on skeletal development and on the maintenance of bone mass in both men and women. Thus, androgens (1) influence growth plate maturation and closure, helping to determine longitudinal bone growth during development, (2) participate in the dichotomous regulation of bone mass that leads to a sexually dimorphic skeleton, (3) modulate peak bone mass acquisition, and (4) inhibit bone loss (Vanderschueren and Bouillon, 1995, 1996; Orwoll, 1996; 1999). In castrate animals, replacement with nonaromatizable androgens (e.g., dihydrotestosterone) yields beneficial effects that are clearly distinct from those observed with estrogen replacement (Turner *et al.,* 1990, 1994). In intact females, blockade of the androgen receptor with the specific androgen receptor antagonist hydroxyflutamide results in osteopenia (Goulding and Gold, 1993). Data suggests that combination therapy with both estrogen and androgenic steroids is more effective than estrogen replacement alone (Watts *et al.,* 1995; Raisz *et al.,* 1996; Rosenberg *et al.,* 1997; Barrett-Connor, 1998). At the same time, nonaromatizable androgen alone and in combination with estrogen also results in distinct changes in bone mineral density in females (Coxam *et al.,* 1996). These reports illustrate the independent actions of androgens and estrogens on the skeleton. Thus, in both men and women it is probable that androgens and estrogens each have important, yet distinct, functions during bone development and in the subsequent maintenance of skeletal homeostasis. With the awakening awareness of the importance of the effects of androgen on skeletal homeostasis, and the potential to make use of this information for the treatment of bone disorders, much is to be learned.

The mechanisms by which androgens affect skeletal homeostasis are thus the focus of intensified research. Androgen receptors have been identified in a variety of cells found in bone tissue (Abu *et al.,* 1997). Characterization of androgen receptor expression in these cells thus clearly identifies bone as a target tissue for androgen. Direct actions of androgen that influence the complex processes of proliferation, differentiation, mineralization, and gene expression in the osteoblast have also been documented (Hofbauer and Khosla, 1999). Androgen effects on bone may also be indirectly modulated and/or mediated by other autocrine and paracrine factors in the bone microenvironment. This chapter reviews progress on the characterization of androgen action in bone cells.

Molecular Mechanisms of Androgen Action in Bone Cells: The Androgen Receptor

A steroid hormone target tissue can be defined as one that possesses both functional levels of the steroid receptor and a measurable biological response in the presence of hormone. As described in this chapter, bone tissue clearly meets this standard with respect to androgen. Direct characterization of androgen receptor expression in a variety of tissues, including bone, was made possible by the cloning of the androgen receptor cDNA (Chang *et al.,* 1988; Lubahn *et al.,* 1988). Colvard *et al.,* (1989) first described the presence of androgen

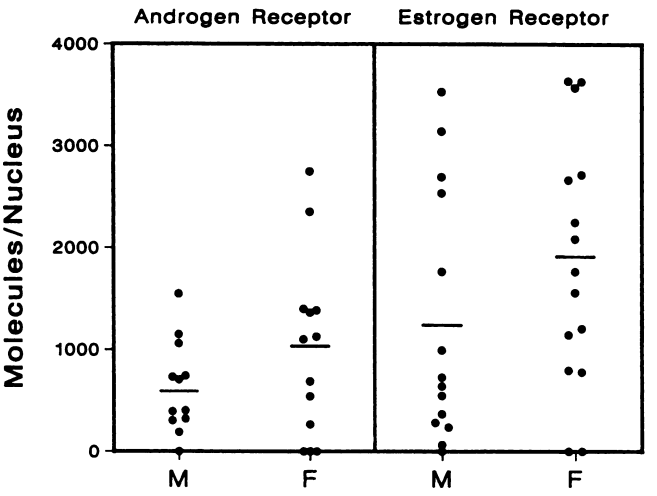

Figure 1 Nuclear androgen and estrogen receptor binding in normal human osteoblast-like cells. Dots represent the mean calculated number of molecules per cell nucleus for each cell strain. (Left) Specific nuclear binding of [^{3}H]R1881 (methyltrienolone, an androgen analog) in 12 strains from normal men and 13 strains from normal women. (Right) Specific nuclear [^{3}H]estradiol binding in 15 strains from men and 15 strains from women. Horizontal lines indicate the mean receptor concentrations (Colvard *et al.,* 1989).

receptor mRNA and specific androgen-binding sites in normal human osteoblastic cells. This report characterized the abundance of both androgen and estrogen receptor proteins as similar in osteoblasts (Fig. 1), suggesting that androgens and estrogens each play important roles in skeletal physiology. Subsequent reports have confirmed androgen receptor mRNA expression and/or the presence of androgen-binding sites in both normal and clonal, immortalized or transformed osteoblastic cells, derived from a variety of species (Benz *et al.,* 1991; Orwoll *et al.,* 1991; Zhuang *et al.,* 1992; Liesegang *et al.,* 1994; Nakano *et al.,* 1994; Takeuchi *et al.,* 1994). The size of the androgen receptor mRNA transcript in osteoblasts (about 10 kb) is similar to that described in prostate and other tissues (Chang *et al.,* 1988), as is the size of the androgen receptor protein analyzed by Western blotting (~110 kDa) (Nakano *et al.,* 1994). There is a report of two isoforms of androgen receptor protein in human osteoblast-like cells (~110 and ~97 kDa) (Kasperk *et al.,* 1997) similar to that observed in human prostate tissue (genital skin) (Wilson and McPhaul, 1994). Whether these isoforms possess similar functional activities in bone, when expressed at similar levels as described in other tissue (Gao and McPhaul, 1998), has yet to be determined.

The number of specific androgen-binding sites in osteoblasts varies, depending on methodology and the cell source, from 1000 to 14000 sites/cell (Masuyama *et al.,* 1992; Liesegang *et al.,* 1994; Nakano *et al.,* 1994; Kasperk *et al.,* 1997a), but is in a range seen in other androgen target tissues. Furthermore, the binding affinity of the androgen receptor found in osteoblastic cells ($K_d = 0.5–2 \times 10^{-9}$) is typical of that found in other tissues. Androgen binding is specific, without significant competition by estrogen, progesterone, or dexamethasone (Colvard *et al.,* 1989; Orwoll *et al.,* 1991; Nakano *et al.,* 1994; Kasperk *et al.,* 1997a). Finally, testosterone and dihydrotestosterone (DHT) appear to have similar binding affinities (Benz *et al.,* 1991; Nakano *et al.,* 1994). All these data are consistent with the notion that the direct biologic effects of androgenic steroids in osteoblasts are mediated, at least in part, via classic mechanisms associated with the androgen receptor.

The Androgen Receptor Signaling Pathway

The androgen receptor is a member of the class I (so-called classical or steroid) nuclear receptor superfamily, as are the estrogen receptor, the progesterone receptor, and the mineralocorticoid and glucocorticoid receptor (Mangelsdorf *et al.,* 1995). These steroid receptors are ligand-inducible transcription factors with a highly conserved modular design consisting of transactivation, DNA binding, and ligand-binding domains. Cellular localization of the androgen receptor in the absence of ligand is somewhat controversial. The unliganded androgen receptor has been found both predominantly in the cytoplasmic compartment (Georget *et al.,* 1997; Noble *et al.,* 1998; Tyag *et al.,* 2000) or, predominantly in the nucleus in a large complex of molecular chaperonins consisting of loosely bound heat-shock and other accessory proteins (Zhuang *et al.,* 1992). As lipids, androgenic steroids can diffuse freely through the plasma membrane to bind the androgen receptor. Once bound by ligand, the androgen receptor is activated and released from this protein complex, allowing the formation of homodimers (or potentially heterodimers) that bind to DNA at palindromic androgen response elements (AREs) in androgen responsive gene promoters (Fig. 2). ARE sequences are found characteristically as a motif represented by an inverted repeat separated by 3 bp (Whitfield *et al.,* 1999), but similar to glucocorticoid response elements (Denison *et al.,* 1989); androgen-specific regulation at nonconventional direct repeat AREs has also been shown (Verrijdt *et al.,* 1999). DNA binding of the activated androgen receptor organizes a cascade of events in the nucleus, leading to transcription and translation of a specific network of genes that is responsible for the cellular response to the steroid (Chang *et al.,* 1995). In the classic model of steroid action, the latent receptor is converted into a transcriptionally active form by simple ligand binding. This model is now considered an oversimplification, with the understanding that signaling pathways and additional proteins (e.g., coactivators or corepressors as described later) within the cell can influence steroid receptor transduction activity. For example, steroid receptor phosphorylation can result from signal transduction cascades initiated at the cell membrane, e.g., with cyclin-dependent kinases (Rogatsky *et al.,* 1999). It has been shown that steroid receptor phosphorylation can lead to alteration of the responsiveness of steroid receptors to cognate ligands or, in some cases, even result in ligand-independent activation (Fig. 2).

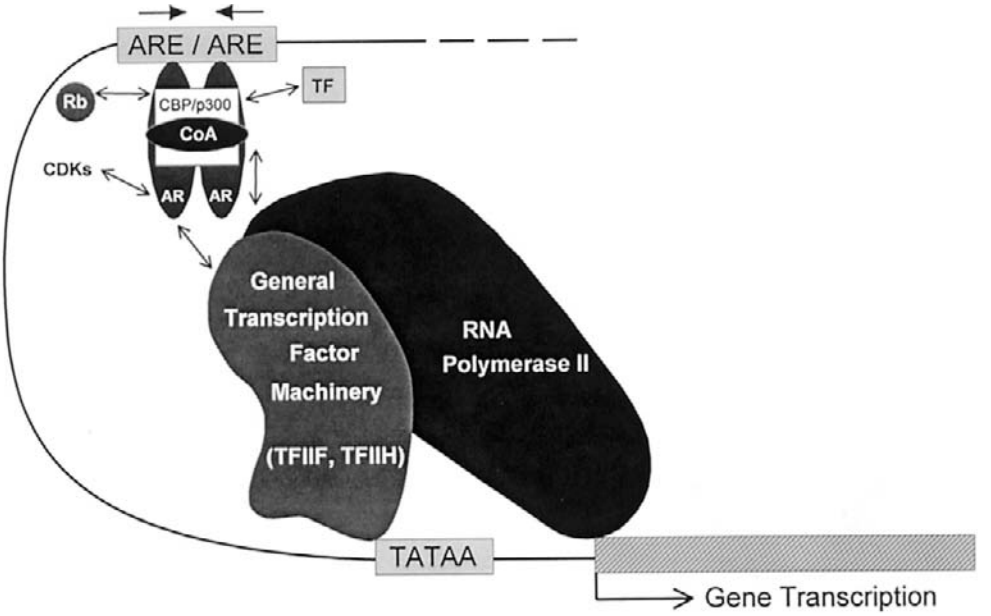

Figure 2 Model of androgen receptor regulation of gene expression. Binding of androgen promotes high-affinity dimerization, followed by DNA binding at the androgen response element (ARE) in an androgen-responsive gene promoter. Coactivators may remodel chromatin through histone acetylase activity to open chromatin structure (Spencer *et al.,* 1997) or act as a bridge to attract TFs that target binding of TATA-binding protein to the TATAA sequence (Beato and Sanchez-Pacheco, 1996). The retinoblastoma tumor suppressor product also activates androgen receptor transactivation (Yeh *et al.,* 1998). Phosphorylation of receptor may result from activation of phosphorylation cascades, such as by cyclin-dependent kinases (CDKs). Androgen receptor can also directly contact TFIIH (Lee *et al.,* 2000) and TFIIF (McEwan and Gustafsson, 1997) in the general transcription machinery. Such interactions between the androgen receptor and the general transcription machinery, leading to stable assembly, result in recruitment of RNA polymerase II and subsequent increased gene transcription.

Such a potential modification(s) of androgen receptor action in bone cells is poorly characterized. Whether the androgen receptor in osteoblasts undergoes posttranslational processing that might thus influence receptor signaling (stabilization, phosphorylation, etc.), as described for androgen receptor in other tissues (Kemppainen *et al.,* 1992; Ikonen *et al.,* 1994), the potential functional implications of such modifications (Blok *et al.,* 1996), are unknown. Ligand-independent activation of AR by cellular phosphorylation cascades has been described in other tissues (Culig *et al.,* 1994; Nazareth and Weigel, 1996), but has not been explored in bone. Androgen receptor activity may also be influenced by receptor modulators, such as the nuclear receptor coactivators or corepressors (Horwitz *et al.,* 1996; McKenna *et al.,* 1999). As outlined in Fig. 2, these coactivators/corepressors can influence the downstream signaling of nuclear receptors through multiple mechanisms, including histone acetylation/deacetylation to remodel chromatin. These activities reflect both the cellular context and the particular promoter. In addition, direct acetylation of the androgen receptor by p300/CBP has been documented (Fu *et al.,* 2000). Androgen receptor-specific coactivators have been identified (MacLean *et al.,* 1997), many of which interact with the ligand-binding domain of the receptor (Yeh and Chang, 1996). Expression and regulation of these modulators may thus influence the ability of steroid receptors to regulate gene expression in bone (Haussler *et al.,* 1997), but this has been underexplored with respect to androgen action. A preliminary report has suggested the presence of androgen-specific coactivators in osteoblastic cells (Wiren *et al.,* 1997).

Another means by which androgen receptor action in bone may be affected is via polymorphisms in the androgen receptor that affect function. Loss of function in the androgen receptor is well known to be associated with reduced bone mass, but less dramatic sequence variations may also be important. For instance, in the first exon of the androgen receptor is a CAG repeat of variable length. Shorter repeat lengths have been associated with increased transcriptional effects, and preliminary data suggest that men with longer repeat lengths have lower bone mineral density.

In addition to the classical androgen receptor present in bone cells, several other androgen-dependent signaling pathways have been described. Specific binding sites for weaker adrenal androgens (dehydroepiandrosterone, DHEA) have been described (Meikle *et al.,* 1992; Kasperk *et al.,* 1997a), raising the possibility that DHEA or similar androgenic compounds may also have direct effects in bone. In fact, Bodine *et al.,* (1995) showed that DHEA caused a rapid inhibition of c-*fos* expression in human osteoblastic cells that was more robust than that seen with the classical androgens (DHT, testosterone, androstenedione). Nevertheless, all androgenic compounds significantly increased Transforming growth factor-β (TGF-β) activity in osteoblastic cells. Androgens may also be specifically bound in osteoblastic cells by a

63-kDa cytosolic protein (Wrogemann *et al.,* 1991). There are reports of distinct androgen receptor polymorphisms identified in different races that may have a biological impact on androgen responses (Pettaway, 1999), but this has not been explored with respect to bone tissue. These different isoforms have the potential to interact in distinct fashions with other signaling molecules, such as c-Jun (Grierson *et al.,* 1999). Androgens may also regulate osteoblast activity via rapid nongenomic mechanisms through elevations in intracellular calcium levels (Benten *et al.,* 1999; Peterziel *et al.,* 1999) mediated by receptors at the bone cell surface (Lieberherr and Grosse, 1994), as has also been shown for estrogen (Lieberherr *et al.,* 1993). Finally, the androgen receptor may also interact with other transcription factors, such as NF-κB, CREB-binding protein, and different forms of AP-1, to generally repress transcription without DNA binding (Aarnisalo *et al.,* 1998, 1999). The role and biologic significance of these nonclassical signaling pathways in androgen-mediated responses in bone are still relatively uncharacterized.

Localization of Androgen Receptor Expression

Clues about the potential sequela of androgen receptor signaling might be derived from a better understanding of the cell types in which expression is documented. In the bone microenvironment, the localization of androgen receptor expression in osteoblasts has been described in intact human bone using immunocytochemical techniques (Abu *et al.,* 1997; Noble *et al.,* 1998). In developing bone from young adults, Abu *et al.* (1997) showed that androgen receptors were expressed predominantly in active osteoblasts at sites of bone formation (Fig. 3). Androgen receptors were also observed in osteocytes embedded in the bone matrix. Importantly, the pattern of both androgen receptor distribution and the level of expression was similar in males and in females. Furthermore, the androgen receptor was also observed within the bone marrow in mononuclear cells and endothelial cells of blood vessels. Expression of the androgen receptor has also been characterized in cultured osteoblastic cell populations isolated from bone biopsy specimens, determined at both the mRNA level and by binding analysis (Kasperk *et al.,* 1997a). Expression varied according to the skeletal site of origin and age of the donor of the cultured osteoblastic cells: AR expression was higher at cortical and intramembranous bone sites and lower in cancellous bone. This distribution pattern correlates with androgen responsiveness. Androgen receptor expression was highest in osteoblastic cultures generated from young adults and somewhat lower in samples from either prepubertal or senescent bone. Again, no differences were found between male and female samples, suggesting that differences in receptor number per se do not underlie development of a sexually dimorphic skeleton. Androgen and estrogen receptors have also been shown in bone marrow-derived stromal cells (Bellido *et al.,* 1995), which are responsive to sex steroids during the regulation of osteoclastogenesis. Because androgens are so important in bone development at the time of puberty, it is not surprising that androgen receptors are also present in epiphyseal chondrocytes (Carrascosa *et al.,* 1990; Abu *et al.,* 1997). Noble *et al.* (1998) described androgen receptor expression mainly in the narrow zone of proliferating chondrocytes in the growth plate, with reduced expression in hypertrophied cells. The expression of androgen receptors in such a wide variety of cell types known to be important for bone modeling during development, and remodeling in the adult, provides evidence for direct actions of androgens in bone and cartilage tissue. These results illustrate the complexity of androgen effects on bone.

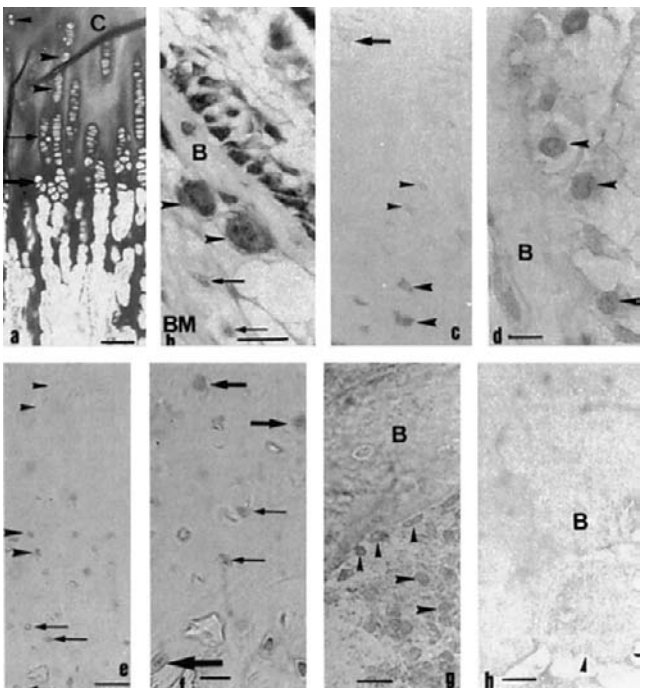

Figure 3 Localization of AR in normal tibial growth plate and adult osteophytic human bone. (a) Morphologically, sections of the growth plate consist of areas of endochondral ossification with undifferentiated (small arrowhead), proliferating (large arrowheads), mature (small arrow), and hypertrophic (large arrow) chondrocytes. Bar: 80 μm. An inset of an area of the primary spongiosa is shown in b. (b) Numerous osteoblasts (small arrowheads) and multinucleated osteoclasts (large arrowheads) on the bone surface. Mononuclear cells within the bone marrow are also present (arrows). Bar: 60 μm. (c) In the growth plate, AR is expressed predominantly by hypertrophic chondrocytes (large arrowheads). Minimal expression is observed in mature chondrocytes (small arrowheads). The receptors are rarely observed in the proliferating chondrocytes (arrow). (d) In the primary spongiosa, AR is predominantly and highly expressed by osteoblasts at modeling sites (arrowheads). Bar: 20 μm. (e) In osteophytes, AR is also observed at sites of endochondral ossification in undifferentiated (small arrowheads), proliferating (large arrowheads), mature (small arrows), and hypertrophic-like (large arrow) chondrocytes. Bar: 80 μm. (f) A higher magnification of e showing proliferating, mature, and hypertrophic-like chondrocytes (large arrows, small arrows, and very large arrows, respectively). Bar: 40 μm. (g) At sites of bone remodeling, the receptors are highly expressed in the osteoblasts (small arrowheads) and also in mononuclear cells in the bone marrow (large arrowheads). Bar: 40 μm. (h) AR is not detected in osteoclasts (small arrowheads). Bar: 40 μm. B, bone: C, cartilage; BM, bone marrow Abu *et al.* (1997).

Osteoclasts may be a target for sex steroid regulation, as estrogen receptors have been reported to be present in osteoclastic cells (Oursler *et al.,* 1991), but a direct effect of androgens on osteoclast function has not been demonstrated. Mizuno *et al.* (1994) described the presence of androgen receptor immunoreactivity in mouse osteoclast-like multinuclear cells, but expression was not detected in *bona fide* osteoclasts in human bone slices (Abu *et al.,* 1997). Because the major effects of androgens on skeletal remodeling and maintenance of bone mineral density seem to be mediated by cells of the osteoblast lineage (Weinstein *et al.,* 1997), the biologic relevance of potential androgen receptor expression osteoclasts is unclear.

Regulation of Androgen Receptor Expression

The regulation of androgen receptor expression in osteoblasts is incompletely characterized. Homologous regulation of the androgen receptor by androgen has been described that is tissue specific; upregulation by androgen exposure is seen in a variety of osteoblastic cells (Zhuang *et al.,* 1992; Takeuchi *et al.,* 1994; Wiren *et al.,* 1997, 1999), whereas in prostatic tissue, downregulation of the androgen receptor after androgen exposure is observed. The androgen-mediated upregulation of the androgen receptor observed in osteoblasts, at least in part, occurs through changes in androgen receptor gene transcription (Fig. 4). As in other tissues, increased androgen receptor protein stability may also play a part. No effect, or even inhibition, of androgen receptor mRNA by androgen exposure in other osteoblastic models has also been described (Hofbauer *et al.,* 1997; Kasperk *et al.,* 1997a). The mechanism(s) that underlies tissue specificity in autologous androgen receptor regulation and the possible biological significance of distinct autologous regulation of androgen receptor are not yet understood. It is possible that receptor upregulation by androgen in bone may result in an enhancement of androgen responsiveness at times when androgen levels are rising or elevated. In addition, androgen receptor expression in

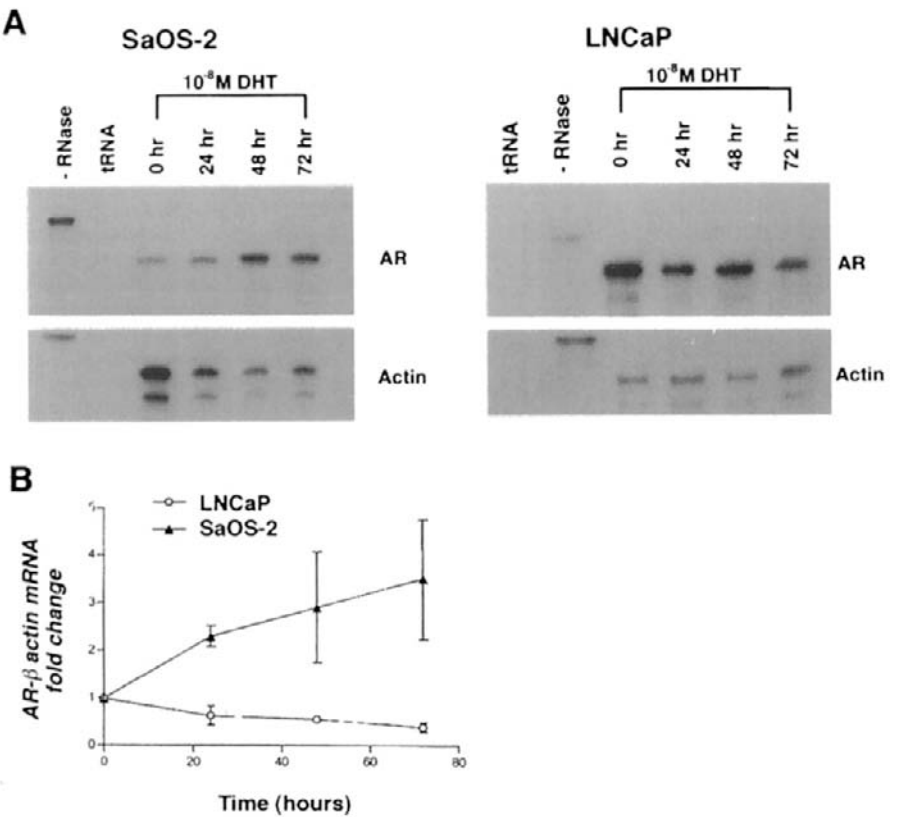

Figure 4 Dichotomous regulation of AR mRNA levels in osteoblast-like and prostatic carcinoma cell lines after exposure to androgen. (A) Time course of changes in AR mRNA abundance after DHT exposure in human SaOS-2 osteoblastic cells and human LNCaP prostatic carcinoma cells. To determine the effect of androgen exposure on hAR mRNA abundance, confluent cultures of either osteoblast-like cells (SaOS-2) or prostatic carcinoma cells (LNCaP) were treated with 10^{-8} *M* DHT for 0, 24, 48, or 72 hr. Total RNA was then isolated and subjected to RNase protection analysis with 50 μg total cellular RNA from SaOS-2 osteoblastic cells and 10 μg total RNA from LNCaP cultures. (B) Densitometric analysis of AR mRNA steady-state levels. The AR mRNA to β-actin ratio is expressed as the mean $\pm$SE compared to the control value from three to five independent assessments (Wiren *et al.,* 1997).

osteoblasts may be upregulated by exposure to glucocorticoids, estrogen, or 1,25-dihydroxyvitamin D_3 (Kasperk *et al.,* 1997a). Except for the immunocytochemical detection of androgen receptor expression in bone slices described earlier, regulation during osteoblast differentiation has not been well characterized. A preliminary report describes changes in mRNA expression of the three sex steroid receptors: androgen receptor and estrogen receptor α and β during osteoblast *in vitro* differentiation (Wiren *et al.,* 2000). Whether any other hormones, growth factors, or agents influence androgen receptor expression in bone is unknown.

Effects of Androgens on Proliferation and Apoptosis of Osteoblastic Cells

Androgens have direct effects on osteoblast proliferation and expression *in vitro.* The effect of androgen exposure on osteoblast proliferation remains controversial; both stimulation and inhibition of osteoblast proliferation have been reported as summarized in Table I. Benz *et al.* (1991) have shown that prolonged androgen exposure in the presence of serum inhibited proliferation (cell counts) by 15–25% in a transformed human osteoblastic line (TE-85). Testosterone and DHT were nearly equally effective regulators. Hofbauer *et al.* (1998) examined the effect of DHT exposure on proliferation in hFOB/AR-6, an immortalized human osteoblastic cell line stably transfected with an androgen receptor expression construct (with ~4,000 receptors/cell). In this line, DHT treatment inhibited cell proliferation by 20–35%. Finally, Kasperk *et al.* (1997b) reported that prolonged DHT pretreatment inhibited normal human osteoblastic cell proliferation (cell counts) in cultures pretreated with DHT.

In contrast, the same group (Kasperk *et al.,* 1989, 1990) also demonstrated that a variety of androgens in serum-free medium increase DNA synthesis ([^{3}H]thymidine incorporation) up to nearly 300% in osteoblast-like cells in primary culture (murine, passaged human). Again, testosterone and nonaromatizable androgens (DHT and fluoxymesterone) were nearly equally effective regulators. Consistent with increased proliferation, testosterone and DHT have also been reported to cause an increase in creatine kinase activity and [^{3}H]thymidine incorporation into DNA in rat diaphyseal bone (Somjen *et al.,* 1989). Variable results have also been reported with the adrenal androgen DHEA on osteoblast proliferation: DHEA was shown to stimulate osteoblast proliferation, but with less potency than DHT (Kasperk *et al.,* 1997b); however, no effect of DHEA alone has been described (Scheven and Milne, 1998). The differences observed with androgen-mediated changes in osteoblastic cell proliferation may be due to the variety of model systems employed (transformed osteoblastic cells vs passaged normal cells) and/or may reflect differences in the culture conditions (e.g., state of differentiation, receptor number, times of treatment, phenol red containing vs phenol red free, or serum containing, charcoal stripped vs serum free). These differences suggest

Table I Complex Effects of Androgens on Proliferation of Osteoblastic Cells

Cells[a]	Steroid[b]	Conditions[c]	% change	Reference
h TE-85 (osteosarcoma)	DHT (10 n*M*), 72 hr	2% FBS	↓ 25	Benz *et al.* (1991)
	T (10 n*M*), 72 hr	2% FBS	↓ 20	Benz *et al.* (1991)

[a] h, human; m, mouse; r, rat; OBs, osteoblasts.
[b] T, testosterone.
[c] cs, charcoal stripped; SF, serum free; psg, passage.

an underlying biologic complexity for the androgen regulation of osteoblast proliferation.

As a component of the control of osteoblast survival, it is also important to consider programmed cell death, or apoptosis (Wyllie *et al.,* 1980). A variety of skeletal cell types have been shown to undergo apoptosis (Hughes and Boyce, 1997; Manolagas and Weinstein, 1999). In particular, as the osteoblast population differentiates *in vitro,* the mature bone cell phenotype undergoes apoptosis (Lynch *et al.,* 1998). Modulation of bone cell apoptosis by steroid hormones has been shown: glucocorticoids enhance apoptosis of osteoclasts (Dempster *et al.,* 1997) and osteoblasts/osteocytes (Manolagas, 1998; Weinstein *et al.,* 1999), which estrogen treatment prevents (Gohel *et al.,* 1999). Furthermore, evidence shows that the osteocytic population is particularly sensitive to the effects of estrogen withdrawal, which induces apoptosis (Tomkinson *et al.,* 1997; 1998). Androgen exposure has been shown to influence apoptosis in other tissues (Lim *et al.,* 1997; Abreu-Martin *et al.,* 1999), but the effects of either androgen exposure or androgen withdrawal in bone have not been described.

In an interesting series of experiments, Manolagas (2000) showed that the effects of androgens (and estrogens) on bone cell proliferation are dependent on classical transcriptional mechanisms, whereas the antiapoptotic effects in osteoblastic cells, and the proapoptotic effects in osteoclastic cells, may be related to a nonclassical effect mediated by the activation of extracellular signal-related kinases (ERKs). The ERK-mediated actions were mechanistically dissociable from transcriptional effects, but were nevertheless receptor dependent. Of potential importance, the ERK-mediated actions were transmitted by either androgens or estrogens via both androgen and estrogen receptors. Obviously, this added complexity offers some intriguing explanations for the observation that androgens and estrogens have similar effects on remodeling in both genders.

Effects of Androgens on Differentiation of Osteoblastic Cells

Osteoblast differentiation can be characterized by changes in alkaline phosphatase activity and/or alterations in the expression of important extracellular matrix proteins, such as type I collagen, osteocalcin, and osteonectin. Enhanced osteoblast differentiation, as measured by increased matrix production, has been shown to result from androgen exposure. Androgen treatment in both normal osteoblasts and transformed clonal human osteoblastic cells (TE-89) appears to increase the proportion of cells expressing alkaline phosphatase activity, thus representing a shift toward a more differentiated phenotype (Fig. 5) (Kasperk *et al.,* 1989). Kasperk and colleagues subsequently reported dose-dependent increases in alkaline phosphatase activity in both high and low alkaline phosphatase subclones of SaOS2 cells (Kasperk *et al.,* 1996) and human osteoblastic cells (Kasperk *et al.,* 1997b). However, there are also reports, in a variety of model systems, of androgens either inhibiting (Hofbauer *et al.,* 1998) or having no effect on alkaline phosphatase activity (Gray *et al.,* 1992; Takeuchi *et al.,* 1994), which may reflect both the complexity and the dynamics of osteoblastic differentiation. There are also reports of androgen-mediated increases in type I α-1 collagen protein and mRNA levels (Benz *et al.,* 1991; Gray *et al.,* 1992; Kasperk *et al.,* 1996; Davey *et al.,* 2000) and increased osteocalcin mRNA or protein secretion (Kasperk *et al.,* 1997b; Davey *et al.,* 2000). Consistent with increased collagen production, androgen treatment has also been shown to stimulate mineral accumulation in a time-and dose-dependent manner (Kapur and Reddi,

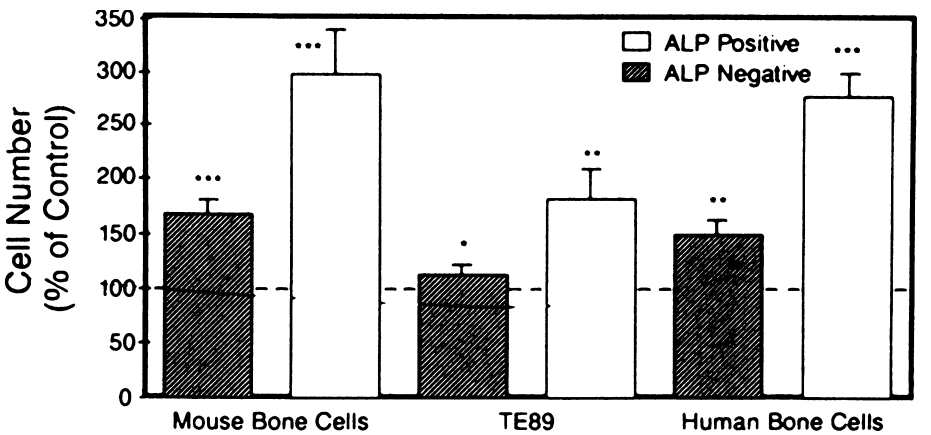

Figure 5 Effect of DHT on ALP-positive (ALP^+) and ALP-negative (ALP^-) cells in a normal mouse, a normal human osteoblast line, and a human osteosarcoma (TE89) monolayer cell culture. ($^{***}p < 0.001$; $^{**}p < 0.01$; $^{*}p < 0.1$). Control values in cells per mm^2 for mouse bone cells, TE89 cells, and human bone cells were 90 ± 5, 75 ± 7, and 83 ± 14, respectively (Kasperk *et al.,* 1989).

1989; Takeuchi *et al.,* 1994; Kasperk *et al.,* 1997b). These results suggest that androgens can enhance osteoblast differentiation under certain conditions and may thus play an important role in the regulation of bone matrix production and/or organization. This effect is also consistent with an overall stimulation of bone formation, as is observed clinically after androgen treatment.

Interaction with Other Factors to Modulate Bone Formation and Resorption

The effects of androgens on osteoblast activity must certainly also be considered in the context of the very complex endocrine, paracrine, and autocrine milieu in the bone microenvironment. Systemic and/or local factors can act in concert, or can antagonize, to influence bone cell function. This has been well described with regard to modulation of the effects of estrogen on bone (see e.g., Horowitz, 1993; Kawaguchi *et al.,* 1995; Kassem *et al.,* 1996). Androgens have also been shown to regulate well-known modulators of osteoblast proliferation or function. The most extensively characterized growth factor influenced by androgen exposure is TGF-β. TGF-β is stored in bone (the largest reservoir for TGF-β) in a latent form and has been show under certain conditions to be either a mitogen for osteoblasts (Centrella *et al.,* 1994; Harris *et al.,* 1994) or to inhibit proliferation (Noda and Rodan, 1986; Pfeilschifter *et al.,* 1987; Datta *et al.,* 1989). Androgen treatment has been shown to increase TGF-β activity in human osteoblast primary cultures (Fig. 6). The expression of some TGF-β mRNA transcripts (apparently TGF-β2) was increased, but no effect on TGF-β1 mRNA abundance was observed (Kasperk *et al.,* 1990; Bodine *et al.,* 1995). At the protein level, specific immunoprecipitation analysis reveals DHT-mediated increases in TGF-β activity to be predominantly TGF-β2 (Kasperk *et al.,* 1990; Bodine *et al.,* 1995). DHT has also been shown to inhibit both TGF-β gene expression and TGF-β-induced early gene expression that correlates with growth inhibition in this cell line (Hofbauer *et al.,* 1998). The TGF-β-induced early gene has been shown to be a transcription factor that may mediate some TGF-β effects (Subramaniam *et al.,* 1995). However, TGF-β1 mRNA levels are increased by androgen treatment in human clonal osteoblastic cells (TE-89), under conditions where osteoblast proliferation is slowed (Benz *et al.,* 1991). These results are consistent with the notion that TGF-β may mediate the complex androgen effects on osteoblast proliferation. Furthermore, the specific TGF-β isoform may determine osteoblast responses. It is interesting to note that at the level of bone, orchiectomy drastically reduces bone content of TGF-β levels, and testosterone replacement prevents this change, (Gill *et al.,* 1998) (Fig. 7). These data support the findings that androgens influence cellular expression of TGF-β and suggest that the bone loss associated with castration could be related to a reduction in growth factor abundance, induced by androgen deficiency.

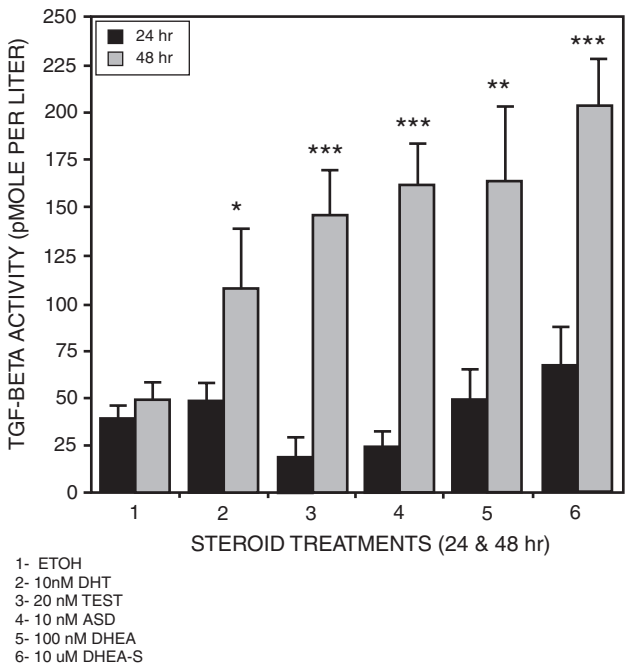

Figure 6 Induction of total TGF-β activity by gonadal and adrenal androgens in human osteoblast (hOB) cell-conditioned media. Cells were treated for 24 or 48 hr with vehicle or steroids. After treatment, conditioned media were saved and processed for the TGF-β bioassay. Results are presented as the mean ±SEM of three to four experiments. $^{*}p < 0.05$; $^{**}p < 0.02$, $^{***}p < 0.0005$ (Behren's Fisher *t* test) compared to the 48-hr ethanol control. ETOH, ethanol; TEST, testosterone; DHT, dihydrotestosterone; ASD, androstenedione; DHEA, dehydroepiandrosterone; DHEA-S, DHEA-sulfate (Bodine *et al.,* 1995).

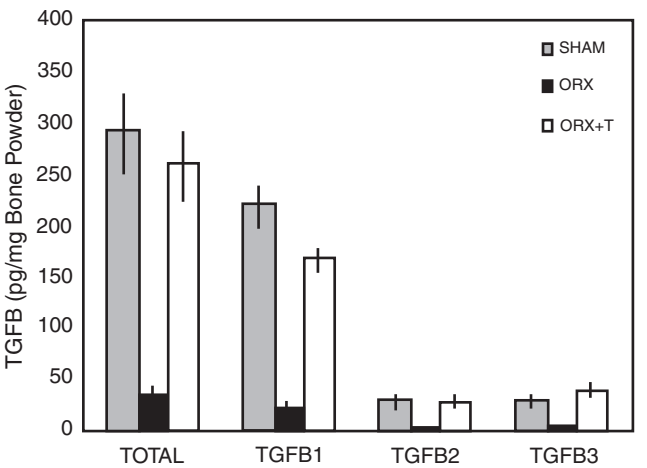

Figure 7 Effects of orchiectomy and T replacement on isoforms of TGF-β in long bones. Results are mean ±SE of four to six animals. Rats underwent sham operation or orchiectomy and 1 week later were given either placebo or 100 mg of testosterone in 60–day slow-release pellets. Specimens were obtained 6 weeks after surgery. All forms of TGF-β were reduced by orchiectomy (at least $p < 0.0002$), while there was no change in those with testosterone replacement (Gill *et al.,* 1998).

Other growth factor systems may also be influenced by androgens. Conditioned media from DHT-treated normal osteoblast cultures are mitogenic, and DHT pretreatment increases the mitogenic response of osteoblastic cells to fibroblast growth factor and to insulin-like growth factor II (IGF-II) (Kasperk *et al.,* 1990). In part, this may be due to slight increases in IGF-II binding in DHT-treated cells (Kasperk *et al.,* 1990), as IGF-I and IGF-II levels in osteoblast-conditioned media are not affected by androgen (Kasperk *et al.,* 1990; Canalis *et al.,* 1991). Although most studies have not found regulation of IGF-I or IGF-II abundance by androgen exposure (Kasperk *et al.,* 1990; Canalis *et al.,* 1991; Nakano *et al.,* 1994), there is a report that IGF-I mRNA levels are significantly upregulated by DHT (Gori *et al.,* 1999). Androgens may also modulate expression of components of the AP-1 transcription factor, as has been shown with inhibition of c-*fos* expression in proliferating normal osteoblast cultures (Bodine *et al.,* 1995). Thus, androgens may accelerate osteoblast differentiation via a mechanism whereby growth factors or other mediators of differentiation are regulated by androgen exposure.

Finally, androgens may modulate responses to other important osteotropic hormones/regulators. Testosterone and DHT specifically inhibit the cAMP response elicited by parathyroid hormone or parathyroid hormone-related protein in the human clonal osteoblast-like cell line SaOS-2, whereas the inactive or weakly active androgen 17α-epitestosterone had no effect (Fig. 8). This inhibition may be mediated via an effect on the parathyroid hormone receptor-G_s-adenylyl cyclase (Fukayama and Tashjian, 1989; Gray *et al.,* 1991; Vermeulen, 1991). The production of prostaglandin E_2 (PGE_2), another important regulator of bone metabolism, is also affected by androgens. Pilbeam and Raisz (1990) showed that androgens (both DHT and testosterone) were potent inhibitors of both parathyroid hormone (Fig. 9) and interleukin 1-stimulated prostaglandin E_2 production in cultured neonatal mouse calvaria. The effects of androgens on parathyroid hormone action and PGE_2 production suggest that androgens could act to modulate (reduce) bone turnover in response to these agents.

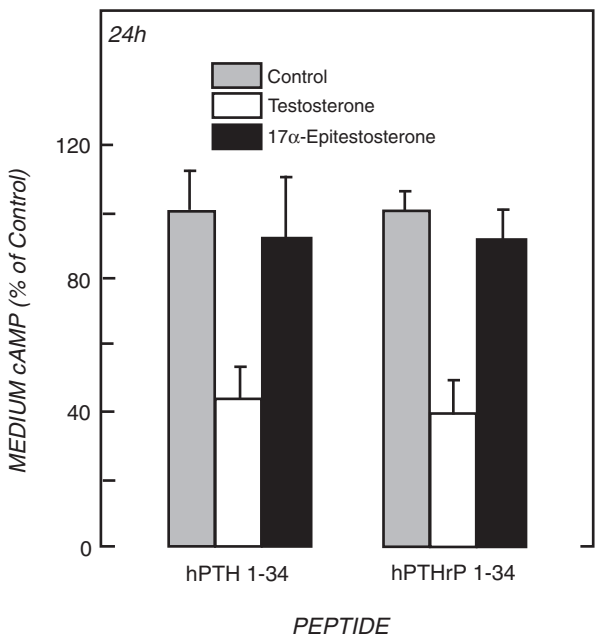

Figure 8 Actions of testosterone and 17α-epitestosterone on cAMP accumulation stimulated by $hPTH^{1-34}$ (5.0 n*M*) or $hPTHrP^{1-34}$ (5.0 n*M*) in human SaOS-2 cells. Cells were pretreated without or with the steroid hormones (10^{-9} *M*) for 24 hr. Each bar gives the mean value, and brackets give the SE for four to five dishes (Fukayama and Tashjian, 1989).

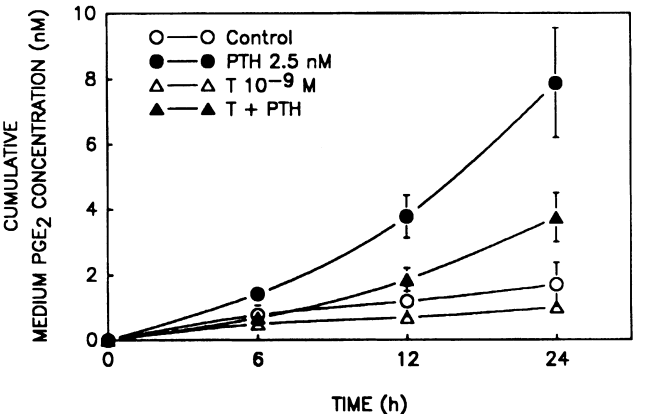

Figure 9 Effect of T on PTH-stimulated PGE_2 production in cultured neonatal calvariae as a function of time. Each bone was precultured for 24 hr in 1 ml medium with or without 10^{-9} *M*T and then transferred to similar medium with 2.5 n*M* PTH. Media were sampled (0.1 ml) at the indicated times. Data were corrected for the media removed. Each point represents the mean ±SEM for six bones in one experiment. The effect of T on PTH-stimulated PGE_2 production was significant ($p < 0.05$) at 6, 12, and 24 hr (Pilbeam and Raisz, 1990).

Finally, both androgen (Hofbauer and Khosla, 1999) and estrogen (Passeri *et al.,* 1993; Kassem *et al.,* 1996) inhibit production of interleukin-6 by osteoblastic cells (but see Rifas *et al.,* 1995). In stromal cells of the bone marrow, androgens have been shown to have potent inhibitory effects on the production of interleukin-6 (Table II) and the subsequent stimulation of osteoclastogenesis by marrow osteoclast precursors (Bellido *et al.,* 1995). Interestingly, adrenal androgens (androstenediol, androstenedione, dehydroepiandrosterone) have similar inhibitory activities on interleukin-6 gene expression and protein production by stroma (Bellido *et al.,* 1995). The loss of inhibition of interleukin-6 production by androgen may contribute to the marked increase in bone remodeling and resorption that follows orchidectomy. Moreover, androgens inhibit the expression of the genes encoding the two subunits of the IL-6 receptor (gp80 and gp130) in the murine bone marrow, another mechanism which may blunt the effects of this osteoclastogenic cytokine in intact animals (Lin *et al.,* 1997). In these aspects, the effects of androgens seem to be very similar to those of estrogen, which may also inhibit osteoclastogenesis via mechanisms that involve interleukin-6 inhibition.

Table II Effect of Androgens on Cytokine-Induced IL-6 Production by Murine Bone Marrow Stromal Cells[a]

Treatment	IL-6
IL-1 + TNF	4.27 ± 1.43
IL-1 + TNF+ testosterone (10^{-12} *M*)	3.87 ± 0.33
IL-1 + TNF+ testosterone (10^{-11} *M*)	2.90 ± 0.42
IL-1 + TNF+ testosterone (10^{-10} *M*)	2.09 ± 0.33
IL-1 + TNF+ testosterone (10^{-9} *M*)	1.12 ± 0.49
IL-1 + TNF+ testosterone (10^{-8} *M*)	1.03 ± 0.04
IL-1 + TNF+ testosterone (10^{-7} *M*)	1.01 ± 0.48
IL-1 + TNF+ dihydrotestosterone (10^{-12} *M*)	4.05 ± 0.19
IL-1 + TNF+ dihydrotestosterone (10^{-11} *M*)	2.97 ± 0.48
IL-1 + TNF+ dihydrotestosterone (10^{-10} *M*)	2.31 ± 0.86
IL-1 + TNF+ dihydrotestosterone (10^{-9} *M*)	1.72 ± 0.43
IL-1 + TNF+ dihydrotestosterone (10^{-8} *M*)	0.65 ± 0.21
IL-1 + TNF+ dihydrotestosterone (10^{-7} *M*)	1.41 ± 0.82

[a] Murine stromal cells (+/+ LDA11 cells) were cultured for 20 hr in the absence or the presence of different concentrations of either testosterone or dihydrotestosterone. Then IL-1 (500 U/ml) and TNF (500 U/ml) were added and cells were maintained for another 24 hr in culture. Values indicate means (±SD) of triplicate cultures from one experiment. Data were analyzed by one-way ANOVA. $^{*}p < 0.05$, versus cells not treated with steroids as determined by Dunnet's test. Neither testosterone nor dihydrotestosterone had an affect on cell number (Bellido *et al.,* 1995).

Metabolism of Androgens in Bone: Aromatase and 5α-Reductase Activities

There is abundant evidence in a variety of tissues that the eventual cellular effects of androgens may be the result not only of direct action of androgen, but also of the effects of sex steroid metabolites formed as the result of local enzyme activities. The most important of these androgen metabolites are estradiol (formed by the aromatization of testosterone) and 5α-DHT (the result of 5α reduction of testosterone). Evidence shows that both aromatase and 5α-reductase activities are present in bone tissue, at least to some measurable extent, but the biologic relevance of androgen metabolism is still controversial.

5α-reductase activity was first described in crushed rat mandibular bone by Vittek *et al.* (1974), and Schweikert *et al.* (1980) reported similar findings in crushed human spongiosa. Two different 5α-reductase genes encode type 1 and type 2 isozymes in many mammalian species (Russell and Wilson, 1994), but the isozyme present in human bone has not been characterized. In osteoblast-like cultures derived from orthopedic surgical waste, androstenedione (the major circulating androgen in women) can be reversibly converted to testosterone via 17β-hydroxysteroid dehydrogenase activity and to 5α-androstanedione via 5α-reductase activity, whereas testosterone is converted to DHT via 5α-reductase activity (Bruch *et al.,* 1992). The principal metabolite of androstenedione is α-androstanedione in the 5α-reductase pathway and testosterone in the 17β-hydroxysteroid dehydrogenase pathway. Essentially the same results were reported in experiments with human epiphyseal cartilage and chondrocytes (Audi *et al.,* 1984). In general, K_m values for bone 5α-reductase activity are similar to those in other androgen responsive tissues (Schweikert *et al.,* 1980; Nakano *et al.,* 1994).

The cellular populations in these studies were mixed and hence the specific cell type responsible for the activity is unknown. Interestingly, Turner *et al.* (1990a) found that periosteal cells do not have detectable 5α-reductase activity, raising the possibilities that the enzyme may be functional in only selected skeletal compartments and that testosterone may be the active metabolite at this clinically important site.

From a clinical perspective, the general importance of this enzymatic pathway is suggested by the presence of skeletal abnormalities in patients with 5α-reductase type 2 deficiency (Fisher *et al.,* 1978). However, Bruch *et al.* (1992) found no significant correlation between enzyme activities and bone volume. In mutant null mice lacking 5α-reductase type 1 (mice express very little type 2 isozyme), the effect on the skeleton cannot be analyzed due to midgestational fetal death (Mahendroo *et al.,* 1997). Treatment of male animals with finasteride (an inhibitor of type 2 5α-reductase activity) does not recapitulate the effects of castration (Rosen *et al.,* 1995), indicating that the reduction of testosterone to DHT by the type 2 isozyme is not a major determinant in the effects of gonadal hormones on bone. Whereas available data point to a possible role for 5α-reduction in the mechanism of action for androgen in bone, the clinical impact of this enzyme, which isozyme may be involved, whether it is present uniformly in all cells participating (involved) in bone modeling/remodeling, or whether local activity is important at all remains uncertain.

The biosynthesis of estrogens from androgen precursors is catalyzed by the microsomal enzyme aromatase cytochrome P450 ($P450_{arom}$, the product of the CYP19 gene). It is an enzyme known to be both expressed and regulated in a very pronounced tissue-specific manner (Simpson *et al.,* 1994). Aromatase activity has been reported in bone from mixed cell populations derived from both sexes (Nawata *et al.,* 1995; Schweikert *et al.,* 1995; Sasano *et al.,* 1997) and from osteoblastic cell lines (Purohit *et al.,* 1992; Tanaka *et al.,* 1993; Nakano *et al.,* 1994). Aromatase expression in intact bone has also been documented by *in situ* hybridization and immunohistochemical analysis (Sasano *et al.,* 1997) (Table III). Aromatase mRNA is expressed predominantly in lining cells, chondrocytes, and some adipocytes, but there is no detectable expression in osteoclasts. At least in vertebral bone, the aromatase fibroblast (1b type) promoter is utilized predominantly (Sasano *et al.,* 1997). The enzyme kinetics in bone cells seem to be similar to those in other tissues, although the V_{max} may be increased by glucocorticoids (Tanaka *et al.,* 1993).

Aromatase can produce the potent estrogen estradiol, but can also result in the weaker estrogen estrone from its adrenal precursors androstenedione and dehydroepiandrosterone (Nawata *et al.,* 1995). In addition to aromatase itself,

Table III Steroid Metabolism in Human Bone[a]

		Dihydrotestosterone			Androstenedione		
Crystallization	Solvent	^{3}H (cpm/mg)	^{14}C (cpm/mg)	$^{3}H/^{14}C$	^{3}H (cpm/mg)	^{14}C (cpm/mg)	$^{3}H/^{14}C$
1	Acetone	409	26	16	811	14	56
2	Benzene-heptane	408	25	16	811	14	57

4	Ethylether-hexane	411	28	15	775	13	59
5	Methanol	393	26	15	791	16	48
Mother liquor		405	24	17	848	16	53

[a] From Schweikert *et al.,* (1980). Confirmation by recrystallization of the identities of [^{3}H]dihydrotestosterone and [^{3}H]androstenedione recovered following the incubation of normal and osteoporotic human bone (ground spongiosa) with [1,2,76,7^{-3}H]testosterone. Pooled samples from 18 separate incubations of bone from various anatomical origins were chromatographed by preparative thin-layer chromatography. Material tentatively identified as [^{3}H]dihydrotestosterone and [^{3}H]androstenedione, respectively, was mixed with 200 mg of the appropriate carrier steroid and with ^{14}C-labeled steroid for recrystallization as described in the text.

osteoblasts contain enzymes that are able to interconvert estradiol and estrone (estradiol-17β hydroxysteroid dehydrogenase) and to hydrolyze estrone sulfate to estrone (estrone sulfatase) (Purohit *et al.,* 1992). Nawata *et al.* (1995) have reported that dexamethasone and 1α,25$(OH)_2D_3$ synergistically enhance aromatase activity and aromatase mRNA ($P450_{arom}$) expression in human osteoblast-like cells. There is no other information concerning the regulation of aromatase in bone, although this is an area of obvious interest given the potential importance of the enzyme and its regulation by a variety of mechanisms (including androgens and estrogens) in other tissues (Abdelgadir *et al.,* 1994; Simpson *et al.,* 1994).

The clinical impact of aromatase activity has been suggested by the reports of skeletal changes in women (Conte *et al.,* 1994) and men (Morishima *et al.,* 1995; Carani *et al.,* 1997) with aromatase deficiencies. The presentation of men with aromatase deficiency is very similar to that of a man with estrogen receptor α deficiency, namely an obvious delay in bone age, lack of epiphyseal closure, and tall stature (Smith *et al.,* 1994), suggesting that aromatase (and thus estrogen action) has a substantial role to play during skeletal development in the male. In one case, estrogen therapy of a man with aromatase deficiency was associated with an increase in bone mass (Bilezikian *et al.,* 1998). Inhibition of aromatization in young growing orchidectomized males, with the nonsteroidal inhibitor vorozole, results in decreases in bone mineral density and changes in skeletal modeling, as does castration, which reduces in both androgens and estrogens. However, vorozole therapy induces less dramatic effects on bone turnover (Vanderschueren *et al.,* 1997). Inhibition of aromatization in older orchidectomized males resembles castration with similar increases in bone resorption and bone loss, suggesting that aromatase activity may also play a role in skeletal maintenance in males (Vanderschueren *et al.,* 1996). Aromatase inhibition results in cancellous and cortical bone loss on older animals (Vanderschueren *et al.,* 2000). Interestingly, the development of aromatase knockout mice revealed the skeletal phenotype to be remarkably mild (Oz *et al.,* 2000), although the data suggested that there were gender differences in effects on bone remodeling (increased remodeling in the females, reduced in the males). These studies herald the importance of aromatase activity (and estrogen) in the mediation of androgen action in bone. The finding of these enzymes in bone clearly raises the difficult issue of the origin of androgenic effects. Do they arise from direct androgen effects (as is suggested by the actions of nonaromatizable androgens), to some extent from the local production of estrogenic intermediates, or both?

Nevertheless, there is substantial evidence that some, if in fact not most, of the biologic actions of androgens in the skeleton are direct. As noted previously, both *in vivo* and *in vitro* systems reveal the effects of the nonaromatizable androgen DHT to be essentially the same as those of testosterone (*vida infra*). In addition, blockade of the androgen receptor with the receptor antagonist flutamide results in osteopenia as a result of reduced bone formation (Goulding and Gold, 1993). These reports clearly indicate that androgens, independent of estrogenic metabolites, have primary effects on osteoblast function. However, the clinical reports of subjects with aromatase deficiency also highlight the relevance of androgen metabolism to biopotent estrogens in bone. Elucidation of the regulation steroid metabolism, and the potential mechanisms by which androgenic and estrogenic effects are coordinated, may have physiological, pathophysiological, and therapeutic implications.

Direct Effects of Androgens on Other Cell Types in Bone *in Vitro*

Similar to the effects noted in osteoblastic populations, androgens regulate chondrocyte proliferation and expression. Androgen exposure promotes chondrogenesis,

as shown with increased creatine kinase and DNA synthesis after androgen exposure in cultured epiphyseal chondrocytes (Carrascosa *et al.,* 1990; Somjen *et al.,* 1991). Increased [^{35}S] sulfate incorporation into newly synthesized (Corvol *et al.,* 1987) and increased alkaline phosphatase activity (Schwartz *et al.,* 1994) are androgen mediated. Regulation of these effects is obviously complex, as they were dependent on the age of the animals and the site from which chondrocytes were derived. Thus, in addition to effects on osteoblasts, multiple cell types in the skeletal milieu are regulated by androgen exposure.

Gender Specificity in Actions of Sex Steroids

Although controversial, there may be gender-specific responses in osteoblastic cells to sex steroids. Somjen and colleagues have shown that the increase in creatine kinase that occurs from bone cells *in vivo* and *in vitro* is gender specific (i.e., male animals, or cells derived from male bones, respond only to androgens, whereas females or female-derived cells respond only to estrogens) (Weisman *et al.,* 1993; Somjen *et al.,* 1994). This gender specificity appears to depend on the previous history of exposure of animals to androgens (or estrogens). How much gender-specific effects might affect bone metabolism in the intact animal is completely unknown. In addition, in most mammals, there is a marked gender difference in morphology that results in a sexually dimorphic skeleton. The mechanisms responsible for these differences are obviously complex and presumably involve both androgenic and estrogenic actions on the skeleton. It is becoming increasingly clear that estrogens are particularly important for the regulation of epiphyseal function and act to reduce the rate of longitudinal growth via influences on chondrocyte proliferation and function, as well as on the timing of epiphyseal closure (Turner *et al.,* 1994). Androgens, however, appear to have opposite effects on the skeleton. Androgens tend to promote long bone growth, chondrocyte maturation, and metaphyseal ossification. Furthermore, the most dramatic effect of androgens is on bone size, particularly cortical thickness (Turner *et al.,* 1994; Kasra and Grynpas, 1995), as androgens appear to have gender-specific effects on periosteal bone formation (Turner *et al.,* 1990b). This difference of course has biomechanical implications, with thicker bones being stronger bones. At the same time, the response of the adult skeleton to the same intervention results is distinct responses in males and females. For example, in a model of disuse osteopenia, in mice antiorthostatic suspension results in significant reduction in bone formation rate at the endocortical perimeter in males. In females, however, a decrease in bone formation rate occurred along the periosteal perimeter (Bateman *et al.,* 1997). Gender-specific responses *in vivo* and *in vitro,* and the mechanism(s) that underlies such responses in bone cells, may thus have significant implications in treatment options for metabolic bone disease.

Summary

Thus, the effects of androgens on bone health are both complex and pervasive. The effects of androgens are particularly dramatic during growth in boys, but almost certainly play an important role during this period in girls as well. Throughout the rest of life, androgens affect skeletal function and maintenance in both sexes. Nevertheless, relatively little has been done to unravel the mechanisms by which androgens influence the physiology and pathophysiology of bone, and there is still much to be learned about the roles of androgens at all levels. The interaction of androgens and estrogens and how their respective actions can be utilized for specific diagnostic and therapeutic benefit are important but unanswered issues. With an increase in the understanding of the nature of androgen effects will come greater opportunities to use their positive actions in the prevention and treatment of a wide variety of bone disorders.

CHAPTER 44

Kinins and Neuro-osteogenic Factors

Ulf H. Lerner and Pernilla Lundberg

Department of Oral Cell Biology, Umeå University, and Centre for Musculoskeletal Research, National Institute for Working Life, S-901 87 Umeå, Sweden

Introduction

Inflammatory processes within soft tissues are characterized by intense vasodilatation, increased blood vessel permeability, and exudation of plasma to the perivascular adjacent tissue, followed by the migration of different leukocytes from the blood into the surrounding tissues. These vascular and cellular reactions are associated with clinical symptoms of inflammation and with altered metabolism in the surrounding milieu. Bone cells can react to a nearby inflammatory process with both anabolic and catabolic reactions. In most cases, this results in osteolytic loss of bone tissue, but in some cases, sclerotic reactions can be seen. These reactions are induced by inflammatory mediators capable of interacting not only with the inflammatory process, but also with bone cells. In recent years, much experimental work has been performed to study the possible role of cytokines in bone metabolism (Rodan and Martin, 2000). This research area has been directed not only because of the possible role of cytokines in inflammatory bone disease, but also due to their possible roles in physiological bone remodeling and osteoclast development (reviewed in Martin *et al.,* 1998; Suda *et al.,* 1999; Hofbauer *et al.,* 2000; Lerner, 2000a), as well as their possible pathophysiological role in osteoporosis (reviewed in Manologas and Jilka, 1995; Spelsberg *et al.,* 1999). The discovery of the pleiotropic cellular effects of cytokines, and their important roles in the communication between different cells in inflammatory processes, has led to that the interest in inflammation-induced bone loss has been focused on the role of these peptides. However, it has been known for many years that other peptides and nonpeptides are also involved in nonimmune, or classical, inflammatory reactions, e.g., the kallikrein–kinin system, the coagulation cascade, the fibrinolytic pathway, and prostaglandins are activated in inflammatory processes and play important roles in the tissue inflammatory response. Although these systems are most well known for their effects on vessel permeability and dilatation, pain, extravascular coagulation, and fibrinolysis, it has been demonstrated that they are also involved in cell activation, proliferation, migration, and control of proteolysis. As regarding bone, we and others have shown that kinins and thrombin stimulate bone resorption *in vitro* (reviewed in Lerner, 1994, 1997). Osteoblasts synthesize plasminogen activators and inhibitors of these activators in a manner controlled by stimulators of bone resorption (Leloup *et al.,* 1991); *in vitro* data indicate that this system may be involved in the degradation of noncollageonous bone matrix proteins without having any effect on osteoclast formation (Daci *et al.,* 1999). Interestingly, *in vivo* data show that the lack of plasminogen activator inhibitor 1 protects ovariectomized mice from trabecular bone loss without affecting cortical bone loss (Daci *et al.,* 2000).

The activities of bone cells can be regulated at a local level not only by cytokines and kinins. The immunohistochemical demonstration of nerve fibers containing different neuropeptides in the vicinity of bone tissue (reviewed in Bjurholm, 1989; Kontinnen *et al.,* 1996; Lundberg, 2000) raises the possibility that neuropeptides, via neuro-osteogenic interactions, may directly or indirectly modulate the activity of bone cells in physiological and pathological conditions (Lerner, 2000b), in line with the view of neuroendocrine and neuroimmune interactions (van Hagen *et al.,* 1999). The presence of receptors for several neuropeptides on osteoblasts (Bjurholm *et al.,* 1992) and the finding that vasoactive intestinal peptide (VIP)

can stimulate bone resorption in organ culture (Hohmann *et al.,* 1983) provide evidence for a possible direct effect of neuropeptides on bone. The reports that neuropeptides enhance the production of cytokines from a variety of cell types, including monocytes and bone marrow cells, indicate that signaling molecules from skeletal nerve fibers may indirectly affect the skeleton via a neuroimmune control of bone cells, in line with the view that neuroimmunoendocrine interactions are important for the regulation of a variety of cells and tissues.

This chapter summarizes the knowledge of the effects of kinins on bone and the neuronal influence on bone tissue, as well as the interactions among kinins, neuro-osteogenic factors, and cytokines, on bone metabolism.

Activation of the Kallikrein–Kinin System

Kinins are blood-derived short peptides released from kininogens due to the enzymatic action of kallikreins, proteolytic enzymes present in most tissues and body fluids (Fig. 1). The biological effects of the kallikrein–kinin system are mainly exerted by bradykinin (BK) and kallidin (Lys-BK) acting on a variety of cells via cell surface receptors of the B2 subtype. In addition, BK and kallidin, without the carboxy-terminal arginine residue (des-Arg^9-BK and des-Arg^{10}-Lys-BK), can exert effects via BK B1 receptors. The kallikrein–kinin system is briefly summarized here, without giving any references to original reports. Readers are referred to extensive reviews in which relevant references can be found (Hall, 1997; Kaplan *et al.,* 1997; Marceau and Bachvarov, 1998; Marceau *et al.,* 1998; Pesquero and Bader, 1998; Raidoo and Bhoola, 1998; Regoli *et al.,* 1998; Stewart *et al.,* 1999).

Hageman Factor

Activation of the plasma kallikrein system is initiated by the Hageman factor (coagulation factor XII), a single chain globulin (molecular weight 80,000), which can be activated by exposure to an activating macromolecular anionic surface and by endotoxin, as well as by an autocatalytic mechanism. The kallikrein system is activated by the Hageman factor by the action of this enzyme on plasma prekallikrein (Fig. 1).

Kallikreins

Plasma prekallikrein is a single chain globulin encoded by a single gene and is synthesized and secreted by hepatocytes as an inactive proenzyme. Activated plasma kallikrein acts on high molecular weight (HMW) kininogen at two sites, Lys-Arg and Arg-Ser, to release BK, a peptide consisting of nine amino acids with arginine at both the amino- and the carboxy-terminal ends (Fig. 1).

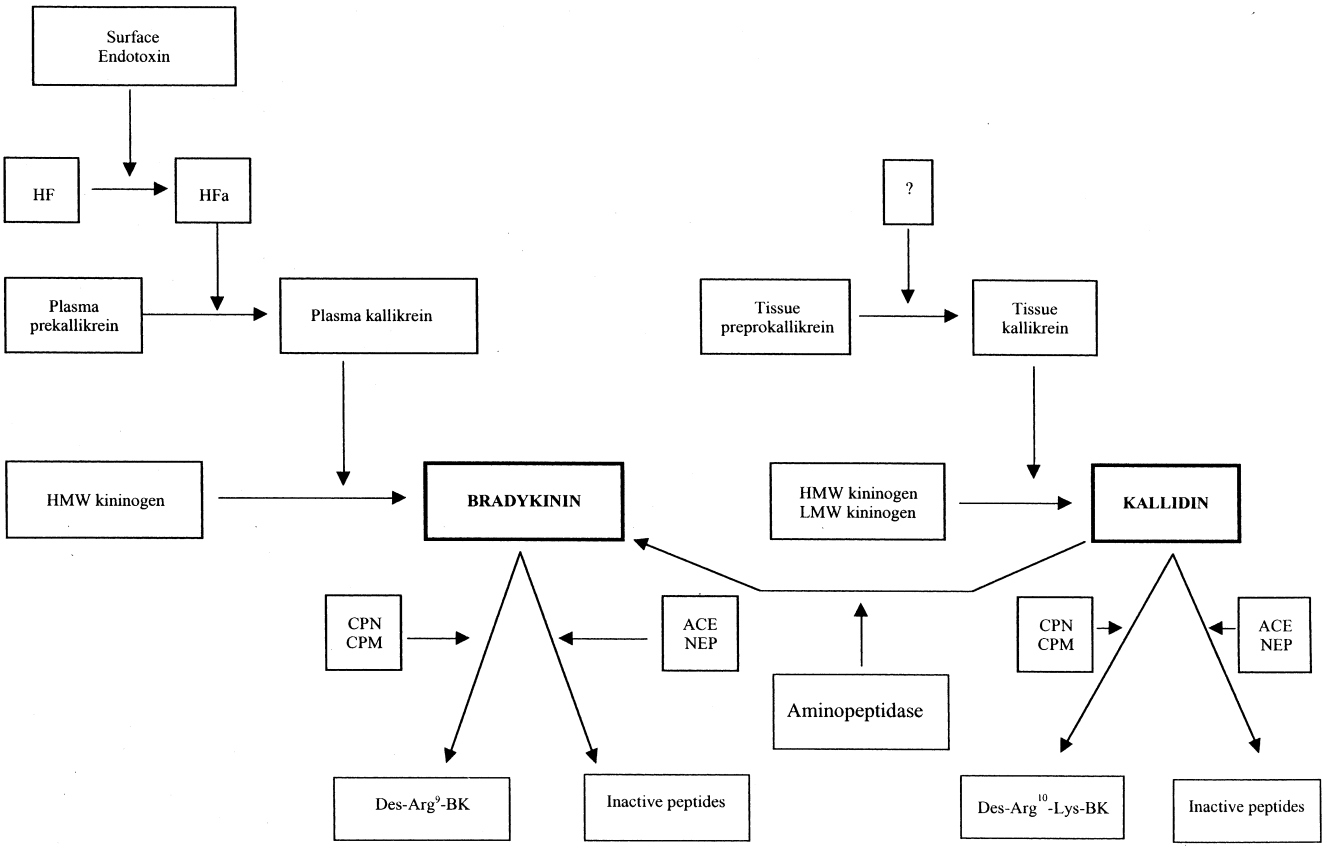

Figure 1 Schematic representation of activation of the kallikrein–kinin system and the formation of kinins.

Plasma kallikrein is inactivated rapidly by the C1 inhibitor and may also be inhibited by α_2-macroglobulin and antithrombin III.

Tissue kallikrein is a member of a multigene family with tissue-specific expression. Several of the serine proteases belonging to this family have important roles in the activation of peptide prohormones and growth factors. Tissue kallikrein liberates kallidin (Lys-BK) from both HMW and (LMW) kininogens, but because LMW kininogen is the most abundant kininogen, the enzyme preferentially uses LMW kininogen as substrate (Fig. 1).

As compared to plasma kallikrein, tissue kallikrein is less susceptible to inhibition. In humans, mainly α_1-antiprotease has some inhibitory capacity. However, a new inhibitor belonging to the serpine superfamily has been identified. In inflammatory processes, tissue kallikrein may be more important for kinin generation, because it seems less susceptible to degradation and because it can use both HMW and LMW kininogen as substrate.

Kininogens

HMW (88–120 kDa) and LMW (50–68 kDa) kininogens are synthesized by hepatocytes as single chain glycoproteins with one amino-terminal heavy chain and one carboxy-terminal light chain. The HMW and LMW kininogens are coded for by a single gene, and the different forms are a consequence of alternate splicing of the gene transcript. The heavy chain of both kininogens contains a domain with cysteine proteinase inhibitory capacity, suggesting the possibility that kininogens may possess both pro- and anti-inflammatory activities.

Rats have a unique kininogen, T-kininogen (68 kDa), from which T-kinin (Ile-Ser-BK) is released by T-kininogenase(s). The levels of T-kininogen in plasma seem to be influenced by estrogen, with concentrations being increased in females at puberty and decreased in mature females by ovariectomy.

Kinins

The term kinin is derived from the Greek word *kineo* (= to move) and was originally used for substances acting on smooth muscles. Today the term kinin is mainly restricted to peptides related to the nonapeptide BK. In this chapter, the word kinin is used for endogenous mammalian peptides with sequence homology to BK, and the kinin analogs refer to synthetic peptides whose amino acid sequence is modified from that of BK.

The kinins are not synthesized and released by cells, but are bioactive, short, and potent peptides that constitute a small part of large proteins (kininogens) from which they are released extracellularly by kininogenases. Four different, but closely related, primary kinins have been described: BK, kallidin, Hyp^3-BK, and T-kinin. The amino acid sequences of these peptides are shown in Table I.

Kinins released have a very short half-life *in vivo,* being estimated to approximately 30 sec, due to the action of different kininases. An interesting aspect is that one of these kininases, cleaving off the carboxy-terminal arginine, gives rise to peptides (des-Arg^9-BK and des-Arg^{10}-Lys-BK) that are biologically active in several cell types and therefore des-Arg^9-BK and des-Arg^{10}-Lys-BK are also included in the group of naturally produced kinins with biological activities.

Kininases

Kinins formed have a short half-life because they are destroyed rapidly by the enzymatic action of different proteases, collectively called kininases (Fig. 2). These enzymes are present both as circulating and as cell-bound enzymes. Several kininases have been described, including carboxypeptidase N (CPN) and carboxypeptidase M (CPM), together called kininase-I. Other kininases are two different kininase-II enzymes called angiotensin-converting enzyme (ACE) and neutral endopeptidase (NEP). A third type of kininases are prolidase and aminopeptidase.

Table I Amino Acid Sequences of Natural Kinins and Bradykinin Analogs with Receptor Antagonistic Properties

			1	2	3	4	5	6	7	8	9
B2 receptor agonists											
Bradykinin			Arg-	Pro-	Pro-	Gly-	Phe-	Ser-	Pro-	Phe-	Arg
Kallidin		Lys-	Arg-	Pro-	Pro-	Gly-	Phe-	Ser-	Pro-	Phe-	Arg
Met-Lys-Bradykinin	Met-	Lys-	Arg-	Pro-	Pro-	Gly-	Phe-	Ser-	Pro-	Phe-	Arg
Hyp^3-bradykinin			Arg-	Pro-	Hyp-	Gly-	Phe-	Ser-	Pro-	Phe-	Arg
T-kinin	Ile-	Ser-	Arg-	Pro-	Pro-	Gly-	Phe-	Ser-	Pro-	Phe-	Arg
B1 receptor agonists											
Des-Arg^9-bradykinin			Arg-	Pro-	Pro-	Gly-	Phe-	Ser-	Pro-	Phe	
Des-Arg^9-Lys-bradykinin		Lys-	Arg-	Pro-	Pro-	Gly-	Phe-	Ser-	Pro-	Phe	
B1 receptor antagonist											
Des-Arg^9-[Leu^8]-bradykinin			Arg-	Pro-	Pro-	Gly-	Phe-	Ser-	Pro-	Leu	
B2 receptor antagonists											
D-Arg-[Hyp^3, Thi^{5,8}, D-Phe^7]-bradykinin		Arg-	Arg-	Pro-	Hyp-	Gly-	Thi-	Ser-	Phe-	Thi-	Arg
Hoe 140		Arg-	Arg-	Pro-	Hyp-	Gly-	Thi-	Ser-	Tic-	Oic-	Arg

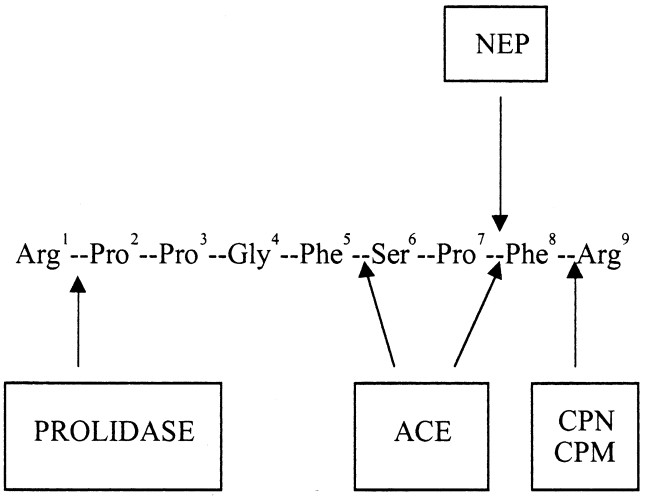

Figure 2 Cleavage sites for different kininases in the bradykinin molecule.

Kininases have been described in biological fluids and in a variety of cells, but no information on the presence of these enzymes in bone is available. However, the fact that some (but not all) kininase II inhibitors potentiate the bone-resorbing effect of BK (Lerner *et al.,* 1987) provides indirect evidence for the presence of BK-inactivating enzymes in bone.

Bradykinin Receptors

Two different BK receptors, termed B1 and B2, have been demonstrated using pharmacological methods such as rank order potencies for different agonists, sensitivity to receptor antagonists, and radioligand-binding studies.

Des-Arg^9-BK and des-Arg^{10}-Lys-BK are the natural agonists for B1 receptors with the latter being the more potent ligand. Substitution of phenylalanine at position 8 in des-Arg^9-BK by an amino acid with an aliphatic side chain gives rise to B1 receptor antagonists, the classical one being des-Arg^9-[Leu^8]-BK. Hoe-140-des-Arg^{10} has also been found to be a potent and selective antagonist for B1 receptors.

The natural kinins with affinity for the B2 receptors are BK and Lys-BK. These agonists are equipotent, or sometimes Lys-BK are slightly more potent than BK. Since the discovery that substitution of proline at position 7 of BK with phenylalanine converts BK agonists to antagonists, several B2 receptor antagonists have been developed, with D-Arg-[Hyp^3, Thi^{5,8}, D-Phe^7]-BK being a very potent one. Hoe 140 (D-Arg-[Hyp^3, Thi^5, D-Tic^7, Oic^8]-BK has been shown to be the first totally selective B2 receptor antagonist. The first nonpeptide BK receptor antagonists with affinity for B2 receptors (the phosphonium WIN 64338 and the quinoline FR 173657) have also been developed.

The distribution of BK receptors in different cells and tissues and the relative expression of B1 and B2 receptors have been studied extensively, mostly by the use of pharmacological methods. B2 receptors seem to be constitutively expressed in a variety of tissues. B1 receptor expression has, so far, been demonstrated in certain cell types. In most cells, however, B1 receptor expresssion can be induced by tissue injury and cytokines/growth factors, including interleukin-1 (IL-1), IL-2, oncostatin M, interferon-γ, and epidermal growth factor, by a mechanism likely to be mediated by mitogen-activated protein (MAP) kinases.

B1 and B2 receptors have been cloned molecularly from human, rabbit, rat, and mice species and found to be highly conserved (70–80% homology). In humans, the predicted sequences of the B1 and B2 receptors show proteins of 357 and 364 amino acids, respectively. However, the homology between the two receptor types is only 36%. Both receptors contain seven transmembrane-spanning domains, typical of G protein-coupled receptors, and are located on chromosome 14q32, in very close proximity to each other. Targeted disruption of the B1 receptor gene by homologous recombination results in mice that develop normally with normotension, although failing to respond to B1 receptor agonists. However, lipopolysaccharide-induced hypotension is blunted and the number of polymorphonuclear leukocytes is reduced in inflamed tissues. Moreover, B1 receptor knockout mice are analgesic in behavioral tests of nociception (Pesquero *et al.,* 2000). Targeted deletion of the B2 receptor gene results in mice with severe hypertension, with end-organ damage, when challenged to excess dietary sodium chloride (Alfie *et al.,* 1996). No data are available concerning the skeletal phenotype of B1 and B2 receptor knockout mice. Both B1 and B2 receptor genes have been found to express several allelic polymorphisms, although any association to physiological or pathophysiological bone metabolism has not been studied.

Effects of Kinins on Bone Metabolism

Studies on the effects of kinins on bone metabolism have been performed *in vitro,* mainly in bone organ cultures. Most of these investigations have used a mouse

calvarial bone culture system, in which bones, prelabeled with ^{45}Ca or [^{3}H]proline *in vivo,* are precultured for 18–24 hr in serum-free medium with added indomethacin. The reason for the preculture period is not to "wash out" loosely bound isotope (not necessary because the skeletons of the young mice are prelabeled for 4 days), but to inhibit the initial rise of endogenously produced prostaglandins often causing a high control (or basal) rate of resorption. After the preculture period, the bones are washed extensively for 24 hr to get rid of indomethacin present in the tissues and then cultured in the absence or presence of different test substances (Lerner, 1987; Ljunggren *et al.,* 1991b).

Treatment of mouse calvarial bones, precultured as described earlier, with BK for 72–96 hr results in increased bone resorption, as assessed either by the release of ^{45}Ca or by the mobilization of stable calcium and inorganic phosphate (Gustafson and Lerner, 1984; Lerner *et al.,* 1987). Also, bone matrix degradation, as assessed by the release of ^{3}H from [^{3}H]proline-labeled bones, is increased by BK (Lerner *et al.,* 1987). BK can stimulate the release of ^{45}Ca also from fetal rat long bones, although the response is less than that seen in mouse calvarial bones (Ljunggren and Lerner, unpublished results). The threshold for action of BK in the mouse calvariae is 3 n*M* and half-maximal stimulation (EC_{50}) is obtained at 100 n*M* (Lerner *et al.,* 1987).

Calcitonin, added simultaneously with BK, inhibits the bone resorptive effect of BK (Lerner *et al.,* 1987). Because calcitonin can inhibit the activity of multinucleated osteoclasts, as well as the recruitment of new osteoclasts, data do not reveal if BK stimulates bone resorption by enhancement of the activity of preformed osteoclasts or by the formation of new osteoclasts. However, morphological studies using both light and electron microscopy have shown that osteoclasts present in the calvariae, when bones are dissected from the mice, disappear after the preculture period (Reinholt and Lerner, unpublished results). This implies that the stimulation of bone resorption in this system is dependent on proliferation(?)/differentiation/fusion of osteoclast progenitor cells to multinucleated active osteoclasts and thus suggests that BK stimulates bone resorption by enhancing osteoclast recruitment, a hypothesis supported by the fact that the action of BK on bone resorption is delayed, with no effect observed until after 24 hr (Lerner *et al.,* 1987). Because no hematopoetic cells are present in the mouse calvarial explants, the osteoclast precursor cells in these bones are probably late precursor cells in the osteoclastic cell lineage. Some stimulators, including PTH and $1,25(OH)_2$ vitamin D_3, enhance bone resorption and osteoclast formation by mechanisms insensitive to inhibition of cell proliferation, probably by stimulating differentiation and/or fusion of a postmitotic pool of mononuclear precursor cells (Lorenzo *et al.,* 1983; Lerner and Hänström, 1989). In contrast, stimulation of bone resorption in the mouse calvariae by glucocorticoids and transforming growth factor β (TGF-β) is decreased by mitotic inhibition (Conaway *et al.,* 1996; Lerner, 1996), indicating that these substances act at a level proximal to the level at which the calcium-regulating hormones do. At which level BK acts is not yet known. In ongoing studies, we have not found any effect on osteoclast formation in mouse bone marrow cultures by BK itself. The stimulatory effect of IL-1 β, however, is clearly potentiated by BK (Lerner *et al.,* in preparation). One possibility may be that BK does not share the stimulatory effects of PTH and $1,25(OH)_2$ vitamin D_3 on early precursor cells, but that it may act at later stages downstream of the effect of IL-1. Another possibility may be that BK potentiates the mechanism by which IL-1 stimulate osteoclastogenesis. Whether stromal cells or osteoclast precursor cells are the target cells for BK is not known at present.

The fact that BPP5a, which is a kininase-II inhibitor, potentiates the bone resorptive effect of BK, without affecting those of PTH and PGE_2 (Lerner *et al.,* 1987), supports the hypothesis that the capacity of BK to stimulate bone resorption is decreased by the action of kininase-II enzymes present in mouse calvarial bones. For reasons not known, the ACE inhibitor captopril does not potentiate BK-induced release of ^{45}Ca.

Inflammatory bone loss may not only be due to enhanced bone resorption, but also to decreased bone formation. As regarding osteoblast cell proliferation, biosynthesis of bone matrix proteins, and the activity of alkaline phosphatase, very little is known about the possible effects of BK. In the human osteoblastic osteosarcoma cell line MG-63, BK does not stimulate cell proliferation or the biosynthesis of type I collagen and osteocalcin (Rosenquist *et al.,* 1996), although these cells express BK B2 receptors coupled to a burst of prostanoid formation (Bernhold and Lerner, in preparation). BK B1 receptors have been suggested to play a role in fibrinogenesis in fibrotic disorders, and B1 receptor agonists have been shown to stimulate type I collagen biosynthesis in human fibroblasts due to the stabilization of connective tissue growth factor mRNA (Ricupero *et al.,* 2000). In MG-63 cells, however, we have not been able to find any effect on type I collagen biosynthesis by B1 agonists, although these cells express B1 receptors (Rosenquist *et al.,* 1996; Bernhold and Lerner, in preparation). In agreement with the findings in MG-63 cells, BK has no effect on the proliferation of osteoblast-like cells isolated from human bone (Frost *et al.,* 1999).

Interestingly, whey protein obtained from milk and known to contain a variety of growth factors has been found to increase bone strength in ovariectomized rats (Takada *et al.,* 1997) and to stimulate proliferation and collagen synthesis in MC3T3-E1 cells (Takada *et al.,* 1996). The growth-promoting activity of milk has been purified and found to be a 17-kDa protein with an amino-terminal amino acid sequence very similar to an internal sequence of HMW kininogen (Yamamura *et al.,* 2000). This observation suggests that kininogens may not only be important for BK formation and cysteine protease inhibition, but also for bone growth.

Prostaglandins as Mediators of Bone Resorption Induced by BK

It was noted early that bone resorption induced by BK was inhibited by indomethacin, a potent inhibitor of prostaglandin biosynthesis (Gustafson and Lerner, 1984). It was later shown that several inhibitors of the cyclooxygenase pathway of arachidonic acid metabolism, including indomethacin, naproxen, meclofenamic acid, and flurbiprofen, abolish BK-induced mineral mobilization and bone matrix degradation (Lerner *et al.,* 1987). Similarly, all these nonsteroidal anti-inflammatory drugs also completely inhibit the bone resorptive effect of kallidin and Met-Lys-BK (Gustafson *et al.,* 1986; Ljunggren and Lerner, 1988). The glucocorticoids hydrocortisone and dexamethasone, which are potent inhibitors of prostaglandin biosynthesis, also inhibit BK-induced bone resorption (Lerner *et al.,* 1987). These observations indicate that the bone resorptive effect of BK is totally dependent on the capacity of this peptide to activate prostaglandin formation. Interestingly, most stimulators of bone resorption *in vitro* also stimulate prostanoid formation in bone tissue and bone cells, although the magnitude of the prostaglandin response varies considerably between different stimulators. However, the bone resorptive effect and the biosynthesis of prostaglandins are not necessarily linked to each others. There are stimulators of bone resorption, including PTH, $1,25(OH)_2$ vitamin D_3, TNF-α/TNF-β, and TGF-β, that are totally independent of prostaglandin formation (Ljunggren and Lerner, 1989; Lerner and Ohlin, 1993; Lerner, 1996). Other stimulators, *e.g.,* IL-1, have a larger capacity to stimulate bone resorption in the presence of endogenous prostaglandin production, although a bone resorptive effect of IL-1 still can be seen in the absence of prostaglandins (Lerner *et al.,* 1991). To a third group of stimulators, being unable to stimulate bone resorption in the absence of prostaglandin production, belong BK, kallidin, and Met-Lys-BK.

In primary cultures of mouse calvarial osteoblasts, BK causes a rapid burst of PGE_2 and 6-keto-$PGF_{1\alpha}$ (the stable breakdown product of PGI_2) that is maximal after 5–10 min (Lerner *et al.,* 1989). The half-maximal effect for the prostaglandin response (10 n*M*) is less than that for the bone resorptive effect (100 n*M*), again probably due to differences in the degradation of BK in short-term cell incubations compared to long-term organ cultures. The nontransformed mouse calvarial osteoblastic cell line MC3T3-E1, which both enzyme-histochemically and biochemically express a significantly lower activity of alkaline phosphatase compared to primary mouse calvarial osteoblasts (indicating that the MC3T3-E1 cells may represent a preosteoblastic phenotype; Lundberg and Lerner, unpublished results), also responds to BK with a burst of prostanoid formation (Lerner *et al.,* 1989). The time course, threshold for action, and EC_{50} value are similar to those found in primary mouse calvarial osteoblasts. A very similar prostanoid response to BK is also obtained in nonenzymatically isolated human bone cells (Ljunggren *et al.,* 1990; Rahman *et al.,* 1992) and in the human osteoblastic osteosarcoma cell line MG-63 (Bernhold and Lerner, in preparation).

BK-induced prostanoid biosynthesis can be abolished by a variety of structurally different nonsteroidal anti-inflammatory drugs and glucocorticoids (Lerner *et al.,* 1989). The inhibitory effect of glucocorticoids is only seen in cells pretreated with the steroids for several hours, in contrast to the effect of the nonsteroidal anti-inflammatory drugs, which require a very short preincubation period to be fully active. This is not an unexpected finding considering the different mechanisms by which these compounds are regarded to inhibit prostaglandin biosynthesis; nonsteroidal drugs inhibiting cyclooxygenase activity and steroids exerting their effects via a genomic action. However, bone resorption induced by BK can be inhibited by the simultaneous addition of glucocorticoids (Lerner *et al.,* 1987). This could be explained if the rapid burst of prostaglandins produced is not sufficient to stimulate bone resorption, but that prostaglandins synthesized later during the bone organ cultures are rate limiting in the bone resorption process. Such a hypothesis raises the possibility that the kininase-I metabolite of BK, des-Arg^9-BK, may contribute to the effect of BK. This octapeptide has also been found to stimulate bone resorption and prostaglandin production, but the effects are very much delayed as compared to those by BK (Lerner *et al.,* 1987; Ljunggren and Lerner, 1990), thereby making it possible for glucocorticoids to exert an inhibitory effect. The fact that glucocorticoids, added together with BK, inhibit the bone resorptive effect could also indicate that the effect of these compounds is unrelated to the inhibition of prostaglandin biosynthesis, but exerted at a step distal to the burst of prostaglandin biosynthesis. However, the observation that glucocorticoids potentiate the bone resorptive effect of exogenous PGE_2 (Conaway *et al.,* 1997) does not support such a view. Whatever the mechanism in glucocorticoid-induced inhibition of BK-induced bone resorption is, the findings that several different cyclooxygenase inhibitiors, as well as 5,8,11,14-eicosatetraynoic acid, a competitive inhibitor of arachidonic acid metabolism, abolish the bone resorptive effect of BK convincingly demonstrate the importance of prostanoids as mediators of the bone resorptive action of BK.

Kinin Receptors in Bone Cells

BK, Lys-BK, and Met-Lys-BK have been demonstrated to stimulate bone resorption in mouse calvariae, indicating the presence of B2 receptors (Gustafson *et al.,* 1986; Lerner *et al.,* 1987; Ljunggren and Lerner, 1988). This view is further supported by the fact that the B1 receptor antagonist des-Arg^9-[Leu^8]-BK does not affect the bone resorptive effect of BK (Lerner *et al.,* 1987), an observation that also suggests that the effect of BK is not due to the conversion of BK by kininase-I to the the B1 receptor agonist des-Arg^9-BK.

Pretreatment of BK with kininase-I does not affect BK-induced bone resorption, whereas the effect of PTH is reduced significantly (Lerner *et al.,* 1987). This observation

suggests that des-Arg^9-BK, a B1 receptor agonist, may be able stimulate bone resorption. In agreement with this view, it has been shown that the addition of des-Arg^9-BK to mouse calvarial bones results in enhanced release of ^{45}Ca (Lerner *et al.,* 1987; Ljunggren and Lerner, 1990), an effect that is inhibited by the B1 receptor antagonist des-Arg^9-[Leu^8]-BK (Ljunggren and Lerner, 1990), indicating that bone cells are also equipped with B1 receptors. The effect of des-Arg^9-BK is abolished by indomethacin, flurbiprofen, and hydrocortisone. In addition, prostanoid biosynthesis in mouse calvarial bones is stimulated by des-Arg^9-BK in 72-hr cultures, but, in contrast to BK, no prostaglandin response is seen in bones incubated for 30 min with des-Arg^9-BK.

Data obtained with mouse calvarial bones demonstate the presence of both B1 and B2 receptors linked to bone resorption by a process requiring the stimulation of prostaglandin biosynthesis. Differences in the kinetics for the prostaglandin response indicate different molecular mechanisms of action in B1 and B2 receptor stimulation of bone resorption.

Using the burst of PGE_2 and 6-keto-$PGF_{1\alpha}$ biosynthesis in primary mouse calvarial osteoblasts and in the osteoblastic cell line MC3T3-E1 as parameters, the following rank order potency for different agonist has been shown: BK = Lys-BK>Met-Lys-BK>>>>des-Arg^9-BK, demonstrating the presence of B2 receptors on these osteoblasts (Ljunggren *et al.,* 1991c). The fact that D-Arg^0-[Hyp^3, Thi^{5,8}, D-Phe^7]-BK, but not des-Arg^9-[Leu^8]-BK, inhibits the inital rise of prostaglandins induced by BK further supports the presence of B2, and not B1, receptors on mouse osteoblasts. It has been shown that the human osteosarcoma cell line MG-63 shows a prostanoid burst in response to a wide variety of natural kinins and kinin analog with affinity to BK B2 receptors. The effect of BK in these cells is inhibited by B2 receptor antagonists, but not by B1 receptor antagonists (Bernhold and Lerner, in preparation). These observations and the finding that [Hyp^3]-BK is a weak agonist and T-kinin is a potent agonist further indicate that osteoblasts are equipped with B2 receptors linked to a burst of prostaglandin biosynthesis. This view is also compatible with the observations that BK and D-Arg^0-[Hyp^3, Thi^{5,8}, D-Phe^7]-BK, but not des-Arg^9-BK, compete with the binding of [^{3}H]BK to osteoblasts (Ljunggren *et al.,* 1991c). Leis *et al.* (1997) have demonstrated that responsiveness to BK, specific binding of [^{3}H]BK, and mRNA expression of BK B2 receptors in subclones of the murine osteoblastic cell line MC3T3-E1 are highest in clones with low alkaline phosphatase activity, indicating that it is mainly osteoblasts at early stages of differentiation that are responsive to BK. This observation is in agreement with findings by Lerner *et al.* (1989) demonstrating that the more confluent mouse calvarial osteoblasts are in cell cultures, the less is the BK responsiveness. Using BK-sensitive MC3T3-E1 cells, it has been shown that these cells express a single category of binding sites for [^{3}H]BK (Windischhofer and Leis, 1997). Radioligand-binding assays in MG-63 cells, using [^{3}H]BK as ligand, have demonstrated specific binding sites that can be competed for by B2 receptor agonists and antagonists. The rank order potency for kinin-induced stimulation of prostaglandin formation and radioligand-binding studies strongly indicate the constitutive expression of B2 receptors in MG-63 cells, a conclusion further supported by RT-PCR analysis showing mRNA expression of BK B2 receptors (Bernhold and Lerner, in preparation).

The acute rise of prostaglandin production in osteoblasts in response to BK is preceded by an accumulation of inositol phosphates, a transient increase of intracellular calcium, and an activation of protein kinase C (Ljunggren *et al.,* 1991a, 1993; Leis *et al.,* 1997). The initial, transient rise of intracellular calcium and the sustained influx of extracellular calcium seem to be regulated by different protein kinase C isoenzymes (Sakai *et al.,* 1992). By studying BK-induced release of arachidonic acid from MC3T3-E1 cells, evidence shows that BK receptors are linked to G proteins (Yanaga *et al.,* 1991), well in agreement with cloning data. These findings suggest that activation of BK receptors leads to a phospholipase C-mediated breakdown of phosphatidylinositol 4,5-bisphosphate with subsequent formation of the two putative second messengers: inostiol 1,4,5-trisphosphate (IP3) and diacylglycerol (DAG).

In agreement with the observation in mouse calvarial bones, treatment of primary mouse calvarial osteoblasts with des-Arg^9-BK results in a delayed enhancement of PGE_2 formation that can be observed at and after 24 hr (Ljunggren and Lerner, 1990). The effect of des-Arg^9-BK is inhibited by des-Arg^9-[Leu^8]-BK, indicating that des-Arg^9-BK exerts its effect via B1 receptors. Similar observations have been made in MG-63 cells using des-Arg^9-BK, des-Arg^{10}-Lys-BK, [Tyr-Gly-Lys-Aca-Lys]-des-Arg^9-BK, and Sar[D-Phe8]-des-Arg^9-BK as agonists. Stimulation caused by these B1 receptor agonists is inhibited by a variety of B1 receptor antagonists, but not by B2 receptor antagonists. In addition, MG-63 cells display specific binding sites using [^{3}H]-des-Arg^{10}-Lys-BK as ligand and mRNA expression of human B1 receptors (Bernhold and Lerner, in preparation). The delay in the action of B1 receptor agonists (as compared to B2 receptor agonists) could be due to different postreceptor signal-transducing mechanisms (indicated by findings that des-Arg^9-BK does not stimulate IP3 formation, intracellular calcium, and translocation of protein kinase C) or differencies in the mechanism by which prostaglandin biosynthesis is stimulated. An alternative explanation could be that B1 receptors are not constitutively expressed on osteoblasts, but are rather gradually induced in culture (Phagoo *et al.,* 1999).

The observation that BK can stimulate depletion of calcium from intracellular stores and enhance inositol phosphate production in the human osteoclast-like cell line GCT23 indicates that preosteoclasts, and possibly also multinucleated osteoclasts, may be equipped with BK receptors (Seuwen *et al.,* 1999). However, whether BK may be able to directly stimulate osteoclast formation and/or activity is not known. Our finding that BK can stimulate osteoclastogenesis in mouse bone marrow cultures does not reveal if stromal cells or osteoclast progenitor cells are the target cells (Lerner *et al.,* in preparation).

Interactions among Kinins, Cytokines, and Neuropeptides

Although much interest has been focused on the role of cytokines, growth factors, hormones, kinins, and neuropeptides in bone metabolism and cell activities in general, the approach has often been to study the effect of these substances in systems in which they have been tested one by one. It is apparent that cells are exposed *in vivo* to several agonists simultaneously and therefore the ultimate cell and tissue response will be dependent on interactions among a variety of hormones, cytokines, growth factors, kinins, and neuropeptides.

The possibility that kinins may interact with cytokines is supported by the findings that BK can stimulate IL-1 and TNF production in murine macrophages (Tiffany and Burch, 1989), cytokine release in rat spleen mononuclear cells (Reissmann *et al.,* 2000), and IL-6 formation in human bone cells (Rahman *et al.,* 1992). The capacity of BK to affect cytokine production has also been demonstrated in human gingival fibroblasts; in these cells, BK does not affect IL-1 production, but potentiates the stimulatory effect of TNF on the biosynthesis of IL-1α and IL-1β (Yucel-Lindberg *et al.,* 1995). Interestingly, hyperalgesia induced by BK is blocked by the IL-1 receptor antagonist and is enhanced by antiserum neutralizing the IL-1 receptor antagonist (Cunha *et al.,* 2000). Such observations should prompt future studies on the possible role of cytokines in BK-induced bone resorption.

Although the role of cytokines, including the recently discovered receptor activator of NF-κB (RANK), RANK ligand (RANKL), and osteoprotegerin (OPG) (Martin *et al.,* 1998; Suda *et al.,* 1999; Hofbauer *et al.,* 2000; Lerner, 2000a; Teitelbaum, 2000), in the mechanism by which BK stimulates bone resorption is elusive at present, data suggest that kinins and cytokines may act in concert. It has been shown that BK synergistically potentiates the stimulatory effects of IL-1α and IL-1β on bone resorption and prostanoid biosynthesis in mouse calvarial bones (Lerner, 1991). A similar interaction in mouse calvariae has also been observed between BK and TNF (Lerner *et al.,* in preparation). We have observed that several BK B2 receptor agonists, as well as B1 receptor agonists, synergistically potentiate IL-1- and TNF-induced biosynthesis of PGE_2 and 6-keto-$PGF_{1\alpha}$ in the human osteoblastic cell line MG-63 (Bernhold and Lerner, in preparation). The effect is associated with a cytokine-induced upregulation of binding sites for B1 and B2 receptor-specific ligands. As mentioned already, BK potentiates osteoclastogenesis in mouse bone marrow cultures induced by IL-1 (Lerner *et al.,* in preparation). The synergistic interactions between BK and cytokines are not restricted to bone cells, as it can also be obtained in human gingival and dental-pulp fibroblasts, as well as in periodontal ligament cells (Lerner and Modéer, 1991; Ransjö *et al.,* 1998; Sundqvist and Lerner, 1995). The molecular mechanism involved in the interaction between cytokines and kinins is not known, but could involve changes of receptor number or affinity, signal transduction, or arachidonic acid release and/or metabolism.

Pretreatment of human osteoblast-like cells with estrogen upregulates the subsequent stimulation of prostaglandi production induced by BK (Cissel *et al.,* 1996), suggesting the existence of steroid hormone/kinin interactions in bone.

There are indications that the skeleton may be systemically affected in patients with chronic inflammatory diseases and in rats with experimentally induced chronic inflammation (Minne *et al.,* 1984; Motley *et al.,* 1993). The systemic factor involved is not known, but could be related to the demonstration that haptoglobin, one of the acute-phase proteins induced in the liver during chronic inflammation, stimulates bone resorption in neonatal mouse calvariae (Lerner and Fröhlander, 1992). Interestingly, BK synergistically potentiates the stimulatory effect of haptoglobin on PGE_2 formation in mouse calvarial osteoblasts (Fröhlander *et al.,* 1991).

Data indicate that skeletal neuropeptides may play important roles as local mediators regulating bone metabolism (see later). The novel observations that (i) BK stimulates the expression of β-adrenergic receptors (Yasunaga *et al.,* 2000), (ii) BK enhances the release of calcitonin gene-related peptide (Averbeck *et al.,* 2000), and (iii) kinins participate in neurokinin-1 receptor-dependent neutrophil accumulation in inflamed skin (Cao *et al.,* 2000) raise the possibility of a link between neurohormonal- and kinin-regulated bone metabolism. Our finding that the skeletal neuropeptide vasoactive intestinal peptide regulates the mRNA expression of RANKL, RANK, and OPG in mouse bone marrow cultures (Mukohyama *et al.,* 2000b) and preliminary observations indicating that the same neuropeptide can affect the mRNA expression of IL-6 and its receptor components gp 80 and gp 130 (Persson *et al.,* unpublished results) suggest the possibility of a neuroimmune interplay in bone cell activities.

Neuronal Influence on Bone Tissue

The activities of and interactions between different bone cells are regulated by a variety of systemic hormones, cytokines, growth factors, and inflammatory mediators. Another proposed regulatory element is the nervous system, which, through the release of neuronal messengers, has been suggested to participate in bone metabolism. Although Hohmann *et al.* (1983) reported that the neuropeptide VIP can stimulate bone resorption in mouse calvariae, it has only been since the early 1990s that the possible role of neuroactive substances in the control of bone cell activities has been appreciated. This field of interest is based partly on the recognition of an intense network of skeletal nerve fibers and partly on the view that the neuronal systems may not only have sensory functions and regulatory roles in the control of vessel and muscle activities, but may also exert a neurohormonal control of a variety of tissues, with one example being neuroendocrine–immune interactions (Bellinger *et al.,* 1992; Besedovsky and Rey, 1996).

Innervation of Bone

During the first decades of the 20th century the presence of nerve fibers in bone and periosteum was demonstrated using routine histological techniques (reviewed by Hurrel, 1937; Sherman, 1963). The techniques applied were useful in establishing the distribution of nerves and in discriminating between myelinated and unmyelinated nerves in bone, but the information provided was limited by morphology. Three decades ago, a breakthrough in neuroscience occurred when the immunohistochemical technique was developed and made visualization of nerves according to their transmitter content possible. Numerous neuroactive substances have been demonstrated in many different tissues, but the difficulty in bone tissue was to demineralize the bone without destroying the antigenicity of the neuro-related substances. Bjurholm *et al.* (1989) and Hill and Elde (1990) developed techniques making it possible to preserve neuroactive substances in decalcified bone specimens. Following these reports, a number of neuronal messengers and their distribution in bone have been mapped extensively .

In addition to transmitter phenotyping with immunohistochemical techniques, surgical or chemical selective denervation has established the origin of the nerves in bone (reviewed by Lundberg, 2000). Both sensory and autonomic nerve fibers are present in bone tissue. Overall, a substantial part of skeletal nerve fibers are seen along blood vessels, but blood vessel-unrelated and free nerve endings have also been demonstrated. Fibers are spread in all the cell layers of the periosteum of bone and are expressed at a higher density in the epiphysis than in the diaphysis. Small branches of periosteal nerve fibers enter the cortical bone, usually associated with blood vessels located in Volkmann's canals or in Haversian canals (Bjurholm, 1989; Hill and Elde, 1991a; Hukkanen *et al.,* 1992). Entering the inner compartments of bone, nerve fibers are spread in the bone marrow and richly innervate the osteochondral junction of the growth plate. Interestingly, the epiphyseal part of the growth plate is intensively supplied by peptidergic nerves, whereas the metaphyseal part is innervated more poorly (Hukkanen *et al.,* 1992; Hukkanen, 1994).

The immunohistochemical staining of bone tissue sections has demonstrated the presence of a wide variety of neuronal messengers, including both slowly acting transmitters, so-called neuropeptides, and rapidly acting small molecules, so-called classical neurotransmitters, in bone. Presently, the neuropeptides demonstrated in bone are substance P (SP), calcitonin gene-related peptide (CGRP), neurokinin A, and pituitary adenylate cyclase activating peptide 27 (PACAP 27) and 38 (PACAP 38), mainly representing the sensory system; vasoactive intestinal peptide (VIP) and neuropeptide Y (NPY), mainly representing the autonomic system; and met-enkephalin, representing the opioid system. The classical neurotransmitters present in bone are the amines serotonin and the catecholamine noradrenaline (NA) and the excitatory amino acid glutamate (reviewed by Kontinen *et al.,* 1996; Lerner, 2000b; Kreicbergs and Ahmed, 1997; Lundberg, 2000). In addition to morphological demonstrations, neuroactive substances in bone have also been quantified biochemically. A technique has been developed to extract and quantify neuropeptides in bone and joints using RIA (Ahmed *et al.,* 1994). Using this technique, extracts from diaphyseal rat bone tissue, periosteum, and bone marrow have been analyzed for their contents of neuropeptides. SP, CGRP, NPY, and VIP could all be quantitated at all three localizations, with NPY exhibiting the highest concentration at all sites (Ahmed *et al.,* 1994). Moreover, neurotrophic factors such as neurotrophins, known to be important factors required for the development and maintenance of the central and peripheral nerve systems, have been demonstrated in bone tissue. Neurothrophins demonstrated in bone tissue so far are nerve growth factor (NGF), brain-derived neurotrophic factor (BDNF), and neurotrophin-3 (NT-3) (Asaumi *et al.,* 2000).

A neuronal regulation of bone metabolism would not only require the presence and release of neuronal messengers in the vicinity of bone cells, but also the presence of functional receptors for such factors on bone-forming or bone-resorbing cells. Therefore, several attempts have been made to study whether different neuropeptides, neurotransmitters, and neurotrophins can affect receptor-associated functions in osteoblasts and osteoclasts.

Receptors and Effects by Neuropeptides in Bone

Vasoactive Intestinal Peptide

VIP is a member of the growing family denoted VIP/secretin/glucagon family of neuropeptides, which also includes the structurally related peptides secretin, gastric inhibitory peptide, growth hormone-releasing hormone, peptide histidine isoleucine amide (PHI), PACAP 27 and 38, and the reptilian venom peptides helodermin, helospectin, and exendine.

VIP was first discovered as a vasodilator peptide (Said and Mutt, 1969). Isolation of VIP from porcine gut (Said and Mutt, 1970) revealed an amidated 28 amino acid peptide (Mutt and Said, 1974). VIP is a cleavage product of the 170 amino acid precursor pre-pro VIP, which also is the parent molecule of PHI (Itoh *et al.,* 1983). Using RIA and the immunofluorescence technique, VIP immunoreactivity was discovered in many tissues outside the gastrointestinal tract. In 1976, the finding of VIP in the brain and in peripheral nerves (Said and Rosenberg, 1976) introduced VIP as a neuropeptide.

VIP has been investigated extensively, and a broad range of biological actions has been ascribed to this peptide, both in animal and in human studies. Important actions of VIP in the cardiovascular (Sakai *et al.,* 1998), reproductive (Ottesen and Fahrenkurg, 1995), pulmonary (Maggi *et al.,* 1995), immune (Sirinek and O'Dorisio, 1991; Ganea, 1996), and gastrointestinal systems (Schuttleworth and Keef, 1995) have been reviewed. General physiologic effects encompass vasodilatation, bronchodilatation, immunosuppression, hormonal

secretion, and increases in gastric motility. In the nervous system, VIP seems to participate in neuronal survival, maturation, and maintenance (reviewed by Gozes and Brenneman, 1993).

VIP is widely distributed in both the central (CNS) and the peripheral nervous systems (PNS). In the brain, VIP immunoreactive neurons are found in the hypothalamus and the cerebral cortex (Hökfelt *et al.,* 1982). In the PNS, VIP immunoreactive nerves, nerve plexus and terminals supplying blood vessels, nonvascular smooth muscles, glandular acinis, and ducts, in a variety of organs, have been described (Hökfelt *et al.,* 1982). VIP immunoreactivity is detected in nerve fibers with both sympathetic and parasympathetic origin and, to a minor extent, in sensory nerve fibers.

In 1986, Tashijan and collegues initially demonstrated VIP immunoreactive (IR) nerve fibers in bone tissue (Hohmann *et al.,* 1986). VIP-IR nerve fibers with a postganglionic sympathetic origin were localized in the periosteum, associated with vascular elements of bones from different species. In a large study of neuropeptide expression in rat bone nerve fibers, Bjurholm *et al.* (1988a,c) detected VIP-IR nerve fibers preferentially in the periosteum and the epiphysis. These VIP-IR nerve fibers, whose origins are uncertain, were only occasionally associated with blood vessels. In line with these data, Hill and Elde (1991a) also demonstrated VIP-IR in rat periosteum. These nerves were only partially associated with vascular elements. VIP, NPY, and dopamine-β-hydroxylase (DβH) immunoreactive nerves were reduced dramatically in guanethidine-treated animals, strongly indicating a sympathetic origin of theses nerves (Hill and Elde, 1991b).

Tashjian and co-workers provided the first *in vitro* evidence for functional neuropeptide receptors on bone cells, demonstrating that VIP stimulates calcium release in neonatal mouse calvariae (Hohmann *et al.,* 1983). In osteoblasts, the presence of functional receptors for VIP, linked to enhanced formation of cyclic AMP, has been demonstrated in a human osteosarcoma cell line (Saos-2) (Hohmann and Tashjian, 1984; Bjurholm *et al.,* 1992; Lerner *et al.,* 1994), in the rat osteosarcoma cell line UMR 106-01 cells, but not in rat osteosarcoma cell line ROS 17/2.8 cells (Bjurholm *et al.,* 1992; Lerner *et al.,* 1994). In addition, VIP has been found to stimulate cyclic AMP formation in isolated mouse calvarial osteoblasts and in the cloned, nontransformed, osteoblastic cell line MC3T3-E1 (Bjurholm *et al.,* 1992; Lerner *et al.,* 1994).

Since the early 1990s, three different subtypes of VIP receptors have been cloned. These receptors are designated VIP-1 receptors (VIP-1R), VIP-2 receptors (VIP-2R), and PACAP-receptors (PACAP-R) (reviewed by Rawling and Hezareh, 1996). They are all seven transmembrane, G protein-coupled receptors and members of the VIP/secretin/PTH receptor superfamily. All three receptors are distributed both in the CNS and the PNS and can be distinguished by comparing their relative adenylate cyclase-activating capacities and by radioligand-binding assays. PACAP-R bind PACAP with a much higher affinity (100- to 1000-fold) than VIP. VIP-1R and VIP-2R bind PACAP and VIP with similar affinities. The fact that VIP-1R bind secretin, and VIP-2R do not, can be used to distinguish between these two VIP receptors.

We have characterized the VIP-binding receptors in mouse calvarial osteoblasts. By comparing the rank order of response of peptides in the VIP/secretin/glucagon family on cyclic AMP formation, we found that PACAP 38 was 10-fold more potent than VIP (Lundberg *et al.,* 2001). A similar 10-fold difference in potency between PACAP and VIP has also been detected in the rat osteoblast-like tumor cell line UMR 106 (Kovacs *et al.,* 1996) and in the nontransformed murine calvarial cell line MC3T3-E1 (Susuki *et al.,* 1994). By comparing the relative potency of VIP and related peptides to displace ^{125}I-PACAP binding, we found a rank order of response similar to that obtained when cyclic AMP enhancement was quantified. The fact that PACAP-preferring VIP receptors do not bind secretin was confirmed by demonstrating that secretin did not elevate cyclic AMP levels and failed to displace ^{125}I-VIP or ^{125}I-PACAP 38 binding. Using atomic force microscopy (AFM), a novel technique modified recently to detect specific binding sites on cell surfaces, we have demonstrated specific binding of VIP, but not secretin, on mouse calvarial osteoblasts. Reverse transcriptase PCR further demonstrated that these undifferentiated osteoblasts express mRNA for VIP-2R, but not for VIP-1R or PACAP-R. When these osteoblasts were cultured for 20 days to induce bone noduli formation, VIP-1R, in addition to VIP-2R, were expressed when the nodules started to mineralize at 12 days (Lundberg *et al.,* 2001). Taken together, these data demonstrate that mouse calvarial osteoblasts express functional VIP-2R, with higher affinity binding for PACAP than for VIP, and that VIP-1R expression is induced during osteoblastic differentiation. Information on mRNA expression of VIP/PACAP receptors in osteoblasts is limited to observations in mouse calvarial osteoblasts and to a report by Togari *et al.* (1997), demonstrating that primary human osteoblasts and human osteosarcoma cell lines express VIP-1R, but not VIP-2R or PACAP-R. The observed differences in VIP-R expression in mouse and human osteoblasts may be a matter of differentiation discrepancies, although it cannot be excluded that it is due to species differences.

Interestingly, a differentiation-dependent manner of receptor expression in mouse osteoblasts is not only observed for VIP receptors, but also for vascular endothelial growth factors (VEGF) and their receptors in mouse osteoblasts (Deckers *et al.,* 2000). A role for VEGF in endochondral bone formation has been proposed because inactivation of VEGF inhibits endochondral bone formation via inhibition of angiogenesis (Gerber *et al.,* 1999). Therefore, the increased expression of VEGF receptors and their ligands during osteoblastic differentiation and mineralization supports the theory that VEGF plays an important role in the regulation of bone metabolism. The role of VIP-1R induction during osteoblastic differentiation remains to be elucidated. In contrast to differentiation-induced upregulation of VIP-1R and VEGF receptors, the expression of glutamate transporter in rat osteoblasts declines

when mineralization starts in rat osteoblast cultures (Bhangu *et al.,* 2000).

Whether VIP receptors on osteoblasts are coupled to anabolic actions of VIP has been evaluated *in vitro* using mouse calvarial osteoblasts (Lundberg *et al.,* 1999b). After 6 days of culture, VIP stimulates activity of the bone mineralization-associated enzyme alkaline phosphatase (ALP), and the mRNA expression of this enzyme, without affecting cell proliferation. The ALP-staining pattern in histochemical analysis demonstrated that VIP, to a minor extent, increased the number of ALP-stained cells, but mainly increased the staining of individual cells. These morphological analyses suggest that VIP treatment causes an increased differentiation of committed osteoblasts. In line with this, we found that VIP initially causes an increased accumulation of calcium in osteoblasts during the formation of mineralized bone nodules, but does not change the total amount of calcium found at the end of the culture. Our preliminary finding that VIP does not change the mRNA expression of type I collagen in osteoblast cultures further supports the view that VIP does not increase bone formation, but rather stimulates the differentiation of bone forming committed osteoblasts. The capacity of VIP to regulate osteoblastic differentiation is also indicated by the observations in mouse calvarial osteoblasts demonstrating that VIP increases the mRNA expression of osteonectin and decreases those of osteopontin and bone sialoprotein at 4 and 8 days of culture. After 20 days of treatment, the expressions of osteonectin and ALP are decreased, whereas that of osteopontin is increased (Mukohyama *et al.,* 2000a). The fact that VIP stimulates ALP activity at 6 days of culture, a time point when only VIP-2R are expressed (Lundberg *et al.,* 2001), together with the absence of effect by secretin on ALP activity, clearly suggest that VIP-2R receptors mediate the anabolic events in bone caused by VIP (Lundberg, unpublished data). Whether VIP-1R may mediate similar bone-forming effects has to be ascertained.

The first documented *in vitro* effect of a neuropeptide on bone was that of Tashjian and co-workers, demonstrating a catabolic effect by VIP on bone metabolism (Hohmann *et al.,* 1983). Thus, VIP stimulated calcium release in organ-cultured mouse calvarial bones. This stimulation of calvarial bone resorption by VIP may be due either to enhanced activity of osteoclasts or to stimulation of osteoclast formation.

Morphological studies of isolated rat osteoclasts revealed that VIP treatment caused a rapid cytoplasmic contraction along with an associated decrease in motility (Lundberg *et al.,* 2000). Functional studies using an *in vitro* resorption assay showed that VIP caused a transient inhibition of osteoclastic bone resorption. When the osteoclast incubations were extended over time and performed in the presence of marrow-derived stromal cells/osteoblasts, the osteoclasts escaped from the initial inhibition and VIP caused a delayed stimulation of osteoclastic pit formation in bone slices. Similar to VIP, the initial inhibitory effect of calcitonin (CT) was lost over time. However, in contrast to VIP, CT-treated osteoclasts never start to resorb bone more than unstimulated controls. The finding of inhibitory effects, both on osteoclast morphology and on resorptive capacity, suggests that osteoclasts are equipped with VIP receptors and that VIP might be acting directly on osteoclasts.

In order to localize binding sites for VIP on osteoclasts, we took advantage of the newly developed AFM technique. Using AFM and measurements of intracellular calcium, specific VIP-binding sites on osteoclasts were found (Lundberg *et al.,* 2000). Further evidence for the presence of VIP receptors in osteoclasts is our finding of mRNA for VIP-1R and PACAP-R in mouse bone marrow osteoclasts isolated by micromanipulation (Ransjö *et al.,* 2000). The late stimulatory effect of VIP is probably the basis of the finding that VIP stimulates resorption in calvarial organ culture (Hohmann *et al.,* 1983). When AFM was used to analyze the presence of VIP receptors in stromal cells/osteoblasts, we found that approximately 20% of the stromal cells/osteoblasts expressed specific binding sites for VIP. This was supported further by the observation that these cells also responded to VIP with a rapid enhancement of intracellular calcium (Lundberg *et al.,* 2000). These receptors might mediate the indirect bone-resorbing effect caused by VIP, both in the resorption pit assay and in the calvariae.

VIP has been reported to stimulate IL-6 production in stromal cells (Cai *et al.,* 1997) and in an osteosarcoma cell line (Greenfield *et al.,* 1996). We have confirmed these observations using mouse calvarial osteoblasts and, in addition, demonstrated that VIP-induced IL-6 production is mediated via VIP-2R (Lundberg *et al.,* 1999a). PTH also induces IL-6 production in osteoblasts. Interestingly, the stimulation of PTH on rat osteoclast pit formation is inhibited by antiserum-neutralizing IL-6 (Ransjö *et al.,* 1999). These findings suggest that the stimulatory effect of VIP on rat osteoclast pit formation may be due to VIP-induced IL-6 release.

The stimulation of bone resorption by VIP in organ-cultured mouse calvariae can be explained either by an effect on osteoclast activity or by an effect on osteoclast formation. When osteoclastogenisis was studied in mouse bone marrow cultures, VIP did not enhance the number of osteoclasts (Mukohyama *et al.,* 2000b). In contrast, VIP caused an inhibition of osteoclast formation induced either by $1,25(OH)_2$ vitamin D_3 or by PTH. The antiosteoclastogenic effect of VIP is associated with inhibitory effects of these peptides on the $1,25(OH)_2$ vitamin D_3-induced upregulation of RANK (receptor activator of NF-κB) and RANK ligand (RANKL). In addition, VIP counteracts the decrease of osteoprotegerin (OPG) caused by $1,25(OH)_2$ vitamin D_3 (Mukohyama *et al.,* 2000b). In summary, VIP inhibits osteoclast formation, probably by regulating the expression of RANK, RANKL, and OPG, three molecules known to be important for osteoclast formation.

The fact that VIP stimulates osteoclast activity and inhibits osteoclast recruitment suggests that VIP may have a unique role in bone metabolic processes by acting as a fine tuner of osteoclastic resorption.

Pituitary Adenylate Cyclase-Activating Peptide

PACAP was first isolated from ovine hypothalamus and described on the basis of its ability to increase adenylate cyclase activity in rat pituitary cells (Miayata *et al.,* 1989). PACAP occurs in two molecular forms: the 38 amino acid peptide PACAP 38 and the C-terminally truncated form PACAP 27. Both forms of PACAP share 68% amino acid homology with VIP at their N-terminal domains (reviewed by Arimura, 1991, 1992).

In addition to exhibiting extensive molecular similarities to VIP, PACAP partially shares receptors as well as functions with VIP. PACAP has been shown to be a pleiotropic neuropeptide, functioning as a hypothalamic hormone, neurotransmitter, neuromodulator, vasodilator, and a neurotropic factor. Examples of endocrine functions by PACAP are numerous. PACAP (i) stimulates the secretion of adrenaline from the adrenal medulla, (ii) stimulates insulin release from pancreatic β cells, and (iii) causes an increase of $[Ca^{2+}]_i$ in pancreatic β cells. One important developmental biological action of PACAP seems to be as a neurotrophic factor during the development of the brain (reviewed by Arimura, 1998).

PACAP immunoreactivity is detected in nearly all organs and tissues. In the brain, the highest concentration is found in the hypothalamus. In the PNS, the adrenal medulla and testis contain the highest concentrations of PACAP immunoreactivity when compared to those found in the gut and the adrenal gland. PACAP 38 is the predominant form in tissues, making up 90% of the total PACAP (reviewed by Arimura, 1998).

PACAP 27 and PACAP 38 have been demonstrated in cartilage channels in tissue sections from pigs (Strange-Vogsen *et al.,* 1997). Varicose PACAP immunoreactivity fibers were demonstrated in association with blood vessels. Nearly all PACAP immunoreactive fibers contain CGRP and SP, suggesting that these are sensory nerve fibers (Strange-Vogsen *et al.,* 1997).

In mouse calvariae and in mouse calvarial osteoblasts, the presence of functional receptors for PACAP 27 and PACAP 38, linked to the enhanced formation of cyclic AMP, has been demonstrated (Lerner *et al.,* 1994). As described earlier (see VIP), VIP and PACAP share receptors. In addition to VIP-1R and VIP-2R, which bind VIP and PACAP with equal affinity, several reports describe the cloning of a high-affinity PACAP receptor (PACAP-R). PACAP-R were, within a year, cloned from rat, human (Ogi *et al.,* 1993), and bovine tissues (Miyamoto *et al.,* 1994). Moreover, PACAP-R were demonstrated to exist in six splice variant forms (Svoboda *et al.,* 1993; Journot *et al.,* 1995). PACAP is 100- to 1000-fold more potent than VIP in binding and stimulating adenylate cyclase activity in cells transfected with PACAP-R (Rawlings and Hezareh, 1996). PACAP-R have a widespread distribution in the CNS, with the highest levels being found in the olfactory bulb, the dental gyrus of hippocampus, pituitary, cerebellum, thalamus, and hypothalamus. Messenger RNA for PACAP-R has been detected in a variety of tissues, including liver, lung, spleen, and intestine (reviewed by Christophe, 1993; Arimura, 1992; Arimura and Shioda, 1995).

Concerning skeletal cells, the presence of PACAP-R and VIP-1R mRNA has been demonstrated in microisolated mouse marrow osteoclasts (Ransjö *et al.,* 2000). Using an AFM technique, both VIP and PACAP 38 showed high-affinity binding to rat marrow osteoclasts (Lundberg *et al.,* 2000). If rat osteoclasts express the same VIP/PACAP receptor subtypes as mouse osteoclasts is unknown. However, our preliminary observations that PACAP 38, as well as VIP and secretin, causes a decrease in isolated rat osteoclastic bone resorption indicate that VIP-1R may have a functional role in the regulation of osteoclast function. Whether PACAP-R also have a functional role in the rat osteoclasts is not known.

Similar to VIP, PACAP 38 inhibits $1,25(OH)_2D_3$-stimulated osteoclastogenesis in mouse bone marrow cultures (Mukohyama *et al.,* 2000b). PACAP 38 also decreases RANKL and RANK expression and increases OPG in these bone marrow cultures.

Although PACAP seems to interact with osteoblastic bone formation by regulating the expressions of the bone mineralization associated enzyme ALP and the release of IL-6, as well as with osteoclast activity and recruitment, further studies have to be performed to ascertain the role of PACAP in bone metabolism.

Calcitonin Gene-Related Peptide

Calcitonin gene-related peptide (CGRP) is a 37 amino acid peptide belonging to a superfamily of peptides including CT, CGRP-I, CGRP-II, amylin, and adrenomedullin (Wimalawansa, 1997). One domain of the insulin β chain also shares homology with these peptides, indicating that they may have diverged from a common ancestral gene during evolution. CGRP is produced by tissue-specific alternative splicing of the initial gene transcript encoding the precursor for CT. Consequently, CGRP is produced, not only in nerve fibers, but also in thyroid parafollicular C cells, together with CT. However, CGRP and CT seem not to be released in parallel, probably due to the fact that plasma levels of CGRP have a neurogenic origin. Amylin is expressed predominantly in pancreatic β cells, whereas adrenomedullin is synthesized in several different tissues and is released from endothelial cells. CGRP and amylin both have an amino-terminal ring created by a disulfide bond; this is lacking in adrenomedullin, which has a linear amino-terminal extension.

CT, CGRP, amylin, and adrenomedullin act via related heptahelical receptors. Whereas a CT receptor was cloned already 1991 (Lin *et al.,* 1991), the receptors for CGRP, amylin, and adrenomedullin have been more elusive. CGRP and adrenomedullin both bind to a CT receptor-like receptor (CRLR), originally described as an orphan seven transmembrane receptor. Interestingly, CRLR requires interaction with single transmembrane proteins called receptor activity-modi-

fying proteins (RAMP; Foord and Marshall, 1999). Three different RAMPs (RAMP1, RAMP2, and RAMP3) have been cloned and sequenced and found to be expressed in a wide variety of tissues. Cotransfection of CRLR and RAMP1 results in CGRP responsive receptors, whereas cotransfection of CRLR and RAMP2, or RAMP3, leads to expression of adrenomedullin responsive receptors (Bühlmann *et al.,* 1999). RAMPs are expressed more abundantly than CRLR, suggesting that RAMPs could be involved in the regulation of other receptors than CRLR. Intestingly, RAMP1, or RAMP3, cotransfection with a CT receptor results in a high-affinity amylin receptor (Muff *et al.,* 1999). The expression of CRLR and RAMPs has not yet been studied in bone cells.

Receptors for CGRP, as assessed by a cyclic AMP response, have been demonstrated on the rat osteosarcoma cell line UMR 106-01 (but not on ROS 17/2.8), the human osteosarcoma cell line Saos-2, the mouse calvarial osteoblastic cell line MC3T3-E1, and enzymatically isolated osteoblastic cells from chick, rat, and mouse (Michelangeli *et al.,* 1986, 1989; Thiebaud *et al.,* 1991; Bjurholm *et al.,* 1992). Expression of receptors for CGRP seems to be a feature of the osteoblastic phenotype, as the degree of cyclic AMP formation in primary osteoblasts correlates with the activity of alkaline phosphatase and to the responsiveness to PTH (in terms of cyclic AMP formation; Michelangeli *et al.,* 1989). Receptors recognizing CGRP have been demonstrated on mouse bone marrow cells using radioligand binding (Mullins *et al.,* 1993). Activation of CGRP receptors in osteoblasts also leads to stimulation of phospholipase C and a transient rise of intracellular calcium (Drissi *et al.,* 1998; Kawase *et al.,* 1995) by mechanisms separate from those stimulating cyclic AMP (Drissi *et al.,* 1999; Aiyar *et al.,* 1999). Interestingly, the activation of CGRP receptors in osteoblasts also leads to an inhibition of calcium uptake (Kawase *et al.,* 1996). Using RT-PCR, CGRP receptors have been demonstrated in human periosteum-derived osteoblastic cells and in human osteosarcoma cell lines (Togari *et al.,* 1997). The presence of receptors recognizing amylin and adrenomedullin in osteoblasts is suggested by the observations that amylin stimulates cyclic AMP formation and that both peptides stimulates [^{3}H]thymidine incorporation into osteoblasts (Tamura *et al.,* 1992; Cornish *et al.,* 1995, 1997).

CGRP receptors are coupled to the stimulation of osteoblast proliferation and enhanced bone colony formation *in vitro* (Shih and Bernard, 1997a; Cornish *et al.,* 1999). An anabolic effect of CGRP *in vivo* is demonstrated by the findings that the targeted expression of calcitonin gene-related peptide to osteoblasts, under the control of the osteocalcin promotor, results in enhanced trabecular bone density, trabecular bone volume, and increased bone formation rates in mice (Ballica *et al.,* 1999). The same group has also reported that injection of CGRP into ovariectomized rats can partly prevent the bone loss caused by estrogen deficiency (Valentijn *et al.,* 1997).

Occupancy of amylin receptors in osteoblasts stimulates anabolic activities both *in vitro* and *in vivo.* Thus, amylin stimulates cell proliferation in osteoblast cell cultures (Cornish *et al.,* 1995, 1998; Villa *et al.,* 1997); amylin is more potent than CGRP but seems to act via a common CGRP/amylin receptor (Cornish *et al.,* 1999). Treatment of mice or rats with amylin leads to enhanced trabecular bone volume as a consequence of both increased trabecular thickness and number (Romero *et al.,* 1995; Cornish *et al.,* 1998). The increase of bone volume can also be achieved by injection of the amino-terminal fragment amylin 1-8, although the effect is less than that obtained by full-length amylin (Cornish *et al.,* 2000). Treatment with amylin leads to enhanced mechanical bone strength (Cornish *et al.,* 2000).

The stimulatory effects of CGRP and amylin on osteoblast cell proliferation are shared by adrenomedullin, which in fact is more potent than the other two peptides (Cornish *et al.,* 1997). The effect of adrenomedullin, similar to that of amylin, can be blocked by the amylin receptor antagonist amylin 8-37, indicating that adrenomedullin, amylin, and CGRP act via a common receptor. Injection of adrenomedullin into mice increases bone mass, as assessed by enhanced bone formation and increased mineralized bone area (Cornish *et al.,* 1997).

The strong anabolic effects of CGRP, amylin, and adrenomedullin in the skeleton raise the possibility that these peptides, or nonpeptidergic activators of their receptors, may potentially be useful in the treatment of diseases with bone loss, including osteoporosis. It should, however, be kept in mind that the *in vivo* anabolic effects of these compounds may not only be a consequence of their effects on bone formation, but may also be attributed to inhibitory effects on bone resorption.

The interest of CGRP in bone resorption was initially prompted by the findings that CGRP shows amino acid sequence homology to CT in the amino-terminal region and that CGRP is costored with CT in thyroid C cells. Injection of CGRP into rats and rabbits causes a hypocalcemic reaction (Tippins *et al.,* 1984; Roos *et al.,* 1986). The fact that CGRP inhibits bone resorption in fetal rat long bones (Roos *et al.,* 1986; D'Souza *et al.,* 1986; Tamura *et al.,* 1992) and in neonatal mouse calvariae (Yamamoto *et al.,* 1986) indicates that the decrease of serum calcium in intact animals is due to CGRP-induced inhibition of bone resorption. In the mouse calvarial system, rat CGRP-II is slightly more potent than rat CGRP-I, which is slightly more potent than human CGRP (Lerner, unpublished results). Similar to CT, the effect of CGRP is transient both in fetal rat long bones and in neonatal mouse calvariae (Roos *et al.,* 1986; Lerner, unpublished results). Inhibition of bone resorption can be due to inhibition of osteoclast activity and/or recruitment. An inhibitory effect of osteoclast activity has been observed in isolated rat osteoclasts as assessed by decreased pit formation (Zaidi *et al.,* 1987a,b). In this system, CGRP-I and -II are equipotent. The hypocalcemic effect of CGRP, as well as the inhibitory effects on bone resorption in organ culture and on osteoclastic pit formation, is mimicked by amylin (Datta *et al.,* 1989; MacIntyre, 1989; Zaidi *et al.,* 1990; Tamura *et al.,* 1992; Pietschmann *et al.,* 1993). Interestingly, adrenomedullin does not inhibit PTH-stimulated bone resorption in neonatal mouse calvariae (Cornish *et al.,* 1997; Lerner *et al.,* unpublished results).

Calcitonin-induced inhibition of bone resorption by isolated rat osteoclasts is associated with increased levels of intracellular Ca^{2+} and and cyclic AMP, as well as with rectraction and ceased motility of osteoclasts (Alam *et al.,* 1992b). At variance, inhibition caused by CGRP and amylin is associated with enhanced cyclic AMP and ceased motility, but not with increased intracellular Ca^{2+} and retraction (Alam *et al.,* 1991, 1992a,b). These observations have prompted the speculation that the effects of CT are mediated via two separate receptors and that CGRP and amylin act only via one of these receptors (the one linked to cyclic AMP and motility). Further support for this hypothesis are the observations that CGRP 8-37 (i) inhibits the effects of amylin and CGRP on motility and (ii) inhibits the effect of CT on motility, but not on retraction. This would imply that retracted osteoclasts are still capable of motility. In contrast, Cornish *et al.* (1998) could not observe any antagonistic effect by CGRP 8-37 (or amylin 8-37) on the amylin-induced inhibition of bone resorption in neonatal mouse calvariae (an observation confirmed in the authors laboratory), although the antagonists blocked the stimulatory effect by amylin on cell proliferation in the calvarial bones. In contrast to the observations by Zaidi and collaborators, we have, in a large series of experiments, been unable to observe any differences on osteoclast motility and retraction caused by CT, CGRP, and amylin. The issue of which receptors in osteoclasts (CT receptor, CRLP/RAMP1, CRLP/RAMP2, CRLP/RAMP3) are used by CGRP (and amylin) and how these receptors are linked to the mechanism causing inhibition of bone resorption still remains an open question. The observation made by Cornish *et al.* (1998) indicates that separate amylin receptors are present on osteoblasts and osteoclasts.

The degree of bone loss is not only dependent on osteoclast activity but also on osteoclast formation. Very few studies deal with effects of CGRP on osteoclastogenesis. Owan and Ibaraki (1994) have demonstrated the presence of CGRP receptors in mouse alveolar macrophages and that osteoclast formation in $1,25(OH)_2D_3$-stimulated cocultures of mouse alveolar macrophages and mouse calvarial osteoblasts is decreased by CGRP. Concomitantly, the number of macrophages was increased substantially. Akopian *et al.* (2000) reported that CGRP inhibits GM-CSF induced CFU-GM colony formation from unfractionated, as well as $CD34^+$, bone marrow cells via receptors blocked by CGRP 8-37. It was also shown tht CGRP inhibits osteoclast formation in bone marrow mononuclear cell cultures stimulated by $1,25(OH)_2D_3$. This response may be due to an effect of CGRP on stromal cells, on preosteoclasts, or on both cell types. The fact that CGRP inhibits CFU-GM colony formation from $CD34^+$ cells indicates that the effect, at least partially, is due to inhibition of preosteoclast proliferation/differentiation.

Effects of CGRP on bone may not only be due to direct effects on osteoblasts, preosteoclasts, and osteoclasts, but may also be mediated by cytokines/growth factors released from nearby cells regulated by CGRP. Thus, CGRP has been shown to increase IGF-I, both at the mRNA and at the protein level (Vignery and McCarthy, 1996), to decrease the production of TNF-α, and to increase that of IL-6 in fetal rat calvarial osteoblasts (Millet and Vignery, 1997).

Substance P

Primary human osteoblastic cells and osteosarcoma cell lines do not express mRNA for SP receptors (Togari *et al.,* 1997). At variance from this, neurokinin-1 (NK-1) receptors recognizing SP have been immunolocalized in rat bone osteoblasts (but considerably weaker than in osteoclasts; Goto *et al.,* 1998). Osteogenesis, as assessed by bone colony formation in bone marrow cell cultures, can be stimulated by SP (Shih and Bernard, 1997b). Thus, whether SP exerts any anabolic effects on bone still remains to be shown.

The abundance of NK-1 receptors in rat bone osteoclasts (Goro *et al.,* 1998) can be reconciled with observations that SP causes an acute rise of intracellular Ca^{2+} in rabbit osteoclasts and an increased pit area (but not an increase of pit number) excavated by osteoclasts when incubated on dentine slices (Mori *et al.,* 1999). The effects were blocked by two different NK-1 receptor antagonists. These observations indicate that SP may stimulate osteoclast activity by a direct effect on terminally differentiated osteoclasts. It is not known if SP may also affect osteoclastogenesis. In this context, it is interesting that SP stimulates the proliferation of fibroblastic cells, as well as production of stem cell factor and IL-1 in bone marrow cells (Rameshwar and Gascon, 1995; Rameshwar *et al.,* 1997).

Neuropeptide Y

NPY is often costored with noradrenaline (NA) in the same nerve fibers and it may therefore be of special interest that the NA-induced cyclic AMP rise in UMR 106-01 cells is inhibited by NPY (Bjurholm *et al.,* 1988b). However, this interaction is not specific for NA and NPY, as NPY also inhibits PTH stimulated cyclic AMP formation in UMR 106-01 cells. The mechanism by which NPY interacts with the noradrenergic and PTH-induced cyclic AMP formation is not known, but seems to be distal to the level of receptor–receptor cross-talk, because NPY also inhibits forskolin-induced cyclic AMP (Bjurholm *et al.,* 1992). The presence of NPY receptors in osteoblasts has been confirmed by Togari *et al.* (1997) showing the mRNA expression of NPY receptors in human periosteum-derived osteoblastic cells and in human osteosarcoma cell lines.

The mouse NPY receptor Y1 is present in two isoforms originating from a single gene. The Y1-α receptor has been found in several tissues, whereas the Y1-β receptor is expressed in bone marrow cells and in hematopoetic cell lines (Nakamura *et al.,* 1995). Whether NPY receptors are present in cells in the osteoclastic lineage is not yet known.

Opioid Peptides

The opioid family of peptides is synthesized from three different precursor molecules: proopiomelanocortin (POMC), proenkephalin (PENK), and prodynorphin (PDYN). Due to tissue-specific processing, different opioid peptides are produced, not only in the nervous and endocrine systems, but also in several other tissues, including the skeleton (Rosen *et al.,* 1998). Opioid peptides exert their opiate-like activity via three different receptors — μ-opioid, δ-opioid, and κ-opioid receptors — all of which are seven transmembrane G protein-coupled receptors linked to inhibition of adenylate cyclase.

Prompted by their initial observation that PENK mRNA is expressed highly and transiently during embryonic development in mesenchymal tissues, including bone and cartilage (Keshet *et al.,* 1989), Rosen *et al.* (1991) reported that PENK mRNA, but not POMC or PDYN mRNAs, is highly expressed in rat calvarial osteoblasts, in rat osteosarcoma cell lines ROS 17/2.8 and ROS 25/1, and weakly in mouse MC3T3-E1 osteoblastic cells and in human Saos-2 osteosarcoma cells. The expression of PENK mRNA in osteoblasts is decreased by $1,25(OH)_2D_3$, PTH, and TGF-β (Rosen *et al.* 1991, 1995, 1998). In addition, it has been shown that osteoblasts synthesize enkephalin-containing peptides, including Met-enkephalin. Using immunohistochemistry, Met-enkephalin has been demonstrated not only in bone cells and bone marrow cells, but also in skeletal nerve fibers (Elhassan *et al.,* 1998).

The fact that Met- and Leu-enkephalin, as well as Met-enkephalin-Arg-Phe, decrease alkaline phosphatase activity in ROS 17/2.8 cells indicates that osteoblasts are equipped with opioid receptors and that opioid peptides may act as local regulators of bone cell differentiation in an auto- or paracrine manner (Rosen *et al.,* 1991). The reciprocal interrelationships between osteoblast maturation (as assessed by alkaline phophatase) and PENK expression further indicate that opioid peptide expression is linked to osteoblast differentiation. Based on these observations, Rosen and Bar-Shavit (1994) have proposed the hypothesis that the retained capacity in the adult skeleton to synthesize PENK-derived peptides, in a defined population of undifferentiated cells, may be important in local remodeling of the skeleton, including fracture repair.

In contrast to the observations in rat osteoblasts, opioid receptor agonists such as morphine and DAMGO do not affect alkaline phosphatase activity in the human osteosarcoma cell line MG-63 (Pérez *et al.,* 1997). This was not due to an absence of opioid receptors, as $1,25(OH)_2D_3$-stimulated secretion of osteocalcin was decreased by morphine and DAMGO, an effect that was abolished by naloxone. This effect was, however, seen only at very high concentrations of agonists. Also, human osteoblast-like cells isolated from cancellous bone seem to be equipped with opioid receptors; Met-enkephalin inhibits cell proliferation by a mechanism sensitive to inhibition by the opioid receptor antagonist naltrexone (Elhassan *et al.,* 1998). No analysis of alkaline phosphatase was performed in these cell cultures and therefore it is not known if Met-enkephalin affects osteoblast differentiation in human bone cells.

The effect of opioid peptides on osteoclast activity is indicated by the observation that the synthetic analgesic opioid buprenorphine inhibits rat osteoclast activity, as assessed by the pit formation assay (Hall *et al.,* 1996). However, the effect seems unrelated to opioid receptors, as it was not shared by other opioid receptor agonists nor blocked by the opioid antagonist naloxone.

Interestingly, Elhassan *et al.* (1998) found that Met-enkephalin levels are decreased significantly in ankle joints from Lewis rats with adjuvant arthritis. Using immunohistochemistry, a significant decrease was observed in synovial type A cells. If Met-enkephalin levels were affected also in bone cells was not reported.

Somatostatin

Somatostatin receptors have been immunolocalized to metaphysis immediately adjacent to hypertrophic cartilage (Mackie *et al.,* 1990). Somatostatin-binding cells stain positive for alkaline phosphatase and are probably osteoblast precursor cells, suggesting that somatostatin may be involved in the regulation of osteoblastic differentiation during enchondral ossification. Mature osteoblasts, as well as osteoclasts and chondrocytes, are negative for somatostatin receptors, which are also lacking in membranous bones. Somatostatin receptor agonists do not affect basal or PTH-stimulated bone resorption in neonatal mouse calvariae (Lerner and Feyen, unpublished observations).

Receptors and Effects by Neurotransmitters in Bone

Catecholamines

The presence of adrenergic receptors on osteoblasts is indicated by the cyclic AMP response induced by norepinephrine in rat UMR 106-01 and ROS 17/2.8 osteosarcoma cell lines, in mouse MC3T3-E1 cells, and in the human osteosarcoma cell line Saos-2 (Bjurholm *et al.,* 1992). Interestingly, estrogen inhibits isoproterenol-induced cyclic AMP in MC3T3-E1 cells (Majeska *et al.,* 1994). In human osteoblasts and osteosarcoma cell lines, mRNA expression of β_1- and β_3- but not β_2-adrenergic receptors has been observed by Togari *et al.* (1997). When screening several human osteoblastic osteosarcoma cell lines and human primary osteoblast cDNA libraries, Kellenberger *et al.* (1998) were able to find expression, to different degrees in the different cell types, of β_1, β_2, and β_3 receptors; β_2 receptors were expressed in most cell types. β_2 receptors induced c-fos gene expression. In the ROS 17/2.8 cell line, radioligand binding and RT-PCR have demonstrated β_2- but not β_1-adrenergic receptors (Moore *et al.,* 1993).

α-adrenergic receptors stimulate cell proliferation and alkaline phosphatase in MC3T3-E1 cells (Suzuki *et al.,* 1998). Stimulation of alkaline phosphatase seems to be

mediated via p38 MAP kinase and cell proliferation via the ERK pathway (Suzuki *et al.,* 1999). These observations indicate a possible anabolic effect of catecholamines. However, epinephrine does not affect osteocalcin, or type I collagen, expression in MC3T3-E1 cells (Suzuki *et al.,* 1999); in ROS 17/2.8 cells, isoproterenol inhibits osteopontin expression (Noda and Rodan, 1989).

In mouse calvariae, norepinephrine (in the presence of a phosphodiesterase inhibitor and an antioxidant) stimulates calcium release (Moore *et al.,* 1993). It is not known if this response is due to enhanced osteoclast activity or osteoclast formation or if it is caused by the stimulation of adrenergic receptors in osteoblasts, preosteoblast, or terminally differentiated osteoclasts. However, the observations that catecholamines inhibit cell proliferation, increase tartrate-resistant acid phosphatase activity, IL-6 production, mutinuclearity, and the response to CT in the human osteoclast precursor cell line FLG 29.1 indicate that catecholamines can stimulate osteoclastogenesis via the activation of adrenegic receptors on preosteoclasts (Frediani *et al.,* 1996). Alternatively, the bone resorptive response may be mediated indirectly by cytokines, as isoproterenol induces IL-6 and leukemia inhibitory factor expression in osteoblasts, two cytokines known to stimulate bone resorption (Greenfield *et al.,* 1996).

Glutamate, Glutamate Receptors, and Glutamate Transporter

The activity of excitatory amines released into synapses is controlled by a family of homologous transporters, which are responsible for the reuptake of such amines into presynaptic terminals, a mechanism for the termination of synaptic transmission. To this group belong the glutamate/aspartate transporter (GLAST), dopamine, and serotonin transporters. The expression of these transporters in the nervous system is well known, but their presence in nonneural tissues has also been recognized. The expression of GLAST, dopamine, and serotonin transporters has been demonstrated in bone cells. Mason *et al.,* (1997) reported the expression of GLAST in osteocytes and osteoblasts, both at the mRNA and protein level, and the downregulation of its expression by mechanical loading using differential RNA display in samples from rat ulnae. Immunohistochemistry demonstrated that the GLAST expression in osteocytes disappeared after loading, whereas it was upregulated in periosteal osteoblasts at sites showing enhanced cellular proliferation and bone formation. The expression of GLAST is regulated *in vitro,* being downregulated during rat osteoblatic differentiation (Bhangu *et al.,* 2000). Osteoblasts are capable of taking up glutamate and releasing glutamate by calcium-sensitive mechanisms, similar to those used by neuronal cells. Skerry (1999) has put forward the hypothesis that glutaminergic signaling may be involved in the coupling between mechanical loading and anabolic events in the skeleton. The origin of glutamate in bone is, however, not fully known. Human and mouse osteoblasts are able to actively release glutamate (Genever and Skerry, 2000), but the possibility of glutamatergic innervation in bone is indicated by the immunolocalization of glutamate in skeletal nerve fibers (Serre *et al.,* 1999).

The action of glutamate is mediated by two different types of receptors: ionotropic receptors, which use the regulation of transmembrane ion fluxes as a signal-transducing mechanism, and metabotropic receptors, which are seven transmembrane-spanning domain, G protein-coupled receptors, using either stimulation of phospholipase C or inhibition of adenylate cyclase as intracellular signaling mechanisms. Ionotropic receptors can be subdivided into three groups based on their sensitivities to *N*-methyl-D-aspartate (NMDA), AMPA, and kainate.

Using immunohistochemistry, *in situ* hybridization, and radiolabeled ligand binding, NMDA receptors have been demonstrated in rat, rabbit, and human osteoclasts (Chenu *et al.,* 1998; Patton *et al.,* 1998; Itzstein *et al.,* 2000). The presence of functional NMDA receptors in osteoclasts has been confirmed using electrophysiological patch-clamp techniques (Espinosa *et al.,* 1999; Peet *et al.,* 1999). However, controversy exists as to whether these receptors can regulate the activity of terminally differentiated osteoclasts. Chenu and collaborators have reported that an antibody directed to the NMDA receptor 1 subunit, as well as four different specific NMDA receptor antagonists (D-AP5, MK 801, DEP and L-689,560), inhibits rabbit osteoclastic bone resorption and decreases the percentage of osteoclasts with actin rings, while having no effect on osteoclast adhesion or apoptosis (Chenu *et al.,* 1998; Itzstein *et al.,* 2000). In contrast, Peet *et al.* (1999) reported that the NMDA receptor antagonist MK 801 inhibits glutamate-induced current in rabbit mature osteoclasts, but has no effect on actin ring formation in these cells nor inhibits pit formation by mature rabbit and rat osteoclasts or basal ^{45}Ca release from neonatal mouse calvarial bones. The reason why similar observations were made on mature rabbit osteoclasts concerning NMDA receptor expression and electrophysiological function, while different results were obtained by both groups regarding the regulation of bone-resorbing activity, is presently unknown.

The possibility that glutamate NMDA receptors may be involved in the regulation of osteoclastogenesis has been suggested by Peet *et al.* (1999). MK 801 inhibits osteoclast size, nuclearity, TRAP expression, and resorptive activity in cocultures of mouse bone marrow cells and calvarial osteoblasts stimulated by $1,25(OH)_2D_3$, suggesting that osteoclastogenesis is dependent on constitutive glutamate signaling. Whether this signaling is dependent on glutamate receptors expressed by stromal cells/osteoblasts or preosteoclasts is not known. Interestingly, NMDA receptor subunit 1 knockout mice do not seem to have any skeletal phenotype (Peet *et al.,* 1999), which could be due to redundancy given the expression of the many different glutamate receptor subtypes.

Immunohistochemistry and *in situ* hybridization have revealed the expression of ionotropic NMDA receptors in rat and human osteoblasts (Chenu *et al.,* 1998; Patton *et al.,* 1998; Gu and Publicover, 2000). NMDA glutamate receptors

have also been demonstrated in the human osteoblastic cell lines MG-63 and Saos-2 using radioligand binding and electrophysiological assessements (Laketic-Ljubojevic *et al.,* 1999). Activation by glutamate resulted in increased levels of intracellular Ca^{2+} via a receptor sensitive to inhibition by MK 801, suggesting the presence of active NMDA receptors in these osteoblastic cell lines. Similarly, NMDA was found to increase intracellular Ca^{2+} in rat osteoblasts (Gu and Publicover, 2000). The functional significance of NMDA glutamate receptors in osteoblasts is, however, not yet known.

Gu and Publicover (2000) reported the presence of metabotropic glutamate receptor 1b (but not 2, 3, 4, 5, or 6) in primary rat osteoblasts using RT-PCR analysis. Activation of these receptors resulted in an elevation of intracellular Ca^{2+}. Interestingly, electrophysiologic analysis and fluorometric studies on intracellular Ca^{2+} showed interactions between ionotropic and metabotropic glutamate receptors in these cells, suggesting a complex glutamatergic signaling in bone cells.

Serotonin Receptors and Serotonin Transporter

Using RT-PCR and radiolabeled ligand binding, Bliziotes and co-workers (personal communication) demonstrated the expression of the serotonin (5-HT) transporter (5-HTT) in several different rat osteoblastic cell lines and primary rat osteoblasts. The functional expression of 5-HTT was confirmed by studies on [^{3}H]5-HT uptake in ROS 17/2.8 cells. In addition, it was shown that rat osteoblasts express four different 5-HT receptors: 5-HT1A, 5-HT1D, 5-HT2A, and 5-HT2B. Interestingly, the expression of 5-HTT increased during the differentiation of rat osteoblasts (Bliziotes *et al.,* 2000a), in contrast to that of GLAST (Bhangu *et al.,* 2000). These findings show that osteoblasts can both respond to and regulate 5-HT activity. However, the presence of serotinergic skeletal nerve fibers or serotonin-expressing bone cells, as well as the role of serotonin in bone biology, remains to be elucidated. The finding that 5-HT can potentiate PTH-stimulated cyclic AMP formation in immortalized osteoblasts (Bliziotes *et al.,* 2000a) indicates a possible role of 5-HT in PTH-stimulated bone resorption.

Dopamine Transporter

The dopamine transporter (DAT) is believed to control the activity of released dopamine (DA) into presynaptic terminals (or possibly other DAT-expressing cells). Mice deficient in DAT exhibit decreased bone mass due to diminished cancellous bone volume, increased trabecular spacing, and reduced trabecular volume (Bliziotes *et al.,* 2000b). The skeletal phenotype includes a reduction in cortical thickness, cortical strength, and decreased femur length. It is not yet known whether the osteopenic phenotype is due to DAT deficiency in bone cells or is mediated by indirect mechanisms. RT-PCR in UMR 106-01 and ROS 17/2.8 cells has failed to demonstrate mRNA for DAT in these osteoblastic cell lines. No data are available regarding the possible expression of DA in skeletal nerve fibers or bone cells. The fact that serum and urinary calcium and phosphorous, as well as circulating PTH, are normal indicates that the mechanism does not involve abnormalities in calcium and phosphorous homeostasis. The possibility may exist that the pathogenesis may, at least partly, be related to the decreased body weight or the anterior pituitary hypoplasia observed in *dat*$^{-/-}$ mice.

Receptors and Effects by Neurotrophins in Bone

Neurotrophic factors, including the neurotrophins NGF, BDNF, and NT-3, are known to play important roles in development of the central and peripheral nervous systems (Levi-Montalcini *et al.,* 1987). These factors are also known to promote the differentiation and survival of various types of neurons. The *trk* protooncogenes *trk*A, *trk*B, and *trk*C have been identified as receptors, linked to the activation of tyrosine kinase, for these neurotrophins. Thus, the neurotrophins selectively recognize these receptors and NGF, BDNF, and NT-3 bind to the products of *trk*A, *trk*B and *trk*C, respectively. Several neurotrophins have been found to be expressed in bone, and it has been suggested that these factors may have a role not only in bone-associated neuronal biology, but also in bone metabolism.

In the case of bone tissues, there are several reports of osteoblastic expression of neurotrophins and neurotrophin receptors. Nakanishi *et al.* (1994a) reported that the mouse osteoblastic cell line MC3T3-E1 expresses mRNA for NGF, BDNF, and NT-3 and that the expresssion levels were upregulated during differentiation. The rat ROS 17/2.8 cell line expresses mRNA for NGF, but not for BDNF, and NGF levels are increased by $1,25(OH)_2D_3$ (Jehan *et al.,* 1996). MC3T3-E1 cells have also been demonstrated to express mRNA encoding *trk*C, the receptor for NT-3 (Nakanishi *et al.,* 1994b). A functional role of this receptor was suggested by the observations that NT-3, but not NGF, stimulated the proliferation of MC3T3-E1 cells and calcium incorporation in the cell layers. Also, ROS 17/2.8 cells have binding sites for NGF (Jehan *et al.,* 1996), although the regulatory role of NGF receptors in these cells has not been assessed. Furthermore, it has been shown that exogenous NT-3 induces DNA-binding activities in MC3T3-E1 cells at several sites, including the cyclic AMP responsive element, partly due to activation of c-fos and c-jun (Iwata *et al.,* 1996). In addition, NGF enhances cell proliferation and the biosynthesis of proteoglycans during chondrogenesis in organ culture (Kawamura and Urist, 1988). These *in vitro* findings suggest that neurotrophins may participate in the regulation of bone formation as auto- or paracrine factors.

Studies of neurotrophins and neurotrophic receptor expression during fracture healing further support the idea of neurotrophic effects in bone. Increased sensory and sympathetic innervation during fracture healing has been reported in animal experiments (Hukkannen *et al.,* 1993). NGF has been immunolocalized in normal rat bone preferentially in osteoprogenitor cells. During fracture healing, however,

osteoprogenitor cells, as well as bone marrow stromal cells, osteoblasts, young osteocytes, and most of the chondrocytes in the callus, are expressing NGF protein (Grills and Schuijers, 1998). No NGF was seen in osteoclasts. In a large study including 70 rib-fractured mice, NGF, BDNF, and NT-3 were demonstrated in bone-forming cells at the fracture callus (Asaumi *et al.,* 2000). Interestingly, expressions of the three neurotrophins were increased during the process of healing, especially those of NGF and NT-3. Messenger RNA encoding their respective receptors, *trk*A and *trk*C, were also detected in the bone-forming cells at the fracture callus. An interesting speculation, made by the authors, is that the expression of NT-3 and *trk*C in osteoblast-like cells at the fracture callus and the increasing expression of NT-3 mRNA during the week after fracture indicate autocrine loop functions for the neurotrophic factor during fracture healing (Asaumi *et al.,* 2000). Such a view is supported by the findings that local application of NGF, at the site of fractured rat ribs, results in dramatically increased levels not only of norepinephrine and epinephrine, but also in increased healing rate and bone strength (Grills *et al.,* 1997). A possible local regulation of NGF expression in fracture sites by bone-derived molecules is suggested by the observation that BMP-2 (in the presence of TNF-α) strongly upregulates NGF in fibroblasts (Hattorl *et al.,* 1996).

Leptin Control of Bone Metabolism: A Role for the Central Nervous System in Bone Biology?

Leptin, the product of the *ob* gene, is a small polypeptide hormone produced by white adipose tissue, but also by several other organs, including placenta and fetal tissues. It influences body weight homeostasis through the effects on food intake and energy expenditure by negative feedback at the hypothalamic nuclei. In addition to the effects on the central nervous system, leptin has various physiological actions on lipid metabolism, hematopoiesis, ovarian functions, thermogenesis, and angiogenesis. The leptin receptor gene is widely expressed, with several splice variants. Leptin is known to exert its central effects through several neuroendocrine systems, including neuropeptide Y, glucagon-like peptide-1, and melanocortins (reviewed by Trayhurn *et al.,* 1999; Ducy *et al.,* 2000b).

Ducy *et al.* (2000a) presented evidence that leptin, through a hypothalamic relay, may control bone metabolism. To test this hypothesis, leptin-deficient (ob^-/ob$^-$) and leptin receptor-deficient (db^-/db$^-$) mice that are obese and hypogonadic have been studied. Despite hyogonadism and hypercortisolism, increased bone mass was seen in both mutant forms of mice, independent of obesity. Similar studies have also been performed in rats with essentially identical results (Holzmann *et al.,* 2000). Histomorphometric analysis indicates that leptin exerts its effect on osteoblastic bone formation and not on osteoclastic resorption.

An intracerebroventricular infusion of leptin in leptin-deficient mouse and wild-type mice caused bone loss. Interestingly, Ducy and colleagues could not find any differences in osteoblast number in the leptin-deficient mice or in the leptin receptor knockout mice, nor could any leptin receptors in osteoblasts be found, suggesting that the inhibitory action by leptin on bone formation has to be the result of an action on osteoblast differentiation via a central regulatory role by leptin. These findings point to the existence of a neuroendocrine pathway that controls bone mass. There is no information on what mediates the central leptin signal, and it is therefore unknown which mechanisms are involved at the local level of the bone metabolic unit. In contrast to the findings by Ducy *et al.* (2000a), there are reports of both leptin and leptin receptor expression in osteoblasts. The mouse calvarial osteoblastic cell line (MC3T3-E1) and a mouse chondrocytic cell line have been demonstrated to express mRNA encoding leptin (Kume *et al.,* 2000). In both cell types, mRNA for three of the leptin receptor splice variants was expressed (Sufang *et al.,* 2000). Moreover, human mesenchymal stem cells undergoing osteogenic differentiation are demonstrated to express leptin and functional leptin receptors (Bassilana *et al.,* 2000).

Taken together, these results point to a regulatory role of leptin in the control of bone mass. Further investigations are necessary to reveal if the regulatory pathway for leptin is of central nature or if a local loop may also be involved.

Experimental Denervation

The idea that there is a close interaction among the bone neural network, the regulation of bone cell activity, and skeletal turnover is supported by experimental denervation in animals. It has been shown that developmental skeletal growth in the rat hind foot is reduced after surgical denervation. In denervated animals, CGRP and SP immunoreactive nerve fibers were not observed in the perichondrium or periosteum of the metatarsal bones. Metatarsal bones on the contralateral unoperated side exhibited a normal pattern of innervation. The skeletal phenotype could not be due to decreased physical activity, as tendectomiesed control rats exhibited normal metatarsal bone lengths (Edoff *et al.,* 1997). These results indicate that sensory nerve fibers have growth-promoting effects on immature limb bones.

The possibility that neuropeptides may also influence the metabolism of adult skeleton is suggested by studies demonstrating a significant change in osteoclast numbers in jaw bones as a consequence of sensory and sympathetic denervation (Hill and Elde, 1991b). Treatment with guanethidine results in a dramatic decrease of the immunohistochemical staining for VIP, NPY, and DβH in the periosteum of mandible and calvariae in rats, indicating a sympathetic origin of these nerve fibers. This resulted in no change of bone formation, as assessed by periosteal apposition rate in tibiae, but a 50% increase of bone surface in mandible covered by osteoclasts. This could indicate that VIP, NPY, and/or catecholamines may have an inhibitory effect on osteoclast formation and/or activity. These results are in line with our

findings that both VIP and PACAP decrease osteoclastogenesis in mouse marrow cultures (Mukohyama *et al.,* 2000b). However, capsaicin treatment results in a 20% decrease of bone surface occupied by osteoclasts and, again, no effect on the periosteal apposition rate (Hill and Elde, 1991b).

In line with the effects of sympathetic depletions demonstrated by Hill and Elde (1991b), deprived sympathetic innervation of rat mandibular alveolar bones showed an increase of osteoclast number per sockets (Sandhu *et al.,* 1987). Moreover, the periosteal and endosteal apposition and mineralization rate was reduced in the sympathectomized jaw bones (Sandhu *et al.,* 1987). Because the jaw bones are unloaded, these bone metabolic effects cannot be due to decreased loading. Together, these data indicate that sympathetic neurons modulate bone resorption and bone remodeling *in vivo.*

Clinical Observations

Skeletal pain in patients with inflammatory and neoplastic disorders clearly suggests the existence of an extensive sensory nervous system in bone tissues. An increased fracture rate in paraplegic children due to myelomeningocele, subdural hematoma, spinal fractures associated with cord lesions, lumbrosacral root avulsion, transverse myelitis, and cord tumors indicates a role of the nervous system also in skeletal metabolism. Excessive callus formation during fracture healing in paraplegic patients further suggests a role of skeletal nerve fibers in bone metabolism (for references, see Lundberg *et al.,* 1999b). The fact that the neurotoxin thalidomide induces skeletal malformation further implicates the nervous system, not only in bone turnover and fracture healing, but also in embryonic skeletal development (McCredie and McBride, 1973).

Patients with tumors producing an excess of circulating VIP may develop hypercalcemia (Dohmen *et al.,* 1991; Lundstedt *et al.,* 1994). Although the pathogenesis is not known, the possibility may exist, given the capacity of VIP to stimulate osteoclast activity (Lundberg *et al.,* 2000), that VIP-induced enhanced bone resorption may be involved.

It is well known that a high proportion of patients with hip fractures previously have had stroke (Ramnemark, 1999). Skeletal fractures are also a frequent complication in paraplegic patients during rehabilitation. Most of these poststroke fractures are on the paretic side. Although a high incidence of falls may contribute to the high incidence of hip fractures, it has been suggested that decreased bone mass in the paretic side may be an important factor. Cross-sectional studies have all demonstrated reduced bone mass in the paretic side as compared to the nonparetic side (reviewed in Ramnemark, 1999). A prospective study found a time-dependent enhanced loss of bone mineral density in the paretic side during the first year after stroke (Ramnemark *et al.,* 1999a). Another prospective study for 4 months showed similar results (Hamdy *et al.,* 1995). The development of hemiosteoporosis is independent on weight changes after stroke (Ramnemark *et al.,* 1999b). The loss of bone in paraplegic patients is highest during the first 12 months but continues at least for 36 months (Ramnemark, 1999). The fact that the bone resorption marker carboxy-terminal telopeptide of type I collagen (ICTP) is increased in patients with hemiosteoporosis (Fiore *et al.,* 1999; Ramnemark *et al.,* in manuscript) and that osteocalcin, carboxy-terminal propeptide of type I collagen (PICP), and alkaline phosphatase are normal (Ramnemark *et al.,* in manuscript) indicate that the loss of bone in the paretic side is mainly due to enhanced bone resorption. Interestingly, both osteocalcin and PICP are increased significantly over a 12-month poststroke period (Ramnemark *et al.,* in manuscript), indicating the presence of high turnover osteoporosis in the paretic skeleton.

Patients with spinal cord injuries, similar to stroke patients, lose bone mineral contents in paralyzed areas of the skeleton (Biering-Sörensen *et al.,* 1988, 1990; Garland *et al.,* 1992; Wilmet *et al.,* 1995; Dauty *et al.,* 2000). The osteopenia is fastest in trabecular bone, showing a total loss of 50% in 18 months and then reaching a plateau phase. The decrease is slower in cortical bones, but continues for longer periods of time. The loss of bone in traumatic paraplegia is associated with an increase in urinary calcium, phosphate, hydroxyproline, and deoxypiridoline (Bergmann *et al.,* 1977–1978; Dauty *et al.,* 2000), indicating that enhanced bone resorption is an important pathogenetic mechanism, similar to the observations in stroke patients. No differences in serum levels of calcium, alkaline phosphate, or osteocalcin were observed. However, serum phosphate was increased.

It may be argued that hemiosteoporosis in paretic patients is due to disuse. However, the population of stroke patients studied by Ramnemark (1999) suffered from severe stroke and was therefore substantially immobilized and still developed local bone loss. Biering-Sörensen *et al.* (1988) reported that the decrease of bone mineral content seen in the lower extremities in patients with spinal cord injuries could not be prevented by spasticity or daily use of long leg braces. In the study by Dauty *et al.* (2000), patients with spinal cord lesions showed a 41% loss of bone mineral density in sublesional areas of the skeleton. However, there was no correlation among daily duration of sitting, daily verticalization, use of long leg braces, or bone mineral density. These observations suggest that osteoporosis in paretic patients cannot simply be classified as disuse osteoporosis. Thus, hemiosteoporosis may be caused by factors unrelated to lack of loading. This raises the possiblity that loss of innervation and local control of bone metabolism by skeletal neuro-osteogenic factors may play a role. Most interestingly, Demulder *et al.* (1998) showed that osteoclast formation in $1,25(OH)_2D_3$-stimulated cultured bone marrow from iliac crest (below the lesional level) is increased significantly as compared to osteoclast formation in sternal bone marrow cultures (above the lesional level) establised from paraplegic patients with spinal cord injuries. No such differences were seen in quadriparetic, quadriplegic, or healthy patients. Differences in the *ex vivo* osteoclast formation rate were observed in cultures established both

Table II Receptor Expression and Effects on Bone Cell Functions by Neuro-osteogenic Factors

Neuro-osteogenic factor	Receptors[a]		Bone cell functions		
	Osteoblasts	Osteoclasts	Bone formation	Bone resorption	Osteoclastogenesis

[a]The presence of receptors has been indicated by mRNA expression, a rise of cyclic AMP/Ca^{2+}i in individual cells, or immunohistochemistry.

[b]VIP and PACAP stimulate ALP; VIP increases calcium accumulation in bone nodules.

[c]VIP causes an initial, transient , "calcitonin-like" inhibition followed by delayed stimulation of rat osteoclasts; VIP stimulates calcium release from mouse calvariae.

[d]VIP and PACAP inhibit osteoclast formation in mouse bone marrow cultures.

[e]PACAP inhibits rat osteoclast pit formation; a possible delayed stimulation has not been assessed.

[f]CGRP stimulates osteoblast proliferation and increases bone mass *in vivo.*

[g]CGRP inhibits bone resorption *in vitro* and causes hypocalcemia *in vivo.*

[h]CGRP inhibits osteoclast formation in human bone marrow cultures.

[i]SP stimulates rabbit osteoclast pit resorption area.

[j]Met-enkephalin, Leu-enkephalin, and Met-enkephalin-Arg-Phe decrease alkaline phosphatase activity in ROS 17/2.8 cells; Met-enkephalin inhibits human osteoblast proliferation.

[k]Epinephrine stimulates cell proliferation and alkaline phosphoatase in MC3T3-E1 cells.

[l]Norepinephrine stimulates calcium release in mouse calvariae.

[m]Glutamate receptor antagonists inhibit rabbit osteoclast resorption.

[n]Glutamate receptor antagonist inhibits osteoclast formation in mouse bone marrow cultures.

[o]BDNF, NGF, and NT-3 are expressed by osteoblasts.

[p]NGF increases fracture healing.

[q]NT-3 stimulates cell proliferation in MC3T3-E1 cells.

6 weeks and 12 months after the spinal cord lesion. The authors speculated that the deficiency of skeletal neuropeptides may be responsible for the enhanced osteoclastogenesis seen in bone marrow from paralyzed skeletal areas of paraplegic patients and have demonstrated that CGRP inhibits human osteoclast formation induced by $1,25(OH)_2D_3$ (Akopian *et al.,* 2000).

Clinical observations, together with findings using experimental denervation to knock out signaling molecules in the nervous system and *in vitro* and *in vivo* data showing effects of and receptor expression for neuropeptides, neurotransmitters, and neurotrophins (see Table II), strongly suggest that skeletal metabolism is controlled by neuro-osteogenic factors. In addition, the nervous system has been suggested to play an important role in the pathogenesis of osteoarthritis as well as rheumatoid arthritis (Vilensky and Cook, 1998; Cerinic *et al.,* 1998). Interestingly, mild mental stress, such as cage change or cold exposure, similar to injection of corticosterone, decreases plasma osteocalcin in rats (Patterson-Buckendahl *et al.,* 1988), suggesting that not only dramatic changes of the neuronal influence on the skeleton, but also more subtile fluctuations, may influence skeletal metabolism.

Acknowledgments

Studies performed in the author's laboratory have been supported in part by The Swedish Medical Research Council, The Swedish Rheumatism Association, The Royal 80 Year Fund of King Gustav V, The County Council of Västerbotten, and Centre for Musculoskeletal Research, National Institute for Working Life, Umeå, Sweden. The comments by Dr. Chantal Chenu, Lyon, France, on the glutamate section are gratefully acknowledged.

CHAPTER 45

The Role of Insulin-like Growth Factors and Binding Proteins in Bone Cell Biology

Introduction

Bone remodeling, a function of bone formation and resorption, depends on many factors, one of the most important being the growth-promoting activity of insulin-like growth factors (IGFs) (Thomas *et al.,* 1999). This chapter reviews what is currently known about key components of the IGF system in bone, including IGF peptides and receptors, IGF-binding proteins (IGFBPs), and IGFBP proteases. The focus is on local regulation and action. At the end we will present a model, based on data discussed herein, for how the IGF system could be involved in the autocrine/paracrine regulation of human bone formation. The interested investigator is encouraged to read the many excellent reviews on IGFs that delve into more detail on molecular, biochemical, and clinical topics and other aspects of IGFs in bone (Baylink *et al.,* 1993; Canalis, 1993; Daughaday and Rotwein, 1989; Delaney *et al.,* 1994; Rosen *et al.,* 1994; Schmid, 1995; Wood, 1995).

IGF Peptides

The insulin-like growth factors (IGFs: IGF-I, IGF-II) are 7-kDa polypeptides that share structural homology with pro-insulin (Zapf and Froesch 1986). Both factors are found in high concentration in serum; in addition, many mammalian cells synthesize and export IGFs. The skeleton is a major source of IGF-I and IGF-II through *de novo* synthesis by bone cells and by virtue of their release from the bony matrix during active skeletal resorption. IGFs can act in an autocrine/paracrine fashion in bone to regulate differentiated cell function. It is also likely that some skeletal IGF is derived from the circulation. In general, the relative proportion of IGF-I:IGF-II is maintained in both the serum and the skeleton of various species (Bautista *et al.,* 1990)

IGF Gene Structure

The IGF-I protein is a 70 amino acid single chain peptide. In mice, rats, and humans, the IGF-I gene consists of 6 exons and 5 introns, spanning more than 80 kB of chromosomal DNA (Rotwein 1991). In mice the IGF-I gene is located on chromosome 10 and in humans chromosome 12. Most mammals produce multiple IGF-I mRNAs through a series of steps, which include differential promoter usage, various transcription start sites, differential RNA splicing, and RNA polyadenylation (Rotwein, 1986). The two promoters in the mammalian IGF-I gene reside in close proximity and include part of exon 1 and 5′ to exon 2 (hence the names P1 and P2) (Rotwein 1986; Adamo *et al.,* 1989).

Exon 1 codes the initial 21 amino acids of the IGF-I signal peptide (Tobin *et al.,* 1990). P1, upstream from exon 1, is the major IGF-I promoter and is active in all tissues. Exon 2 codes the initial 6 amino acids for an alternative signal peptide; P2 governs transcripts primarily in the liver (Adamo *et al.,* 1991). Alternative splicing between exon 1 and 3 or exon 2 and 3 results in variable leader peptides. There are no classical TATAA or CAAT elements within P1, resulting in dispersed initiation sites for transcription of mRNAs that contain exon 1 (Rotwein, 1991). Promoter 2 also lacks a TATAA box and transcription initiates from two clusters in exon 2 located 1.8 kb from the 5′ end of exon 1 (Jansen *et al.,* 1983). There is a CACCC box more proximal to one transcription initiation site that is important for basal promoter 2 activity (Adamo *et al.,* 1991).

The IGF-II protein is a 67 amino acid single chain peptide with a linear organization similar to IGF-I. Like IGF-I it is synthesized as a precursor with an extended C-terminal E domain. The IGF-II gene consists of 10 exons and has been mapped to chromosome 11 in humans. In a manner similar to IGF-I, IGF-II transcripts are produced by the interplay of mechanisms that include differential promoter use, alternative transcription initiation sites, and variable RNA polyadenylation. However, unlike IGF-I, four different promoters have been identified in the human gene and three in the mouse. Overall, IGF-II is also much more active during prenatal life than IGF-I, whereas IGF-I is the principal regulator of pubertal growth in most mammals. In rodents, serum IGF-I concentrations exceed IGF-II, while in humans, it is exactly the opposite (Bautista *et al.,* 1990).

Regulation of IGF-I Gene Expression

Understanding the molecular regulation of IGF-I by growth factors and hormones remains a major challenge, yet it is critical for defining the role of IGF-I in differentiated osteoblast function and the effects of calcitropic factors such as PTH on target bone cells. Much of the transcriptional regulation in both soft and hard tissue is obscure and illustrates the complexity of the IGF-I gene. For example, growth hormone (GH) is one of the most potent regulators of hepatic and skeletal IGF-I synthesis, yet its mode of action is unknown. There are no identifiable GH responsive protein-binding sites near P1 or P2. GH does induce a DNase hypersensitive site within intron 2 of the IGF-I gene, and Benbassat *et al.* (1999), utilizing a C6 neuroblastoma cell line cotransfected with the GH receptor, demonstrated a GH responsive region of the IGF-I gene, which included exons 1, 2, and a fragment of exon 3, as well as introns 1 and 2. However, further studies will be needed to determine the significance of this finding. Several transcription factors have been identified that bind to and enhance the activity of P1 in hepatoma cells. These include C/EBP, HNF-1, and HNF-3 (Nolten *et al.,* 1995). Response elements within the IGF-I gene have also been identified. For example, a cyclic AMP response element (CRE) and a glucocorticoid responsive region have been noted in P1 (McCarthy *et al.,* 1995). Prostaglandins, in particular PGE_2, have been shown to regulate osteoblast production of IGF-I by binding C/EBP, which, in turn, acts via CRE at a location approximately 200 bp 5′ upstream of P1 (McCarthy and Centrella, 1994). Similarly, although the IGF-I promoters lack estrogen response elements, 17β-estradiol suppresses IGF-I gene activation by acting through receptor binding to C/EBP (McCarthy *et al.,* 1997). Glucocorticoids have also been shown to downregulate IGF-I expression in osteoblasts through a steroid response element located approximately 100 bp upstream of P1 (Delany and Canalis, 1995). It seems certain that there are other tissue-specific transcription factors that regulate IGF-I gene expression, although so far none have been mapped to either the P1 or the P2 region in any tissue.

Overview of IGF Regulations in Bone Cells

Osteoblast-like (OB) cells in culture express both IGF-I and IGF-II genes under the control of systemic and local factors. However, there are important qualitative and quantitative differences in IGF expression among the various OB cell models (Table I). Human OB cells produce primarily IGF-II, whereas rodent OB cells produce primarily IGF-I. Transformation of OB cells may alter IGF gene expression, particularly IGF-I. In addition, differences in the state of OB differentiation during *in vitro* conditions will determine the degree of expression and secretion of the IGFs. Also, it is clear that there is unique genetic programming of skeletal IGF expression within a given species. Rosen *et al.* (1997) demonstrated that for two healthy inbred strains of mice (C3H and C57BL6), of the same body length and size, serum and skeletal IGF-I content differed by as much as 30%. Moreover similar interstrain differences in IGF-I expression were observed when calvarial osteoblasts were

Table I IGF Gene Expression in Osteoblastic Cells[a]

	IGF-I mRNA	IGF-II mRNA
hOB	+	++
HOBIT	−	++
TE-85	−	++
U-2	+/−	++
MG-63	−	−
SaOS-2	+/−	+
rOB	++	+
MC3T3-E1	++	+

[a] hOB, normal adult human osteoblastic cells derived from trabecular bone; HOBIT, SV40-immortalized hOB; TE-85, U-2, MG-63, and SaOS-2, human osteosarcoma cell lines; rOB, normal osteoblastic cells derived from fetal or neonatal rat calvaria; MC3T3-E1, clonal mouse osteoblastic cell line.

maintained *in vitro.* Other work also suggests that the strain differences in IGF-I expression are related to differential promoter usage such that there is a more than twofold greater P2 expression in calvarial osteoblasts from C3H mice than B6 (Rosen, 2000; Adamo, personal communication). In sum, the rodent species, the particular inbred strain, the state of OB development, the degree of confluence, and the type of media for culturing all contribute to the variance in expression of IGF-I and therefore are important aspects to consider when selecting study models or interpreting reports on IGF gene expression in bone.

IGF-I and Bone Cells

The results of numerous studies on the regulation of IGF expression in bone cells are compiled in Table II for IGF-I and in Table III for IGF-II. Radioligand assays for IGF measurement in cell-conditioned media have been problematic historically (Bang *et al.,* 1994; Mohan and Baylink, 1995); therefore, the studies discussed focus on mRNA expression and/or validated peptide production. Because of their abundant expression of IGF-I, rodent OB cells have been the principal model for studying IGF-I regulation and action in bone. Expression of IGF-I by fetal rat OB cells is clearly under hormonal control. The major hormones that regulate the skeleton, including parathyroid hormone (PTH), estrogen, glucocorticoids, and 1,25-dihydroxyvitamin D, all have significant effects on skeletal IGF-I. Substantial evidence from *in vitro* and *in vivo* studies shows that the anabolic effects of PTH on rat bone are mediated largely through increased local IGF-I expression (Canalis *et al.,* 1989; Pfeilschifter *et al.,* 1995). PTH exerts its effect on IGF-I synthesis through increased cyclic AMP (cAMP) production (McCarthy *et al.,* 1990a). PTH and other potent stimulators of cAMP in OB cells, such as prostaglandin E_2 (PGE_2), increase IGF-I synthesis via increases in gene transcription (McCarthy *et al.,* 1989a, 1995; Pash *et al.,* 1995). β-Estradiol also enhanced IGF-I synthesis at the transcriptional level in rat bone cells transfected with estrogen receptors (Ernst and Rodan, 1991). As noted previously, no consensus estrogen responsive element has been identified within the cloned promoter regions of the IGF-I gene. Hence, it is likely that estrogen acts through the cAMP-dependent C/EBP pathway either as an inhibitor in some cell lines and species or as a stimulator of IGF-I transcription in rat and human osteoblasts (Ernst and Rodan 1991; McCarthy *et al.,* 1997). $1,25(OH)_2D_3$ has been reported to inhibit IGF-I expression in MC3T3-E1 cells (Scharla *et al.,* 1991), but to reverse inhibition by dexamethasone in primary cultures of rat OB cells (Chen *et al.,* 1991b). As OB cells differentiate *in vitro,* IGF-I secretion decreases (Bimbaum *et al.,* 1995); therefore, hormones such as $1,25(OH)_2D_3$ that induce differentiation may indirectly affect IGF-I expression. Extracellular calcium may also regulate IGF-I synthesis in cultured rodent cells (Canalis and Gabbitas, 1994; Canalis *et al.,* 1993; Hurley *et al.,* 1992; Sugimoto *et al.,* 1994).

Table II Regulation of IGF-I Expression in Osteoblastic Cells

Factor	Effect	Cell model
PTH	↑	rOB, MC3T3-E1
Estrogen	↑	rOB, hOB
Glucocorticoid	↓	rOB
$1,25(OH)_2D_3$	⇵	MC3T3-E1, rOB
PGE_2	↑	rOB
cAMP inducers	↑	rOB, hOB
TGFβ	⇅	hOB, rOB
bFGF	↓	rOB, MC3T3-E1
PDGF	↓	rOB
BMP-2	↑	rOB
Ca^{2+}	↑	MC3T3-E1

Table III Regulation of IGF-II Expression in Osteoblastic Cells

Factor	Effect	Cell model
BMP-2	↑	rOB
BMP-7	↑	SaOS, TE-85
TGFβ	↓	rOB
bFGF	↓	rOB, MC3T3-E1
PDGF	↓	rOB

Skeletal growth factors and cytokines may also regulate IGF expression in osteoblasts (see Table II). BMP-2 increases IGF-I and II mRNA expression in rat osteoblasts and may be a critical factor in early osteoblast recruitment within the remodeling unit. BMP-7 also has a very potent effect on both IGF-I and II production in bone cells, and antisense oligonucleotides of both IGF-I and II can block BMP-7-induced alkaline phosphatase expression. IL-6 may upregulate IGF-I expression in osteoblasts, while its effect on hepatic expression is the opposite. Prostaglandins regulate IGF expression and are produced locally by bone cells providing a major paracrine regulatory circuit in the skeleton. Finally, mechanical loading is a major stimulus to enhanced IGF-I expression in bone cells, possibly through the induction of PGI_2 and PGE_2. Strain-induced production of PGI_2 has been shown to immunolocalize to osteocytes whereas IGF-II is released. PGE_2, also generated by strain, tends to localize to osteoblasts and can induce the generation of either IGF-I or II. Overall, IGF-I and II appear to be important in mediating osteogenic strain, with differences noted in various experimental paradigms a function of the *in vitro* conditions as well as the cell model and species.

In contrast to the extensive work in rodent osteoblastic cells, very little is known about modulation of IGF-I expression in human bone cells (Okazaki *et al.,* 1995a). Studies indicate that forskolin (a potent cAMP inducer) and

transforming growth factor-β (TGFβ) treatment increase IGF-I mRNA expression in hOB cells (Okazaki *et al.,* 1995b), as does estrogen (Kassem *et al*., 1998), suggesting similar regulation of IGF-I expression in human and in rat OB.

IGF-II and Bone Cells

IGF-II is the most abundant mitogen produced by human bone cells, but little is known about its regulation. Unlike IGF-I, skeletal IGF-II synthesis does not appear to be regulated by systemic hormones or intracellular cAMP (McCarthy *et al.,* 1992; Okazaki *et al.,* 1995b). Nonetheless, differences in IGF-II expression occur and can significantly impact bone cell function (Durham *et al.,* 1994a). Skeletal factors produced by bone cells may regulate the synthesis of IGF-II (Gabbitas *et al.,* 1994; Hurley *et al.,* 1995). Studies implicate bone morphogenic proteins (BMPs), members of the TGFβ superfamily, as likely candidates for local IGF-II regulatory factors. BMP-7 stimulated IGF-II expression coincident with increased proliferation and alkaline phosphatase activity in human osteosarcoma cells (Knutsen *et al.,* 1995), and BMP-2 had similar effects in fetal rat calvarial-derived OB cells (Canalis and Gabbitas, 1994).

Mechanical stress, be it from physiological or pathophysiological load adjustments or from electrical stimulation, appears to be an important local regulator of IGF-II expression. Electric field stimulation of TE-85 human osteosarcoma cell proliferation was associated with increases in IGF-II mRNA and protein (Fitzsimmons *et al.,* 1992, 1995).

IGF Expression in Bone Cells *in Vivo*

Messenger RNAs encoding for IGF-I and, to a lesser extent, IGF-II are expressed in osteoblasts in trabecular bone during rat and mouse skeletogenesis (Shinar *et al.,* 1993; Wang *et al.,* 1995). Rat models have also verified regulation of IGF-I expression by PTH in bone cells *in vivo.* Watson *et al.* (1995) studied ovariectomized rats treated intermittently with PTH and found an anabolic effect of PTH on bone associated with increased IGF-I mRNA expression in trabecular OB. Middleton *et al.* (1995) performed *in situ* hybridization for IGF-I and IGF-II mRNA in adult human osteophyte tissue, i.e., bone tissue from the femoral heads of patients with osteoarthritis. IGF-II mRNA abundance was greater than that of IGF-I, and expression for both was highest in active osteoblasts. There was weak or absent mRNA expression in flat cells lining the quiescent bone surface and in cells of the bone marrow. Osteocytes were also negative for IGF-I and IGF-II. Andrew *et al.,* (1993) examined IGF gene expression in the normal human fracture during healing and similarly detected genes for IGF-I and IGF-II in OB at stages of active matrix formation and remodeling with a predominance of IGF-II compared with IGF-I gene expression. Again, both IGF-I and IGF-II mRNA were expressed in plump OB on active osteoid, and flat lining cells in trabecular bone showed no apparent IGF expression. This differential expression among cells of the osteoblast lineage strongly implicates IGFs in bone remodeling.

IGF-I Knockouts, Transgenics, and Targeted Trangenics: Inferences about IGF-I and BMD

Another approach to understanding the *in vivo* role of circulating and skeletal IGF-I in the acquisition of peak bone mass is to examine transgenic and knockout mice. Previous studies have demonstrated enhanced muscle mass and selective organomegaly for both GH and IGF-I transgenic mice in which IGF-I expression is enhanced (Mathews *et al.,* 1988). However, GH and IGF-I transgenics differ in their skeletal phenotypes, primarily in that overexpression of GH results in longer and bigger bones, diffuse organomegaly, and muscle hypertrophy; in contrast, IGF-I transgenics have selective organomegaly but normal bone length and mass. In part, differences in bone size may be a function of GH levels (i.e., high level in GH transgenics, suppressed levels of GH in IGF-I overexpression animals). In contrast to transgenics, IGF-I knockouts (−/−) usually die *in utero;* the few viable animals tend to be very small so that the finding of reduced bone mass might be confounded by partial volume effects of the measurement tool (Bikle, 2000). Targeted transgenics circumvent these confounding variables and provide organ-specific information, which is potentially useful in defining the effect of a single gene on tissue growth and development. Zhao and colleagues (2000) measured spine, femur, and total body using pDXA technology and femoral and vertebral volumetric BMD using pQCT in three lines of mice overexpressing rIGF-I targeted to bone by a human osteocalcin promoter. At 6 weeks of age, there were greater total body, femur, and vertebral BMD in hOCrIGF-I transgenics than their respective littermates. This difference was also noted by pQCT of the proximal femur where both trabecular and cortical BMD were significantly greater in the targeted transgenics than their littermates. These findings were subsequently confirmed by histomorphometric analysis of both cortical and trabecular bone specimens. Similar studies are currently underway utilizing targeting of IGF-I with the Col1A1 promoter, another means of selectively enhancing bone mass *in vivo.*

IGFS in the Bone Matrix

Bone is a major reservoir for the IGFs. Species specificity is maintained in this storehouse with IGF-I predominating in rodent bone and IGF-II in human bone (Bautista *et al.,* 1990). In fact, IGF-II is the most abundant of all the growth factors stored in human bone matrix (Mohan *et al.,* 1987), which is related in part to its binding to IGFBP-5 (see IGFBPs). Other matrix-associated growth factors include TGFβ and BMPs, as well as small amounts of basic fibroblast growth factor (bFGF) and platelet-derived growth factor (PDGF) and, as noted in Tables II and III, these are potential regulators of IGF expression in OB cells. Although found at

concentrations proportional to the levels present in serum, IGFs in skeletal matrix are likely produced and deposited by the bone cells. Pfeilschifter *et al.* (1995) reported that the anabolic effect of intermittent PTH treatment of male rats to increase bone mineral density was accompanied by increases in bone matrix-associated IGF-I content. Intermittent PTH treatment had no effect on serum IGF-I levels in these experiments and in subsequent studies utilizing subcutaneous PTH as an anabolic agent in rodent or human studies. Thus skeletal expression of IGF-I in response to PTH is almost certainly a function of changes in local synthesis and deposition, rather than alterations in circulating concentrations.

Concentrations of the IGFs, as well as other growth factors, vary with changes in architecture in bone; hence there is proportionally more IGF-I in trabecular than cortical bone (Benedict *et al.,* 1994). Moreover, physiologic and pathological conditions can alter IGF content in the bone matrix. Aging, for example, has been shown to be associated with a decline in serum IGF-I and a significant reduction in both trabecular and cortical IGF-I content (Nicholas *et al.,* 1994; Boonen, 1996), whereas bone from patients with osteoarthritis has increased IGF-I and IGF-II content (Dequeker *et al.,* 1993; Nicholas *et al.,* 1994). These changes in matrix-associated IGFs may be significant in other conditions such as osteoporosis. Studies suggest a strong correlation between serum IGF-I and bone mineral density, especially in women, and there is evidence that women with the lowest quartile of serum IGF-I have a greatly enhanced risk of hip fractures independent of bone density (Langlois *et al.,* 1998; Gamero *et al.,* 2000). These findings would be consistent with parallel changes in both circulating and matrix IGFs, leading to lower bone mass and greater skeletal fragility. Murine studies support that tenet. Thus, even though there are differences in tissue-specific regulation of IGF-I, expression patterns for the liver and bone are similar at various times such as peak bone mass or old age (Rosen, 1997; Mora *et al.,* 1999).

Further evidence that IGF-I is important in the skeletal matrix comes from work by Slater *et al.* (1994), who demonstrated that fetal OB cells derived from human trabecular bone incorporate growth factors into extracellular matrix material *in vitro.* IGF-I, IGF-II, and TGFβ were focally deposited and colocalized in extracellular matrix. The intensity of IGF-II immunogold labeling of these human OB cells exceeded that of IGF-I, consistent with the predominant synthesis of IGF-II by human bone cells. Estrogen treatment of fetal hOB cultures increased growth factor incorporation into extracellular matrix. The authors reasoned that if IGFs and other growth factors released from extracellular bone matrix during osteoclast resorption serve as active bone growth factors (Farley *et al.,* 1987), then reduced growth factor incorporation in estrogen deficiency would lead to less growth factor released upon osteoclast resorption, resulting in decreased bone formation during subsequent remodeling. In this context, both deposition and release of IGFs from bone matrix may be regarded as physiological control points in local IGF bioavailability.

IGF Receptors in Bone Cells

IGFs produced by OB or released from bone matrix have the potential to stimulate proliferation and enhance osteoblastic activity. These effects are mediated through binding of IGF peptides to specific plasma membrane receptors identified on various OB cell models (Centrella *et al.,* 1990; Conover and Kiefer, 1993; Furlanetto, 1990; Raile *et al.,* 1994; Slootweg *et al.,* 1990; Wang *et al.,* 1995). The type I IGF receptor is a tyrosine kinase signaling receptor structurally related to the insulin receptor (Nissley and Lopaczynski, 1991). This receptor has preferential affinity for IGF-I and insulin. IGF-I type I receptor number is regulated by various hormonal factors, including I GF-I that downregulates its expression. PDGF, and basic fibroblast growth factor stimulate induction of the IGF type I receptor gene. Besides the well-known action of the type I IGF receptor on cell cycle progression, the IGF–IGF receptor complex has also been implicated in malignant transformation, as shown by high levels of expression in most tumor cell lines. The receptor may also be a target of oncogenes leading to increased receptor number. However, p53, a tumor suppressor, is a potent inducer of apoptosis and directly suppresses the type I IGF receptor promoter. IGF-I, when bound to the IGF type I receptor, prevents programmed cell death (Le Roith *et al.,* 1997) and therefore may be a critical factor in the life cycle of terminally differentiated cells like osteoblasts. Because IGF-I is plentiful in bone, and osteoblasts are the principle source of this peptide, it is likely that therapeutics aimed at enhancing bone formation work through the IGF system and prevent programmed cell death of osteoblasts.

The type II IGF receptor is identical to the mannose-6-phosphate (M-6-P) receptor (Nissley *et al.,* 1991). This receptor binds IGF-II and lysosomal enzymes with high affinity and does not bind insulin. The type II IGF/M-6-P receptor has no intrinsic tyrosine kinase activity but is involved in IGF-II receptor-mediated internalization and in lysosomal enzyme sorting and trafficking; these may be interrelated functions. This receptor has been implicated in insulin- or IGF-induced inhibition of protein catabolism (Kovacina *et al.,* 1989) and could play a role in bone resorption. Rydziel and Canalis (1995) reported that cortisol inhibited type II IGF/M-6-P receptor expression in fetal rat calvarial-derived OB cultures. Cell-associated IGFBP also bind IGFs. In U-2 and MG-63 human osteosarcoma cells, ^{125}IGF-1 binding is primarily to type I IGF receptor, whereas in hOB cells the majority of ^{125}IGF-I binds to cell-associated IGFBP (Conover and Kiefer, 1993; Conover *et al.,* 1996; Furlanetto, 1990). Both cell-associated and soluble IGFBPs are likely to have a profound influence on cell responsiveness and receptor signaling (see IGFBPs).

Effects of IGF on Osteoblasts *in Vitro*

IGFs increase DNA synthesis and replication of cells of the OB lineage and play a major role in stimulating differentiated function of the mature OB. *In vitro,* human and rodent

OB and osteosarcoma cells respond to ligand-activated type I IGF receptor stimulation with increases in DNA and protein synthesis (Canalis, 1993; Jonsson *et al.,* 1993; Raile *et al.,* 1994; Wergedal *et al.,* 1990). Both IGF-I and IGF-II increase type I collagen expression and decrease collagen degradation in fetal rat OB (Canalis *et al.,* 1995; McCarthy *et al.,* 1989b). Whether bone cells register a mitogenic or a differentiated response to IGF stimulus may reflect receptor population and receptor cross-reactivity and depend on cell type and OB lineage. For many of the same reasons, differential functions for IGF-I and IGF-II in bone have been difficult to define.

IGF-I may act in a bimodal fashion. During *in vitro* development of fetal rat calvaria, IGF-I is an autocrine mitogen of pre-OB, and, as pre-OB differentiate, IGF-I secretion decreases (Bimbaum *et al.,* 1995). A second rise in IGF-I secretion occurs later in OB development during matrix formation and mineralization. If this pattern exists *in vivo,* the secondary increase in IGF-I secretion by mature OB could lead to IGF-I sequestered in the bone matrix for release and action during subsequent remodeling cycles.

Effects of Locally Expressed IGF on Bone *in Vivo*

In vivo studies also point to an anabolic role for locally produced IGF-I in rat bone. Using *in situ* hybridization, Shinar *et al.* (1993) found a close correlation between IGF-I expression and osteogenesis during rat development, and estrogen treatment of ovariectomized rats resulted in decreased calvarial IGF-I mRNA levels that preceded a reduction in bone formation (Turner *et al.,* 1992). Lean *et al.,* (1995) undertook a novel study of genes expressed in rat osteocytes after a single, acute episode of dynamic loading to reproduce physiological strains in bone. This protocol induced bone formation on trabecular surface of the loaded bone. Because osteocytes are placed strategically to sense changes in strain distribution and initiate response to such stimuli, the investigators predicted a rapid expression of specific mRNA species in osteocytes after mechanical stimulation. They found IGF-I mRNA expression in osteocytes preceded increases in IGF-I expression and matrix formation in the overlying surface OB cells, providing evidence of a role for osteocytes and IGF-I in the osteogenic response of rat bone to mechanical stimuli. Further support for the importance of the local effects of IGF-I on skeletal acquisition are clearly illustrated by targeted transgenic models (see earlier discussion).

Effects of IGF on Osteoclasts

IGFs may play a role in regulation of bone resorption, although this aspect of the remodeling cycle has been less well investigated. Middleton *et al.* (1995) found that osteoclasts actively engaged in bone resorption expressed IGF-I, IGF-II, and type I IGF receptor mRNA. Type I IGF receptor mRNA was also identified in mature rabbit osteoclasts (Hou *et al.,* 1995), suggesting that osteoclasts may directly respond to IGFs. *In vitro,* IGF-I has been shown to promote the formation of osteoclasts from mononuclear precursors and to stimulate the activity of preexisting osteoclasts (Mochizuki *et al.,* 1992; Slootweg *et al.,* 1992). However, it has been suggested that these effects represent an indirect action of IGF on osteoclast activity via its effects on OB cells (Hill *et al.,* 1995). In that same vein, it has been demonstrated that stromal cells produce osteoprotogerin (OPG) and its ligand, OPGL. OPGL is responsible for activating osteoclasts and coupling resorption to formation, whereas OPG is a member of the TNF receptor superfamily and serves as an extramembrane "dummy receptor" binding OPGL. Studies by Rubin *et al.* (2000) demonstrate that physiologic doses of IGF-I (10 ng/ml) downregulate OPG expression but do not affect OPGL. Hence, the increase in osteoclast resorption with IGF-I may be a function of both direct activation of osteoclasts/osteoclast precursors and suppression of OPG synthesis, thereby making more OPGL available to its true receptor (RANK) on the osteoclast. This may also explain why the administration of rhGH or rhIGF-I to humans has been associated with a marked increase in bone resorption. Whether IGFs participate directly or indirectly in bone resorption *in vivo* remains an important issue to be resolved if we hope to understand and preferentially exploit the stimulatory effects of IGF on bone formation.

IGFBPs

From the foregoing sections, it is clear that IGFs are critical growth factors with active roles in bone formation, renewal, and repair. All cells involved in bone remodeling produce and/or respond to IGFs (pre-OB, OB cells, and osteoclasts). In addition, IGFs influence OB function at all stages of development (proliferation, differentiation, matrix production, and mineralization). However, IGF peptides and receptors are relatively ubiquitous. Any consideration of IGF action must take into account the special binding proteins that modify IGF bioactivity. Knowledge of skeletal IGF-binding proteins, their expression, regulation, and function is fundamental to our understanding of skeletal response to IGFs.

IGFBP Expression in Bone Cells

Six distinct yet structurally homologous IGFBPs have been characterized and designated IGFBP-1 through IGFBP-6 (Shimasaki and Ling, 1991). Wang *et al.* (1995) documented that OB localized in trabecular bone of the postnatal growth plate express IGFBP-2, -4, -5, and -6 mRNAs during the course of skeletogenesis in rat and mouse *in vivo.* All six IGFBPs have been found to be expressed by bone cells *in vitro,* but, like IGF peptide expression, IGFBP expression varies depending on cell type and culture conditions (Table IV). Normal human osteoblast-like (hOB) cells derived from trabecular bone

Table IV IGFBP Expression in Osteoblastic Cells

	BP-1	BP-2	BP-3	BP-4	BP-5	BP-6
hOB	+	−	++	++	++	+
HOBIT	+		++	+++	+	
TE-85	−	+++	−	++	−	
U-2	−	−	−	−	+++	
MG-63	−	+++	+	+	−	
rOB	−	++	+	+	+	
MC3T3-E1	−	+	−	++	+	+
UMR	−	−	−	++	++	−
ROS	−	−	−	+++	−	−

and SV40-immortalized hOB cells express mainly IGFBP-3, -4, and -5. IGFBP-2 expression is abundant in rat calvarial-derived OB and in the human osteosarcoma lines MG-63 and TE-85. U-2 human osteosarcoma cells secrete IGFBP-5 as the primary IGFBP. The rat osteosarcoma cell line ROS 17/2.8 secretes IGFBP-4 exclusively. UMR-106.01 rat osteosarcoma cells express IGFBP-4 and PTH-inducible IGFBP-5. These different osteoblast-like cell lines with their unique patterns of basal secretion and specific responses to hormonal stimuli provide valuable model systems for studying particular cellular and molecular aspects of IGF/IGFBP regulation and action (Hassager *et al.,* 1992).

Biological Effects of IGFBPs

In their native or recombinant state in solution, all six IGFBPs bind IGFs with high affinity, thereby preventing interaction with receptor and effectively inhibiting IGF action. However, there is increasing awareness that there is more to the IGFBP story than simple sequestering of growth factor. Posttranslational modifications produce dramatic changes in structure/function of the IGFBPs and, hence, the fate of IGFs. Moreover, it is difficult to assign a specific physiological role to any individual IGFBP. Ultimate cell response depends on cell phenotype, presence or absence of endogenous IGFs and other IGFBPs, posttranslational alterations of the IGFBP, extracellular matrix interactions, and other growth factors and cytokines. With these caveats in mid, we will present some of the biological studies on IGFBPs in bone cells.

IGFBP-1 can inhibit or enhance IGF action dependent on its phosphorylation state (Jones *et al.,* 1991). In addition, IGFBP-1 stimulates cell migration through interaction with integrins (Jones *et al.,* 1993b). Until now, IGFBP-1 has been considered the IGFBP least likely to play a significant role in bone remodeling. However, data suggest that IGFBP-1 expression in hOB cells is directly stimulated by high-dose glucocorticoid treatment and is associated with suppressed type I collagen (Okazaki *et al.,* 1994; Lee *et al.,* 1997). Because high levels of IGFBP-1 are noted in poorly controlled diabetics and in malnourished individuals, it is conceivable that suppression of bone formation noted in these conditions can be linked to locally high levels of IGFBP-1 expression in the skeleton (Lee *et al.,* 1997; Rosen and Donahue, 1998).

IGFBP-2 is a major IGFBP secreted by rat OB cells. Addition of recombinant human IGFBP-2 inhibited the actions of IGF-I on fetal rat calvarial OB replication and matrix synthesis (Feyen *et al.,* 1991). IGFBP-3 is another Janus-faced IGFBP with both inhibitory and stimulatory potential. In the intact form, exogenous IGFBP-3 is a potent inhibitor of bone cell growth (Schmid *et al.,* 1991). However, Ernst and Rodan (1990) found that accumulation of endogenous IGFBP-3 correlated with enhanced IGF-I activity in OB cells. The ability of cell-associated IGFBP-3 to modulate IGF action and the IGF-independent effects of IGFBP-3 that have been described for various cell systems have only begun to be explored in OB cells (Slootweg *et al.,* 1995).

IGFBP-4 was originally isolated from human bone cell culture media by Mohan *et al.* (1989) as "inhibitory IGFBP." Subsequently, IGFBP-4 has been shown to inhibit IGF-stimulated effects in a variety of bone cell models (Amamani *et al.,* 1993; Kiefer *et al.,* 1992; Mohan *et al.,* 1995). Intact, soluble endogenous or exogenous IGFBP-5 inhibited IGF-stimulated bone cell growth (Conover and Kiefer, 1993; Kiefer *et al.,* 1992). However, IGFBP-5 is not normally intact or in solution in the bone cell environment. IGFBP-5 is located preferentially in the extracellular matrix due to its strong affinity for hydroxyapatite where it appears to be protected from proteases (Bautista *et al.,* 1991; Canalis and Gabbitas, 1995). Bautista *et al.* (1991) have suggested that, in this form, IGFBP-5 serves to anchor IGF-II to the crystalline matrix of human bone. In fibroblasts, IGFBP-5 in the extracellular matrix is associated with the enhancement of IGF action (Jones *et al.,* 1993a). Andress and Bimbaum (1991, 1992) have shown that truncated IGFBP-5, originally purified from U-2 cell-conditioned media, will enhance the mitogenic potency of IGF-I or -II in mouse OB cultures. Interestingly, this truncated IGFBP-5 form also possesses intrinsic mitogenic activity, and preliminary evidence has been presented for an IGFBP-5 receptor on OB cells that could mediate the IGF-independent effects of IGFBP (Andress, 1995). Studies by Mohan *et al.* (1995) also demonstrated IGFBP-5 stimulation of IGF-induced bone cell proliferation. Preliminary studies using recombinant IGFBP-5 in intact animals and *in vitro* demonstrated significant enhancement of bone formation (Richman *et al.,* 1999).

IGFBP-6 is unique among the IGFBPs in its selective affinity for IGF-II over IGF-I (Kiefer *et al.,* 1992; Shimasaki and Ling, 1991). IGFBP-6 expressed by bone cells has the potential to specifically influence IGF-II action. Addition of recombinant human IGFBP-6 preferentially blocked IGF-II-stimulated DNA synthesis in rat bone-derived PyMS cells (Schmid *et al.,* 1995).

Regulation of IGFBP Expression in Bone Cells

Production of IGFBPs by bone cells is regulated by both systemic and local effectors of bone metabolism (Table V). Critical IGFBPs in the normal bone remodeling process appear to be IGFBP-4 and IGFBP-5. Along with IGF-I, these growth factors and binding proteins play a pivotal role in bone remodeling. A summary of the factors that regulate these three peptides are noted in Table VI. However, it should be pointed out that the regulation of IGFBP expression in human and animal model systems differs in various OB systems according to the species (or inbred strain) and the *in vitro* conditions for culturing. So, for example, retinoic acid may enhance IGFBP-5 expression in rat osteoblasts, but decrease it in human osteoblasts. Although the significance of these findings is not clear at present, conclusions from *in vitro* studies must always be viewed with some caution.

IGFBP-4 gene expression in OB cells appears to be a favored target for hormones that regulate the skeleton. PTH increases IGFBP-4 mRNA and protein expression in hOB and UMR-106.01 cells via a cAMP-dependent pathway (Conover *et al.,* 1993a; La Tour *et al.,* 1990). Gao *et al.* (1993) and Strong *et al.* (1993) have characterized cAMP responsive elements in rat and human IGFBP-4 promoter regions, respectively, suggesting that intracellular cAMP modulates IGFBP-4 gene transcription. $1,25(OH)_2D_3$ and estrogen also increase, whereas cortisol decreases, IGFBP-4 mRNA expression in human osteoblastic cells (Kassem *et al.,* 1996; Okazaki *et al.,* 1994; Scharla *et al.,* 1993), but the mechanisms are uncertain. Some of these hormonal effects on IGFBPs may be secondary to effects on pre-OB differentiation. Proliferation and differentiation correlate with changes in IGFBP expression and secretion. In fetal rat calvarial cultures, maximum IGFBP-2 and IGFBP-5 expression is characteristic of proliferating pre-OB, and maximum expression of IGFBP-3, -4, and -6 is associated with the mature differentiated OB phenotype (Bimbaum and Wiren, 1994).

Table V Regulation of IGFBP mRNA Expression in Osteoblastic Cells

Factor	Effect	Cell model
PTH	↑ BP-4, ↑ BP-5	hOB, UMR
Estrogen	↑ BP-4	hOB
$1,25(OH)_2D_3$	↑ BP-3, ↑ BP-4	MG-63, hOB, TE-89, SaOS
Glucocorticoid	↑ BP-1, ↓ BP-2, ↓ BP-3, ↓ BP-4, ↓ BP-5	hOB, rOB, MG-63, TE-89
Insulin	↓ BP-1	hOB
Growth hormone	↑ BP-3, ↑ BP-5	rOB
Retinoic acid	↑ BP-5, ↑ BP-6	rOB, SaOS
PGE_2	↑ BP-3, ↑ BP-4, ↑ BP-5	rOB
TGFβ	↓ BP-4, ↓ BP-5	hOB, rOB
BMP-2	↓ BP-5	rOB
BMP-7	↑ BP-3, ↓ BP-4, ↑ BP-5	MG-63, TE-85, SaOS
bFGF	↓ BP-4, ↓ BP-5, ↓ BP-6	MC3T3-E1, rOB
PDGF	↓ BP-5	rOB
IGF	↓ BP-1, ↑ BP-5	hOB, rOB, UMR

PTH also induces IGFBP-5 mRNA expression in UMR-106.01 rat osteosarcoma cells by a cAMP-dependent mechanism (Conover *et al.,* 1993a). In these bone cell cultures, PTH and IGF-I interact to increase extracellular IGFBP-5 through distinct mechanisms: PTH increases *de novo* synthesis of IGFBP-5 and IGF-I enhances accumulation of the secreted protein. Stimulation of cAMP production increased IGFBP-5 expression in hOB cells, although PTH had no significant effect presumably due to the weak cAMP response generated by PTH in these cells. As discussed in a preceding section, IGF-I is responsible for the stimulatory effect of PTH on rodent bone collagen synthesis when the hormone is delivered in an intermittent fashion. However, continuous administration of PTH overrides IGF-dependent stimulation (Canalis *et al.,* 1989). Perhaps PTH-induced

Table VI Summary of Critical Factors Regulating IGF-I and IGFBPs in Bone Cells

Regulatory agent	Effect on IGF-I	Effect on IGFBP-4	Effect on IGFBP-5
PTH	Increase	Increase	Increase
Estrogen	Increase	Increase	Not determined
PGE_2	Increase	Increase	Increase
Glucocorticoids	Decrease	Decrease	Decrease
TGFβ	Increase/Decrease	Decrease	Decrease
FGF	Decrease	Decrease	Decrease
PDGF	Decrease	Not determined	Decrease
BMP-7	Increase	Decrease	Increase/decrease
IL-6	Increase	Not determined	Increase
IGFs	Decrease	Decrease	Increase

increases in IGFBPs partially explain why prolonged treatment with PTH inhibits collagen synthesis, despite an increase in local IGF-I.

Glucocorticoids decrease expression of IGFBP-3, IGFBP-4, and IGFBP-5 and increase expression of IGFBP-1 in hOB cells (Okazaki *et al.,* 1994). Similar glucocorticoid-induced decreases in IGFBP-2 through -5 expression have been reported for other OB cell models (Chen *et al.,* 1991a; Nakao *et al.,* 1994). In contrast, glucocorticoid regulation of IGFBP-1 in bone cells is specific for untransformed hOB cells (Conover *et al.,* 1996). Furthermore, insulin inhibits both basal and glucocorticoid-induced IGFBP-1 expression in hOB cells. Growth hormone stimulates IGFBP-3 and IGFBP-5 production in rat osteoblasts without affecting IGF-I expression (McCarthy *et al.,* 1994; Schmid *et al.,* 1994), and new data indicate upregulation of IGFBP-5 and IGFBP-6 by retinoic acid (Dong and Canalis, 1995; Zhou *et al.,* 1995).

Evidence is accumulating regarding the regulation of IGFBPs by local skeletal factors such as PGE_2, TGFβ, BMP, bFGF, PDGF, and IGFs (Canalis and Gabbitas, 1995; Conover *et al.,* 1993a; Dong and Canalis, 1995; Durham *et al.,* 1994b; Gabbitas and Canalis, 1995; Hassager *et al.,* 1992; Hurley *et al.,* 1995; Knutsen *et al.,* 1995; McCarthy *et al.,* 1994; Schmid *et al.,* 1992). Canalis and co-workers (1995) have observed that local growth factors with mitogenic properties inhibit IGFBP-5 expression in cultured rat OB cells and agents that induce rOB differentiated function enhance IGFBP-5 expression. In addition, it could be speculated that the resistance to IGF induced by skeletal unloading involves mechanical stimulation of IGFBP expression (Bikle *et al.,* 1994).

IGFBP Proteases

IGFBP bioavailability is determined not only by gene expression, but also through limited proteolysis of the secreted IGFBP. Indeed, local IGF action may be largely controlled by this mechanism. IGFBP proteases that alter the high-affinity binding between IGFs and individual IGFBPs and are activated by particular physiological states have been identified in several human bone cell systems.

IGFBP-4 Proteolysis in Bone Cells

It had been noted by several investigators that IGF-I treatment of normal hOB cells results in a loss of IGFBP-4 in serum-free media, as determined by ligand blot analysis (Durham *et al.,* 1994). Further investigation of this phenomena revealed that the IGF-induced decrease in IGFBP-4 was not due to a decrease in IGFBP-4 mRNA expression or secretion. Rather, the effect could be reproduced in a cell-free assay, suggesting that hOBs secreted a protease that could cleave IGFBP-4, thereby enhancing the biologic activity of the bound IGFs. A novel IGFBP-4-specific protease was subsequently identified in media condition by hOB cells in 1994 (Durham *et al.,* 1994; Kanzaki *et al.,* 1994). This protease was a calcium-requiring metalloprotease that cleaves IGFBP-4 at a single site, attenuating inhibition of IGF action by IGFBP-4 (an inhibitory IGFBP) (Conover *et al.,* 1993; Conover *et al.,* 1995). The IGFBP-4 protease was dependent on IGFs for its functional activity, with IGF-II being more effective than IGF-I. Overexpression of IGF-II conferred constituitive IGFBP-4 protease activity in a subset of hOB cells (Durham *et al.,* 1995). Subsequently, it was found that TGFβ also regulated IGFBP-4 protease in hOB cells (Durham *et al.,* 1994). However, unlike IGF-II, TGFβ did not directly affect proteolysis in cell-free assay, but rather treatment with TGFβ in hOB cells enhanced IGF-dependent IGFBP-4 protease activity in the condition media. TGFβ may also stimulate hOB cell expression and/or secretion of the enzyme. In 1999, Conover and colleagues isolated the protease synthesized by human fibroblasts and osteoblasts as pregnancy-associated plasma protein-A (PAPP-A) (Lawrence *et al.,* 1999). PAPP-A is generated in various osteoblastic cell lines but its greatest expression is in osteoprogenitor cells. Interestingly, IGFBP-4 is the only IGFBP substrate for this protease, which is active in a broad pH range of 5.5–9.0. Estrogen has been shown to decrease IGF-dependent protease IGFBP-4 proteolysis in estrogen responsive cells, although it is unclear whether it works to decrease protease expression or increase inhibition (Kassem *et al.,* 1996). IGFBP-4 proteolysis can also be controlled by inhibitors produced by bone cells. Treatment of hOB cells with phorbol ester tumor promoters or transfection with SV40 T antigen induces a cycloheximide-sensitive inhibitor of the IGFBP-4 proteolytic reaction (Durham *et al.,* 1995b), suggesting an association with early transformation processes. As representative of the fully transformed OB phenotype, U-2, MG-63, and TE-85 human osteosarcoma cells secrete neither IGFBP-4 protease nor protease inhibitor. Thus, transformation appears to alter the IGFBP-4 protease system in bone cells.

IGFBP-5 Proteolysis in Bone Cells

U-2 osteosarcoma cell-conditioned medium readily degrades exogenous and endogenous IGFBP-5 due to a cation-dependent serine protease specific for IGFBP-5 (Conover, 1996; Conover and Kiefer, 1993; Kanzaki *et al.,* 1994). In contrast to their stimulatory role in IGFBP-4 proteolysis, IGFs attenuate IGFBP-5 proteolysis in U-2 cells (Conover and Kiefer, 1993). IGF-regulated IGFBP-5 proteolysis has also been identified in hOB cell-conditioned media (Durham *et al.,* 1994a), and IGFBP-5 protease activity varied during murine OB development (Thraikill *et al.,* 1995). In its various forms, IGFBP-5 may have numerous functions in bone. When intact and soluble, IGFBP-5 inhibits IGF-I action in bone cells *in vitro.* In osteoblasts, in which the IGFBP-5 protease has been identified, a truncated form of IGFBP-5 possesses intrinsic mitogenic activity, possibly acting through a putative IGFBP-5 receptor (Kanzaki *et al.,* 1994; Andress, 1998). In addition, secreted

IGFBP-5 that is not immediately proteolyzed appears to be localized preferentially in the extracellular matrix as the intact form, and in this state is associated with enhanced IGF action. IGFBP-5 also serves the unique function of fixing the IGFs in the bone matrix by virtue of its high affinity to hydroxyapatite.

Other IGFBP Proteases in Bone Cells

MG-63 human osteosarcoma cells secrete an acid-activated IGFBP-3 protease identified as the aspartic protease, cathepsin D, based on acidic pH optimum, inhibition by pepstatin, distinctive proteolytic fragment pattern, and immunoreactivity with cathepsin D antisera (Conover and De Leon, 1994). Acid-activated cathepsin D is not IGFBP specific and will proteolyze IGFBP-1 through -5 (Conover *et al.,* 1995b). IGFs may influence this system as well, as IGF-II modulates type II IGF/M-6-P receptor-mediated binding and uptake of cathepsin D (Nissley *et al.,* 1991). Plasmin is another highly active IGFBP protease in MG-63 osteosarcoma cells. Lalou *et al.,* (1994) demonstrated that IGF-I treatment of MG-63 cells decreased protease activity toward IGFBP-3 via inhibition of plasminogen conversion to plasmin. Plasmin will also degrade IGFBP-5 (Campbell *et al.,* 1995).

Other IGFBP proteases identified in bone cell models include matrix metalloproteases, also under IGF control (Delany *et al.,* 1995; Thrailkill *et al.,* 1995).

It is interesting that we are finding IGFs themselves to be major regulators of IGFBP proteolysis, acting at different levels and by various molecular mechanisms. By modulating IGFBP-specific proteases, skeletal IGFs may autoregulate their biological activity. These highly regulated positive and negative feedback systems could ensure temporal and spatial specificity of the bone response to critical growth factors.

Model

It is generally accepted that IGFs have a defining role in bone remodeling, but just what that role is still remains to be defined. Figure 1 represents a conceptualization of how the various components of the IGF system might interact in the bone cell microenvironment. This model is based on data

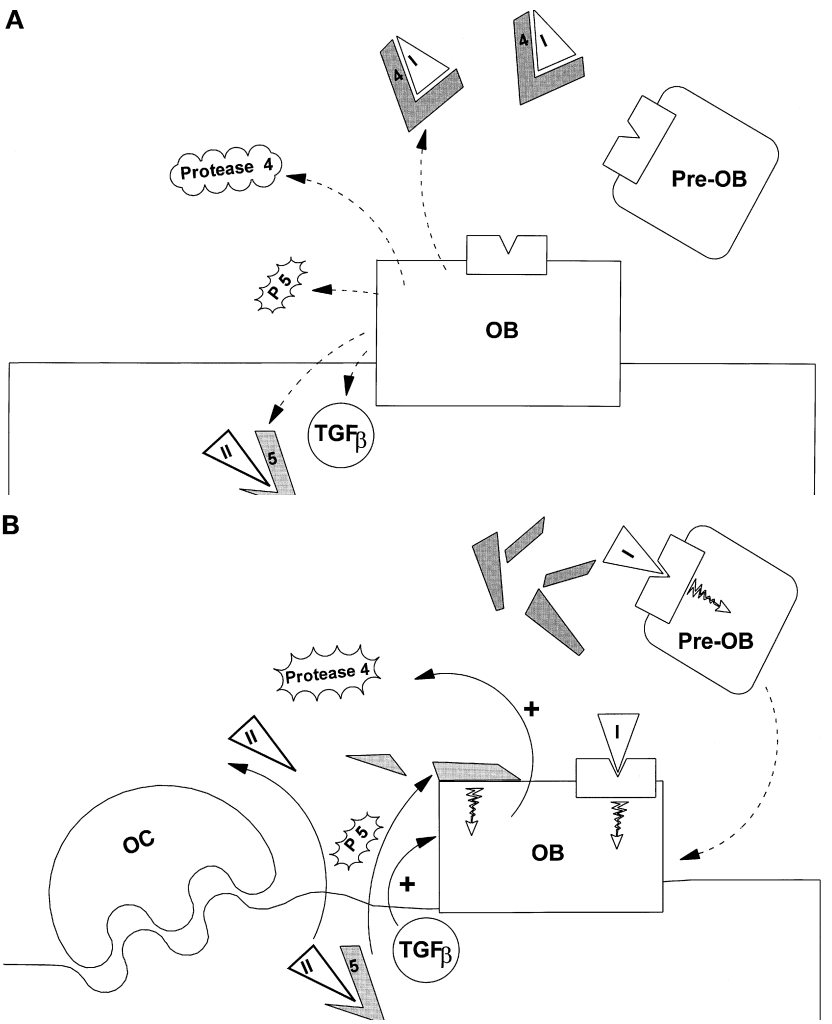

Figure 1 Model of the IGF system in human bone: (A) basal state and (B) osteoclast resorption.

derived from human bone cell studies and incorporates the following data presented in this chapter. (1) hOB cells contain cell surface receptors for IGF-I and respond to receptor activation with increased DNA synthesis and matrix production. IGF-I is more potent than IGF-II in activating type I IGF receptor signaling. (2) hOB cells secrete IGFBP-4 and functionally dormant IGFBP-4 protease. IGF-II is more effective than IGF-I in activating IGFBP-4 proteolysis. (3) hOB cells secrete IGFBP-5 and active IGFBP-5 protease. (4) IGFBP-5 is targeted to matrix and binds IGF-II. (5) IGF-II is the most abundant and TGFβ the second most abundant growth factor stored in human bone matrix.

According to this model, hOB cells are relatively unresponsive to IGF-I stimulation in the basal state (Fig. 1A), but perturbations at any point could result in major changes in response characteristics. Matrix resorption is an example (Fig. 1B). Release of IGFBP-5 during bone resorption by osteoclasts provides a substrate for the IGFBP-5 protease secreted by hOB cells, abolishing the inhibitory activity of intact IGFBP-5 and perhaps generating mitogenic forms of IGFBP-5. Proteolyzed IGFBP-5 has reduced affinity for IGF-II, thereby freeing this growth factor to initiate IGFBP-4 proteolysis. IGFBP-4 cleavage increases IGF-I availability to receptors on OB and pre-OB cells, resulting in stimulation of collagen synthesis and proliferation. TGFβ, released from the matrix in concert with IGF-II and IGFBP-5, could amplify this response by stimulating hOB cell expression/secretion of IGFBP-4 protease. TGFβ increases IGF-I expression by hOB cells as well. Thus, bone resorption initiates an IGF-dependent process, culminating in site-specific bone replacement during remodeling.

This model offers a molecular mechanism for the coupling process that has been proposed by several investigators (Farley *et al.,* 1987; Parfitt, 1984; Rodan and Martin, 1981) and extends previous models put forth by Mohan and Baylink (1991) and Bautista *et al.,* (1991) that include IGF-II and IGFBP-5 as important components in this coupling mechanism. A corollary to this model is that the amount and nature of growth factors stored in bone are determining factors, and alterations in the deposition of growth factors influence the remodeling cycle. Other scenarios can be derived from this model. Changes in synthesis of IGF-II could impact bone formation by its direct autocrine activity, through its deposition in matrix for future action, and in its role to activate IGFBP-4 proteolysis increasing IGF-I available for autocrine/paracrine stimulation. Also, differentiation signals could use this system by altering IGF and IGFBP gene expression to a affect a switch in osteoblast behavior from proliferation to differentiation.

Concluding Remarks

IGFs are abundant in the bone microenvironment. They are produced by bone cells and released from bone matrix to act as autocrine/paracrine regulators of bone formation. Synthesis of skeletal IGFs is regulated by hormones, growth factors, and mechanical stress. Deposition and resorption are also physiological points of regulation of IGF availability that need to be further explored. Activity of the local IGFs can be modified by IGFBPs, which are produced by bone cells and regulated by some of the same agents that modulate IGF synthesis, as well as by specific proteases. Interestingly, proteolytic modification of IGFBP structure/function can be regulated by IGFs. This IGF regulation of IGFBP availability is essential to our overall understanding of IGFs in bone metabolism and growth and of practical importance when considering IGFs as therapeutic agents. Finally, an understanding of the interaction among all the components of the IGF system is likely to be important regarding IGF action in bone cells and needs to be fit into the complex interplay among systemic skeletal factors and locally acting growth factors, cytokines, and extracellular matrix that undoubtedly occurs *in vivo.*

CHAPTER 46

Platelet-Derived Growth Factor and the Skeleton

Ernesto Canalis and Sheila Rydziel

Saint Francis Hospital and Medical Center, and the University of Connecticut School of Medicine, Hartford, Connecticut 06105

Platelet-derived growth factor (PDGF) is a polypeptide with a molecular mass of 30 kDa. PDGF is composed of two polypeptide chains, which may be combined in a homodimeric or heterodimeric form. The chains are the products of distinct but related genes, PDGF A and PDGF B, thus PDGF can exist as either a PDGF AA or BB homodimer or as a PDGF AB heterodimer (Heldin and Westermark, 1989; Westermark and Heldin, 1993). The PDGF B gene shares extensive sequence homology with p28-*sis,* the oncogene product of the simian sarcoma retrovirus (Doolittle *et al.,* 1983). The PDGF A gene is localized to chromosome 7 and is related to the PDGF B gene so that mature PDGF A and B chains share 56% homology in their amino acid sequence (Betsholtz *et al.,* 1986). The homo- and heterodimeric forms of PDGF have the same biological activities, although PDGF BB is more potent than PDGF AA and PDGF AB has intermediate effects in most biological assays.

PDGF was initially isolated from human platelets, but its presence was subsequently found in selected tissues, including bone. In the circulation, PDGF is transported in platelet granules, where its composition is 70% PDGF AB heterodimer, 25% PDGF BB, and 5% PDGF AA homodimer (Hammacher *et al.,* 1988; Hart *et al.,* 1990). PDGF A and B genes are expressed in normal and malignant cells, where they act as local regulators of cell growth. As a local factor, PDGF is expressed primarily in endothelial cells, where it is considered to act as a local regulator of vascular cell function. Because PDGF is present in platelets and is expressed by various cell types, it is considered to act both as a systemic and as a local regulator of cell metabolism. PDGF may become available to a variety of tissues following platelet aggregation, whereas the expression and regulation of the locally synthesized PDGF are specific and cell type dependent.

Synthesis of PDGF by Skeletal Cells

PDGF is synthesized by osteoblasts and osteosarcoma cell lines, and these cells express the PDGF A and B genes (Betsholtz *et al.,* 1986; Sejersen *et al.,* 1986; Rydziel *et al.,* 1992, 1994; Graves *et al.,* 1989). Experiments in normal osteoblasts revealed that the synthesis of PDGF A chains is enhanced by other growth factors produced by skeletal cells (Table I). Transforming growth factor (TGF) β1 and PDGF itself increase PDGF A mRNA and PDGF AA polypeptide levels in cultured rat osteoblasts (Rydziel *et al.,* 1992). This autoregulation of the PDGF A gene is not unique to the osteoblast, as it has also been reported in nonskeletal fibroblasts and mesangial cells (Bhandari *et al.,* 1994). Furthermore, growth factor autoregulation is not specific to PDGF, and other genes, such as TGF β1, are autoregulated (Kim *et al.,* 1989). Mechanisms involved in the synthesis of PDGF A and B in osteoblasts have not been established. In endothelial cells, both phorbol esters and TGF β1 regulate the PDGF A gene at the transcriptional level (Starksen *et al.,* 1987; Kavanaugh *et al.,* 1988). Posttranscriptional regulation of the PDGF A gene in skeletal cells has not been reported, and the rapid induction of PDGF A transcripts following stimulation suggests that transcriptional mechanisms are involved in its synthesis. However, modest reductions in the half-life of PDGF A and B transcripts were reported in mesangial cells following exposure to phorbol esters (Bhandori *et al.,* 1994). The promoter region of the PDGF A gene contains multiple

Table I Stimulation of PDGF A and B Gene Expression in Osteoblasts

PDGF A	PDGF B
PDGF	TGF β
TGF β	
Phorbol esters	

GC-rich regions, a TATA box, multiple Sp-1 and Egr-1-binding sites, and negative regulatory or silencer elements (Takimoto *et al.,* 1991; Lin *et al.,* 1992, 1993). The promoter region of the PDGF A gene contains a serum response element located at base pair −477 to −468, and this element appears to be responsible for the induction of the PDGF A gene by PDGF (Lin *et al.,* 1992). Sites responsible for the regulation of PDGF A by TGF β1 have not been defined. A second PDGF A promoter has been described, and the use of alternate promoters and alternative splicing, as well as multiple polyadenylation signals, results in the expression of multiple species of PDGF A transcripts (Rorsman *et al.,* 1988, 1992). In contrast to the regulation of the PDGF A gene by selected growth factors in osteoblasts, polypeptide, steroid, and thyroid hormones do not modify its synthesis in skeletal cells. This indicates that growth factors, but not hormones, regulate the synthesis of PDGF A in osteoblasts (Rydziel *et al.,* 1992). However, the systemic administration of estrogens enhances expression of the PDGF A and B genes in murine uterus and vagina, indicating that PDGF in selected cells could be a potential mediator of estrogen action (Gray *et al.,* 1995). This effect has not been demonstrated in bone cells.

Normal rat osteoblasts express the PDGF B gene, and TGF β1 increases the expression of PDGF B transcripts in a time- and dose-dependent fashion (Rydziel and Canalis, 1996). In contrast, other growth factors, such as PDGF, insulin-like growth factor I (IGF I), and fibroblast growth factor (FGF) -2, do not modify PDGF B mRNA levels in osteoblasts. At the present time, there is no evidence of hormonal regulation of PDGF B expression in skeletal cells. TGF β enhances PDGF B expression at the transcriptional level in nonskeletal cells (Daniel and Fen, 1988), and a similar level of regulation may be involved in osteoblasts. The PDGF B gene promoter contains a classic TATA box, Sp-1-binding sites, and a transcriptional silencer region (Pech *et al.,* 1989; Jin *et al.,* 1993). A proximal element at bp -58 to -39 relative to the PDGF B transcription start site is essential for the phorbol ester-induced activation of the PDGF B gene (Jin *et al.,* 1993). At the present time there is limited information about the elements responsible for the regulation of the PDGF B gene by TGF β1 in skeletal cells, and studies on the transcriptional regulation and promoter activity of the PDGF B gene in osteoblasts have not been reported. It is possible that specific osteoblast nuclear transcription factors modify the expression of the PDGF B gene in a cell-specific fashion.

Biological Actions of PDGF on Skeletal Cells

PDGF AA, BB, and AB have similar biological actions for cells of the osteoblastic lineage. In skeletal as well as in nonskeletal cells, PDGF BB is more potent than PDGF AA, and PDGF AB has intermediate activity (Centrella *et al.,* 1991). PDGF stimulates bone cell replication and DNA synthesis, both in intact calvariae and in isolated rat osteoblasts. It appears that the primary effect of PDGF in bone is related to its mitogenic activity (Table II) (Canalis *et al.,* 1989). As a consequence of its effect on cell replication, PDGF increases the number of cells capable of synthesizing collagen. However, on a cellular basis, PDGF does not increase collagen synthesis and it may have a modest inhibitory effect on bone collagen production by the osteoblast. In accordance with this observation, PDGF inhibits matrix apposition rates in intact calvariae (Hock and Canalis, 1994). Although acute exposure to PDGF does not enhance the differentiated function of the osteoblast, it is likely to increase the pool of cells of the osteoblastic lineage, which eventually differentiate and express the osteoblastic phenotype. In fibroblasts, PDGF is a competence factor and its presence is required for the effect of IGF I on cell replication (Stiles *et al.,* 1979; Olashaw *et al.,* 1987). This does not seem to be the case in osteoblasts, and the mitogenic effect of PDGF in bone cells is observed in the absence of exogenously added IGF I (Centrella *et al.,* 1991; Canalis *et al.,* 1989). This may be due to the fact that osteoblasts synthesize significant amounts of IGF I and II, which may allow them to progress through the cell cycle.

IGF I and II and bone morphogenetic proteins (BMP) 2, 4, and 6 are synthesized by skeletal cells known to increase the differentiated function of the osteoblast. IGFs stimulate bone collagen synthesis and matrix apposition rates, whereas BMPs induce the differentiation of immature cells into cells of the osteoblastic lineage and stimulate the function of mature osteoblasts (Gazzerro *et al.,* 1998; Zhao *et al.,* 2000). Because PDGF tends to inhibit the differentiated function of the osteoblast, we examined whether it modified the synthesis of IGF I and IGF II and BMPs in skeletal cells (Table III). PDGF caused a time- and dose-dependent inhibition of IGF I and II mRNA and polypeptide levels (Canalis *et al.,* 1993; Gabbitas *et al.,* 1994; Gangi *et al.,* 1998) and inhibited BMP-4 expression in osteoblasts (Pereira *et al.,* 2000). The inhibition of IGF I and II and BMP-4 expression correlate with the inhibitory effect of PDGF on the differentiated function of the osteoblast, although this does not prove

Table II Effect of PDGF on Skeletal Cells

Increases cell replication
Inhibits the differentiated function of the osteoblast
Decreases collagen synthesis
Decreases bone matrix apposition rates
Increases bone resorption
Increases collagen degradation and collagenase expression

Table III Effect of PDGF on Cytokine Expression in Osteoblasts

Decreases IGF I and IGF II synthesis
Increases IGF I receptor binding
Decreases IGFBP-5 synthesis
Decreases BMP-4 expression
Increases IL-6 transcription
Increases HGF/SF expression

that the decrease in IGF I and II or BMP-4 mediates the effect of PDGF on osteoblastic function. PDGF BB decreases the rates of IGF II transcription in osteoblasts without modifying the decay of IGF II in transcriptionally arrested cells. The synthesis of IGF II in osteoblasts is driven by IGF II promoter 3 and its expression is inhibited by PDGF BB (Gangi *et al.,* 1998). Some of the effects of PDGF on the osteoblast, such as the inhibition of type I collagen transcription, occur following a short exposure to PDGF, suggesting direct effects on the differentiated function of the osteoblast. However, persistent or chronic exposure of skeletal cells to PDGF could result in a significant reduction of IGF I and BMP levels, which may be ultimately responsible for a decrease in osteoblastic function and bone formation. The inhibitory effect of PDGF on IGF expression is not related to the mitogenic activity of PDGF, as it is observed when cells are exposed to PDGF in the presence of the DNA synthesis inhibitor hydroxyurea. In addition to the decrease in IGF I and IGF II synthesis, PDGF inhibits the transcription of IGF-binding protein (IGFBP) 5, a binding protein known to stimulate bone cell growth and to enhance the effects of IGF I on this process (Canalis and Gabbitas, 1995). The interactions of PDGF with IGF I in skeletal cells appear relevant to the effects of PDGF in bone. PDGF modifies the synthesis of IGF I and II and of IGFBPs, and it also opposes the effects of IGF I on collagen synthesis in calvariae (Canalis *et al.,* 1989). Surprisingly, PDGF increases IGF I receptor binding in skeletal and nonskeletal cells.

In addition to its effects on bone formation, PDGF increases bone resorption and collagen degradation (Canalis *et al.,* 1989; Walther *et al.,* 1992; Cochran *et al.,* 1993). This effect is likely secondary to an increase in the expression of the matrix metalloproteinases (MMP), collagenase 1 and 3. An increase in MMP expression by PDGF has also been observed in nonskeletal fibroblasts. Collagenases can initiate the cleavage of collagen fibrils at neutral pH (Knauper *et al.,* 1996). Consequently, they are considered central to the process of collagen degradation and matrix breakdown. Three collagenases have been described: collagenase 1, 2, and 3. Human osteoblasts express collagenase 1 (MMP-1) and collagenase 3 (MMP-13), whereas rat osteoblasts secrete collagenase 3, but do not express collagenase 1 (Freije *et al.,* 1994; Rajakumar and Quinn, 1996; Varghese *et al.,* 1996; Ståhl-Bäckdahl *et al.,* 1997). Collagenases 1 and 3 degrade type I collagen fibrils with similar efficiency, but collagenase 3 is more effective on type II collagen (Knauper *et al.,* 1996). Although other proteases, particularly those biologically active at acid pH, are relevant to the bone resorptive process, the importance of collagenase 3 is documented by studies demonstrating that collagenase-neutralizing antibodies inhibit bone resorption (Holliday *et al.,* 1997). Furthermore, studies in mice with a mutation of the type I collagen gene that causes resistance to collagenase 3 cleavage fail to resorb bone following exogenous parathyroid hormone (PTH) (Zhao *et al.,* 1999).

The synthesis of collagenases 1 and 3 by osteoblasts is regulated by hormones and by cytokines present in the bone microenvironment. PDGF enhances collagenase 3 expression by transcriptional and posttranscriptional mechanisms (Varghese *et al.,* 1996). PDGF BB increased the activity of collagenase 3 promoter fragments transiently transfected into osteoblasts. Deletion analysis of the collagenase promoter revealed regions that impaired the induction of collagenase 3 by PDGF BB, but these were not characterized. A collagenase 3 construct spanning bp -53 to 28 in relation to the start site of transcription was fully responsive to PDGF BB when transiently transfected into osteoblasts. Targeted mutations of an AP-1 site in this fragment decreased basal collagenase promoter activity and the responsiveness to PDGF BB. Electrophoretic mobility shift assay revealed AP-1 nuclear protein complexes that were enhanced in extracts from PDGF BB-treated osteoblasts, and supershift assays demonstrated interactions of c-Fos, Fos B, Fra-2, c-Jun, Jun B, and Jun D with AP-1 sequences in extracts from PDGF-treated cells. Furthermore, PDGF caused a rapid induction of these transcription factors known to interact with the AP-1 site (Rydziel *et al.,* 2000). The elements and cytosolic proteins responsible for posttranscriptional regulation have not been reported.

The induction or activation of members of the Fos and Jun family of transcription factors by PDGF BB is consistent with the mitogenic activity of the growth factor in skeletal cells and with its stimulatory effects on bone resorption (Angel and Karin, 1990). PDGF increases osteoclast number in calvariae; this could be due to an increase in osteoclastogenesis or a decrease in osteoclast apoptosis. Mice lacking c-Fos develop osteopetrosis and decreased bone remodeling, and c-Fos appears to be essential for osteoclast differentiation (Wang *et al.,* 1992; Grigoriadis *et al.,* 1994). PDGF may have direct and indirect effects on bone resorption, as it increases the expression of interleukin (IL)-6 in osteoblasts, and IL-6 enhances the recruitment of osteoclasts and is critical to the process of bone resorption (Jilka *et al.,* 1992; Masiukiewicz *et al.,* 2000). The effect of PDGF on IL-6 expression occurs at the transcriptional level and PDGF increases the activity of IL-6 promoter fragments transiently transfected into osteoblasts. Deletion analysis revealed two responsive regions: one containing an AP-1 site located between bp -276 and -257 and a second, less well defined, downstream of -257. Targeted mutations of a cyclic AMP-responsive element (CRE) in the bp -257 to 20 region revealed that this site contributes to IL-6 promoter induction by PDGF BB. Electrophoretic mobility

shift assay revealed nuclear protein complexes, forming with the AP-1 and CRE sites, that were enhanced by PDGF BB. Supershift assays revealed that classic members of the Fos and Jun families of transcription factors interact with AP-1, as well as with CRE sequences in the IL-6 gene, whereas the related activating transcription factor-2 (ATF-2) interacted only with CRE sequences, the known target sequence for this transcription factor (Meyer and Habener, 1993). ATF-2 is known to form heterodimers with members of the Jun family of proteins, which may also be the case in osteoblasts exposed to PDGF BB (Hai and Curran, 1991; Morooka *et al.,* 1995). The induction of IL-6 by PDGF involves a CRE, but PDGF does not increase cyclic AMP in osteoblasts, and ATF-2 is not dependent on cyclic AMP pathway activation.

Changes in IL-6 expression could play a role not only in the actions of PDGF in bone resorption, but also in its effects on collagenase expression and matrix breakdown, particularly as IL-6 is one of the most potent inducers of collagenase 3 in osteoblasts (Franchimont *et al.,* 1997). The actions of PDGF on bone cell replication would suggest a possible role in fracture healing similar to that reported in wound healing (Pierce *et al.,* 1991; Lynch *et al.,* 1987). In addition, PDGF A and B genes are expressed by cells present in normal healing fractures, and reduced expression of PDGF and its receptors results in impaired would healing (Andrew *et al.,* 1995; Beer *et al.,* 1997). PDGF could play a role as a systemic and local regulator of fracture repair. Because TGF β and PDGF are present in platelet granules, it is possible that when these factors are released following platelet aggregation, they induce the expression of PDGF A and B at the fracture site. Along these lines, PDGF, like FGF-2, induces the expression of hepatocyte growth factor/scatter factor (HGF/SF) in osteoblasts (Blanquaert *et al.,* 1999, 2000). HGF/SF is a polypeptide composed of a 69-kDa α chain and a 34-kDa β chain with a serum protease-like sequence linked by disulfide bonds (Nakamura *et al.,* 1989; Strain, 1993). HGF/SF stimulates mitogenesis in hepatic and extrahepatic cells, enhances angiogenesis, and plays a role in tissue repair (Strain, 1993). HGF/SF signals via the product of the protooncogene c-met, a tyrosine kinase-activated receptor, and is mitogenic for cells of the osteoblastic and osteoclastic lineage (Grano *et al.,* 1996). Therefore, it was postulated to have a function in bone remodeling and repair. Interestingly, the stimulatory effect of PDGF and FGF-2 on HGF/SF expression is blunted by glucocorticoids, which are known to delay wound and possibly fracture healing (Blanquaert *et al.,* 2000; Beer *et al.,* 1997).

Although PDGF appears to play a role in fracture repair, this occurs following release, and possibly local *de novo* synthesis of the factor. However, the function of basal concentrations of PDGF and its role in normal skeletal physiology are uncertain. Studies using knockout mice have revealed, following disruption of the PDGF B or the PDGF β receptor genes, serious renal, cardiovascular, and hematological abnormalities (Leveen *et al.,* 1994; Soriano, 1994). Mutant mice developed a bleeding disorder with thrombocytopenia and lacked glomerular development because of absent mesangial cells. The animals had cardiomegaly and dilatation of major vessels. No abnormalities in the musculoskeletal system were reported. However, the embryos died prior to birth, and it is possible that skeletal abnormalities, if they were to occur, could require longer periods of time and postnatal growth. PDGF A knockout mice are phenotypically distinct; about half die *in utero,* and the surviving mice are severely growth retarded and develop emphysema (Bostrom *et al.,* 1996).

PDGF Receptors and Binding Proteins

There are two PDGF receptors: α and β. The two receptors have a 44% overall amino acid sequence homology and have immunoglobulin-like domains in the extracellular region and a tyrosine-kinase domain in the intracellular region (Qiu *et al.,* 1988; Claesson-Welsh *et al.,* 1989a,b; Gronwald *et al.,* 1988; Lee *et al.,* 1990; Matsui *et al.,* 1989; Yarden *et al.,* 1986). PDGF receptors are closely related to the receptor for colony-stimulating factor-1 as well as to the c-*kit* oncogene (Qui *et al.,* 1988). PDGF A chains bind primarily to the α receptor, whereas PDGF B chains bind to either the α or the β receptor (Seifert *et al.,* 1989). PDGF induces dimerization and activation of PDGF receptors, and PDGF also increases PDGF α and β receptor expression (Heldin *et al.,* 1989; Eriksson *et al.,* 1991; Kelly *et al.,* 1991). Skeletal cells express PDGF α and β receptors, which are regulated by other cytokines and growth factors. IL-1 and tumor necrosis factor α enhance PDGF AA binding to rodent osteoblasts, but not to human osteoblasts, by increasing PDGF α receptor transcripts and number (Centrella *et al.,* 1992; Gilardetti *et al.,* 1991; Tsukamoto *et al.,* 1991). The enhanced PDGF AA binding to osteoblasts results in increased biological activity, and after treatment with IL-1, PDGF AA becomes as biologically effective as the more potent PDGF BB. FGF-2 and epidermal growth factor also increase PDGF α receptors in the MC3T3 osteoblastic cell line, whereas TGF β1 has little effect and decreases the binding of PDGF AA in normal rat osteoblasts (Tsukamoto *et al.,* 1991). In addition, TGF β1 inhibits PDGF β receptor expression and PDGF mitogenic activity in fibroblasts (Vaziri and Faller, 1995; Gronwald *et al.,* 1989). The signal transduction pathways involved in the various PDGF effects in bone cells include protein kinase-C pathways, resulting in an induction of Jun and Fos expression, activation of phospholipase C-γ and phosphatidylinositol kinase 3, and changes in intracellular calcium (Okazaki *et al.,* 1992). The same pathways are used in nonskeletal cells (Valius and Kazlauskas 1993; Epstein *et al.,* 1992; Okazaki *et al.,* 1992).

Although there is considerable information about the existence and function of specific binding proteins for many growth factors, including IGFs and TGF β, less is known about specific binding proteins for PDGF. PDGF BB binds to α_2-macroglobulin and osteonectin or SPARC (secreted protein acidic and rich in cysteine) (Crookston *et al.,* 1993; Lane and Sage 1994; Raines *et al.,* 1992), and PDGF is stored in the extracellular matrix by association to osteonectin, as well

Table IV Effect of PDGF on Bone Matrix Proteins

Decreases type I collagen synthesis
Decreases osteonectin expression
Increases osteopontin expression

as to other extracellular matrix proteins (Kelly *et al.,* 1993). The interactions between PDGF and osteonectin may be important, as osteonectin, by binding PDGF B chains, may modify its binding to specific receptors and activity or may prolong the half-life of PDGF. Skeletal cells secrete substantial amounts of osteonectin, and osteonectin plays a critical role in bone remodeling and angiogenesis. Studies in osteonectin null mice have clarified the function of this matrix protein in bone (Delany *et al.,* 2000). Osteonectin −/− mice have decreased bone formation and decreased osteoblast and osteoclast surface and number, leading to decreased bone remodeling with a negative bone balance and osteopenia. These data indicate that osteonectin supports bone remodeling and the maintenance of bone mass in vertebrates, but it is not known whether these findings relate to the binding of PDGF B chains. It is possible that changes in the expression of osteonectin in skeletal cells play a role in the regulation of PDGF activity. In chondrocytes, PDGF increases osteonectin expression, whereas in osteoblasts, PDGF BB and FGF-2 decrease the expression of this matrix protein (Chandrasekhar *et al.,* 1994; Delany and Canalis, 1998) (Table IV). FGF-2 acts by destabilizing osteonectin transcripts, but the mechanisms involved in the action of PDGF have not been explored. PDGF also increases osteopontin expression in osteoblasts, a matrix protein necessary for normal bone resorption. (Sodek *et al.,* 1995).

Role and Clinical Relevance of PDGF

The mitogenic activities of PDGF and its release by platelets suggest a role in wound healing and fracture repair. This is supported further by the demonstration of PDGF A and B gene expression at fracture sites. It is also possible that PDGF plays a role in acute bone repair following inflammation, particularly since the mitogenic actions of PDGF are enhanced in the presence of cytokines released during this process. It is less likely that PDGF A or B plays a role in the maintenance of bone mass in view of its inhibitory effects on the differentiated function of the osteoblast. Because the PDGF A and B genes are expressed by a variety of malignant cells, including osteosarcoma, PDGF may play a role in tumorigenesis. This possibility is supported by the near identity of the PDGF B gene and p28-*sis.* In addition, studies reported that the Wilms' tumor gene product WT1 represses transcription of the PDGF A gene. Consequently, a loss of WT1 or related repressor activities could contribute to the pathogenesis or growth of Wilms' tumors (Wang *et al.,* 1992; Gashler *et al.,* 1992). In view of the mitogenic activity of PDGF, it is unlikely that it will be a suitable agent for the systemic therapy of skeletal disorders. It could, however, be useful in the topical treatment of bone disorders. Systemic administration of PDGF to estrogen-deficient rats prevents bone loss of the spine (Mitlak *et al.,* 1996). Bone histomorphometric analysis of these animals revealed that PDGF increases the number of osteoblasts and, as a consequence, bone formation. These results are consistent with the mitogenic effects of PDGF *in vitro,* which increases the replication of preosteoblasts, resulting in an increased number of osteoblastic cells capable of forming bone. Surprisingly, systemic PDGF did not change osteoclast number in ovariectomized rats, but this may be due to the model chosen, as estrogen-deficient rats display a substantial increase in bone resorption and remodeling that may preclude an additional effect. PDGF administered systemically caused fibroblast replication and fibrosis in extraskeletal tissues, pointing to potential problems if the growth factor were to be used for the treatment of clinical disorders. Topical application of PDGF to rat craniotomy defects results in increased soft tissue repair, but not increased osteogenesis (Marden *et al.,* 1993). This may be due to nonspecific effects of PDGF. The effects of PDGF on endothelial cell proliferation and angiogenesis are likely beneficial to the process of wound and fracture repair, as appropriate vascularization is required for healing (Battegay *et al.,* 1994). Although PDGF enhances the early process of wound healing, the effect is short-lived, and there is less information regarding the possible effectiveness of PDGF in fracture repair.

Introduction

The seminal work that began in the 1970s (Armelin, 1973; Gospodarowicz, 1974, 1975) and early 1980s (Bohlen *et al.,* 1984) with the purification of a single polypeptide possessing a novel bioactivity has evolved dramatically with the discovery of 23 genes encoding a family of structurally (as well as functionally) related polypeptides, the fibroblast growth factors (FGFs). As a family, FGFs act in a paracrine or autocrine manner and display a characteristic affinity for heparin (Gospodarowicz *et al.,* 1984; Shing *et al.,* 1984) which is critical for interactions with signal-transducing receptors (Ornitz, 2000; Weismann and de Vos, 1999). In addition to their property of promoting cell growth and their ability to induce a mitogenic response (Burgess and Maciag, 1989), FGFs also stimulate cell migration (Presta *et al.,* 1986), angiogenesis (Gospodarowicz *et al.,* 1979; Folkman and Klagsbrun, 1987; Klagsbrun and D'Amore, 1991; Montesano *et al.,* 1986), vasculogenesis (Krah *et al.,* 1994), hematopoietic development (Faloon *et al.,* 2000), wound healing and tissue repair (Davidson *et al.,* 1985), differentiation (Kimelman and Kirschner, 1987; Kimelman and Maas, 1992; Olwin *et al.,* 1994), transformation (Sasada *et al.,* 1988), and morphogenesis (Dono and Zeller, 1994; Niswander *et al.,* 1994; Olwin *et al.,* 1994). To mediate such multifarious activities, FGFs function in concert with a similarly complex family of cognate signal-transducing receptors (FGFRs) and nontransducing heparan sulfate-containing proteoglycans (HSPGs), the cysteine-rich receptor (CFR), and binding proteins (BPs). Furthermore, FGFs and their receptors exhibit remarkably varied mechanisms regulating their expression and/or bioavailability. These mechanisms occur at multiple levels of gene expression, including transcription, translation, intracellular protein trafficking, extracellular matrix localization, and release. For additional perspectives into the FGF family, a series of reviews can be referred to for information not provided herein (Basilico and Moscatelli, 1992; Delrieu, 2000; Martin, 1998; McKeehan *et al.,* 1998; Nugent and Iozzo, 2000; Okada-Ban *et al.,* 2000; Szebenyi and Fallon, 1999).

The Fibroblast Growth Factor Family of Bioactive Polypeptides

Fibroblast growth factors isolated from many sources act to modify the growth of cell types of epithelial, neuroectodermal, and mesenchymal origin (Burgess and Maciag, 1989). Structurally, the FGF family encompasses the polypeptides encoded by 23 distinct genes. As new members of the FGF family were identified, a standardized system for assigning nomenclature was adopted in 1991 (Baird and Klagsburn, 1991). Thus, aFGF became FGF-1 (Jaye *et al.,* 1986) and bFGF became known as FGF-2 (Abraham *et al.,* 1986). In contrast to the nearly ubiquitous tissue distribution of FGF-2 and the wide distribution of FGF-1, the expression of FGFs 3–21 is restricted both temporally and/or spatially. FGF-3/int-2 (Dickson and Peters, 1987) was identified as an activated gene product following retroviral insertion into mouse mammary tumor cells. The fourth family member is also known as the Kaposi's sarcoma FGF/K-FGF (Taira *et al.,* 1987), or the human stomach-transforming gene/HSTF-1/hst-1 (Delli Bovi *et al.,* 1987). FGF-5 was isolated as a transforming activity detected after transfection of DNA from a human bladder carcinoma into NIH/3T3 cells (Zhan *et al.,* 1988). FGF-6/hst-2, or the hst-1-related gene (Marics *et al.,* 1989), was originally identified by low-stringency screening of a human genomic library using an FGF-4-derived probe and FGF-7 [or keratinocyte growth factor (KGF)] as a selective mitogen for epithelial cells but not fibroblasts (Finch *et al.,* 1989).

Next in order of discovery is FGF-8, or androgen-induced growth factor/AIGF (Tanaka *et al.,* 1992), purified from a murine androgen-dependent carcinoma, and FGF-9, originally termed glia-activating factor (GAF), was purified from a human glioma cell line (Miyamoto *et al.,* 1993). In addition, the single copy FGF-8 gene directs the synthesis of multiple primary AUG-initiated translation products via differential mRNA processing of various 5′exons. The cDNA for FGF-10 was first isolated from human lung (Emoto *et al.,* 1997) and has been shown to modulate limb development (Sekine *et al.,* 1999). As a subgroup, FGFs 11–14 (also known as FGF homologous factors) are distinguished by the fact that when synthesized *de novo,* they appear to be preferentially targeted for direct intracellular trafficking into the nucleus (Smallwood *et al.,* 1996; Munoz-Sanjuan, 2000), as are the high molecular weight isoforms of FGF2 and FGF-3. Interestingly, there are

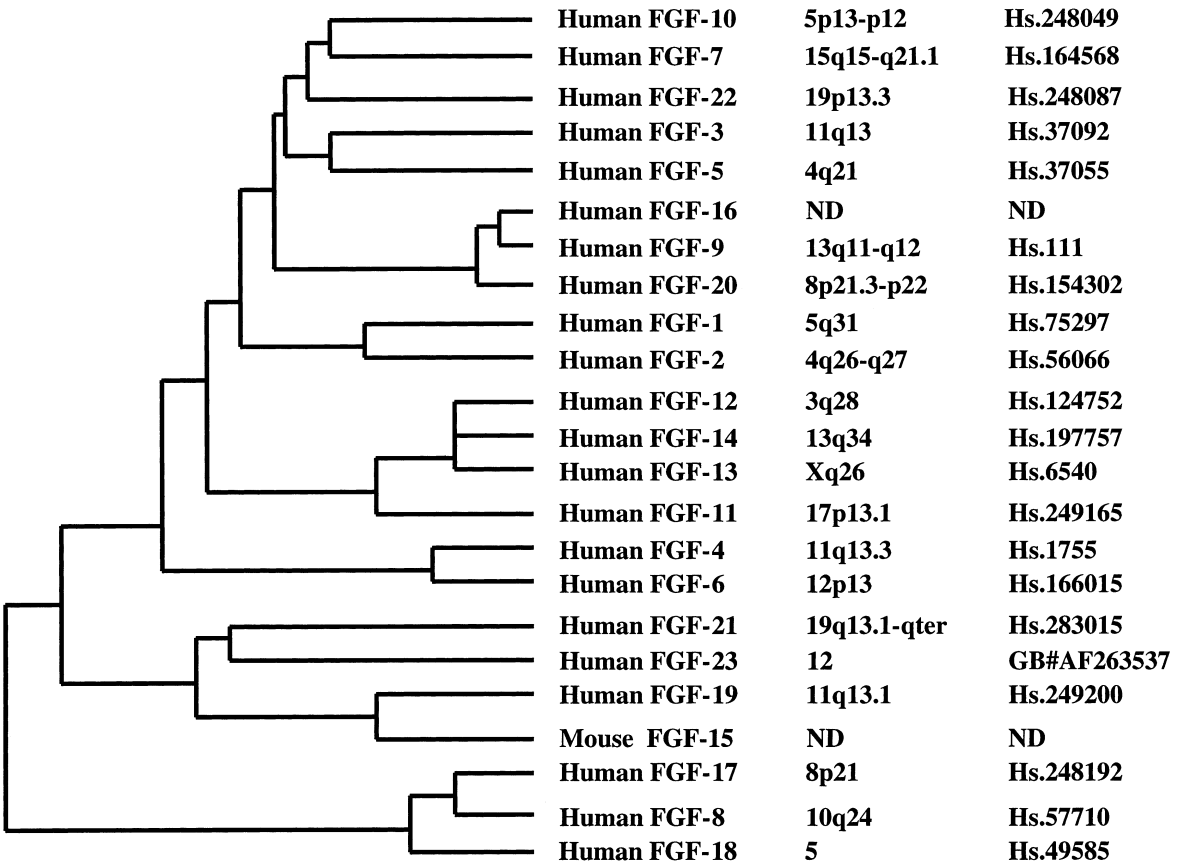

Figure 1 The human FGF gene family is made up of 23 genes. A dendrogram depicting the sequence relationship between members of the family is shown along with their human chromosomal location and corresponding unigene number. For FGF-15, no human homologue has been published and the chromosomal location of FGF-16 has not yet been determined.

alternative AUG-initiated translation products associated with the genes encoding FGFs 11–14. FGF-15 was identified in a murine model of pre-B-cell leukemia harboring a chromosomal translocation that results in the expression of a chimeric transcription factor mediating gene activation (McWhirter *et al.,* 1997); a human homologue, however, has yet to be characterized. Other publications have described cDNA cloning, chromosomal gene mapping, and embryonic patterns of expression for FGF-16 (Miyake *et al.,* 1998), FGF-17 (Hoshikawa *et al.,* 1998; Xu *et al.,* 1999), FGF-18 (Hu *et al.,* 1998; Ohbayashi *et al.,* 1998), FGF-19 (Nishimura *et al.,* 1999; Xie *et al.,* 1999), FGF-20 (Kirikoshi *et al.,* 2000), and FGF-21 (Nishimura *et al.,* 2000). The identification of FGF-22 and FGF-23 has not appeared in publication but may be found in nucleotide sequence data bases with accession numbers 10119766 and 10119773, respectively; both are likely to be classically secreted. In summary, the evolutionary relationship between the entire human FGF family (to date) and with their chromosomal locations and unigene identificarion number are shown in Fig. 1.

Distinctive Features That Regulate the *de Novo* Synthesis of FGFs

FGF Promoters

The FGF family can be divided into those with multiple or single promoters and/or transcription start sites. For example, there are at least two, possibly four, regions that functionally define the FGF-1 promoter (Chotani *et al.,* 1995; Myers *et al.,* 1995). Four mRNAs may be transcribed, each with a different transcription start site (Myers *et al.,* 1993). The four mRNAs represent alternative splice variants that place different noncoding exons 5′ of the FGF-1 translation start site. In addition, promoter choice and the appearance of different mRNAs occur in a pattern of expression that is tissue or cell-type specific. The entire FGF-1 transcription unit has been examined from rodent cells (Madiai *et al.,* 1999). Correspondingly complex mechanisms also regulate the transcription of other members of the FGF family.

The FGF-2 promoter has been functionally mapped and shown to contain both negative and positive *cis*-acting regulatory domains (Shibata *et al.,* 1991), as illustrated in Fig. 2. A novel transcription factor mediates the negative regulation of FGF-2 (Ueba *et al.,* 1999). Interestingly, in contrast to FGF-1, the human FGF-2 gene contains one core promoter region that directs the transcription of multiple mRNAs possessing the same transcription start site. Hormonal and transsynaptic receptor-mediated intracellular signaling pathways are thought to regulate the activity of the FGF-2 promoter in a fashion that may be of physiologic significance (Stachowiak *et al.,* 1992; Logan *et al.,* 1992), including astrocyte cell plasticity (Moffett *et al.,* 1998). In addition, the FGF-2 promoter has been shown to be positively regulated by the mutant p53 gene product, leading to speculation that the constitutive expression of FGF-2 may correlate with the development of some forms of cancer (Ueba *et al.,* 1994). Posttranscriptional regulation of FGF-2 gene expression through the synthesis of an endogenous antisense mRNA transcript was originally described for *Xenopus* (Kimelman and Kirschner, 1989). Expression of antisense FGF-2 mRNA is developmentally regulated, encodes a protein of 35 kDa, and modulates translation of FGF-2 (Li and Murphy, 2000). In addition, the gene promoter for antisense FGF-2 has been characterized in human cells (Gagnon *et al.,* 1999).

The FGF-3 gene is transcribed into multiple classes of mRNA with different transcription start sites, in mouse embryonal carcinoma cells (Dickson *et al.,* 1990a; Murakami *et al.,* 1993), a human colon carcinoma cell line (Galdemard *et al.,* 1995), mouse mammary tumors (Dickson *et al.,* 1990b), and in developing mouse embryos. One FGF-3 promoter region is located within intronic sequences 3′ of noncoding exon 1, the other is 5′ of the transcription start site. Further studies have functionally characterized several transcription factor-binding sites (Murakami *et al.,* 1999) and expression in tumorigenic and nontumorigenic colon carcinoma cell lines (Galdemard *et al.,* 2000). The FGF-4 promoter was initially shown to be developmentally regulated in F9 teratocarcinoma cells (Koda *et al.,* 1994; Ma *et al.,* 1992). In F9 cells, the FGF-4 promoter is regulated via binding of nuclear factor NF-Y to motifs within the core promoter region (Hasan *et al.,* 1994). Additional enhancer-like sequences are contained within the 3′ noncoding region of exon III (Curatola and Basilico,1990). Transcription factor-binding sites (Sox-2 and Sp1) within sequences defining the promoter and enhancer have been characterized (Luster *et al.,* 2000). Genomic sequence analysis indicated a region likely to contain the FGF-5 promoter (Zhan *et al.,* 1988). The location of sequences within the FGF-5 promoter that function during differentiation of retinal pigment epithelial cells has been mapped (Gelfman *et al.,* 1998). The cell type specific activation of the FGF-7 promoter has been described, including the identification of two promoter regions containing sequence elements that regulate expression negatively (Finch *et al.,* 1995), as well as corresponding transcription factors (Zhou and Finch, 1999). Differential promoter recognition and mRNA processing drive the expression of numerous isoforms of FGFs 11–14 (Munoz-Sanjuan, 2000).

A Distinctive Translation Initiation Mechanism Mediates Expression of FGF-2 and FGF-3

While all FGFs are encoded by single copy genes, multiple isoforms of both FGF-2 (Florkiewicz and Sommer, 1989; Prats *et al.,* 1989) and FGF-3 (Dickson and Acland 1990) have been detected. The novel mechanism by which this occurs distinguishes these FGFs from all other known growth factors and ultimately may prove to be a critical point from which FGF-2 and FGF-3 gene expression is qualitatively regulated. Each of the multiple isoforms is a

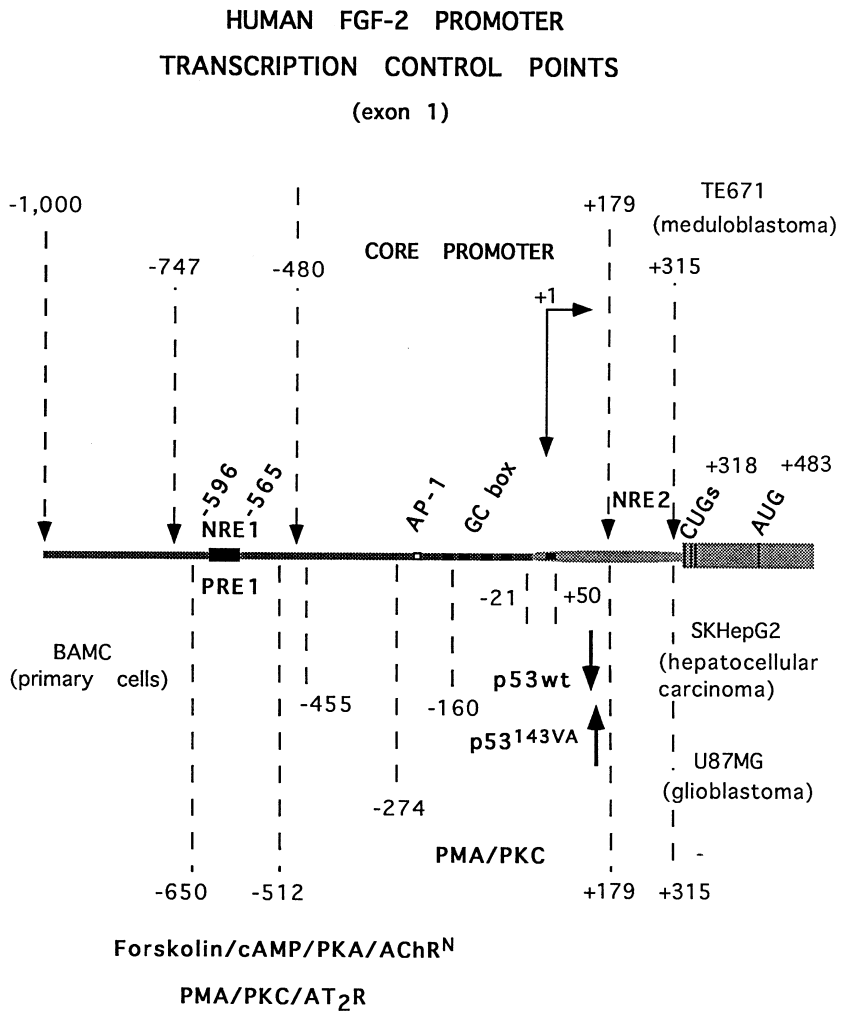

Figure 2 Summary of regulatory regions within the human FGF-2 promoter. The various cell types used and intracellular signaling pathways are labeled along with the location of the AP-1 site and GC box of the core promoter. The approximate location of p53 regulation is shown. The promoter contains positive (PRE) as well as negative regulatory regions (NRE). The sequence of the entire region has been published previously (Florkiewicz *et al.,* 1991).

primary translation product with no precursor–product relationship. The larger isoforms are colinear amino-terminal extended versions of the shorter isoforms. Moreover, translation of each of the four high molecular weight (HMW) human FGF-2 isoforms (22, 23, and 24 kDa) is initiated with an unconventional CUG translation initiation codon; a 34-kDa isoform of FGF-2 has also been described (Arnaud *et al.,* 1999). In contrast, translation of the 18-kDa isoform is initiated with a classical AUG codon located downstream of the four CUG codons. Multiple HMW isoforms of rodent FGF-2 also initiate translation with CUG codons (Powell and Klagsbrun, 1991). Curiously, the rainbow trout FGF-2 gene appears to encode only an 18-kDa translation product, even though preferential CUG translation initiation from transfected human cDNA expression vectors does occur (Hata *et al.,* 1997). Likewise, the larger isoform of FGF-3 (31.5 kDa) utilizes a CUG codon, whereas the 28.5-kDa isoform uses an AUG codon to initiate translation (Dickson and Acland, 1990). In the case of FGF-2, CUG-initiated HMW isoforms are not minor translation products, and in some cases the HMW isoforms are expressed at levels equal to or greater than the 18-kDa isoform (Coffin *et al.,* 1995). Thus, the unusual utilization of CUG codons to initiate the translation of HMW FGF-2 effectively diversifies this single copy gene.

The uncommon use of CUG codons to initiate FGF-2 translation prompted speculation that selecting a CUG, as opposed to AUG translation initiation codon, may represent a physiologically relevant mechanism regulating FGF-2 gene expression. Three observations support this possibility. The first is that the CUG-initiated translation products of FGF-2 and FGF-3 localize to the nucleus preferentially, whereas their respective AUG-initiated isoforms are predominantly cytosolic or extracellular (Florkiewicz *et al.,* 1991). Second, the HMW isoforms of FGF-2 are expressed in a tissue-specific pattern distinct from the 18-kDa isoform

that is maintained in transgenic model systems (Coffin *et al.,* 1995), as well as during development of the central nervous system (Giordano *et al.,* 1992). Third, partially purified HMW and 18-kDa FGF-2 isoforms have similar *in vitro* extracellularly mediated mitogenic activities (Florkiewicz and Sommer, 1989), but when synthesized in continuously expressing transfected cells, the HMW isoforms are transforming whereas the 18-kDa isoform is not (Quarto *et al.,* 1991). Although FGF-2 appears to be widely expressed when detected by immunohistochemical techniques and *in situ* hybridization, it is likely that the different molecular isoforms are expressed in a spatially and temporally restricted manner. Therefore, in order to put the complete FGF-2 picture into perspective, it will be necessary to determine the qualitative, as well as quantitative, patterns of expression.

As noted previously, the HMW isoforms of human FGF-2 initiate translation from CUG codons that are differentially recognized in a *de novo* pattern that is tissue specific. Regulating translation is one mechanism by which eukaryotic cells control gene expression, including start site selection followed by formation of a highly order translation initiation complex (Hershey *et al.,* 1996; Kosak, 1999). In most circumstances, ribosomes arrive at the site of translation initiation after establishing contact and assembling at the 5′ end of eukaryotic mRNAs and then scan 3′ until encountering the most favorable combination of mRNA structure and sequence to initiate protein synthesis. However, in some cases, ribosomes recognize translation initiation sites directly without scanning, termed internal ribosome entry (Le and Maizel, 1997). The CUG-mediated translation initiation of FGF-2 HMW isoforms is an example of internal ribosome entry that is also maintained in a tissue-specific manner (Creancier *et al.,* 2000; Vagner *et al.,* 1995). A number of factors are likely to be involved in this process (Kevil *et al.,* 1995; Touriol *et al.,* 2000). Although the sophisticated cellular mechanism mediating CUG-initiated translation of HMW FGF-2 is being elaborated, their physiological significance remains an enigma. Ultimately, selected expression in transgenic animal model systems will be necessary for a thorough analysis. In addition to the isoform-specific phenotypes reported previously, other publications show that 24-kDa FGF-2 modulates interleukin-6 promoter activity (Delrieu *et al.,* 1999) and cell migration (Piotrowicz *et al.,* 1999).

Export or Secretion of FGFs?

FGFs are known to be released from cells by two clearly distinct intracellular pathways: one that is or likely to be endoplasmic reticulum (ER)/Golgi dependent (FGF-3 through 10 and 15 through 23) and another that is ER/Golgi independent (FGF-1 and -2). Although considered to be prototypic members of the FGF family, FGF-1 and FGF-2 are distinctive in that they are found extracellularly but do not possess hydrophobic signal peptide sequences. Historically, this has been one of the most intriguing features of FGFs because their signal transducing receptors are extracellular (Rifkin and Moscatelli, 1989). In contrast, with the exception of FGFs 11–14, the other FGFs contain typical or noncleaved internal hydrophobic amino acid signal sequences that function as ER-targeting motifs. Consequently, FGF-3 through 10 and 15 through 23 are secreted proteins. However, an alternative exocytic ER/Golgi-independent trafficking pathway must also exist because FGF-1 and FGF-2 are detected routinely on the cell surface or in the extracellular matrix (Bashkin *et al.,* 1992; Florkiewicz *et al.,* 1991; Folkman *et al.,* 1988; Gonzalez *et al.,* 1990), in vitreous fluid (Baird *et al.,* 1985), in cell culture media (Florkiewicz *et al.,* 1995), and in the urine (Nguyen *et al.,* 1994) and serum (Dietz *et al.,* 2000) of patients with cancer. Several key publications have demonstrated unequivocally the existence of an energy and plasma membrane-dependent "export" pathway for FGF-2 pictured in Fig. 3 (Florkiewicz *et al.,* 1991, 1995; Mignatti *et al.,* 1992). Evidence has also been presented for the involvement of a heat shock response mechanism in the export of FGF-1 (Jackson *et al.,* 1992). A number of proteins have been characterized as functional components of the intracellular trafficking "export" pathway for FGF-2 and FGF-1 (Florkiewicz *et al.,* 1998; Frisel and Maciag, 1999). In addition, a critical FGF-1 and FGF-2 targeting signal(s) that mediates trafficking through the export pathway has been identified (Shi *et al.,* 1997). It is particularly interesting to note that interleukins 1α and β, which share structural homology with the FGF family, are also exported

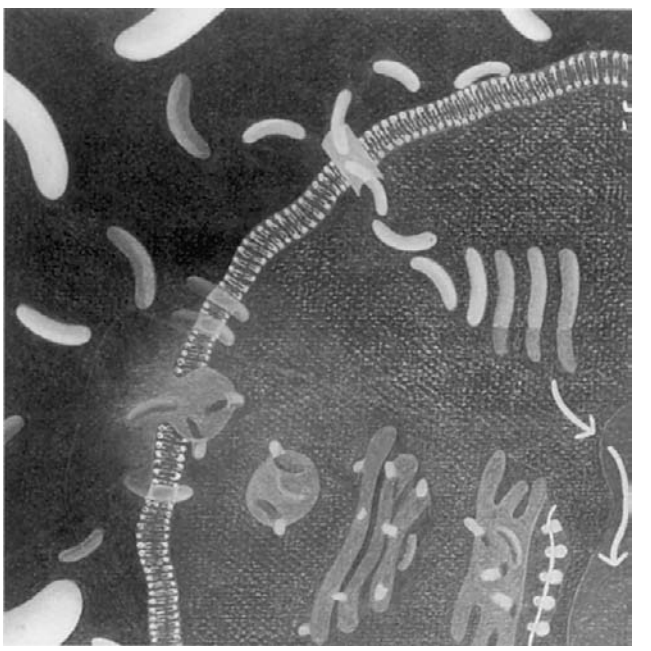

Figure 3 Two pathways traffic and release proteins from cells. One requires ER/Golgi, vesicular intermediates, and is signal sequence dependent. A second pathway exists for proteins without hydrophobic signal peptide sequences, such as 18-kDa FGF-2. These proteins are "exported" directly through a translocation apparatus located at the plasma membrane. The amino-terminally extended high molecular weight FGF-2 isoforms are targeted to the nucleus.

through a yet to be defined ER/Golgi-independent pathways (Muesch *et al.,* 1990). In any instance, it is likely that the export pathway(s) of FGF-1, FGF-2, and the interleukins is clinically important and of therapeutic value. Inhibitors of export would be predicted to interfere with the bioavailability of these potent growth-promoting polypeptides (Florkiewicz *et al.,* 1995).

Complex Interactions with Receptors, HSPGs, and Binding Proteins Regulate the Bioactivity of Extracellular FGFs

In a paracrine and/or autocrine manner, the receptor-binding and signal-transducing activities of the FGFs are initiated extracellularly. On the cell surface, at least three types of proteins may interact with the FGFs, shown conceptually in Fig. 4. The first class are high-affinity (K_d ~2–10 p*M*) integral plasma membrane proteins with three extracellular immunoglobulin (Ig)-like loop structures. These true signaling receptors contain an intracellular domain with intrinsic tyrosine kinase activity (Johnson and Williams, 1993; Givol and Yayon, 1992). Within this tyrosine kinase domain are hydrophilic amino acids that are also a site of receptor autophosphorylation.

The second type of receptor are low-affinity (K_d ~50–500 n*M*) binding sites, identified as HSPGs (Moscatelli, 1987). HSPGs do not possess intrinsic tyrosine kinase activity, but are important molecules regulating FGF bioavailability (Klagsbrun and Baird, 1991; Roghani *et al.,* 1994; Yayon *et al.,* 1991). The third type of protein, a cysteine-rich FGFR (CFR), was originally isolated and characterized from chicken embryos (Burrus and Olwin, 1989; Burrus *et al.,* 1993). Although not yet firmly established, a physiological significance is under investigation (see later). All three types of receptor proteins form dynamic interactions with the FGFs that are compensatory with their respective bioactivities.

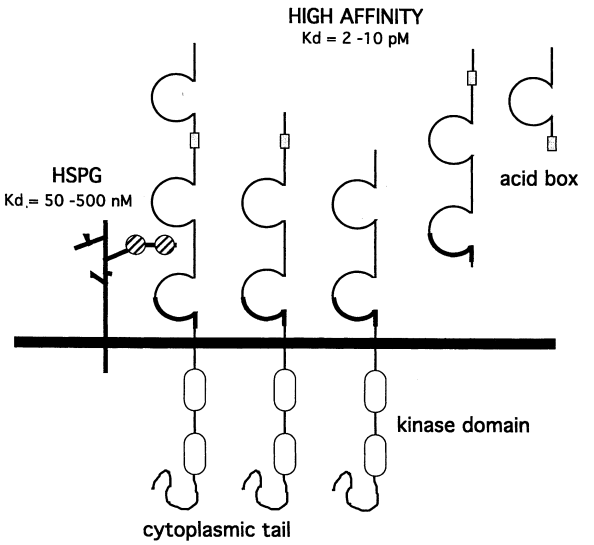

Figure 4 Cell surface FGF receptors. The low-affinity HSPG type, which protects and stabilizes FGF (hatched circles) in a conformationally dependent manner for presentation to its high-affinity receptor. Second, the high-affinity receptor containing two or three extracellular immunoglobulin-like loop structures. The characteristic location of an extracellular acid box is labeled (shaded box). Soluble splice variants of the high-affinity receptor without transmembrane domains are also diagrammed. Intracellularly, the high-affinity receptor contains a split tyrosine kinase domain and cytoplasmic tail. The third type, cysteine-rich receptor or MG-160, is found in the Golgi apparatus and is not shown here.

High-Affinity Receptors

A family of four genes encode distinct high-affinity FGFRs. The FGFRs have appeared in the literature under different names, including FGFR1/flg (Ruta *et al.,* 1988; Lee *et al.,* 1989) or cek1 (Pasquale, 1990); FGFR2/bek (Kornbluth *et al.,* 1988; Dionne *et al.,* 1990), K-Sam (Hattori *et al.,* 1990), or cek3 (Pasquale, 1990); and FGFR3 (Keegan *et al.,* 1991), flg-2 (Avivi *et al.,* 1991), or cek2 (Pasquale, 1990). The large number of dedicated reviews supports the interest and wealth of information regarding fundamental receptor–ligand interactions, developmental implications, and human diseases linked to FGFRs (Vajo *et al.,* 2000; Ornitz, 2000; Friessel and Maciag, 1999; Xu *et al.,* 1999). The most notable is the involvement of FGFRs in skeletal disorders (De Moerlooze and Dickson, 1997; Webster and Donoghue, 1997). Although structurally diverse, each of the FGFRs individually can bind different FGF family members with varying affinities (Chellaiah *et al.,* 1994; Ornitz and Leader, 1992). Mapping specific molecular interactions between FGF and FGFR suggests that multiple binding domains exist (Wang *et al.,* 1999; Venkataraman *et al.,* 1999). In some instances, expression of the FGFRs has also been shown to be tissue or cell-type specific and developmentally regulated (Patstone *et al.,* 1993). The crystal structure of the FGF–FGFR complex has been elucidated (Weismann and de Vos, 1999). Numerous subspecies of FGFR-1 and FGFR-2 can be generated via an alternative mRNA splicing mechanism (Johnson and Williams, 1993; Reid *et al.,* 1990; Yan *et al.,* 1993). As a result, alternative splicing introduces even more structural diversity into the extracellular and/or intracellular domains of the FGFRs, including secreted receptor isoforms that may then function as soluble receptor-binding proteins (Guillonneau *et al.,* 1998). In addition, certain FGFRs clearly localize in the nucleus following internalization from the cell surface (Klingenberg *et al.,* 2000). However, it is not yet known if nuclear FGFR can interact with colocalized HMW FGF-2. In some cases, it is likely that both activation of plasma membrane localized FGFR signal transduction and subsequent nuclear localization of ligand and receptor are required for biological activity (Mehta *et al.,* 1998). It is not known how the internalized, presumably transmembrane trapped, receptor actually becomes intranuclear and it is not known how many other associated proteins are contained in the translocated receptor complex. Although speculative at best, is it possible that vesicle fusion with the

nuclear membrane positions some receptor in the nuclear membrane with an orientation capable of supporting backward (nuclear to cytosolic) signaling? The diversity in structure, intracellular localization, and a regulated pattern of FGFR expression, plus their varying affinities for the FGF family members, result in a similarly complicated and delicately balanced set of intracellular signals.

High-affinity FGFRs have emerged as important regulators of bone growth and development (Trippel *et al.,* 1993). In particular, bone appears to respond rather dramatically to functional imbalances that are manifested by FGF-ligand/receptor interactions. Notably, a number of human dysmorphic syndromes have been linked genetically to mutations in different FGFRs. These syndromes include achondroplasia (Rousseau *et al.,* 1994; Shiang *et al.,* 1994) and thanatophoric dysplasia (Tavormina *et al.,* 1995), which correlate with mutations in FGFR-3; Crouzon (Reardon *et al.,* 1994) and Jackson-Weiss (Jabs *et al.,* 1994) syndromes with mutations in FGFR-2; and Pfeiffer syndrome (Muenke *et al.,* 1994), with mutations in FGFR-1. In the case of achondroplasia, ectopic overexpression of FGF-2 in transgenic animals results in a phenotypically identical syndrome (Coffin *et al.,* 1995).

Low-Affinity Receptors and Binding Proteins

A second type of FGF receptor(s) is commonly referred to as cell surface and/or extracellular matrix (ECM) low-affinity proteoglycan-binding sites (Moscatelli, 1987; Ruoslahti and Yamaguchi, 1991). As a class of ECM proteins, HSPGs are required for high-affinity FGF/receptor activation and signal transduction (Chang *et al.,* 2000; Klagsbrun and Baird, 1991; Lin *et al.,* 1999; Mason, 1994; McKeehan *et al.,* 1999; Rapraeger *et al.,* 1991; Reiland and Rapraeger, 1993; Yayon *et al.,* 1991). Perlecan and syndecan-1 are specific examples of HSPGs known to potentate FGF/receptor interactions, whereas others may actually interfere with FGF-receptor interactions (Filla *et al.,* 1998; Aviezer *et al.,* 1994; Mali *et al.,* 1993; Guimond *et al.,* 1993). HSPG-binding sites are purported to "reduce the dimensionality" of cell surface FGF diffusion from three to two dimensions (Schlessinger *et al.,* 1995) while presenting a conformationally dependent multivalent FGF–heparan sulfate complex to high-affinity FGFRs, inducing dimerization. It is likely that HSPGs in the ECM also function as an extracellular storage compartment protecting FGF from degradation (Saksela and Rifkin, 1988) until becoming bioavailable, possibly following modification such as phosphorylation (Vilgrain and Baird, 1991) or proteolytic processing of the ECM (Saksela *et al.,* 1990). The bioavailability of FGF in the ECM may also be regulated by secreted binding proteins (FGF-BPs). One such secreted FGF-BP, not derived from an alternatively spliced FGFR mRNA, is postulated to displace FGF-2 sequestered in the extracellular matrix (Wu *et al.,* 1991; Czubayko *et al.,* 1994) and may participate in the development of certain forms of cancer (Kurtz *et al.,* 1997; Harris *et al.,* 2000). There are at least three members of this emerging family of FGF-Bps (Lametsch *et al.,* 2000), others are sure to follow.

The Cysteine-Rich FGF Receptor

The third class of FGF receptor-like protein, CFR, is not found complexed with high-affinity receptors and is not known to transduce an intracellular signal (Burrus and Olwin, 1989; Burrus *et al.,* 1992). An FGF-binding domain on CFR has been characterized by Zhou *et al.,* (1997). Another protein named MG-160 also binds FGF-2 (Gonatas *et al.,* 1995) and shares greater than 90% sequence homology with the CFR. However, MG-160 is an intracellular transmembrane sialoglycoprotein retained in the medial cisternae of the Golgi apparatus (Gonatas *et al.,* 1989) and is not found on the cell surface of PC-12 cells or cells of developing chick embryos (Stieber *et al.,* 1995). Furthermore, the mouse protein named ESL-1, a ligand for E-selectin, has been shown to be 94% identical to CRF (Steegmaier *et al.,* 1995), and a *Drosophila* protein named sprouty also encodes a cysteine-rich membrane protein that appears to function as a FGF antagonist (Hacohen *et al.,* 1998). Although the function of MG-160/CFR in the Golgi apparatus is still unknown, one intriguing possibility is that it serves to regulate the posttranslation processing and/or classical secretion of the FGFs. Alternatively, MG-160/CFR may represent a retrieval mechanism removing unwanted FGF-1 or FGF-2 inadvertently localized in the ER/Golgi secretory pathway; overexpression and forced targeting of FGF-1 and -2 result in cell transformation (Blam *et al.,* 1988; Rogelj *et al.,* 1988). Thus, intracellular interactions with MG-160/CFR may play a role in regulating FGF bioavailability; recent publications support this hypothesis (Fayein *et al.,* 1996; Kohl *et al.,* 2000).

Transgenic Animal Model Systems

The use of transgenic animal model systems (ectopic and targeted overexpression as well as gene ablation) has added significant insight into the physiologically relevant activities of the FGFs and FGFRs. Most surprising has been the mild phenotypic effects following FGF-1 (Miller *et al.,* 2000) or FGF-2 (Dono *et al.,* 1998; Ortega *et al.,* 1998; Zhou *et al.,* 1998) single gene knockouts. A more obvious impact might have been expected because of the wide tissue-specific pattern of expression for both prototypic members of the FGF family, the tendency of FGF-1 to interact with all FGFRs, and the fact that the FGF-2 gene encodes and differentially expresses multiple primary translation products in a pattern that is tissue specific. In fact, the phenotypic consequence of simultaneously ablating FGF-1 and FGF-2 is again most remarkable because of the absence of an overt phenotypic change. However, although it has been rather challenging to characterize, the FGF2 knockout can be distinguished from wild-type controls. The most exciting consequences were decreased trabecular bone formation observed in 4.5-month-old mice (Figs. 5 and 6) and a profound impairment of mineralization in stromal cell-derived cell cultures (Fig. 7) from FGF2 knockout mice (Montero

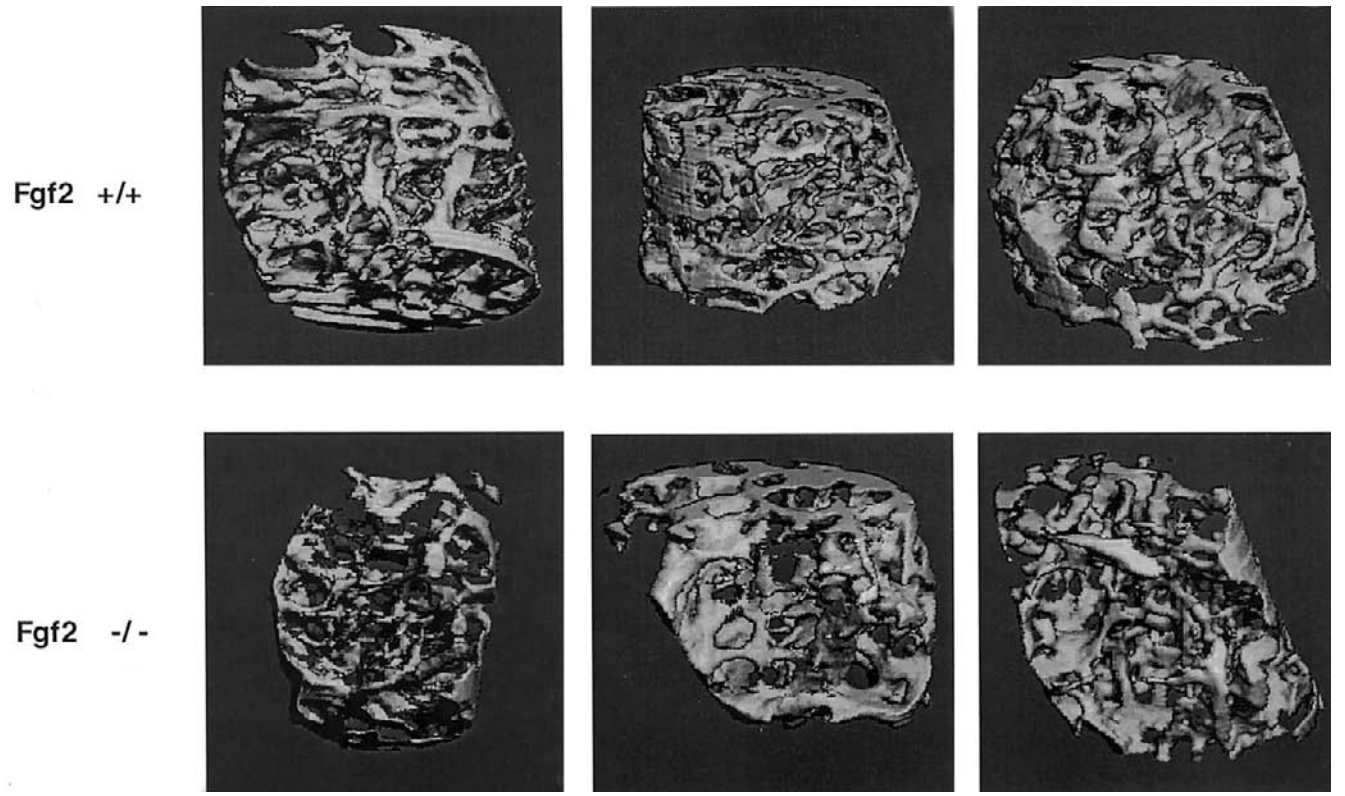

Figure 5 Morphological study by micro-CT scanning of trabecular bone of femurs of 4.5-month-old Fgf2+/+ and Fgf2−/− mice. The three-dimensional trabecular bone architecture of distal femoral metaphysis of 4.5-month-old male Fgf2+/+ and Fgf2−/− mice was analyzed by micro-CT. Note that the plate-like architecture of the trabecular bone is reduced markedly and the connecting rods of trabeculae are disrupted in Fgf2−/− mice compared with Fgf2+/+.

et al., 2000). As these mice aged, there is a progressive decrease in trabecular number in the secondary spongiosa of the distal femur (Fig. 8, Table I).

Other studies have also demonstrated that mice with Fgf2 gene knockouts exhibit a slower rate of soft tissue wound repair, neuronal defects, abnormal regulation of blood pressure, and a defect in the stromal cell-mediated formation of myeloid progenitor cells (Miller *et al.,* 2000). In addition, transgenic overexpression (gain of function) has also served to emphasize several FGF-mediated biological activities. Ectopic overexpression of FGF2 clearly results in abnormal bone growth in which the principal affect is manifested as chondrodysplasia (Coffin *et al.,* 1995) and an amplified angiogenic response (Fulgham *et al.,* 1999). Specific myocardial expression of FGF-1 increases the density of coronary arteries (Fernandez *et al.,* 2000).

Regarding FGFRs, targeted disruption of both FGFR1 (Deng *et al.,* 1994; Yamaguchi *et al.,* 1994) and FGFR2

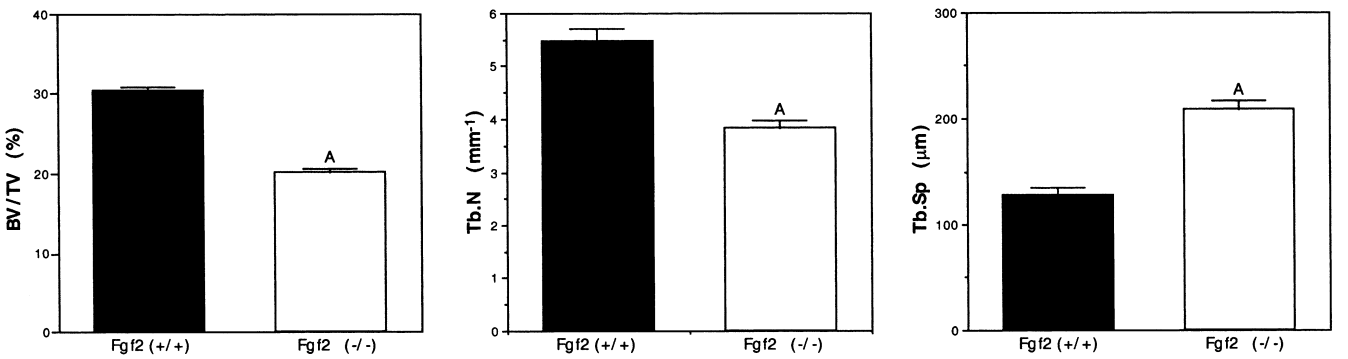

Figure 6 Three-dimensional microstructural parameters calculated using two-dimensional data obtained from micro-CT of femoral bones from 4.5-month-old Fgf2+/+ and Fgf2 −/− mice. Calculated morphometric indices included bone volume density [bone volume (BV)/trabecular volume (TV)] trabecular number [Tb.N=(BV/TV)/Tb.Th], and trabecular separation [Tb.Sp=(1/Tb.N)-Tb.Th]. [A]Significantly different from Fgf2+/+ group; $P<0.05$, Tukey–Kramer multiple comparison test (ANOVA).

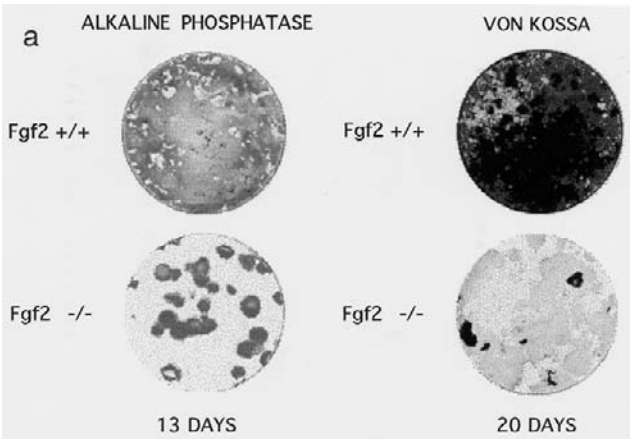

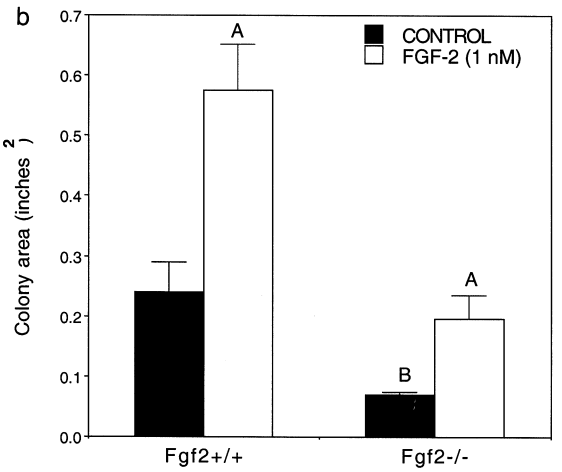

Figure 7 (a) Comparison of the ability to form ALP colonies and mineralized nodules as determined by von Kossa staining in mouse bone marrow cultures from Fgf2+/+ and Fgf2−/− mice. Cells were plated at a density of 20 million cells per well in αMEM containing penicillin/streptomycin and 10% heat-inactivated fetal calf serum (FCS). On day 3, media were changed and cells were cultured in differentiation media (αMEM, 10 n*M* dexamethasone, 10% FCS, 8 m*M* β-glycerophosphate, 50 μg/ml ascorbic acide) for the indicated times. (See also color plate.) (b) Effect of FGF-2 on colony area in mouse bone marrow cultures from Fgf2+/+ and Fgf2−/− mice. Cells were plated at a density of 1 million cells per well in αMEM containing penicillin/streptomycin and 10% heat-inactivated FCS in the absence or presence of FGF-2 (10 n*M*). On day 3, media were changed and cells were cultured in differentiation media (αMEM, 10 n*M* dexamethasone, 10% FCS, 8 m*M* β-glycerophosphate, 50 μg/ml ascorbic acid) for another 11 days. [A]Significantly different from control cultures; $P < 0.05$. [B]Significantly different from Fgf2+/+; $P < 0.05$.

(Arman *et al.,* 1998, 1999; Xu *et al.,* 1998) has been shown to be embryonic lethal, whereas disruption of the FGFR3 gene results in an abnormal bone phenotype (Colvin *et al.,* 1996; Deng *et al.,* 1996). Analysis of FGFR3 in transgenic model systems identified a single point mutation in the transmembrane domain responsible for the bone phenotype (Naski *et al.,* 1998). Furthermore, the mutation identified in FGFR3 is consistent with a naturally occurring autosomal-dominant negative (gain of function) FGFR3 mutant responsible for human dwarfism (Vajo *et al.,* 2000). The phenotypically dramatic human skeletal disorders characterized as being linked genetically to FGFR3-activating mutations, as well as overexpression of FGF ligands in transgenic model systems, provide the fundamentals necessary for a full understanding of the underlying biochemical events taking place.

Table I Three-dimensional Parameters of Micro-CT of Femora from 8-Month-Old Fgf2+/+ and Fgf2−/− Mice

Genotype	*n*	Bone volume (%)	Trabecular number (mm^{-1})	Trabecular thickness (μm)	Trabecular separation (μm)
Fgf2+/+	3	22.0 (4.8)	3.9 (0.3)	57.0 (11.1)	203 (22)
Ffg2−/−	3	7.4 (2.4)[a,b]	1.8 (0.7)[a,b]	41.7[a,b] (3.2)	564[a,b] (190)

[a]$P < 0.05$, significantly different from Fgf+/+ group, Mann–Whitney *U* test.
[b]$P < 0.05$, significantly different from Fgf+/+ group, Tukey–Kramer multiple comparison test (ANOVA).

Fibroblast Growth Factors and Bone

Studies have suggested an important role for members of the heparin-binding fibroblast growth factor family and their receptors in normal limb development, bone growth, and fracture repair and the inherited human chondrodysplastic syndromes with their attendant skeletal abnormalities. FGF-1 and FGF-2 are potent agonists with stimulatory effects on bone resorption and both stimulatory and inhibitory effects on bone formation. The inhibitory effects on collagen synthesis have been demonstrated in cell and organ culture and appear to involve inhibition of transcription of the collagen gene and to be independent of effects on cell replication. The resorptive effects of FGFs appear to be both prostaglandin dependent and independent and also involve the replication and differentiation of osteoclasts. *In vivo,* exogenous FGF-1 and FGF-2 increase bone formation by some yet unknown mechanisms. However, the effects of FGF *in vivo* may be mediated in part by transforming growth factor β (TGFβ) and prostaglandins (PGs), as the production of these factors can be regulated by FGFs. Fibroblast growth factor production in bone can be regulated by TGβ as well as by FGF itself.

Expression of FGF Receptors in Bone

The expression of FGFs and FGF receptors (FGFRs) is regulated temporally and spatially during skeletal development. Several FGF members are expressed during early stages of development in mammals (Yamaguchi and Rossant, 1995; Niswander, 1996) and their expression is related to skeletal development (Johnson and Tabin, 1997; Naski and Ornitz, 1998). During intramembranous bone formation, FGF-2 transcripts are found in mesenchymal cells and in osteoblasts (Mehara *et al.,* 1998; Rice *et al.,* 2000), together with FGF-9 (Kim *et al.,* 1998). During intramembranous bone formation, FGF-2 is produced by cells located

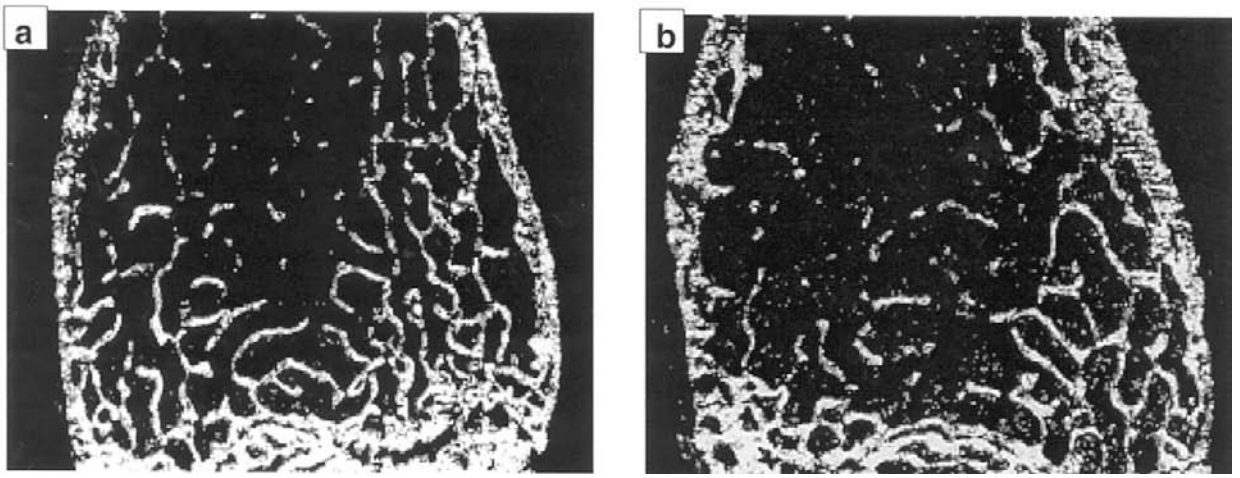

Figure 8 Undecalcified sections of the distal femur of (a) an 8-month-old Fgf2+/+ mouse and (b) a FGF−/− mouse (dark-field illumination). Trabecular number is decreased in the secondary spongiosa of the Fgf2−/− mouse.

in the resting and proliferating zones of the epiphyseal growth plate (Twal *et al.,* 1994; Tajima *et al.,* 1998). At later stages of skeletal development, FGF-1 or FGF-2 is expressed in osteoblasts and chondroblasts (Gonzalez *et al.,* 1996). FGF-2 is produced by mature osteoblasts and is stored in the extracellular matrix (Globus *et al.,* 1989; Hurley *et al.,* 1994).

FGFs actions are dependent on the expression and interactions with FGFRs. During skeletal tissue development, the spatiotemporal pattern of FGFR-1, -2, and -3 expression differs (Hughes *et al.,* 1997; Orr-Urtreger *et al.,* 1991; Wanaka *et al.,* 1991; Peters *et al.,* 1992; Patstone *et al.,* 1993; Wilke *et al.,* 1997; Delezoide *et al.,* 1998). During endochondral development, FGFR-1 transcripts are expressed in the mesenchyme and later in hypertrophic cartilage and osteoblasts, whereas FGFR-2 is expressed at sites of ossification and later in cartilage, perichondrium, and periosteum (Peters *et al.,* 1992; Delezoide *et al.,* 1998). In contrast, FGFR-3 transcripts are found mainly in cartilage rudiment and then in proliferating and prehypertrophic chondrocytes (Naski *et al.,* 1998) and are not found in mesenchymal cells or perichondral or periosteal cells until late stages of development (Peters *et al.,* 1993, Delezoide *et al.,* 1998). Consistently, the expression of FGFR-3 increases during the development of chondrogenesis *in vitro* (Szebenyi *et al.,* 1995; Moltni *et al.,* 1999a). In the human cranial suture, FGFR-1 immunostaining is localized in proliferating mesenchymal cells and preosteoblasts, whereas FGFR-2 and FGFR-3 immunostaining is found mainly with FGF-2 in preosteoblasts and osteoblasts (Delezoide *et al.,* 1998; Marie *et al.,* 2000). In the mouse, FGFR-2 transcripts are present at the osteogenic fronts of the cranial suture (Iseki *et al.,* 1997; Kim *et al.,* 1998, Johnson *et al.,* 2000), and FGFR-2 expression is associated with endogenous FGF-2 expression (Mehara *et al.,* 1998; Most *et al.,* 1998; Rice *et al.,* 2000). *In vitro,* FGFR-1 and FGFR-2 immunostaining is found in neonatal rat calvaria cells (Molténi *et al.,* 1999a) and in human calvaria osteoblastic cells (Debiais *et al.,* 1998). Although the spatiotemporal pattern of expression of FGF and FGFRs suggests that skeletal development is controlled by FGF/FGFR interactions, the FGF effects on bone cells may be modulated by the various affinity and specificity of FGF binding to the various alternative splice forms of FGFRs (Ornitz *et al.,* 1996).

FGF Receptors and Human Chondrodystrophies

Skeletal abnormalities are characteristic of human chondrodystrophies. High-affinity FGFRs have emerged as important regulators of bone growth and development (Globus *et al.,* 1988; Trippel *et al.,* 1993). In particular, bone appears to respond rather dramatically to functional imbalances that are manifested by FGF-ligand/receptor interactions. Notably, a number of human dysmorphic syndromes have been linked genetically to mutations in different FGFRs. These syndromes include achondroplasia (Rousseau *et al.,* 1994; Shiang *et al.,* 1994) and thanatophoric dysplasia (Tavormina *et al.,* 1995), which correlate with mutations in FGFR-3; Crouzon (Reardon *et al.,* 1994) and Jackson–Weiss (Jabs *et al.,* 1994) syndromes with mutations in FGFR-2; and Pfeiffer syndrome (Muenke *et al.,* 1994) with mutations in FGFR-1.

FGF Receptors and Human Craniosynostosis

The important role of FGFRs during cranial development is supported by genetic evidence that FGFR mutations induce abnormal ossification of the cranial sutures (craniosynostosis) in humans (Park *et al.,* 1995; Muenke and Schelle, 1995). Several mutations in FGFRs are associated with heritable human skeletal disorders involving craniofacial abnormalities, causing Apert, Crouzon, Pfeiffer, and Jackson–Weiss syndromes (Wilkie, 1997; Webster

and Donoghue, 1997). Mutations in the Ig III domain or in the linker between the Ig II and Ig III domain of FGFR-1 and FGFR-2 induce constitutive activation of the receptor (Neilson and Friesel, 1995, 1996; Galvin *et al.,* 1996; Robertson *et al.,* 1998; Plotnikov *et al.,* 2000). In Crouzon syndrome, the C342Y mutation in FGFR-2 results in the activation of FGFR-2 signaling and decreased binding of FGF-2 to the receptor (Mangasarian *et al.,* 1997). In Apert syndrome, FGFR-2 mutations enhance receptor occupancy by FGF ligands or prolongation of the duration of receptor signaling (Park *et al.,* 1997; Anderson *et al.,* 1998).

In mice, a secreted soluble dominant-negative FGFR-2 causes skull abnormalities resembling those induced by FGFR mutations (Celli *et al.,* 1998), suggesting that decreased or decreased FGFR signaling induces skeletal abnormalities. The phenotypes induced by FGFR genetic mutations have been studied in mice and humans. The P250R FGFR1 mutation in the mouse causes premature fusion of calvaria sutures associated with increased expression of Cbfa1, a transcription factor involved in osteoblast differentiation (Zhou *et al.,* 2000). Consistantly, implantation of FGF-2 or FGF-4 accelerates suture closure in mice (Iseki *et al.,* 1997; Kim *et al.,* 1998).

In humans, FGFR-2 mutations in Apert syndrome activate osteoblast differentiation without affecting cell proliferation or the response to FGF-2 (Fragale *et al.,* 1999; Lomri *et al.,* 1998; Lemonnier *et al.,* 2000c; Marie, 1999). The S252W FGFR-2 Apert mutation constitutively increases osteoblast marker genes in calvaria preosteoblasts through activation of PKC (Lemonnier *et al.,* 2000b). This accelerated osteoblast differentiation program induced by the mutation implicates an increased cell–cell adhesion and N-cadherin overexpression (Lemonnier *et al.,* 2000b). Consistent with this effect induced by the FGFR-2-activating mutation, exogenous FGF-2 was found to increase N-cadherin expression in human calvaria osteoblasts through activation of the PKC pathway (Debiais *et al.,* 2000). Additionally, there is a selective and PKC-independent downregulation of FGFR-2 in Apert mutant preosteoblasts and osteoblasts *in vitro* and *in vivo* (Lemonnier *et al.,* 2000c), which may contribute to increased osteoblast differentiation. This is consistent with the decreased expression of FGFR-2 in Crouzon syndrome (Bresnick *et al.,* 1995) and with the downregulation of FGFR-2 transcripts induced by FGF-2 in the mouse suture (Iseki *et al.,* 1997). In addition to affecting osteoblast differentiation, the Apert S252W FGFR-2 mutation promotes apoptosis in human calvaria osteoblasts. The constitutive activation of PKC in mutant osteoblasts leads to overexpression of IL-1 and Fas receptor, activation of caspase-8, increased Bax/Bcl-2 ratio, and premature apoptosis (Lemonnier *et al.,* 2000a). Consistently, mouse calvaria cells transfected with the S252W Apert FGFR-2 mutation show apoptosis, and FGF-2 increases osteoblast apoptosis in differentiated mouse calvaria osteoblasts (Mansukhani *et al.,* 2000). The premature ossification induced by activating FGFR mutations may thus result from alterations of both differentiation and apoptotic programs in osteoblasts.

FGF and Cartilage

FGF-2 is expressed in growth plate chondrocytes *in vivo* (Twal *et al.,* 1994) and may be an autocrine growth factor (Luan *et al.,* 1996). Exogenous FGF-2 stimulates chondrocyte cell growth and inhibits cell differentiation (Kato *et al.,* 1990; Wroblewski *et al.,* 1995), indicating that FGF/FGFR interactions control cartilage cell growth and differentiation. There is multiple *in vivo* evidence that FGFs play an important role in chondrogenesis (Ornitz, 2000a). Excess exogenous FGF-2 causes chick limb developmental abnormalities (Cohn *et al.,* 1995), and FGF-2 overexpression induces chondrodysplasia and shortening of long bones in mice (Coffin *et al.,* 1995; Lightfoot *et al.,* 1997). The negative role of FGFR-3 in endochondral growth is emphasized by the finding that FGFR-3−/− mice show excessive long bone growth, associated with increased chondrocyte proliferation (Colvin *et al.,* 1996; Deng *et al.,* 1996). In humans, mutations in FGFR-3 cause constitutive activation of FGFR-3, resulting in chondrodysplasia syndromes, including achondroplasia, the most common form of dwarfism, hypochondroplasia, and thanatophoric dysplasias (Bellus *et al.,* 1995; Rousseau *et al.,* 1994; Shiang *et al.,* 1994; Supert-Furga *et al.,* 1995; Naski *et al.,* 1996; Webster *et al.,* 1996; Tavormina *et al.,* 1995; Rousseau *et al.,* 1995), which demonstrates a role for FGFR-3 in the control of long bone cartilage growth. Several FGFR-3 mutations cause abnormal chondrogenesis in the mouse (Chen *et al.,* 1999; Segev *et al.,* 2000). Overexpression of activated FGFR-3 in mice reduces chondrocyte cell proliferation (Naski *et al.,* 1998; Ornitz, 2000), showing that activated FGFR-3 signaling inhibits chondrocyte proliferation and decreases differentiation (Li *et al.,* 1999; Naski, 2000). In addition, constitutive activation of FGFR-3 induced by the R248C mutation triggers premature apoptosis, which is mediated by activation of the STAT1 signaling pathway (Legeai-Mallet *et al.,* 1998). The expression in the growth plate of Ihh and BMP4 was found to be downregulated in mice overexpressing FGFR-3 and increased in mice lacking FGFR-3, suggesting that FGFR-3 may act on multiple signaling molecules to control endochondral bone growth (Naski *et al.,* 1996; Ornitz, 2000b).

Fibroblast Growth Factor Production and Regulation

Although there are 23 members of the fibroblast growth factor family, only FGF-1 and FGF-2 have been studied extensively in bone. FGF-2 and FGF-1 are found in the bone matrix (Hauschka *et al.,* 1986) and are produced by bone cells, with FGF-2 being 10-fold higher than FGF-1 when measured by radioimmunoassay (Seyedin *et al.,* 1985; Globus *et al.,* 1989).

In nonosseous tissues Weich *et al.* (1991) reported that there is transcriptional regulation of FGF-2 gene expression in capillary endothelial cells, which are known to synthesize

and store FGF-2. FGF-2 induces its own mRNA in these cells and there is a similar increase in FGF-2 mRNA in response to thrombin and phorbol esters. In more recent studies, Stachowiak *et al.* (1994) found that stimulation of adenylate cyclase with forskolin, or protein kinase C with PMA, increases FGF-2 protein in adrenal medullary cells. The induction of FGF-2 by forskolin and PMA is due to transcriptional activation of the FGF-2 gene. In addition, the regulation of FGF-2 protein content also involves posttranscriptional mechanisms. FGF-2 expression in the anterior pituitary of rats is decreased by castration and can be restored by testosterone. Neither adrenalectomy nor chemical thyroidectomy alters FGF-2 gene expression (Yoshimura *et al.,* 1994).

There are few data on the regulation of FGF expression in bone. In cultures of mouse osteoblastic MC3T3-E1 cells, exogenous FGF-2 increases its own mRNA (Hurley *et al.,* 1994). TGF-β also increases FGF-2 mRNA and protein in MC3T3-E1 cells (Hurley *et al.,* 1994). TGF-β increases FGF-2 protein in both the cytoplasm and the nucleus. However, there is no measurable FGF-2 in the conditioned medium. The significance of TGF-β regulation of FGF-2 in osteoblasts is not clear. Amplification of the responses to both FGF and TGF-β could occur by an increase in endogenous FGF. In addition, parathyroid hormone (PTH) (Hurley *et al.,* 1999) and prostaglandins (Sabbieti *et al.,* 1999) increase FGF-2 mRNA and protein levels in bone cells, suggesting that anabolic factors for bone may act in part by stimulating endogenous FGF-2 in osteoblasts.

Fibroblast Growth Factors and Bone Formation

Osteoblast Proliferation

FGF-1 and FGF-2 stimulate bone cell replication (Canalis and Raisz, 1980; Rodan *et al.,* 1987; Globus *et al.,* 1988, 1989; McCarthy *et al.,* 1989; Shen *et al.,* 1989; Hurley *et al.,* 1992). Canalis and Raisz (1980) demonstrated that partially purified fibroblast growth factor stimulated fetal rat calvarial cell proliferation. Subsequent studies using purified or recombinant FGF-1 and FGF-2 confirmed this initial report (Rodan *et al.,* 1987; McCarty *et al.,* 1989; Shen *et al.,* 1989; Hurley *et al.,* 1992), not only in bone organ culture but also in osteoblast-enriched cells from fetal rat calvaria. In osteosarcoma-derived ROS 17/2.8 cells, which express osteoblastic features, Rodan *et al.* (1989) found that FGF-2 stimulated cell proliferation when cells are seeded at low density in serum-free media but not when seeded at high density in the presence of serum. In contrast in mouse osteoblastic MC3T3-E1 cells, FGF-2 stimulates cell proliferation in the presence of serum at both high and low density (Hurley *et al.,* 1993). FGF-1 and FGF-2 also activate the growth of rat and human stromal bone cells (Noff *et al.,* 1989; Pitaru *et al.,* 1993; Locklin *et al.,* 1995; Hanada *et al.,* 1997; Berrada *et al.,* 1995; Pri-Chen *et al.,* 1998). In human calvaria cells, FGF-2 also promotes cell proliferation, although this was observed only at an early stage of differentiation (Debiais *et al.,* 1998). It is noteworthy that the mitogenic effect of FGF-2 on rat calvaria cells decreases with age (Kato *et al.,* 1995; Tanaka *et al.,* 1999).

Osteoblast Differentiation

In vitro FGFs inhibit markers of the osteoblast phenotype. FGFs reduce differentiation-related markers such as alkaline phosphatase (Rodan *et al.,* 1989; Shen *et al.,* 1989). FGF-2 inhibits parathormone responsive adenylcyclase activity in part via a pertussis toxin-sensitive G protein (Rodan *et al.,* 1989). Type I collagen is the major product of the osteoblast and FGF-2 affects its production. Both stimulatory and inhibitory effects of FGF-2 on collagen synthesis in osteoblasts have been reported (Canalis *et al.,* 1988; McCarty *et al.,* 1989). Similar to FGF-2, FGF-1 has stimulatory and inhibitory effects on collagen synthesis in fetal rat calvariae (McCarty *et al.,* 1989; Shen *et al.,* 1989). Short-term treatment with FGF-2, which is 24 hr of treatment followed by removal of FGF from the osteoblast cultures, results in the stimulation of collagen synthesis. However, continuous or chronic FGF treatment inhibits type I collagen synthesis. FGF-2 appear to have independent effects on osteoblast proliferation and differentiation. In bone organ cultures, the inhibitory effect of FGF-2 on collagen synthesis is similar in the presence or absence of aphidicolin, an inhibitor of cell replication (Hurley *et al.,* 1992). Rodan *et al.* (1989) found that under conditions where FGF-2 had no effect on the proliferation of ROS 17/2.8 cells, there is a reduction in alkaline phosphatase activity, osteocalcin synthesis, and type I collagen mRNA. A similar dissociation is observed in chondrocytes where terminal differentiation and calcification are inhibited by FGF-2 independent of cell proliferation (Kato and Iwamoto 1990). In myoblasts, FGF inhibits differentiation independent of effects on cell proliferation (Clegg *et al.,* 1987).

The inhibitory effect of FGF-2 on collagen synthesis appears to be transcriptional (Rodan *et al.,* 1989; Hurley *et al.,* 1993) and is consistent with previous studies showing that a predominant mechanism of hormonal and growth factor regulation of collagen synthesis is at a pretranslational site (Canalis *et al.,* 1988). In studies in osteoblastic MC3T3-E1 cells, it has been shown that FGF-2 reduces the transcription of the type I collagen gene by nuclear run-on analysis (Hurley *et al.,* 1993). Our initial studies on transcription of the collagen gene suggest that a DNA locus between -3.5 and -2.3 kb of the collagen promoter is negatively regulated by FGF-2 (Hurley *et al.,* 1993). The mechanism(s) by which FGF-2 negatively regulates collagen gene transcription is unknown.

FGF-2 also affects the expression of other bone matrix proteins. FGF-2 stimulates osteopontin and modulates osteonectin in rat osteosarcoma cells (Rodan *et al.,* 1989; Shiba *et al.,* 1995; Delany and Canalis, 1998). Although FGF-1 inhibits osteocalcin expression in rat calvaria cells (Tang *et al.,* 1996), it enhances osteocalcin in bovine bone

cells (Schedlich *et al.,* 1994) and directly affects osteocalcin transcription in mouse calvaria cells (Boudreaux *et al.,* 1996; Newberry *et al.,* 1996). In these cells, FGF-2 and cAMP have synergistic effects on osteocalcin expression, and some elements conferring FGF-2 responsiveness in the osteocalcin promoter have been identifed (Schedlich *et al.,* 1994; Newberry *et al.,* 1997). FGF may also affect osteoblast function by acting on functional membranous proteins. FGFs downregulate the expression of connexin-43 associated with decreased gap junction-mediated communication (Shiokawa-Sawada *et al.,* 1997), and FGF-2 upregulates the expression of N-cadherin in osteoblasts (Debiais *et al.,* 2000). FGF-2 also increases sodium-dependent phosphate transport in mouse calvaria cells, which may contribute to regulate intramembranous calcification (Suzuki *et al.,* 1998).

FGF Regulation of Growth Factors and Cytokines in Bone

Insulin-like growth factor-I and insulin-like growth factor-II (IGF-I and IGF-II) proteins are made by bone cells (Canalis *et al.,* 1991; Delany *et al.,* 1994) and are major modulators of bone cell function (Hock *et al.,* 1988), and FGF-2 has been shown to affect the production of IGF-I and -II and their binding proteins in osteoblasts. FGF-2 decreases IGF-I mRNA and protein levels in mouse osteoblastic MC3T3-E1 cells (Hurley *et al.,* 1992) and rat bone cell cultures (Canalis *et al.,* 1993). The inhibitory effects of FGF-2 on IGF-I mRNA and protein are not specific for osteoblasts, as similar results are reported in smooth muscle cells (Bornfeldt *et al.,* 1990). FGF-2 inhibits IGF-I mRNA in the presence of aphidicolin, an inhibitor of cell replication, thereby suggesting that the effects of FGF-2 are independent of cell replication. FGF-2 decreases the mRNA and protein levels for several IGF-binding proteins *in vitro,* in MC3T3-E1 cells (Hurley *et al.,* 1995a). In contrast to the studies of Chen *et al.* (1993), 24 hr treatment with FGF-2 does not inhibit IGF-binding protein mRNA in rat osteoblast-like cells. The inhibitory effects on IGFs and their binding proteins could play a role in the inhibition of bone formation by FGF. However, the *in vivo* effects of FGF-2 on IGF-I and -II and the IGF-binding proteins have not been examined.

Both FGF-1 and FGF-2 increase the production of TGFβ *in vitro* and *in vivo* (Noda and Vogel, 1989). In addition, TGFβ and FGF-1 and FGF-2 interact to modulate their mitogenic effects in osteoblasts (Globus *et al.,* 1989). In human calvaria cells, FGF-2 decreases TGFβ2 production in immature cells but increases TGFβ2 synthesis by more differentiated cells (Debiais *et al.,* 1998). However, FGF-2 increases vascular endothelial cell growth factor (VEGF) expression in rat and mouse calvaria cells independently of TGFβ synthesis (Saadeh *et al.,* 2000). FGF-2 also induces hepatocyte growth factor expression in osteoblasts (Blanquaert *et al.,* 1999), which may play a role in bone repair. Additionally, FGF-2 increases IL-6 transcripts and protein in mouse calvarial osteoblastic cells (Hurley *et al.,* 1996), an effect that is dependent on intracellular calcium mobilization and is autoregulated by PKC activation. These factors may perhaps mediate some of the actions of FGF on bone cells.

Bone Formation *in Vitro*

Studies have shown that FGF-2 has both stimulatory and inhibitory effects on bone formation *in vitro.* In long-term culture, the effects of FGFs on osteoblastic cell differentiation are dependent on the cell culture. FGF-1 reduces bone nodule formation in the rat calvaria system (Tang *et al.,* 1996), whereas FGF-2 inhibits osteoblast differentiation markers in human marrow stromal cells (Rifas *et al.* 1995; Berrada *et al.,* 1995; Martin *et al.,* 1997). However, FGF-2 increases cell differentiation and matrix mineralization in rat bone marrow stromal cells (Noff *et al.,* 1989; Pitaru *et al.,* 1993) and in dexamethasone-treated rat (Locklin *et al.,* 1995) and human bone marrow stromal cells (Martin *et al.,* 1997; Pri-Chen *et al.,* 1998; Scutt and Bertram, 1999; Walsh *et al.,* 2000). Interestingly, Giuliani *et al.* (1995) reported that alendronate induces mineralized nodule formation in human bone marrow cultures, which is associated with an increase in endogenous FGF-2 production. In human calvaria cells, FGF-2 initially reduces osteocalcin synthesis, whereas a prolonged treatment increases both osteocalcin synthesis and matrix mineralization, indicating that the effects of FGF-2 are dependent on the osteoblast maturation stage (Debiais *et al.,* 1998).

Bone Formation *in Vivo*

As described previously, FGF-2 stimulates proliferation of osteoblastic cells, but can inhibit collagen synthesis and osteogenic cell differentiation *in vitro.* These results are in contrast to the effects of FGFs *in vivo.* Local injection of FGF-1 promotes calvaria bone formation (Mundy *et al.,* 2000). At the endosteal level, FGF-2 at low dose also stimulates bone formation in growing rats (Aspenberg *et al.,* 1991; Nakamura *et al.,* 1995; Kawaguchi *et al.,* 1994; Mayara *et al.,* 1993; Nagai *et al.,* 1995). In normal rabbits, intraosseous application of FGF-2 increases bone formation and bone mineral density (Nakamura *et al.,* 1996; Okazaki *et al.,* 1999). Exogenous FGF-1 and FGF-2 appear to act by increasing the recruitment of osteoblast precursor cells, which then differentiate into osteoblasts (Nakamura *et al.,* 1995). It is also possible that FGF-2 acts indirectly by increasing the expression of TGFβ in osteoblasts (Nakamura *et al.,* 1995; Kawaguchi *et al.,* 1994). In osteoblastic MC3T3-E1 cells, FGF-2 enhances TGFβ1 gene expression (Noda and Vogel, 1989). Moreover, TGFβ increases FGF-2 mRNA and protein in these cells (Hurley *et al.,* 1994). Thus, it is also possible that the complex biphasic effects of TGFβ may be due in part to TGFβ altering the endogenous production of other growth factors such as FGF-2. Glypican, syndican, and β-glycan are cell surface proteoglycans

that bind FGF via their heparin sulfate moieties and are believed to present FGF to the signaling receptors. β-Glycan also binds to TGFβ, thereby providing a physical link between FGF and TGFβ (Nilsen-Hamilton, 1994).

Fibroblast Growth Factors in Fracture Repair

Fibroblast growth factors also appear to play an important role in fracture repair in rats (Kawaguchi *et al.,* 1994) and in humans (Wildburger *et al.,* 1994). During fracture repair, FGF-1 and -2 are expressed in the granulation tissue (Scully *et al.,* 1990), suggesting that FGFs may increase cell migration and angiogenesis at early stages of bone repair. At later stages, FGF-1 expression increases during callus formation, whereas FGF-2 expression is stable (Joyce *et al.,* 1991). Several studies indicate that exogenous FGF-2 can accelerate bone repair (Hiroshi *et al.,* 1994; Radomsky *et al.,* 1998). Although FGF-1 increases the proliferation of chondrocyte precursors (Cuevas *et al.,* 1988) and fibrous callus, it does not enhance bone repair in rats (Jingushi *et al.,* 1990). In various animal models of bone defects, FGF-2 at low doses was found to stimulate chondrogenesis and bone formation (Wang *et al.,* 1996; Aspenberg *et al.,* 1991; Andreshak *et al.,* 1997; Inui *et al.,* 1998; Kato *et al.,* 1998; Okazaki *et al.,* 1999; Tabata *et al.,* 1999; Zellin and Linde, 2000), suggesting that FGF may improve bone regeneration (Radomsky *et al.,* 1998). Part of the effects of FGF on bone repair may involve the release of HGF (Blanquaert *et al.,* 1999) or VEGF (Saadeh *et al.,* 2000) by osteoblasts.

FGF Signaling in Bone Cells

Few data are available on the signaling mechanisms involved in the regulation of bone cells by FGF. FGF-2 activates MAP kinase signal transduction and extracellular signal-regulated kinase 2 (ERK2) in osteoblastic cells (Hurley *et al.,* 1996; Newberry *et al.,* 1997; Chaudhary and Avioli, 1997), but the role of signaling pathways in the FGF effects on osteoblastic cell function is far from being understood. The Erk signaling pathway mediates the downregulation of procollagen gene expression by FGF-2 in osteoblasts (Chaudhary and Avioli, 2000). In contrast, the FGF-2 transcriptional activation of the matrix metalloproteinase MMP1 is independent of Erk1/Erk2 MAPK activity in mouse osteoblasts (Newberry *et al.,* 1997). However, the increased IL-6 synthesis induced by FGF-2 involves p38 MAP kinase activation (Kozawa *et al.,* 1999). The PKC pathway appears to be an important pathway regulating FGF actions in osteoblasts. FGF-2 activates PKC activity in human osteoblasts, and this pathway is implicated in the expression of N-cadherin expression induced by FGF-2 (Debiais *et al.,* 2000). The PKC pathway is also involved in the growth response of FGF-2 in Py1a rat osteoblastic cells (Hurley *et al.,* 1996) and in the FGF-2-induced increase in sodium-dependent phosphate transport in calvaria cells (Suzuki *et al.,* 1998). Additionnaly, PKC signaling is constitutively activated by the S252W FGFR-2 mutation in human mutant osteoblasts and is responsible for the increased osteoblast phenotype and premature apoptosis in these cells (Lemonnier *et al.,* 2000a,b). In chondrocytes, however, FGF signaling and activating FGFR-3 mutations activate STAT1 signaling pathway, leading to growth arrest and apoptosis (Sahni *et al.,* 1999; Li *et al.,* 1999; Legeai-Mallet *et al.,* 1998; Su *et al.,* 1997). In osteoclasts, FGF-2 activates FGFR-1 and MAPK to stimulate cell function (Chikazu *et al.,* 2000). Thus, multiple pathways are involved in the FGF effects on bone cells.

Fibroblast Growth Factors and Bone Resorption

FGF and Bone Resorption

FGF-1 induces bone resorption in fetal rat long bone via a prostaglandin-mediated mechanism (Shen *et al.,* 1989). FGF-2 is also a potent bone-resorbing agent in the fetal rat long bone model (Simmons *et al.,* 1991). However, in fetal rat long bones, the effects of FGF-2 on bone resorption appear to be independent of endogenous prostaglandin production (Simmons *et al.,* 1991). In contrast to the report by Shen *et al.* (1989), Simmons *et al.* (1991) reported that FGF-1 induces calcium release only in the presence of heparin and that this effect is not blocked by indomethacin. FGF-2 increases bone resorption in neonatal mouse calvariae, which is partially blocked by indomethacin, suggesting that the resorptive effects of FGF-2 are mediated in part by prostaglandins. In the presence of both an inhibitor of DNA synthesis and prostaglandin production, FGF-2-induced bone resorption is completely blocked. These results suggest that FGF-2 has direct effects on resorption through its effects on osteoclasts precursor proliferation and an indirect effect that is mediated by prostaglandin (Kawaguchi *et al.,* 1995a). These findings are important because prostaglandins are potent local regulators of bone metabolism (Kawaguchi *et al.,* 1995b).

FGF Regulation of Prostaglandins in Bone

FGF-2 induces mRNA and protein for prostaglandin GH synthetase 2 (PGHS-2), the major enzyme in arachidonic acid conversion to prostaglandins by a transcriptional mechanism in MC3T3-E1 cells (Kawaguchi *et al.,* 1995). In these cells, FGF-2 also increases PGE_2production in the presence of the substrate arachidonic acid. In the presence of exogenous arachidonic acid, FGF-2-stimulated PGE_2 production is paralleled by the stimulaton of PGHS-2 promoter luciferase activity, indicating transcriptional regulation of PGHS-2.

FGF Regulation of the Collagenase Gene in Bone

FGF may also modulate bone matrix degradation by regulating collagenase expression and activity. Interstitial collagenase is required to initiate the degradation of type I

collagen (Delaisee *et al.,* 1988), and inhibitors of metalloproteinases inhibit bone resorption (Delaisee *et al.,* 1988). In rat calvaria bone cells, FGFs increase interstitial collagenase-1 and -3 expression by a prostaglandin- and PKC-dependent pathway (Varghese *et al.,* 1995; Tang *et al.,* 1996). In contrast, in mouse cells the effects of FGF-2 on the collagenase gene are not affected by either indomethacin or staurosporine (Hurley *et al.,* 1995b). Similar to FGF-2, FGF-1 also upregulates the collagenase gene (M. M. Hurley, unpublished observation). FGF-2 transcriptionally regulates collagenase gene expression in mouse calvaria cells, and the tyrosine kinase inhibitors genistein and herbimycin A completely block the effect of FGF-2 on the collagenase promoter (Hurley *et al.,* 1995b). FGF response elements in the collagenase promoter have been identified (Newberry *et al.,* 1997). FGF-2 stimulates collagenase-3 gene transcription through an effect on the AP-1 site on the promoter (Varghese *et al.,* 2000) and induces the expression of tissue inhibitors of metalloproteinases (TIMP) 1 and 3 (Varghese *et al.,* 1995), which regulate collagenase activity. Although FGF-2 decreases stromelysin-3 mRNA stability, it increases gene transcription (Delany and Canalis, 1998), which may contribute to the control of the bone matrix degradation.

FGF and Osteoclastogenesis

Histologic examination reveals that FGF-1 treatment increases osteoclast number in fetal rat long bones (Shen *et al.,* 1989) and in 21-day fetal rat calvariae (Hurley *et al.,* 1992) suggesting a role for FGFs in osteoclastogenesis. Osteoclasts are derived from a hematopoietic precursor that is common to the granulocyte and the macrophage. The immediate progenitor of the osteoclast is the CFU-GM (colony-forming unit for granulocytes and macrophages) (Mundy and Roodman 1995), and studies show that FGF-2 stimulates the formation of CFU-GM in human marrow cultures (Gabrilove *et al.,* 1994). The production of osteoclasts from progenitor cells is regulated by cytokines (Roodman, 1995) and requires or is enhanced by interactions between marrow progenitor cells and either osteoblastic or stromal cells (Suda *et al.,* 1992). Interstingly, FGF-2 is a potent mitogen for stromal cells (Oliver *et al.,* 1990), which are multipotential mesenchymal cells in the marrow environment that are the precursors of osteoblasts, chondroblasts, fibroblasts, and other connective tissue cells in bone. FGF-2 is produced by bone marrow stromal cells (Brunner *et al.,* 1993) and hence may be autostimulatory.

FGF-2 has been found to increase the formation of multinuclear-resorbing osteoclast-like cells in mouse bone marrow cultures, an effect mediated by PGE_2 production (Hurley *et al.,* 1998; Kawaguchi *et al.,* 2000). Indeed, FGF-2 stimulates PGE_2 production rapidly in mouse calvaria cells through the transcriptional regulation of PGHS-2 (Kawaguchi *et al.,* 1995). FGF-2 also increases osteoclast formation by a mechanism involving COX-2 stimulation and prostaglandin formation, leading to increased osteoclast differentiation factor (ODF) production (Nakagawa *et al.,* 1999). Apart from this indirect effect of FGF-2 through osteoblastic cells, FGF-2 acts directly on mature osteoclasts to stimulate bone resorption (Kawaguchi *et al.,* 2000) through the activation of FGFR-1 and MAPK activation (Chikazu *et al.,* 2000).

Interaction of Heparin and Fibroblast Growth Factors

FGF-2 and FGF-1 bind to high-affinity cell surface tyrosine kinase receptors (Sakaguchi *et al.,* 1991; Ullrich and Schlessinger, 1991). This binding may not occur in the absence of prior binding to low-affinity membrane-associated heparan sulfate proteoglycans (HSPGs) that act as low-affinity coreceptors to modulate FGF actions (Feige *et al.,* 1989; Yayon *et al.,* 1991; Ornitz, 2000; Schlessinger *et al.,* 2000). Other studies show that site-directed mutagenesis of the heparin-binding domains of the FGF-2 gene results in structural analogs of FGF-2 with greater or lesser mitogenic activity related to changes in their affinity for heparin (Heath *et al.,* 1991). Enzymatic degradation or inhibition of sulfation of heparin inhibits binding of FGF-2 to its receptor, thus blocking the mitogenic activity of FGF-2 in fibroblasts, as well as its ability to repress myoblast differentiation (Rapraeger *et al.,* 1991). Thus heparin appears to modulate the biological responses of tissues to FGF-1 and FGF-2. Heparin sulfate proteoglycans are made by osteoblasts (Beresford *et al.,* 1987), and Globus *et al.* (1989) suggested that the FGF–heparin sulfate complex is released in an active form, resulting in osteoblast proliferation and new bone formation.

Studies suggest a direct role for heparin in modulating the biological effects of FGF-1 and FGF-2 in bone (Simmons *et al.,* 1991; Hurley *et al.,* 1992). Heparin enhances the mitogenic effect, as well as the resorptive effect of FGF-1, in fetal rat long bone cultures (Simmons *et al.,* 1991). In contrast, heparin does not enhance the mitogenic effect of FGF-2 in fetal rat long bone or in fetal rat calvarial cultures (Simmons *et al.,* 1991; Hurley *et al.,* 1992). Heparin does, however, enhance the resorptive effect of FGF-2 in fetal rat long bone cultures (Simmons *et al.,* 1991), as well as the inhibitory effect on FGF-2 on percentage collagen synthesis in fetal rat calvariae (Hurley *et al.,* 1992). The effects of heparin to enhance FGF-mediated bone resorption and inhibition of collagen synthesis may be important in heparin-induced osteoporosis.

Some cell surface transmembrane HSPGs named syndecans interact with FGF binding and signaling (Yahon *et al.,* 1991; David, 1993; Rapraeger, 1993; Bernfield *et al.,* 1993). During development, syndecan-1 is expressed in mesenchymal cells (Vainio *et al.,* 1991) and limb bud (Solursh *et al.,* 1990) and affects bone cell differentiation (Dhodapkar *et al.,* 1998). Syndecan-2 is abundant in prechondrogenic cells and is expressed in the perichondrium and periosteum at the onset of *in vitro* osteogenesis (Molténi *et al.,* 1999a). Syndecan-3 is expressed in mesenchymal cells during limb bud formation, is regulated by FGFs (Gould *et al.,* 1992),

and mediates the ability of FGFs to promote mesoderm proliferation (Dealy *et al.,* 1997). Thereafter, precartilage cells and immature chondrocytes express syndecan-3, which may control chondrocyte proliferation during endochondral ossification (Shimazu *et al.,* 1996). Syndecan-4 is strongly expressed in chondrocytes (Kim *et al.,* 1994) and osteoblasts (Molténi *et al.,* 1999a). The coexpression of syndecans and FGFRs during osteogenesis suggests a role for these HSPGs in the control of bone formation. For example, rat chondrocytes coexpress FGFR-3, syndecan-2, and syndecan-4, and their expression decreases during *in vitro* differentiation. In contrast, rat calvaria osteoblasts express syndecan-1, -2, and -4 with FGFR-1 and FGFR-2, indicating that syndecans can interact with FGFRs to control FGF actions during *in vitro* chondrogenic and osteogenic differentiation (Molténi *et al.,* 1999a). Moreover, alterations of matrix- and cell-associated proteoglycan sulfation or synthesis inhibit the growth response to FGF-2 in cultured rat mandibular condyle (Molténi *et al.,* 1999b), indicating that syndecans and other HSPGs may be important coreceptors modulating FGF/FGFR interactions in bone cells.

Heparin, Fibroblast Growth Factors, and Osteoporosis

In humans, the prolonged use of heparin is associated with the development of clinical osteoporosis and spontaneous fractures (Megard *et al.,* 1982). Heparin is the predominant glycosaminoglycan in mast cells and may play a role in the osteoporosis often seen in mast cell disease (Chines *et al.,* 1991). The bone marrow of postmenopausal women who are osteoporotic show increased numbers of heparin-rich mast cells (Frame and Nixon, 1968). *In vivo* studies in rats treated with heparin for 33–65 days reveal significant reduction in bone mineral mass (Thompson 1973). In studies in bone organ culture, heparin decreases collagen synthesis (Hurley *et al.,* 1990), and this effect is reversed by exogenous IGF-I (Hurley *et al.,* 1992). Heparin also potentiates the inhibitory effect of FGF-2 on collagen synthesis and procollagen mRNA levels in fetal rat calvariae (Hurley *et al.,* 1992). In bone, heparin augments FGF-1 and FGF-2-induced bone resorption (Simmons *et al.,* 1991). Studies by Thompson *et al.* (1990) revealed that heparin infusion into rabbits results in an increase in FGF-2-like activity in plasma. The mechanisms by which heparin induces osteoporosis are not known. It is possible that modulation of the availability or action of local factors such as IGF-I and FGF-2 is important in heparin-induced osteoporosis.

The role of fibroblast growth factors in the development of osteopenia and postmenopausal osteoporosis in humans has not been defined. However, the studies of Montero *et al.* (2000) clearly documented a role for FGF-2 in bone remodeling and maintenance of bone mass. These studies show that disruption of the Fgf 2 gene in mice results in decreased osteoblast replication, decreased mineralized nodule formation in bone marrow cultures, and decreased new bone formation *in vivo.* There was a progressive decrease in trabecular number and trabecular bone volume as these mice aged. These data are the first to demonstrate an important role for endogenous FGF-2 in maintaining bone mass, as well as bone formation. These data further suggest that the redundancy of members of the FGF family cannot compensate to prevent bone loss when the Fgf 2 gene is disrupted in mice.

A therapeutic role for FGFs in osteopenic states is suggested by studies in animal models. In osteopenic mice, FGF-2 stimulates endocortical bone modeling (Nagai *et al.,* 1999). In ovariectomized rats, FGF-1 or FGF-2 administration also stimulates bone formation and restores bone volume (Nakamura *et al.,* 1997; Dunstan *et al.,* 1999; Liang *et al.,* 1999). The mechanism of this effect has not been studied. Studies to examine the effects of menapause, as well as oophorectomy on FGF expression in bones, are needed.

Conclusion

Mutiple experimental and genetic evidence indicates that FGFs and FGFRs play important roles in the control of endochondral and intramembranous bone formation (Table II). However, the cellular and molecular effects of FGFs in bone cells are not fully understood. Identification of the signal transduction pathways that are activated by FGF/FGFR

Table II Effects of FGF/FGFR Interactions in Skeletal Cells

Chondrogenesis	Bone formation	Bone resorption/degradation
Modulate chondroblast proliferation	Increase osteoblast proliferation	Promote osteoclast formation
Inhibit chondrocyte differentiation	Decrease collagen synthesis	Promote osteoclast formation
Promote chondrocyte apoptosis	Inhibit alkaline phosphatase Modulate osteopontin, osteonectin, and osteoclacin Downregulate connexin-43, upregulate N-cadherin Increases Na-dependent P_i transport Increase osteogenesis by marrow osteoprogenitors Promote osteoblast apoptosis Increase bone formation and promote bone repair *in vivo*	Regulate collagenase-1 and −3 Promote TIMP 1 and 3

interactions and that lead to the expression of specific genes in skeletal cells may help to better understand the regulatory effects of FGFs during osteogenesis *in vivo,* and may allow for the development of therapeutic approaches to stimulate bone formation and to improve bone regeneration.

effects of glucocorticoids, 732–733
targeted disruption of, 904
isoforms, 903–904
latency, 909–911
-RANKL, cross-communication between, 121
receptors, 906–907
role in
BMD, 1266–1267
bone cancer metastasis, 911–912
collagen synthesis, 194–196
osteoblast apoptosis, 160
osteoblast development, 71–73, 72
signaling pathways, 908–909
superfamily, 903
Transgenes, tissue-directed, 1494–1496
Transilial bone biopsy
in clinical research, 1633
complications, 1617
histology, 1628–1629
morphometric methods, 1629, 1631
in patient care, 1632
practical considerations, 1633
procedure, 1615–1616
reference data, 1631–1632
regions evaluated, 1629, 1631
specimen processing, 1617
timing, 1633
Transmission disequilibrium test, 1262
Transplantation
heart, associated bone loss, 1561–1562
kidney, associated bone loss, 1562
as osteopetrosis therapy, 1224–1225
TRAP. *see* Tartrate-resistant acid phosphatase
T scores. *see* Desitometry
Tumor necrosis factors
effects on bone, 963–964
expression, 109
α
effects on VEGF-A expression, 891
osteoporosis pathophysiology and, 1278–1279
role in collagen synthesis, 197–198
in osteoblasts, effects of estrogen, 662–663
receptor-associated, 118–119
role in
HHM, 1094–1095
MAH, 1087–1088
osteoclast
apoptosis, 158–159
formation, 693–695
ovariectomy-induced bone loss, 699–702
β, in cancer cells, 1098
Tumors
bone disease, 1376–1377
extrathyroidal neuroendocrine, 630
nonneuroendocrine, 630
suppressor genes, 1022, 1024
Turnover, bone
effects of
GH, 1443–1446
IGF-I, 1447–1448
Mg, 350
raloxifene, 682–683
as fracture risk marker, 1296–1298
postmenopausal rate, animal model, 1637
Tyrosine kinase, 889

U

Ultrasound, BMD, 1292–1293
Urokinase-type plasminogen activator, 257
Uterus, effects of PTH/PTHrP, 523–524

V

Vascular endothelial growth factor
  in bone formation, effects of FGF, 837
  effects on
    bone, 893–896
    cartilage, 893–896
    osteoclast formation, 948–949
  ligand family
    alternative splicing, 884–885
    postranslation processing, 885
    structure, 885–886
    viral, 886
  receptors
    activation, 889–890
    expression, 891–892
    structure, 886
    types, 887–888
  type A
    activities, 889–891
    expression, 891–892
    mechanisms, 889–891
Vasculature
  cells, uniquness, 883
  PTH in, 473–475
  PTHrP in
    effects on
      anatomy, 532–533
      contractile mechanisms, 532–533
      smooth muscles, 534
    expression, 533–534
    mode of action, 535–536
  role in remodeling, 311
Vasoactive intestinal peptide
  characterization, 781–783
  clinical observations, 791–792
Vasodilation, VEGF-A-induced, 891
VEGF. *see* Vascular endothelial growth factor
Versican (PG-100), 226
Viral vectors, description, 1510–1511
Viscoelasticity, 23–24
Vitamin D
  absorption, genetic determinants, 1269
  binding proteins, receptor interactions, 1413–1415
  compounds
    activating enzymes, 1412–1413
    analogs, 1409, 1411, 1416
    binding proteins, 1413
    clinical applications, 1411–1412
    genomic mechanisms, unraveling, 1417–1418
    hepatic clearance, 1416
    modeling, 1418
    molecular mechanisms of action, 1416–1417
    prodrugs, 1408
    target cell catabolic enzymes, 1415–1416
  deficiency, animal models, 1205
  effects of osteocytes, 98–99
  effects on chondrocytes, 47
  endocrine system, 548–549
  enhancer domain, 178
  function, 1195–1196
  hereditary deficiencies (*see* Osteomalacia; Rickets)
  metabolism
    effects of
      glucocorticoids, 725–726
      Mg depletion, 348–349
      PTH, 492–493
      sunlight, 573–574, 590–591
    in type II rickets, 1199
  osteoporosis pathophysiology and, 1280–1281
  production, hereditary deficiency, 1197–1198
  pseudohypoparathyroidism therapy, 1154–1156
  related genes
    response elements, 577–579
    transcriptional regulation, 579–581
  role in
    collagen synthesis, 199
    FBHH, 1036
    MAH, 1087
Vitamin D_3
  analogs, 561–565
  as arthritis treatment, 598
  conformational flexibility, 545–548
  effects on
    bone, 574–575
    calcitriol levels, 1204
    differentiation, 576–577
    hormone secretion, 577
    immune system, 577
    intestine, 575
    kidney, 575–576
    parathyroid glands, 576
    proliferation, 576–577
  genomic mechanism of action, 574
  nuclear receptor
    characterization, 551–552
    dimerization, 552–553
    evidence for, 558–559
    hormone response element, 553–554
    knockout model, 556–558
    ligand binding, 554–555
    ligand shape, 559–561
    mutations, 556
    receptor structure, 555–556
  photosynthesis, 587–590
  posttranscritpional effects *in vitro,* 1202–1203
  role in
    malignancy-associated hypercalcemia, 1081
    PTH gene regulation, 409–412
    PTHrP repression, 1086–1087
  signal transduction pathways, 549–551
  as skin disease treatment, 595–597
  structure, 545
  transcriptional regulation by, 577–579
  transcriptional effects *in vitro,* 1202–1203

Vitamin D receptors
in cancer cells, 591–592
characterization, 551–552
compound interactions, 1413–1415
deficient
DNA binding, 1201
hormone binding, 1201
nuclear uptake, 1201
dimerization, 552–553
evidence for, 558–559
function, 1195
genes, role in BMD, 1264–1265
heterodimerization, 580
homodimerization, 580
hormone response element, 553–554
in immune system, 592–594
interacting proteins complex, 581
knockout model, 556–558
ligand binding, 554–555
ligand shape for, 559–561
mutations, 556
phamacologic actions, 595
phosphorylation, 579–580
physiolgic actions, 595
receptor structure, 555–556
regulation, 579
reproductive system, 594–595
-transcription machinery interaction, 580–581
Vitamin K, role in osteoclast apoptosis, 159
Vitronectin, 231

W

Water metabolism, 379–381
WHO. *see* World Health Organization
Wolff's law, 17, 99, 1477
World Health Organization
osteopenia definition, 1582
osteoporosis classification, 1573–1574
Wounding healing, 821
Woven bone, 315

X

X-linked hypophosphatemic rickets, 326–329
X-linked recessive hypophosphatemic rickets, 333
X-ray energy, 1612–1613

Y

Yield point, 21–22
Young's modulus, 21

Z

Zone of polar activity, 38, 40
ZPA. *see* Zone of polar activity

Contents

VOLUME 2

Contributors xi
Preface to the Second Edition xix
Preface to the First Edition xxi

CHAPTER 48
Vascular Endothelial Growth Factors **883**
Shun-ichi Harada and Kenneth A. Thomas

CHAPTER 49
Transforming Growth Factor-β **903**
L. F. Boneward

CHAPTER 50
Bone Morphogenetic Proteins **919**
Vicki Rosen and John M. Wozney

CHAPTER 51
Bone Morphogenetic Protein Receptors and Actions **929**
Kohei Miyazono

CHAPTER 52
Colony-Stimulating Factors **943**
Willy Hofstetter and Matthew T. Gillespie

CHAPTER 53
Local Regulators of Bone: IL-1, TNF, Lymphotoxin, Interferon-γ, IL-8, IL-10, IL-4, the LIF/IL-6 Family, and Additional Cytokines **961**
Mark C. Horowitz and Joseph A. Lorenzo

CHAPTER 54
Prostaglandins and Bone Metabolism **979**
Carol C. Pilbeam, John R. Harrison, and Lawrence G. Raisz

CHAPTER 55
Nitric Oxide and Other Vasoactive Agents **995**
Lee D. K. Buttery, Lucia Mancini, Niloufar Moradi-Bidhendi, Meg C. O'Shaughnessy, Julia M. Polak, and Iain MacIntyre

PART II
MOLECULAR MECHANISIMS OF METABOLIC BONE DISEASES

CHAPTER 56
Molecular Basis of PTH Overexpression **1017**
Geoffrey N. Hendy and Andrew Arnold

CHAPTER 57
Familial Benign Hypocalciuric Hypercalcemia and Neonatal Primary Hyperparathyroidism **1031**
Ghada El-Hajj Fuleihan, Edward M. Brown, and Hunter Heath III

CHAPTER 58
Multiple Endocrine Neoplasia Type 1 1047
Maria Luisa Brandi, Cesare Bordi, Francesco Tonelli, Alberto Falchetti, and Stephen J. Marx

CHAPTER 59
The Role of the *RET* Protooncogene in Multiple Endocrine Neoplasia Type 2 1067
Robert F. Gagel and Gilbert J. Cote

CHAPTER 60
Systemic Factors in Skeletal Manifestations of Malignancy 1079
Janet E. Henderson, Richard Kremer, and David Goltzman

CHAPTER 61
Local Factors in Skeletal Malignancy 1093
Gregory R. Mundy, Toshiyuki Yoneda, Theresa A. Guise, and Babatunde Oyajobi

CHAPTER 62
Molecular Basis of PTH Underexpression 1105
R. V. Thakker

CHAPTER 63
Jansen's Metaphysical Chondrodysplasia and Blomstrand's Lethal Chondrodysplasia: Two Genetic Disorders Caused by PTH/PTHrP Receptor Mutations 1117
Harald Jüppner, Ernestina Schipani, and Caroline Silve

CHAPTER 64
Pseudohypoparathyroidism 1137
Michael A. Levine

CHAPTER 65
Other Skeletal Diseases Resulting from G Protein Defects: Fibrous Dysplasia of Bone and McCune–Albright Syndrome 1165
Lee S. Weinstein

CHAPTER 66
Osteogenesis Imperfecta 1177
David W. Rowe

CHAPTER 67
Hereditary Deficiencies in Vitamin D Action 1195
Uri A. Liberman

CHAPTER 68
Oncogenic Osteomalacia 1209
Kenneth W. Lyles

CHAPTER 69
Osteopetrosis 1217
L. Lyndon Key, Jr., and William L. Ries

CHAPTER 70
Hypophosphatasia: Nature's Window on Alkaline Phosphatase Function in Man 1229
Michael P. Whyte

CHAPTER 71
Paget's Disease of Bone 1249
Frederick R. Singer and G. David Roodman

CHAPTER 72
Genetic Determinants of Bone Mass and Osteoporotic Fracture 1259
Stuart H. Ralston

CHAPTER 73
Pathophysiology of Osteoporosis 1275
Gideon A. Rodan, Lawrence G. Raisz, and John P. Bilezikian

CHAPTER 74
Evaluation of Risk for Osteoporosis Fractures 1291
Patrick Garnero and Pierre D. Delmas

PART III
PHARMACOLOGICAL MECHANISMS OF THERAPEUTICS

CHAPTER 75
Parathyroid Hormone 1305
A. B. Hodsman, D. A. Hanley, P. H. Watson, and L. J. Fraher

CHAPTER 76
Calcium 1325
Robert P. Heaney

CHAPTER 77
Calcium Receptors as Novel Drug Targets 1339
Edward F. Nemeth

CHAPTER 78
Bisphosphonates: Mechanisms of Action 1361
Herbert Fleisch, Alfred Reszka, Gideon A. Rodan, and Michael Rogers

CHAPTER 79
Fluoride in Osteoporosis 1387
Johann D. Ringe

CHAPTER 80
The Pharmacology of Estrogens in Osteoporosis 1401
Robert Lindsay and Felicia Cosman

CHAPTER 81
Vitamin D and Analogs 1407
Glenville Jones

CHAPTER 82
Molecular and Clinical Pharmacology of Calcitonin 1423
Mone Zaidi, Angela M. Inzerillo, Bruce Troen, Baljit S. Moonga, Etsuko Abe, and Peter Burckhardt

CHAPTER 83
Growth Hormone and Insulin-like Growth Factor-I Treatment for Metabolic Bone Diseases 1441
Clifford J. Rosen

CHAPTER 84
Anabolic Steroid Effects on Bone in Women 1455
Azriel Schmidt, Shun-ichi Harada, and Gideon A. Rodan

CHAPTER 85
Estrogen Effects on Bone in the Male Skeleton 1467
John P. Bilezikian, Sundeep Khosla, and B. Lawrence Riggs

CHAPTER 86
Mechanisms of Exercise Effects on Bone 1477
Robert Marcus

PART IV
METHODS IN BONE RESEARCH

CHAPTER 87
Application of Transgenic Mice to Problems of Skeletal Biology 1491
Stephen Clark and David Rowe

CHAPTER 88
Use of Cultured Osteoblastic Cells to Identify and Characterize Transcriptional Regulatory Complexes 1503
Dwight A. Towler and Rene St. Arnaud

CHAPTER 89
Current Methodologic Issues in Cell and Tissue Culture 1529
Robert J. Majeska and Gloria A. Gronowicz

CHAPTER 90
Biochemical Markers of Bone Metabolism 1543
Markus J. Seibel, Richard Eastell, Caren M. Gundberg, Rosemary Hannon, and Huibert A. P. Pols

CHAPTER 91
Methods and Clinical Issues in Bone Densitometry and Quantitative Ultrasonometry 1573
Glen M. Blake and Ignac Fogelman

CHAPTER 92
Controversial Issues in Bone Densitometry 1587
Paul D. Miller

CHAPTER 93
Macro- and Microimaging of Bone Architecture 1599
Yebin Jiang, Jenny Zhao, and Harry K. Genant

CHAPTER 94
Transilial Bone Biopsy **1625**
Robert R. Recker and
M. Janet Barger-Lux

CHAPTER 95
Animal Models in Osteoporosis Research **1635**
Donald B. Kimmel

CHAPTER 96
Defining the Genetics of Osteoporosis: Using the Mouse to Understand Man **1657**
C. J. Rosen, L. R. Donahue, and W. G. Beamer

Index for Volumes 1 and 2 1667

VOLUME 1

Contributors xiii
Preface to the Second Edition xxi
Preface to the First Edition xxiii

PART I
BASIC PRINCIPLES

A. Cell Biology

CHAPTER 1
Structure and Development of the Skeleton **3**
Sandy C. Marks, Jr., and Paul R. Odgren

CHAPTER 2
Biomechanics of Bone **17**
Dennis M. Cullinane and Thomas A. Einhorn

CHAPTER 3
Embryonic Development of Bone and the Molecular Regulation of Intramembranous and Endochondral Bone Formation **33**
Andrew C. Karaplis

CHAPTER 4
Mesenchymal Stem Cells and Osteoblast Differentiation **59**
Jane E. Aubin and James T. Triffitt

CHAPTER 5
Transcriptional Control of Osteoblast Differentiation and Function **83**
Thorsten Schinke and Gerard Karsenty

CHAPTER 6
The Osteocyte **93**
P. J. Nijweide, E. H. Burger, and J. Klein-Nulend

CHAPTER 7
Cells of Bone: Osteoclast Generation **109**
Naoyuki Takahashi, Nobuyuki Udagawa,
Masamichi Takami, and Tatsuo Suda

CHAPTER 8
Osteoclast Function: Biology and Mechanisms **127**
Kalervo Väänänen and Haibo Zhao

CHAPTER 9
Integrin and Calcitonin Receptor Signaling in the Regulation of the Cytoskeleton and Function of Osteoclasts **141**
Le T. Duong, Archana Sanjay, William Horne,
Roland Baron, and Gideon A. Rodan

CHAPTER 10
Apoptosis in Bone Cells **151**
Brendan F. Boyce, Lianping Xing, Robert J. Jilka,
Teresita Bellido, Robert S. Weinstein,
A. Michael Parfitt, and Stavros C. Manolagas

CHAPTER 11
Involvement of Nuclear Architecture in Regulating Gene Expression in Bone Cells **169**
Gary S. Stein, Jane B. Lian, Martin Montecino,
André J. van Wijnen, Janet L. Stein,
Amjad Javed, and Kaleem Zaidi

B. Biochemistry

CHAPTER 12
Type I Collagen: Structure, Synthesis, and Regulation **189**
Jerome Rossert and Benoit de Crombrugghe

CHAPTER 13
Collagen Cross-Linking and Metabolism 211
Simon P. Robins and Jeffrey D. Brady

CHAPTER 14
Bone Matrix Proteoglycans and Glycoproteins 225
Pamela Gehron Robey

CHAPTER 15
Osteopontin 239
Masaki Noda and David T. Denhardt

CHAPTER 16
Bone Proteinases 251
Richard C. D'Alonzo, Nagarajan Selvamurugan, Stephen M. Krane, and Nicola C. Partridge

CHAPTER 17
Integrins and Other Cell Surface Attachment Molecules of Bone Cells 265
Michael A. Horton, Stephen A. Nesbitt, Jon H. Bennett, and Gudrun Stenbeck

CHAPTER 18
Intercellular Junctions and Cell–Cell Communication in Bone 287
Roberto Civitelli, Fernando Lecanda, Niklas R. Jørgensen, and Thomas H. Steinberg

C. Bone Remodeling and Mineral Homeostasis

CHAPTER 19
Histomorphometric Analysis of Bone Remodeling 303
Susan M. Ott

CHAPTER 20
Phosphorus Homeostasis and Related Disorders 321
Marc K. Drezner

CHAPTER 21
Magnesium Homeostasis 339
Robert K. Rude

CHAPTER 22
Metals in Bone: Aluminum, Boron, Cadmium, Chromium, Lead, Silicon, and Strontium 359
Felix Bronner

CHAPTER 23
Biology of the Extracellular Ca^{2+}-Sensing Receptor (CaR) 371
Edward M. Brown

D. The Hormones of Bone

CHAPTER 24
Receptors for Parathyroid Hormone (PTH) and PTH-Related Peptide 389
Thomas J. Gardella, Harald Jüppner, F. Richard Bringhurst, and John T. Potts, Jr.

CHAPTER 25
Parathyroid Hormone: Molecular Biology 407
Justin Silver, Tally Naveh-Many, and Henry M. Kronenberg

CHAPTER 26
Parathyroid Hormone–Receptor Interactions 423
Michael Chorev and Michael Rosenblatt

CHAPTER 27
Actions of Parathyroid Hormone 463
Janet M. Hock, Lorraine A. Fitzpatrick, and John Bilezikian

CHAPTER 28
Renal and Skeletal Actions of Parathyroid Hormone (PTH) and PTH-Related Protein 483
F. Richard Bringhurst and Gordon J. Strewler

CHAPTER 29
Physiological Actions of Parathyroid Hormone (PTH) and PTH-Related Protein: Epidermal, Mammary, Reproductive, and Pancreatic Tissues 515
John J. Wysolmerski, Andrew F. Stewart, and T. John Martin

CHAPTER 30
Vascular, Cardiovascular, and Neurological Actions of Parathyroid-Related Protein 531
Thomas L. Clemens and Arthur E. Broadus

CHAPTER 31
1α,25(OH)$_2$Vitamin D$_3$: Nuclear Receptor Structure (VDR) and Ligand Specificities for Genomic and Rapid Biological Responses 545
Anthony W. Norman

CHAPTER 32
Vitamin D Gene Regulation 573
Sylvia Christakos

CHAPTER 33
Photobiology and Noncalcemic Actions of Vitamin D 587
Michael F. Holick

CHAPTER 34
Structure and Molecular Biology of the Calcitonin Receptor 603
Deborah L. Galson and Steven R. Goldring

CHAPTER 35
Calcitonin Gene Family of Peptides: Structure, Molecular Biology, and Effects 619
Kenneth L. Becker, Beat Müller, Eric S. Nylén, Régis Cohen, Jon C. White, and Richard H. Snider, Jr.

CHAPTER 36
Amylin and Calcitonin Gene-Related Peptide 641
Ian R. Reid and Jill Cornish

E. Other Systemic Hormones That Influence Bone Metabolism

CHAPTER 37
Estrogens and Progestins 655
David Rickard, Steven A. Harris, Russell Turner, Sundeep Khosla, and Thomas C. Spelsburg

CHAPTER 38
Selective Estrogen Receptor Modulators 677
Douglas B. Muchmore and Geoffrey Greene

CHAPTER 39
Mechanisms of Estrogen Action in Bone 693
Roberto Pacifici

CHAPTER 40
Thyroid Hormone and Bone 707
Paula H. Stern

CHAPTER 41
Clinical and Basic Aspects of Glucocorticoid Action in Bone 723
Barbara E. Kream and Barbara P. Lukert

CHAPTER 42
Effects of Diabetes and Insulin on Bone Physiology 741
Johan Verhaeghe and Roger Bouillon

CHAPTER 43
Androgens: Receptor Expression and Steroid Action in Bone 757
Kristine M. Wiren and Eric S. Orwoll

CHAPTER 44
Kinins and Neuro-osteogenic Factors 773
Ulf H. Lerner and Pernilla Lundberg

F. Local Regulators

CHAPTER 45
The Role of Insulin-like Growth Factors and Binding Proteins in Bone Cell Biology 801
Cheryl A. Conover and Clifford Rosen

CHAPTER 46
Platelet-Derived Growth Factor and the Skeleton 817
Ernesto Canalis and Sheila Rydziel

CHAPTER 47
Fibroblast Growth Factor (FGF) and FGF Receptor Families in Bone 825
Marja M. Hurley, Pierre J. Marie, and Robert Z. Florkiewicz

Index for Volumes 1 and 2 853

Contributors

Numbers in parentheses indicate the volume and pages on which the authors' contributions begin.

Etsuko Abe (2:1423)
Departments of Medicine and Geriatrics, Mount Sinai Bone Program, Mount Sinai School of Medicine, and Bronx Veterans Affairs Geriatrics Research Education and Clinical Center (GRECC), New York, New York 10029

Andrew Arnold (2:1017)
Center for Molecular Medicine and Division of Endocrinology and Metabolism, University of Connecticut School of Medicine, Farmington, Connecticut 06030

Jane E. Aubin (1:59)
Department of Anatomy and Cell Biology, University of Toronto, Toronto, Ontario, Canada M5S 1A8

M. Janet Barger-Lux (2:1625)
Osteoporosis Research Center, Creighton University, Omaha, Nebraska 68131

Roland Baron (1:141)
Department of Cell Biology and Orthopedics, Yale University School of Medicine, New Haven, Connecticut 06510

W. G. Beamer (2:1657)
The Jackson Laboratory, Bar Harbor, Maine 04609

Kenneth L. Becker (1:619)
Veterans Affairs Medical Center and George Washington University, School of Medicine, George Washington University, Washington, DC 20422

Teresita Bellido (1:151)
Division of Endocrinology and Metabolism, Center for Osteoporosis and Metabolic Bone Diseases, Central Arkansas Veterans Healthcare System, University of Arkansas for Medical Sciences, Little Rock, Arkansas 72205

Jon H. Bennett (1:265)
Department of Oral Pathology, Eastman Dental Institute, London WC1X 8LD, United Kingdom

Michael Chorev (1:423)
Division of Bone and Mineral Metabolism, Charles A. Dana and Thorndike Memorial Laboratories, Department of Medicine, Beth Israel Deaconess Medical Center and Harvard Medical School, Boston, Massachusetts 02215

Sylvia Christakos (1:573)
Department of Biochemistry and Molecular Biology, University of Medicine and Dentistry of New Jersey, New Jersey Medical School, Newark, New Jersey 07103

Roberto Civitelli (1:287)
Departments of Medicine and Cell Biology and Physiology, Division of Bone and Mineral Diseases, Washington University School of Medicine and Barnes-Jewish Hospital, St. Louis, Missouri 63110

Stephen Clark (2:1491)
Department of Genetics and Developmental Biology, University of Connecticut Health Center, Farmington, Connecticut 06030

Thomas L. Clemens (1:531)
Division of Endocrinology & Metabolism, University of Cincinnati College of Medicine, Cincinnati, Ohio 45267

Régis Cohen (1:619)
University of Paris, Hôpital Avicenne, Bobigny, France

Cheryl A. Conover (1:801)
Mayo Clinic and Foundation, Rochester, Minnesota 55905

Jill Cornish (1:641)
Department of Medicine, University of Auckland, Auckland, New Zealand

Felicia Cosman (2:1401)
Helen Hayes Hospital, West Haverstraw, New York 10993; and Department of Medicine, Columbia University, New York, New York 10027

Gilbert J. Cote (2:1067)
Department of Endocrine Neoplasia and Hormonal Disorders, University of Texas M.D. Anderson Cancer Center, Houston, Texas 77030

Dennis M. Cullinane (1:17)
Department of Orthopaedic Surgery, Boston University Medical Center, Boston, Massachusetts 02118

Richard C. D'Alonzo (1:251)
Department of Physiology and Biophysics, Robert Wood Johnson Medical School, Piscataway, New Jersey 08854

Benoit de Crombrugghe (1:189)
University of Texas M.D. Anderson Cancer Center, Houston, Texas 77030

Pierre D. Delmas (2:1291)
INSERM Unit 403, Hôpital E. Herriot, and Synarc, Lyon 69003, France

David T. Denhardt (1:239)
Department of Cell Biology and Neuroscience, Rutgers University, Piscataway, New Jersey

L. R. Donahue (2:1657)
The Jackson Laboratory, Bar Harbor, Maine 04609

Marc K. Drezner (1:321)
Department of Medicine, Section of Endocrinology, Diabetes, and Metabolism, University of Wisconsin, Madison, Wisconsin 53792

Le T. Duong (1:141)
Department of Bone Biology and Osteoporosis, Merck Research Laboratories, West Point, Pennsylvania 19486

Richard Eastell (2:1543)
Clinical Sciences Center, Northern General Hospital, Sheffield S5 7AU, United Kingdom

Thomas A. Einhorn (1:17)
Department of Orthopaedic Surgery, Boston University Medical Center, Boston, Massachusetts 02118

Ghada El-Hajj Fuleihan (2:1031)
Calcium Metabolism and Osteoporosis Program, American University of Beirut, Beirut 113-6044, Lebanon

Alberto Falchetti (2:1047)
Department of Internal Medicine, University of Florence, 6-50139 Florence, Italy

Lorraine A. Fitzpatrick (1:463)
Department of Medicine, Mayo Clinic and Foundation, Rochester, Minnesota 55905

Herbert Fleisch (2:1361)
University of Berne, Berne CH-3008, Switzerland

Robert Z. Florkiewicz (1:825)
Ciblex Corporation, San Diego, California 92121

Ignac Fogelman (2:1573)
Department of Nuclear Medicine, Guy's Hospital, London SE1 9RT, United Kingdom

L. J. Fraher (2:1305)
Department of Medicine and the Lawson Health Research Institute, St. Joseph's Health Centre, and the University of Western Ontario, London, Ontario, Canada N6A 4V2

Robert F. Gagel (2:1067)
Division of Internal Medicine, University of Texas M.D. Anderson Cancer Center, Houston, Texas 77030

Deborah L. Galson (1:603)
Department of Medicine, Harvard Medical School, and Division of Rheumatology, Beth Israel Deaconess Medical

Center, and the New England Baptist Bone & Joint Institute, Boston, Massachusetts 02215

Thomas J. Gardella (1:389)
Departments of Medicine and Pediatrics, Endocrine Unit, Harvard Medical School, Massachusetts General Hospital, Boston, Massachusetts 02129

Patrick Garnero (2:1291)
INSERM Unit 403, Hôpital E. Herriot, and Synarc, Lyon 69003, France

Harry K. Genant (2:1599)
Osteoporosis and Arthritis Research Group, Department of Radiology, University of California, San Francisco, San Francisco, California 94143

Matthew T. Gillespie (2:943)
St. Vincent's Institute of Medical Research, Fitzroy, Victoria 3065, Australia

Steven R. Goldring (1:603)
Department of Medicine, Harvard Medical School, and Division of Rheumatology, Beth Israel Deaconess Medical Center, and the New England Baptist Bone & Joint Institute, Boston, Massachusetts 02215

David Goltzman (2:1079)
Calcium Research Laboratory, Royal Victoria Hospital, Montreal, Quebec, Canada H3A 1A1

Geoffrey Greene (1:677)
Ben May Institute for Cancer Research, University of Chicago, Chicago, Illinois 60637

Gloria A. Gronowicz (2:1529)
Department of Orthopaedics, University of Connecticut School of Medicine, Farmington, Connecticut 06032

Theresa A. Guise (2:1093)
Department of Medicine, University of Texas Health Science Center, San Antonio, Texas 78284

Caren M. Gundberg (2:1543)
Department of Orthopedics and Rehabilitation, Yale University School of Medicine, New Haven, Connecticut 06520

D. A. Hanley (2:1305)
Division of Endocrinology and Metabolism, Faculty of Medicine, University of Calgary, Calgary, Alberta, Canada

Rosemary Hannon (2:1543)
Division of Clinical Sciences (NGHT), University of Sheffield, Northern General Hospital, Sheffield S5 7AU, United Kingdom

Shun-ichi Harada (2:883; 2:1455)
Department of Bone Biology and Osteoporosis Research, Merck Research Laboratories, West Point, Pennsylvania 19486

Steven A. Harris (1:655)
Bayer Corporation, West Haven, Connecticut 04516

John R. Harrison (2:979)
Department of Orthodontics, University of Connecticut Health Center, Farmington, Connecticut 06030

Robert P. Heaney (2:1325)
Creighton University, Omaha, Nebraska 68178

Hunter Heath III (2:1031)
Lilly Research Laboratories, Eli Lilly and Company, Indianapolis, Indiana 46285

Janet E. Henderson (2:1079)
Department of Medicine, Lady Davis Institute, Montreal, Quebec, Canada H3T 1E2

Geoffrey N. Hendy (2:1017)
Calcium Research Laboratory, Royal Victoria Hospital, and Departments of Medicine and Physiology, McGill University, Montreal, Quebec, Canada H3A 1A1

Janet M. Hock (1:463)
Department of Anatomy and Cell Biology, Indiana University School of Medicine, Indianapolis, Indiana 46202

A. B. Hodsman (2:1305)
Department of Medicine and the Lawson Health Research Institute, St. Joseph's Health Centre, and the University of Western Ontario, London, Ontario, Canada N6A 4V2

Willy Hofstetter (2:943)
Department of Clinical Research, Group for Bone Biology, University of Berne, CH-3010 Berne, Switzerland

Michael F. Holick (1:587)
Boston University School of Medicine, Boston, Massachusetts 02118

William Horne (1:141)
Department of Cell Biology and Orthopedics, Yale University School of Medicine, New Haven, Connecticut 06510

Mark C. Horowitz (2:961)
Departments of Orthopaedics and Rehabilitation, Yale University School of Medicine, New Haven, Connecticut 06520; and the Department of Medicine, The University of Connecticut Health Center, Farmington, Connecticut 06032

Michael A. Horton (1:265)
Department of Medicine, Bone and Mineral Center, The Rayne Institute, University College London, London WC1E 6JJ, United Kingdom

Maria M. Hurley (1:825)
Department of Medicine, Division of Endocrinology and Metabolism, The University of Connecticut Health Center, Farmington, Connecticut 06032

Angela M. Inzerillo (2:1423)
Departments of Medicine and Geriatrics, Mount Sinai Bone Program, Mount Sinai School of Medicine, and Bronx Veterans Affairs Geriatrics Research Education and Clinical Center (GRECC), New York, New York 10029

Amjad Javed (1:169)
Department of Cell Biology and UMass Cancer Center, University of Massachusetts Medical School, Worcester, Massachusetts 01655

Yebin Jiang (2:1599)
Osteoporosis and Arthritis Research Group, Department of Radiology, University of California, San Francisco, San Francisco, California 94143

Robert L. Jilka (1:151)
Division of Endocrinology and Metabolism, Center for Osteoporosis and Metabolic Bone Diseases, Central Arkansas Veterans Healthcare System, University of Arkansas for Medical Sciences, Little Rock, Arkansas 72205

Glenville Jones (2:1407)
Department of Biochemistry, Queen's University, Kingston, Ontario, Canada K7L 3N6

Nikklas R. Jørgensen (1:287)
Osteoporosis Research Clinic, Copenhagen University Hospital, Hvidovre DK-2650, Denmark

Harald Jüppner (1:389; 2:1117)
Department of Medicine, Endocrine Unit, and MassGeneral Hospital for Children, Massachusetts General Hospital, and Harvard Medical School, Boston, Massachusetts 02114

Andrew C. Karaplis (1:33)
Department of Medicine and Lady Davis Institute for Medical Research, Division of Endocrinology, Sir Mortimer B. Davis–Jewish General Hospital, McGill University, Montreal, Quebec, Canada H3T 1E2

Gerard Karsenty (1:83)
Baylor College of Medicine, Houston, Texas 77030

L. Lyndon Key, Jr. (2:1217)
Department of Pediatrics, General Clinical Research Center, Medical University of South Carolina, Charleston, South Carolina 29425

Sundeep Khosla (1:655; 2:1467)
Department of Internal Medicine, Division of Endocrinology and Metabolism, Mayo Clinic and Foundation, Rochester, Minnesota 55905

Donald B. Kimmel (2:1635)
Department of Bone Biology and Osteoporosis Research, Merck Research Laboratories, West Point, Pennsylvania 19486

J. Klein-Nulend (1:93)
Department of Oral Cell Biology, ACTA-Vrije Universiteit, 1081 BT Amsterdam, The Netherlands

Stephen M. Krane (1:251)
Department of Medicine, Harvard Medical School, Boston, Massachusetts 02114

Barbara E. Kream (1:723)
Department of Medicine, Division of Endocrinology and Metabolism, University of Connecticut Health Center, Farmington, Connecticut 06030

Richard Kremer (2:1079)
Calcium Research Laboratory, Royal Victoria Hospital, Montreal, Quebec, Canada H3A 1A1

Henry M. Kronenberg (1:407)
Endocrine Unit, Massachusetts General Hospital, Harvard Medical School, Boston, Massachusetts 02114

Fernando Lecanda (1:287)
Department of Histology and Pathology, University of Navarra, Pamplona, Spain

Ulf H. Lerner (1:773)
Department of Oral Cell Biology, Umeå University, and Centre for Musculoskeletal Research, National Institute for Working Life, S-901 87 Umeå, Sweden

Michael A. Levine (2:1137)
Department of Pediatrics, Division of Pediatric Endocrinology, The Johns Hopkins University School of Medicine, Baltimore, Maryland 21287

Jane B. Lian (1:169)
Department of Cell Biology and UMass Cancer Center, University of Massachusetts Medical School, Worcester, Massachusetts 01655

Uri A. Liberman (2:1195)
Division of Endocrinology and Metabolism, Rabin Medical Center, Beilinson Campus, and Department of Physiology and Pharmacology, Sackler Faculty of Medicine, Tel Aviv University, Petach Tikvah 49100, Israel

Robert Lindsay (2:1401)
Helen Hayes Hospital, West Haverstraw, New York 10993; and Department of Medicine, Columbia University, New York, New York 10027

Joseph A. Lorenzo (2:961)
Departments of Orthopaedics and Rehabilitation, Yale University School of Medicine, New Haven, Connecticut 06520; and the Department of Medicine, The University of Connecticut Health Center, Farmington, Connecticut 06032

Barbara P. Lukert (1:723)
Division of Endocrinology, Metabolism, and Genetics, University of Kansas Medical Center, Kansas City, Kansas 66103

Pernilla Lundberg (1:773)
Department of Oral Cell Biology, Umeå University, and Centre for Musculoskeletal Research, National Institute for Working Life, S-901 87 Umeå, Sweden

Kenneth W. Lyles (2:1209)
GRECC, Veterans Affairs Medical Center, and Department of Medicine, Sarah W. Stedman Center for Nutritional Studies, Duke University Medical Center, Durham, North Carolina 27710

Iain MacIntyre (2:995)
Division of Pharmacology, William Harvey Research Institute, St. Bartholomew's and the Royal London School of Medicine and Dentistry, London EC1M 6BQ, United Kingdom

Robert J. Majeska (2:1529)
Leni and Peter W. May Department of Orthopaedics, Mount Sinai School of Medicine, New York, New York 10029

Lucia Mancini (2:995)
Division of Pharmacology, William Harvey Research Institute, St. Bartholomew's and the Royal London School of Medicine and Dentistry, London EC1M 6BQ, United Kingdom

Stavros C. Manolagas (1:151)
Division of Endocrinology and Metabolism, Center for Osteoporosis and Metabolic Bone Diseases, Central Arkansas Veterans Healthcare System, University of Arkansas for Medical Sciences, Little Rock, Arkansas 72205

Robert Marcus (2:1477)
Aging Study Unit, Geriatrics Research, Education, and Clinical Center, Veterans Affairs Medical Center, Palo Alto, California 94304

Pierre J. Marie (1:825)
INSERM Unit 349, Lariboisiere Hospital, 75475 Paris, France

Sandy C. Marks, Jr. (1:3)
Department of Cell Biology, University of Massachusetts Medical School, Worcester, Massachusetts 01655

T. John Martin (1:515)
St. Vincent's Institute of Medical Research, Fitzroy, Victoria 3065, Australia

Stephen J. Marx (2:1047)
Metabolic Diseases Branch, National Institute of Diabetes and Digestive and Kidney Diseases, National Institutes of Health, Bethesda, Maryland 20892

Paul D. Miller (2:1587)
University of Colorado Health Sciences Center and Colorado Center for Bone Research, Lakewood, Colorado 80227

Kohei Miyazono (2:929)

Preface to the Second Edition

The success of the first edition of *Principles of Bone Biology* clearly indicated that this text met an important need in our field. Well-worn copies (often with a cracked spine!) can be found on the shelves of bone biology research laboratories and offices throughout the world. We knew from the outset that undertaking the first edition would include a commitment to producing a second one. Advances in bone biology over the past five years have moved forward at a dizzying pace, clearly justifying the need for a second edition at this time. The elucidation of the molecular interactions between osteoblasts and osteoclasts is one of many examples documenting this point. Studies of animals in which critical genes have been deleted or over-expressed have produced some surprises and added still further complexity to what we have already recognized as an extremely complex regulatory system controlling the development and maintenance of skeletal structures. These and many other advances have provided the background for further development of effective therapeutic approaches to metabolic bone diseases.

In preparing the second edition, we have asked all authors to provide extensive revisions of their chapters. Additionally, the second edition features new authors who have written 10 new chapters. Some chapters from the first edition have been consolidated or otherwise reconfigured to keep the total number of chapters essentially the same as in the first edition. Although the number of chapters and their organizational structure has been retained, the extraordinary amount of new information has led to an increase in size of many of the chapters along with more extensive referencing. As a result, the substantially larger second edition is being published in two volumes. Each volume contains a full table of contents and full indexing to help the reader find specific information. The somewhat smaller individual volumes should be easier to handle and hold up better to the extensive use we expect from readers.

As was the case in the first edition, we asked our authors to meet a tight schedule so that the text would be as up-to-date as possible. We are indebted to our many authors who successfully met this challenge. The updated chapters as well as the new ones have, therefore, been written in such a way that the newest and most exciting breakthroughs in our field are still fresh. This task could not have been completed without the help of the staff at Academic Press. We acknowledge, in particular, Jasna Markovac and Mica Haley. They have been enormously helpful in all phases of this effort.

We have enjoyed very much the task of bringing this second edition to you. We trust that this second edition will be even more useful to you than the first. Enjoy the book!

Preface to the First Edition

The world of modern science is undergoing a number of spectacular events that are redefining our understanding of ourselves. As with any revolution, we should take stock of where we have been, where we are, and where we are going. Our special world of bone biology is participating in and taking advantage of the larger global revolution in modern science. Often with shocking but delightful suddenness, we are gaining new insights into difficult issues, discovering new concepts to explain old observations, developing new approaches to perennial mysteries, and applying novel technological advances from other fields to our own. The pace with which the bone world is advancing is impressive not only to the most ardent optimists, who did not expect so much so soon, but also to the more sober minded who, only several years ago, would have brushed off the notion that progress could come with such lightening speed.

The rationale for this book is rooted in the recognition of the revolution in bone biology. We need a new repository of knowledge, bringing us both to the core and to the edge of our universe. Our goal is to provide complete, truly up-to-date, and detailed coverage of this exciting and rapidly developing field. To achieve this, we assembled experts from all over the world and asked them to focus on the current state of knowledge and the prospects for new knowledge in their area of expertise. To this end, *Principles of Bone Biology* was conceived. It is designed to be useful to students who are becoming interested in the field and to young investigators at the graduate or postgraduate level who are beginning their research careers. It is also designed for more established scientists who want to keep up with the changing nature of our field, who want to mine this lode to enrich their own research programs, or who are changing their career direction. Finally, this book is written for anyone who simply strives for greater understanding of bone biology.

This book is intended to be comprehensive but readable. Each chapter is relatively brief. The charge to each author has been to limit size while giving the reader information so complete that it can be appreciated on its own, without necessary recourse to the entire volume. Nevertheless, the book is also designed with a logic that might compel someone to read on, and on, and on!

The framework of organization is fourfold. The first 53 chapters, in a section titled "Basic Principles," cover the cells themselves: the osteoblast, the osteoclast, and the osteocyte; how they are generated; how they act and interact; what turns them on; what turns them off; and how they die. In this section, also, the biochemistry of collagenous and noncollagenous bone proteins is covered. Newer understandings of calcium, phosphorus, and magnesium metabolism and the hormones that help to control them, namely, parathyroid hormone, vitamin D metabolites, calcitonin, and related molecules, are presented. A discussion of other systemic and local regulators of bone metabolism completes this section.

The second section of this book, "Molecular Mechanisms of Metabolic Bone Diseases," is specifically devoted to basic mechanisms of a variety of important bone diseases. The intention of these 17 chapters is not to describe the diseases in clinical, diagnostic, or therapeutic terms but rather to illustrate our current understanding of underlying mechanisms. The application of the new knowledge summarized in Part I to pathophysiological, pathogenetic, and molecular mechanisms of disease has relevance to the major metabolic bone disorders such as osteoporosis, primary hyperparathyroidism, and hypercalcemia of malignancy as well as to the more uncommon disorders such as familial benign hypocalciuric hypercalcemia, pseudohypoparathyroidism, and osteopetrosis.

The third section of this book, "Pharmacological Mechanisms of Therapeutics," addresses the great advances that have been made in elucidating how old and new drugs act to improve abnormalities in bone metabolism. Some of these drugs are indeed endogenous hormones that under

specified circumstances are useful therapies: estrogens, vitamin D, calcitonin, and parathyroid hormone are representative examples. Others agents such as the bisphosphonates, fluoride, and calcium are reviewed. Finally, agents with therapeutic potential but still in development such as calcimimetics, insulin-like growth factors, transforming growth factor, bone morphogenetic protein, and fibroblast growth factor are presented with a view to the future. The intent of this 12-chapter section is not to provide step-by-step "how-to" instructions for the clinical uses of these agents. Such prescribing information for established therapies is readily found in other texts. Rather, the underlying mechanisms by which these agents are currently believed to work is the central point of this section.

The fourth and final section of this book, "Methods in Bone Research," recognizes the revolution in investigative methodologies in our field. Those who want to know about the latest methods to clone genes, to knock genes out, to target genes, and to modify gene function by transfection and by transcriptional control will find relevant information in this section. In addition, the selection and characteristics of growth conditions for osteoblastic, osteoclastic, and stem cells; animal models of bone diseases; assay methodologies for bone formation and bone resorption and surrogate bone markers; and signal transduction pathways are all covered. Finally, the basic principles of bone densitometry and bone biopsies have both investigative and clinical relevance. This 15-chapter section is intended to be a useful reference for those who need access to basic information about these new research technologies.

The task of assembling a large number of international experts who would agree to work together to complete this ambitious project was formidable. Even more daunting was the notion that we would successfully coax, cajole, and otherwise persuade authors of 97 chapters to complete their tasks within a six-month period. For a book to be timely and still fresh, such a short time leash was necessary. We are indebted to all the authors for delivering their chapters on time.

Finally, such a monumental undertaking succeeds only with the aid of others who helped conceive the idea and to implement it. In particular, we are grateful to Jasna Markovac of Academic Press, who worked tirelessly with us to bring this exciting volume to you. We also want to thank Tari Paschall of Academic Press, who, with Jasna, helped to keep us on time and on the right course. We trust our work will be useful to you whoever you are and for whatever reason you have become attracted to this book and our field. Enjoy the book. We enjoyed editing it for you.

CHAPTER 48

Vascular Endothelial Growth Factors

Shun-ichi Harada* **and Kenneth A. Thomas†**

**Department of Bone Biology and Osteoporosis Research and †Department of Cancer Research, Merck Research Laboratories, West Point, Pennsylvania 19486*

Introduction

The evolution of complex animal life has depended on the development of many adaptations. One of the most apparent of these is a vascular system that allows cells within an organism to have continuous access to an adequate supply of oxygen and nutrients and a means by which potentially toxic by-products of metabolism can be removed. In addition, the vascular network provides an efficient means for the transport of hormones that coordinate rapid physiologic responses and of immune cells that help combat invading pathogens and remove cellular debris. Virtually all organs, including bone, contain a vascular system that develops during early embryogenesis. Even the few adult tissues that have either only a marginal or no vascular supply, such as hyaline cartilage and the cornea, were vascularized during their development, later becoming avascular by a controlled regression of many or all of the original vessels.

The vascular system is lined from the interior of the heart to the smallest capillaries by a unique cell type denoted the vascular endothelial cell. The stability of the vascular system is reflected by very low vascular endothelial cell proliferation rates corresponding to intervals of years between rounds of division for each cell. Despite this general mitotic quiescence, endothelial cells can respond rapidly and robustly to appropriate mitogenic stimuli. The growth of new blood vessels, or angiogenesis, is typically initiated by the migration of vascular endothelial cells from existing capillaries and smaller venules and is sustained by mitosis of these cells. In healthy adults, however, little spontaneous angiogenesis appears to occur, except during the female estrus cycle and to support tissue repair.

The molecular mechanisms by which growth, maintenance, and remodeling of the vascular system are controlled have been elucidated in increasing detail over the past two decades. Protein mitogens, including several members of the fibroblast growth factor family, have been described that can induce mitosis and migration of a variety of cells in culture, including vascular endothelial cells, and can promote blood vessel growth *in vivo.* However, in the late 1980s a protein growth factor was discovered that is a uniquely selective mitogen for vascular endothelial cells. It was identified and purified by several groups on the basis of two substantially different activities—the induction of vascular permeability *in vivo* and mitosis of cultured vascular endothelial cells—thereby giving rise to the names vascular permeability factor (VPF) and vascular endothelial growth factor (VEGF). This protein is not only a selective mitogen for vascular endothelial cells, but also is able to promote angiogenesis *in vivo.* An additional intriguing feature of VEGF is the induction of its expression by hypoxia, perhaps one of the earliest recognized inducers of physiologically appropriate angiogenesis.

Because the focus of this chapter and most current work on this protein centers on its control of vascular growth, the VEGF nomenclature will be used. We will provide an overview of this angiogenic protein and of several homologous family members and will describe recent progress in elucidating the biology of this group of protein growth factors, including their relevance to bone biology. Several other reviews on this topic have been published (Thomas, 1996; Ferrara and Davis-Smyth, 1997; Neufeld *et al.,* 1999; Larrivee and Karsan, 2000).

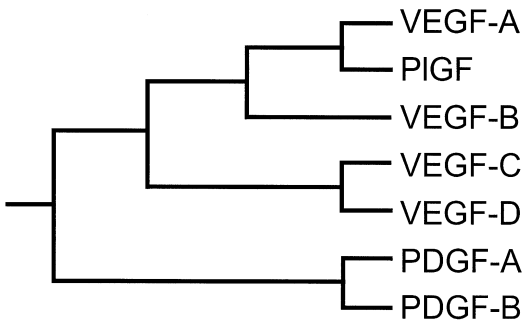

Figure 1 VEGF/PDGF dendritic tree. The degree of relatedness among PDGF and VEGF family members, inferred by their amino acid sequence homology, is shown schematically. VEGF family members are more closely related to each other than to either of the more distantly related PDGFs (Yamada *et al.,* 1997).

VEGF Ligand Family

Soon after the amino acid sequence of VEGF was established, it was recognized to be distantly related to platelet-derived growth factor (PDGF). Subsequently, four additional homologous VEGF family members, denoted placental growth factor (PlGF), VEGF-B, VEGF-C, and VEGF-D were identified. To distinguish the originally discovered VEGF from several other VEGF family members that were subsequently identified, it is now also denoted VEGF-A. On the basis of amino acid sequence homologies, the evolutionary relatedness of these proteins has been inferred (Yamada *et al.,* 1997), as illustrated in Fig. 1. Mapping of the VEGF genes (Vincenti *et al.,* 1996; Mattei *et al.,* 1996; Paavonen *et al.,* 1996; Yamada *et al.,* 1997) has shown them to be dispersed throughout the human genome with no two family members located on the same chromosome. Nevertheless, genomic cloning of each of the VEGF family members has revealed a generally similar exon/intron arrangement (Fig. 2).

Alternative Splicing

Alternative splicing of exons that encode polypeptides within the C-terminal regions of several of these proteins generates distinct isoforms. For example, the VEGF-A gene is composed of eight coding exons (Tischer *et al.,* 1991) with exons 3 and 4 encoding the core PDGF homologous receptor-binding region. Alternative mRNA splicing gives rise to three major and several minor polypeptide isoforms. Inclusion of all eight coding exons ($VEGF_{189}$), removal of exon 6 ($VEGF_{165}$), or deletion of exons 6 and 7 ($VEGF_{121}$) generate the principal isoforms. A less common form is generated by deletion of exon 7 ($VEGF_{145}$). Exons 6 and 7 encode polypeptide regions rich in positively charged basic amino acid residues that promote ionic binding to negatively charged heparan-containing proteoglycans. These

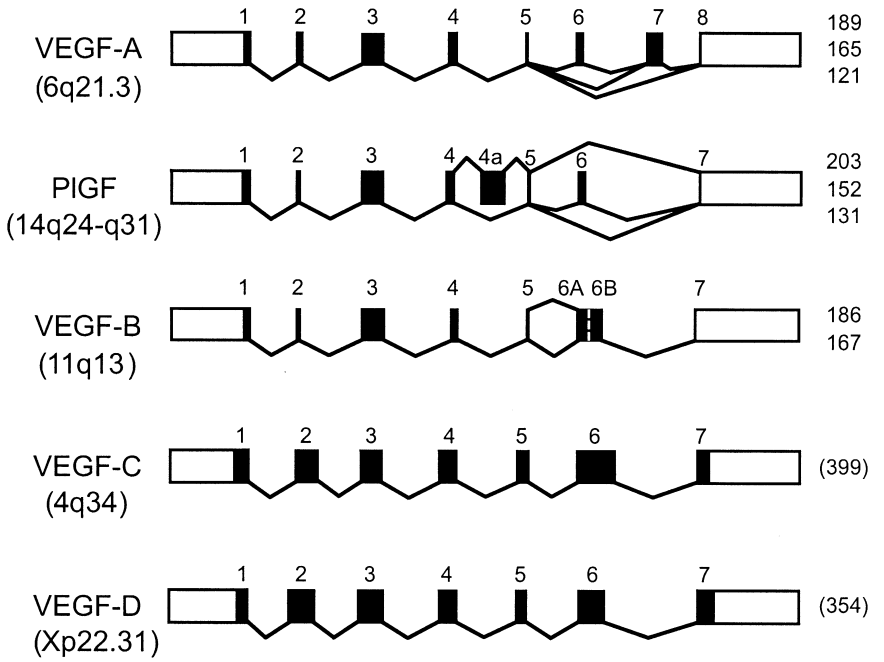

Figure 2 VEGF gene locations and structures. The human chromosomal location is listed in parentheses below the VEGF name. The exon/intron structure of the VEGF family members is shown. Exons are numbered sequentially and connected to represent alternative splicing. The mature amino acid lengths of the isoforms are listed on the right. VEGF-C and -D lengths listed in parentheses are full-length translation products because the secretory signal peptide lengths are not experimentally established and extensive and potentially heterogeneous posttranslation proteolytic modifications occur.

heparan proteoglycans are found on cell surfaces and within extracellular matrices, including basement membranes, upon which many types of cells reside, including vascular endothelial cells. $VEGF_{121}$, devoid of both cationic polypeptides inserts, does not bind to heparan proteoglycans. In contrast, $VEGF_{165}$ binds in a readily reversible manner to these sulfated oligosaccharides and $VEGF_{189}$ binds notably tighter. The heparan sulfate-binding forms can be released from matrix either by cleavage of the heparan oligosaccharide chains with heparanases or by proteolysis of the VEGF carboxy-terminal heparan-binding region by plasmin and perhaps other proteases (Houck *et al.,* 1992).

Somewhat different splicing events also generate three PlGF isoforms that, after removal of the 18 residue secretory leader sequence, contain 131, 152, and 203 amino acid residues (Fig. 2). Again, the shortest form is devoid of C-terminal heparin-binding sequences, whereas the 152 amino acid form contains a 21 residue cationic C-terminal region that promotes heparin binding (Maglione *et al.,* 1993). $PlGF_{203}$ is generated by inclusion of an exon encoding 72 amino acid residues but is devoid of the cationic polypeptide sequence that promotes binding of $PlGF_{152}$ to heparin (Cao *et al.,* 1997).

VEGF-B transcripts are also subject to alternative splicing (Fig. 2). Exon 6 can utilize two different splice acceptor sites (Grimmond *et al.,* 1996; Olofsson *et al.,* 1996). If the internal splice site is used then the 5′ end of this exon (exon 6A) is skipped, resulting in the translation of exons 6B and 7 to encode VEGF-B_{167}. Alternatively, if the splice acceptor at the 5′ end of exon 6 is used then translation proceeds through exon 6A and, in a different reading frame, into exon 6B. Translation is terminated by an in-frame stop codon within the alternative reading frame of exon 6B to generate VEGF-B_{186}. Although exon 7 is still transcribed, it is not translated. The C terminus of VEGF-B_{186} is not homologous to other VEGF sequences. The VEGF-C and VEGF-D genes each contain seven coding exons (Chilov *et al.,* 1997; Rocchigiani *et al.,* 1998). To date, no functional alternative splice forms have been described.

Posttranslational Processing

The primary translation products of all of the VEGF family members contain amino-terminal hydrophobic secretory leader sequences that are proteolytically removed upon secretion. The exact lengths of these leader sequences have not been determined for VEGF-C or -D. All of the VEGFs contain N-glycosylation sites and are secreted as glycoproteins. In addition to alternative splicing, posttranslational limited proteolysis can further modify some of the VEGF isoforms. For example, removal of the cationic C-terminal region from VEGF-A_{189} by urokinase can promote its binding to high-affinity receptors (Plouet *et al.,* 1997). The processing pathway of VEGF-C, shown in Fig. 3, involves the removal of N- and long C-terminal sequences (Joukov *et al.,* 1997) encoded by exons 5–7. Exon 6 generates a silk-like motif, and exons 5 and 7 encode Cys-rich sequences; the functions of these regions are unknown. As described later, receptor binding can be modulated by these proteolytic modifications. Similar proteolytic processing of VEGF-D (Stacker *et al.,* 1999) removes N- and Cys-rich C-terminal regions (Rocchigiani *et al.,* 1998).

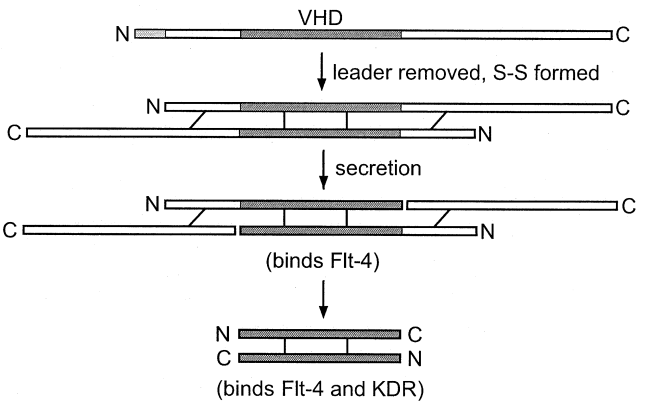

Figure 3 VEGF-C posttranslational processing. The N-terminal secretory leader region is shown in light gray and the VEGF homology domain (VHD) is denoted in dark gray. After secretion, the leader is removed proteolytically and interchain disulfides are made. The chains are cleaved near the C terminus of the VHD domains but the C-terminal extensions are still retained through intersubunit disulfide bonds. These dimers can bind Flt-4 but not KDR. A second set of proteolytic cleavages near the N termini of the two chains generates VEGF-C dimers consisting of the VHD receptor-binding domains that can bind Flt-4 and KDR (Enholm *et al.,* 1998).

VEGF Structure

All of the VEGF family members appear to function as dimers. The crystal structure of the core region of VEGF-A common to all of the receptor-binding isoforms has confirmed the similarity of its tertiary structure (Muller *et al.,* 1997a,b) with that determined previously for PDGF-B. As shown in Fig. 4 (see also color plate), each dimeric subunit is composed of an N-terminal helix that interacts principally with the adjacent subunit and is essential for dimerization (Siemeister *et al.,* 1998) and a central four-stranded β sheet. The subunits are arranged in a side-by-side antiparallel manner. The eight Cys residues within each subunit that are conserved among all VEGF and PDGF homologues participate in three intrasubunit and two intersubunit disulfide bonds. Disulfide bonds between subunits have also been identified in PlGF and VEGF-B (Olofsson *et al.,* 1996), although, surprisingly, nondisulfide-linked homodimers have been proposed to predominant in the mature fully processed forms of VEGF-C (Joukov *et al.,* 1997) and VEGF-D (Stacker *et al.,* 1999). In addition to homodimers, VEGF-A has been shown to form stable disulfide cross-linked heterodimers with PlGF (DiSalvo *et al.,* 1995), VEGF-B (Olofsson *et al.,* 1996), and VEGF-C (Joukov *et al.,* 1997). VEGF/PlGF heterodimers, identified in normal rhesus bronchial epithelial cells (Cao *et al.,* 1996), promote endothelial cell mitosis and migration and are angiogenic *in*

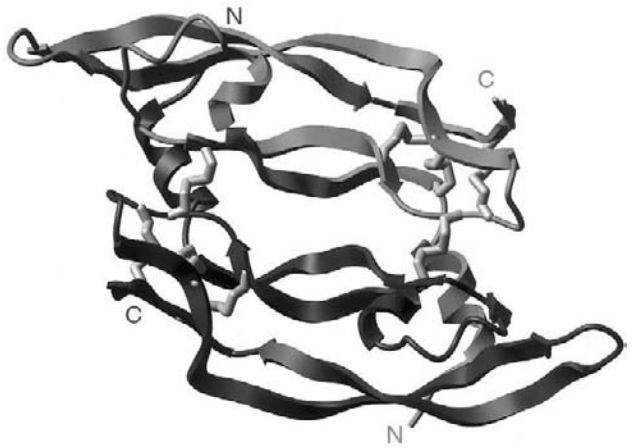

Figure 4 VEGF-A structure. The high-resolution crystal structure of the VEGF-A dimer, corresponding to the 121 isoform, shows the two subunits to be related by a twofold rotation axis perpendicular to the plane of the illustration. Each subunit is composed of four β strands and a single N-terminal α helix that interacts primarily with the adjacent subunit. Each subunit also has eight conserved Cys residues that form three intrachain disulfide bonds near one end of the subunit fold and two interchain disulfide bonds at opposite ends of the fold (Muller *et al.,* 1997a,b). (See also color plate.)

vivo (Cao *et al.,* 1996), albeit with lower specific activities than VEGF-A homodimers.

Viral VEGFs

Two virus-derived proteins have been identified that bind and activate VEGF receptors. The first, denoted VEGF-E, is a dimeric VEGF homologue encoded by an orf virus that normally infects sheep and, with much lower frequency, humans (Lyttle *et al.,* 1994). Infection is characterized by the appearance of highly vascularized edematous dermal lesions. The second is the HIV-1 tat protein (Albini *et al.,* 1996; Mitola *et al.,* 1997), also known as a transactivator of HIV and host genes. The selective advantage provided by the viral acquisition of these genes and retention of their ability to activate VEGF receptors has not been established experimentally.

VEGF Receptor Family

Three homologous transmembrane receptors, denoted Flt-1 (VEGFR-1), KDR/Flk-1 (VEGFR-2), and Flt-4 (VEGFR-3), have been identified that bind with high affinity (K_d ~10–400 p*M*) to different subsets of the known VEGFs (Fig. 5). The cellular responsiveness to different VEGFs is determined principally by the restricted expression of these receptors. Flt-1 is present on many types of endothelial cells, monocytes (Barleon *et al.,* 1996), and dendritic cell progenitors (Wu *et al.,* 1996). The expression of KDR is almost exclusively limited to vascular endothelial cells and their progenitors (Asahara *et al.,* 1997). Flt-4 is expressed primarily by lymphatic endothelial cells. However, during development it is expressed by a subset of

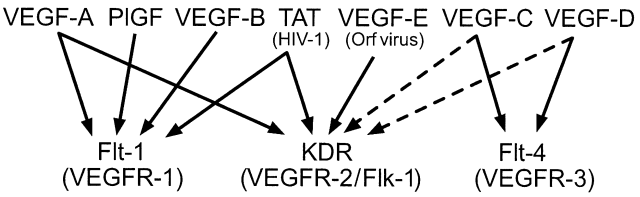

Figure 5 Ligand–receptor-binding selectivity. The seven VEGF ligand family members are listed along the top with arrows pointing to which of the three high-affinity tyrosine kinase receptors they each bind. Dotted arrows from VEGF-C and -D to KDR denote high-affinity binding only following full proteolytic processing. Tat and VEGF-E are HIV-1 and orf vial homologues.

venule vascular endothelial cells that differentiate into lymphatic endothelial cells (Kaipainen *et al.,* 1995).

Receptor Structure and Ligand Interaction

Flt-1, KDR, and Flt-4 have been mapped to human chromosomes 13q12 (Imbert *et al.,* 1994), 4q12 (Spritz *et al.,* 1994; Terman *et al.,* 1992), and 5q33-q35 (Armstrong *et al.,* 1993), respectively. The intron/exon structures of mouse Flt-1 (Kondo *et al.,* 1998) and human KDR have been determined to contain 30 and 28 exons (Yin *et al.,* 1998). Each approximately 1300 amino acid long 200-kDa receptor is composed of seven extracellular immunoglobulin (Ig)-like domains, a single short transmembrane-spanning polypeptide, and an intracellular tyrosine kinase (Fig. 6). The VEGF-binding regions of Flt-1 (Cunningham

	Chromosome	Length (aa)
Flt-1/VEGFR-1	13q12	1338
sFlt-1/sVEGFR-1	13q12	687
KDR/VEGFR-2	4q11-q13	1355
Flt-4/VEGFR-3	5q33-q35	1298

Figure 6 VEGF receptor–ligand complex schematic. As shown in the left most complex, the membrane-spanning tyrosine kinase receptors (Flt-1, KDR, and Flt-4) are composed of seven extracellular immunoglobulin (Ig)-like domains, a single transmembrane-spanning polypeptide, and an intracellular split kinase domain. VEGF binding has been mapped to Ig-like domains 2 and 3. The fourth Ig-like domains appear to interact directly with each other in a ligand-induced receptor dimer. A complex between the truncated soluble Flt-1 receptor and a full-length receptor is shown in the center. The sFlt-1 receptor can form stable homodimers and heterodimers with the corresponding extracellular region of KDR so are thought to be able to form dimers with full-length Flt-1 and KDR. Finally, a VEGF-stabilized dimer of sFlt-1 is shown on the right.

et al., 1997) and KDR (Fuh *et al.,* 1998) have been localized to extracellular Ig-like domains 2 and 3. Deletion of domain 2 in Flt-1 abolishes VEGF-A binding, which can be restored by insertion of domain 2 of KDR. The chimeric receptor exhibits the ligand-binding specificity of KDR rather than Flt-1. The Flt-4 receptor binds VEGF-C and -D with high affinity but not the other VEGF family members, including VEGF-A. Replacement either of the first three domains or of just domain 2 in Flt-4 with the corresponding Flt-1 domains generates chimeric receptors that can bind VEGF-A (Davis-Smyth *et al.,* 1996).

Ligand–Receptor Complex Structure

A crystal structure of VEGF-A bound to domain 2 of Flt-1 (Weismann *et al.,* 1997) has revealed their relative orientations, as illustrated in Fig. 7 (see also color plate), and details of the interaction surface. Both subunits within the VEGF-A homodimer interact with each Flt-1 domain 2 molecule through an interaction surface partitioned approximately 65 and 35% between the two ligand subunits. The interface between VEGF-A and receptor is predominately hydrophobic, as is typical of other protein–protein interactions. It also contains a single buried ion pair between a Flt-1 Arg and a VEGF-A Asp residue and 14 buried water molecules, 7 of which bridge the ligand and receptor. VEGF-A appears to undergo no major conformational change on complex formation. Because the approximately cylindrical VEGF-A dimer can bind a receptor at each end, it promotes Flt-1 receptor dimerization, which is also stabilized by direct contacts between Ig-like domain 4 (Barleon *et al.,* 1997). Similar interactions could occur within KDR and Flt-4 homodimers and Flt-1/KDR heterodimers (Kendall *et al.,* 1996).

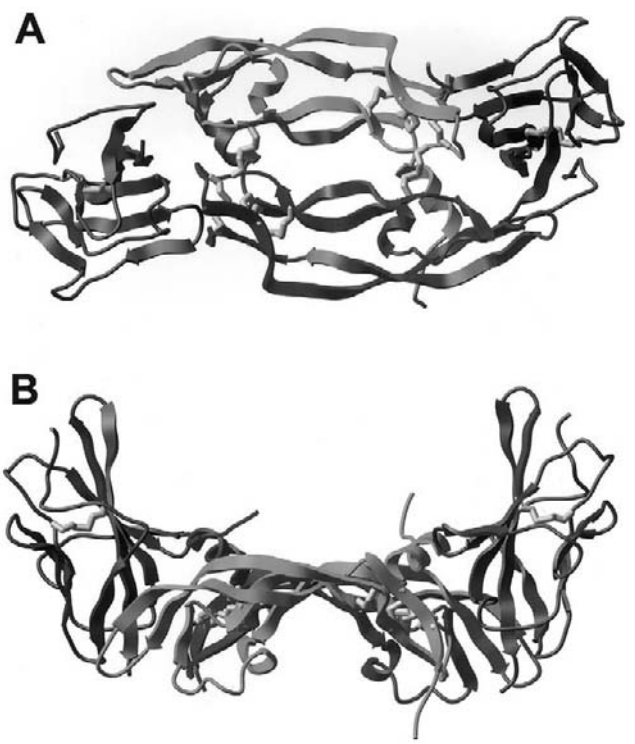

Figure 7 Structure of a complex between VEGF-A and domain 2 of Flt-1. (A) The backbone conformation determined by crystal structure analysis shows the interaction between the ends of the VEGF-A dimer subunits (red and blue) with domain 2 of Flt-1 (green). Both VEGF-A subunits interact with each receptor domain. Additional interactions are thought to occur with domain 3. (B) The same complex rotated 90° (Weismann *et al.,* 1997). (See also color plate.)

Soluble Receptor

A naturally occurring truncated soluble form of the Flt-1 receptor, sFlt-1, contains the N-terminal six Ig-like domains but is devoid of the membrane proximal Ig-like domain, transmembrane polypeptide, and intracellular kinase, all of which are replaced by a unique 31 amino acid sequence (Fig. 6). The soluble receptor is generated by alternative splicing of the Flt-1 primary transcript in which 31 codons of a retained intron are translated through to the first in-frame stop codon (Kendall and Thomas, 1993). It binds VEGF-A, PlGF (Kendall *et al.,* 1994), and presumably VEGF-B and HIV-1 tat with high-affinity characteristic of full-length Flt-1 but, because it is not able to initiate signal transduction, functions as an inhibitor. The sFlt-1 receptor forms VEGF-stabilized homodimers in a manner presumably equivalent to the interactions that stabilize dimerization of the extracellular regions of the full-length Flt-1 receptor. In addition, sFlt-1 can form VEGF-stabilized heterodimers with the corresponding extracellular region of KDR (Kendall *et al.,* 1996). The ability of these extracellular regions to dimerize infers that (1) dimerization of sFlt-1 with either full-length Flt-1 or KDR can abrogate receptor activation in a dominant-negative manner by preventing receptor kinase transphosphorylation as described in the following section on receptor activation and (2) heterodimers can also form between full-length Flt-1 and KDR in a manner analogous to that established to exist between PDGF receptor α and β. Stable expression of sFlt-1 by tumor cells can inhibit their angiogenesis-dependent growth as xenografts *in vivo* (Goldman *et al.,* 1998) consistent with its inhibitory activity *in vitro.*

Additional Receptors

In addition to high-affinity receptors, heparin-binding VEGF isoforms can bind to at least two additional types of lower affinity receptors. Neuropilin-1 (NP-1) is a 130-kDa membrane-bound protein containing a short intracellular tail that can mediate cell adhesion and bind the chemorepellant semaphorin-3A in neuronal cells. NP-1 is also expressed on vascular endothelial cells and has been found to bind the heparin-binding isoforms VEGF-A_{165}, $PlGF_{152}$, VEGF-B_{167}, and VEGF-E, but not the nonheparin-binding isoforms VEGF-A_{121}, $PlGF_{131}$, and $PlGF_{203}$ (Soker *et al.,* 1998; Makinen *et al.,* 1999; Migdal *et al.,* 1998; Wise *et al.,* 1999). The NP-1 receptor enhances the binding of

VEGF-A_{165} to KDR so appears to facilitate its function (Soker *et al.,* 1998). A natural 90-kDa soluble NP-1, generated like sFlt-1 by translation of a retained intron through to the first in-frame stop codon within an alternatively spliced mRNA, is expressed and presumably antagonizes the function of NP-1 (Gagnon *et al.,* 2000). The homologous NP-2, which binds semaphorins-C and -3F, has also been shown to bind VEGF-A_{165} and, in contrast to NP-1, VEGF-A_{145} (Gluzman-Poltorak *et al.,* 2000).

The identity of the heparan sulfate proteoglycans that can bind to the polycationic regions of VEGFs are not yet well characterized. However, one such heparan proteoglycan has been identified as the glycosylphosphatidylinositol-anchored glypican-1 (Gengrinovitch *et al.,* 1999), the only glypican known to be expressed in the vascular system. As expected, it binds VEGF-A_{165} but not VEGF-A_{121}.

The biologic relevance of the differential binding of VEGF isoforms to neuropilins and heparan proteoglycans is not entirely clear. They could increase the apparent potency of isoforms of VEGF to which they bind by partitioning them to the cell surface, thereby increasing their local concentration in the vicinity of the high-affinity receptor. In addition, they could participate in ternary complexes with VEGF ligands and high-affinity receptors. The affinity of VEGF-A_{165} and, to an even greater degree, VEGF-A_{189} for heparan proteoglycans in extracellular matrices, including basement membranes, could contribute to their localization within the vicinity where they are expressed. Another possible function of the binding of the longer forms of VEGF to heparan proteoglycans might be to sequester them to extracellular matrices in a form that can later be mobilized rapidly by lysis with either proteoglycanases or proteases (Houck *et al.,* 1992). The more readily diffusible VEGF-A_{121} might contribute to establishing chemotactic gradients for endothelial cells and, if cleared more rapidly, might provide transient stimulation.

Receptor Activation

The binding of VEGF to its high-affinity receptors can increase receptor tyrosine kinase catalytic activity and trigger the activation of signal transduction proteins by binding to receptor phosphotyrosine residues.

Tyrosine Kinase Activity

Ligand-mediated dimerization of high-affinity transmembrane growth factor receptors brings the intracellular tyrosine kinase domains into close proximity where they can effectively transphosphorylate each other on specific tyrosine residues. The consequence of this receptor transphosphorylation has been shown to increase the effective activity of the kinase and to trigger the binding of downstream signal transduction proteins. The details of VEGF receptor kinase structure and function are becoming available. A crystal structure of a modified form of the KDR kinase, in which 50 of 68 amino acid residues in the long "kinase insert loop" were removed to facilitate crystallization, has been determined (McTigue *et al.,* 1999). Like other receptor tyrosine kinases, it is formed of two domains with the active site in between them as shown in Fig. 8 (see also color plate). The amino-terminal domain consists of a twisted five-strand antiparallel β sheet and one α helix, whereas the larger C-terminal domain contains two antiparallel β strands and seven helices. Several functionally important loops between elements of secondary structure are present near the catalytic site. The flexible activation loop contains two tyrosine residues at positions 1054 and 1059 that, in the unphosphorylated state, are thought to interfere with substrate binding. Once phosphorylated, the analogous loops of related tyrosine kinases change conformation, perhaps mediated by the interaction of the phosphotyrosine side chains with other surface residues, thereby facilitating the access of ATP and peptide substrates. Phosphorylation of the two tyrosines in this KDR loop increase substrate binding as reflected by lower K_M values, resulting in greater potential catalytic turnover. In contrast, K_{cat}, the intrinsic catalytic activity at saturating substrate concentrations, does not appear to change (Kendall *et al.,* 1999).

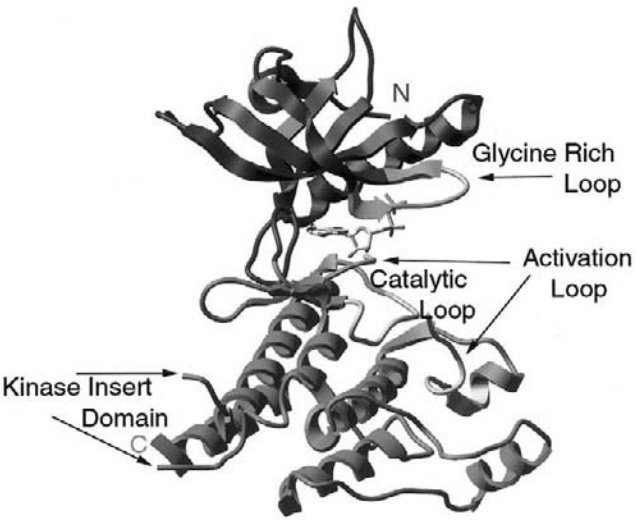

Figure 8 Structure of KDR tyrosine kinase domains. The backbone conformation of the split intracellular tyrosine kinase domain, determined by X-ray crystal structure analysis, is shown with the amino- and carboxy-terminal halves in blue and red, respectively. The amino-terminal half is largely composed of a β sheet with a single long α helix, whereas the C-terminal half consists of mainly α helical structure. ATP- and polypeptide-binding sites are near the interface of these N- and C-terminal folding domains. The glycine-rich, activation and kinase insert loops are shown in yellow, black, and green, respectively. The activation loop contains tyrosine residues 1054 and 1059 that upon autophosphorylation are thought to increase access of substrates to their binding sites. Most of the kinase insert loop was removed to facilitate crystallization so its conformation is largely unknown (McTigue *et al.,* 1999). (See also color plate.)

Signal Transduction Protein Binding

In related kinases, phosphorylated tyrosine residues have been identified not only in activation loops, but also in juxtamembrane regions, kinase insert loops, and sequences C-terminal of the kinase domains. These phosphorylated tyrosine residues can contribute to signal transduction by serving as binding sites for other signal transduction proteins that can themselves become phosphorylated and mediate one or more downstream signaling pathways. In addition to the two phosphorylated tyrosine residues in the activation loop of KDR, two more at positions 951 and 996 (Dougher-Vermazen *et al.,* 1994) in the kinase insert loop and one at position 1175 in the C-terminal region (Igarashi *et al.,* 1998) have been identified and several others likely exist. VEGF-induced phosphorylation of KDR results in the association of signaling adapter proteins, kinases, and phosphatases at several phosphorylated KDR sites. The downstream sequence of steps in signaling has not been fully elucidated and, in fact, several pathway branches corresponding to different biological activities, such as mitosis, survival, migration, vasodilation, permeability, and induction of extracellular matrix degradation, might exist (reviewed in Petrova *et al.,* 1999; Larrivee and Karsan, 2000).

VEGF-A Activities and Mechanisms

The angiogenic activity of VEGF-A has been the focus of much of the effort to understand its biologic activity *in vivo.* VEGF-A is active in animal models of angiogenesis and in peripheral (Baumgartner *et al.,* 1998) and cardiac ischemia (Pearlman *et al.,* 1995). In addition, VEGF has been shown to drive pathologic angiogenesis in neovascular ocular diseases, some types of inflammation, and a wide range of cancers.

The genetics of VEGF-A and its receptors demonstrate their importance in normal development. Not only homozygous but also heterozygous gene knockouts are embryonically lethal in mice (Carmeliet *et al.,* 1996; Ferrara *et al.,* 1996). The phenotypes show a noticeable deficit in vascularization in heterozygous mice that is amplified proportionally in homozygotes. This very unusual lethal heterozygous phenotype demonstrates the importance of appropriate VEGF levels for viable embryonic development. Conversely, transgenic expression of VEGF-A under the control of either the keratin K6 or rhodopsin gene regulatory regions results in hypervascular development in the skin (Larcher *et al.,* 1998) and retina (Okamoto *et al.,* 1997), respectively.

Homozygous, but not heterozygous, gene knockouts of the VEGF-A receptors KDR (Shalaby *et al.,* 1995) and Flt-1 (Fong *et al.,* 1995) are each embryonically lethal but with substantially different phenotypes. KDR mouse knockouts exhibit a virtual absence of vascular endothelial cells. In contrast, endothelial cell-lined vessels are present in Flt-1 knockout mice but appear disorganized. These mice have an increased number of endothelial cell progenitors, thought to be the consequence of an increased commitment to hemangioblast generation that leads to altered vessel pattern formation (Fong *et al.,* 1999). Surprisingly, mice with a homozygous knockout of just the Flt-1 kinase region develop normal vessels and survive. However, they do exhibit strongly suppressed macrophage migration (Hiratsuka *et al.,* 1998) consistent with the known chemotaxic response to VEGF-A and PlGF mediated by Flt-1 (Barleon *et al.,* 1996).

VEGF-A can directly induce the principal activities in the cascade of events culminating in vessel growth, including endothelial cell mitogenesis, survival, adhesion, and migration. In addition, VEGF-A can induce vasodilation and vascular permeability that might contribute to vascular tone and barrier functions. Although the details of how VEGF-A induces these responses are not completely defined, several aspects of the signaling pathways have been identified.

Mitogenesis

Vascular endothelial cell mitogenic activity is mediated predominantly, if not solely, through the KDR receptor, which is almost exclusively expressed on vascular endothelial cells. VEGF induces maximal tyrosine phosphorylation of KDR after 5 min of exposure followed by receptor downregulation, reflecting internalization (Esser *et al.,* 1998). Several growth factors induce mitogenesis by a receptor-mediated cytoplasmic signal transduction cascade that starts with receptor autophosphorylation, which promotes binding of the adapter protein Shc through its SH2 phosphotyrosine-binding domain. Shc then binds a second adapter Grb2 that complexes with SOS, a protein that promotes the release of GDP from inactive Ras and its subsequent binding and activation by GTP. Activated Ras can bind and activate the Ser/Thr kinase Raf that then phosphorylates and activates MEK, a dual kinase that phosphorylates MAPK/ERK on both Thr and Tyr residues. Upon activation, MAPK translocates into the nucleus where it modulates transcriptional events required for the initiation of cell division.

Shc can bind to phosphotyrosine 1175 on activated KDR (Warner *et al.,* 2000), become phosphorylated on Tyr-317, and bind the Grb2-SOS complex (Kroll and Waltenberger, 1997). The Shc-like kinase Sck can also bind to KDR phosphotyrosine 1175 (Igarashi *et al.,* 1998) and might function in a similar manner to that proposed for Shc. Although the level of GTP-bound Ras is increased and the Raf-MEK-MAPK pathway is activated in endothelial cells in response to VEGF-A, surprisingly a dominant-negative Ras has been reported not to block VEGF-induced phosphorylation of MAPK. However, inhibitors of protein kinase C (PKC) do significantly reduce the MEK activation of MAPK and subsequent DNA synthesis (Takahashi *et al.,* 1999).

The Raf-MEK-MAPK downstream pathway could be activated by an alternate upstream pathway starting with the activation of the c-Src tyrosine kinase upon binding to an unidentified phosphotyrosine on KDR and the binding of phospholipase Cγ (PLCγ) through the VEGF-receptor-associated protein (VRAP), an adapter protein that binds through its central SH2 domain to KDR phosphotyrosine 951 (Wu *et al.,* 2000b). PLCγ is then activated by tyrosine phosphorylation that occurs, at least in part, by KDR-activated c-Src (He *et al.,* 1999). Activated PLCγ hydrolyzes the membrane-anchored phosphatidylinositol 4,5-bisphosphate (PIP_2), generating water-soluble inositol 1,4,5-trisphosphate (IP_3) and the membrane product diacylglycerol (DAG). IP_3 binds and activates an IP_3-gated Ca^{2+} release channel in the endoplasmic reticulum, resulting in the release of Ca^{2+} that, either directly or through promotion of calmodulin binding to target proteins, can modulate multiple cellular processes. Elevated Ca^{2+} can also alter PKC so that it translocated to the membrane where it is activated by binding to DAG. Exactly how PKC activates Raf is not yet established.

Ca^{2+} released by PLCγ-generated IP_3 can also activate endothelial cell nitric oxide synthase (eNOS) (He *et al.,* 1999) at least, in part, by promoting calmodulin binding to it. Nitric oxide (NO) can activate guanylate cyclase, thereby generating cGMP that can activate protein kinase G (PKG) by binding to four sites on its regulatory subunit. The Ser/Thr PKG can in turn bind and activate Raf that, as described earlier, stimulates the MEK-MAPK mitogenic pathway (Hood and Granger, 1998; Parenti *et al.,* 1998). In this manner, VEGF-stimulated growth of endothelial cells is also dependent on NO generated by eNOS.

KDR might also be able to initiate negative feedback control of its activation. In response to VEGF-A stimulation, GAP, a protein that decreases Ras activity by accelerating the hydrolysis of Ras-bound GTP to GDP, also becomes phosphorylated and complexes either directly or indirectly to KDR (Guo *et al.,* 1995). In addition, the tyrosine phosphatases SHP-1 and SHP-2 associate with phosphorylated KDR presumably through their SH2 domains. Tumor necrosis factor (TNF), which diminishes VEGF-stimulated KDR activity, appears to do so by promoting the association of SHP-1 with KDR (Guo *et al.,* 2000).

Cell Survival

VEGF-A promotes the survival of vascular endothelial cells under a variety of stresses, such as serum starvation in culture (Gerber *et al.,* 1998). This survival activity is also mediated through KDR. The regulatory subunit of phosphatidylinositol 3-kinase (PI3K), an enzyme that phosphorylates phosphatidylinositols at the D3 position of the inositol ring, has two SH2 domains that can bind directly to receptor phosphotyrosine residues and becomes phosphorylated in response to VEGF, which allows it to recruit the PI3K catalytic subunit (Thakker *et al.,* 1999). In addition, the KDR adapter protein VRAP can bind constitutively to PI3K (Wu *et al.,* 2000). The 3-phosphoinositol product of VEGF-activated PI3K can bind and activate PKB/Akt, a Ser/Thr kinase that inhibits the activity of caspases, proteases that mediate programmed cell death or apoptosis. Akt is also activated by PI3K-dependent phosphorylation possibly mediated through the 3-phosphoinositol-mediated activation of another kinase. Therefore, VEGF binding to KDR induces both proliferation and survival. Inhibition of survival signals can initiate the apoptosis of vascular endothelial cells, leading to vascular regression.

Adhesion and Migration

VEGF-A promotes adhesion of endothelial cells to extracellular matrix components by several integrins, including the vitronectin-binding $\alpha v\beta 5$ and $\alpha v\beta 3$ integrins (Byzova *et al.,* 2000; Friedlander *et al.,* 1995; Watanabe and Dvorak, 1997). Phosphorylated KDR forms complexes either directly or indirectly with the $\beta 3$ integrin subunit (Soldi *et al.,* 1999) and activates $\alpha v\beta 3$ ligand binding by an activated KDR-dependent mechanism involving PI3K and Akt (Byzova *et al.,* 2000). VEGF induces increased endothelial cell expression of the $\alpha 1\beta 1$ and $\alpha 2\beta 1$ collagen (Senger *et al.,* 1997) and $\alpha v\beta 3$ vitronectin (Senger *et al.,* 1996)-binding integrins and the intracellular adhesion molecule ICAM-1 (Radisavljevic *et al.,* 2000). VEGF also induces the phosphorylation of focal matrix adhesion kinase and the focal adhesion-associated component paxillin (Abedi and Zachary, 1997; Wu *et al.,* 2000a) and promotes actin reorganization (Morales-Ruiz *et al.,* 2000).

The growth of new capillaries requires vascular endothelial cell migration, which depends on the modulation of matrix attachment, intercellular adhesion, and cytoskeletal proteins. VEGF increases the migration of vascular endothelial cells probably initiated through its activation of KDR, as the KDR-specific ligand VEGF-E promotes endothelial cell migration (Meyer *et al.,* 1999). Within 15 to 60 min of VEGF-induced KDR phosphorylation, the cellular adherens junction components VE-cadherin, β-catenin, plakoglobulin, and p120 become tyrosine phosphorylated, perhaps loosening cell–cell contacts to facilitate not only mitosis but also migration and possibly permeability (Esser *et al.,* 1998). VEGF also promotes endothelial cell migration by activating $\alpha v\beta 3$, $\alpha v\beta 5$, $\alpha 5\beta 1$, and the collagen-binding $\alpha 2\beta 1$ integrins (Byzova *et al.,* 2000). Although the details of the migration signaling pathway are not yet clear, it appears to require active PI3K (Byzova *et al.,* 2000), Akt, and eNOS (Morales-Ruiz *et al.,* 2000; Radisavljevic *et al.,* 2000). Activated Akt phosphorylates eNOS Ser-1177, which appears to be necessary and, in fact, sufficient to induce endothelial cell migration (Dimmeler *et al.,* 2000). NO has been shown to promote spontaneous oscillations in matrix adhesion that, in the presence of a gradient of a chemotactic factor such as VEGF-A, could

facilitate directed migration (Eisei *et al.,* 1998). VEGF-A, PlGF, and HIV-1 Tat can also promote the migration of monocytes. Although these cells are devoid of KDR, they do have Flt-1 (Barleon *et al.,* 1996) to which these ligands bind and can induce phosphorylation (Gruber *et al.,* 1995; Mitola *et al.,* 1997).

Vasodilation

VEGF-A induces NO-dependent vasodilation *in vivo* that contributes to the control of vascular tone. The receptor responsible for this response might not be KDR. An antibody that specifically activates KDR but not Flt-1 was reported to elicit an angiogenic but not a vasodilatory response (Malavaud *et al.,* 1997). The NO activation pathway appears to be similar, at least in part, to that contributing to mitogenesis (Papapetropoulos *et al.,* 1997). The activation of Akt also leads to the production and release of the potent vasodilator nitric oxide. Endothelial NO formation activates smooth muscle guanylate cyclase, causing cGMP production. VEGF also leads to the activation of phospholipase A_2, resulting in a three- to four-fold increase of the vasodilator prostacyclin (PGI_2) within 45 to 60 min (He *et al.,* 1999).

Vascular Permeability

As described previously, VEGF-A was originally identified in tumor ascites fluid as vascular permeability factor (VPF) on the basis of its activity in a guinea pig vascular dye extravasation assay (Senger *et al.,* 1983). Increased permeability promotes the leakage of fibrinogen and other plasma proteins that are proposed to provide a matrix that facilitates the migration of endothelial cells (Dvorak *et al.,* 1995). NO also appears to function in the signaling pathway mediating permeability by the activation of guanylyl cyclase to produce cGMP, which activates PKG (Wu *et al.,* 1996). NO donors and prostacyclin analogs administered together but not alone increase VEGF-induced permeability, whereas the cyclooxygenase (COX) inhibitor indomethacin inhibits VEGF-induced vascular permeability, thus implicating prostaglandin metabolites as contributors to this activity (Murohara *et al.,* 1998).

Expression of VEGFs and VEGFRs

The primary cellular source of VEGF-A appears to be cells other than those of the vascular endothelium. This paracrine expression of VEGF allows various organs and tissues to control their vascularization and is under the control of a variety of mediators, including other growth factors and cytokines, oncogenes, hormones, metabolites, and, notably, hypoxia. Induction of transcription and stabilization of mRNA can each contribute to increased VEGF-A protein expression.

Growth Factors and Cytokines

VEGF-A expression can be increased by the mitogenic growth factors PDGF (Brogi *et al.,* 1994; Mukhopadhyay *et al.,* 1995; Stavri *et al.,* 1995), bFGF (Koochekpour *et al.,* 1995), FGF-7/KGF (Frank *et al.,* 1995), EGF (Sone *et al.,* 1996), heregulin β1 (Yen *et al.,* 2000), and IGF-1 (Warren *et al.,* 1996) in a variety of normal and malignant cultured cells. It is also induced by TGF-β1 (Pertovaara *et al.,* 1994), TNFα (Frank *et al.,* 1995), IL-1β (Li *et al.,* 1995), and IL-6 (Cohen *et al.,* 1996). In the case of PDGF, induction of expression has been mapped to GC-rich Sp1 recognition sites within the VEGF-A promoter (Finkenzeller *et al.,* 1997). The ability of these factors to induce VEGF-A expression could explain reported angiogenic activities of some of them that do not directly stimulate endothelial cell mitosis.

Oncogenes

Several downstream signal transduction-related oncogenes have also been shown to induce VEGF-A expression. Mutant K-Ras (Okada *et al.,* 1998), H-Ras (Rak *et al.,* 1995), and v-Raf (Grugel *et al.,* 1995) each induce VEGF-A expression in different transformed tumor cells that presumably contribute to tumor angiogenesis. Wild-type p53, p73, the von Hippel-Lindau (VHL) suppressor gene, and Smad4 can each inhibit VEGF-A promoter activity. Inactivating p53 mutations increase VEGF-A expression (Mukhopadhyay *et al.,* 1995) and also diminish expression of the antiangiogenic protein thrombospondin (Volpert *et al.,* 1997). Similarly, silencing of the p53-like p73 gene by hypermethylation in some leukemias and lymphomas can eliminate its ability to repress VEGF-A promoter function (Salimath *et al.,* 2000). Loss of function of the VHL tumor suppressor protein that normally represses VEGF-A transcription by directly binding the promoter-binding Sp1 transcription factor results in increased VEGF expression (Mukhopadhyay *et al.,* 1997). Deletion of Smad4, a protein in the TGF-β1 signal transduction pathway that is lost at high frequency in pancreatic and gastrointestinal cancers, results in increased VEGF-A expression and diminished expression of thrombospondin (Schwarte-Waldhoff *et al.,* 2000).

Hormones and Metabolites

Hormones, including estrogen (Hyder *et al.,* 1996), testosterone (Joseph *et al.,* 1997; Ruohola *et al.,* 1999), and thyroid-stimulating hormone (Kanji *et al.,* 1995), can each stimulate VEGF-A expression. Progesterone and several synthetic progestins used in oral contraceptives also increase VEGF expression, whereas the antiprogestin RU-486 blocks induction by progesterone (Hyder *et al.,* 1998). VEGF-A transcription but not stabilization is also induced by the prostaglandin PGE_2 (Harada *et al.,*

1994). COX-2, an inducible cyclooxygenase that converts arachidonate to PGH_2, the substrate for a set of prostaglandin synthases, is overexpressed in benign polyps and colon cancers (Williams *et al.,* 1999). COX-2 inhibitors have been shown to retard tumor growth in mice. Fibroblasts from COX-2 homozygous knockout mice exhibit a greater than 90% reduction in their ability to produce VEGF-A, and decreased vascular density was observed in tumors grown in these mice (Williams *et al.,* 2000).

Advanced glycation end products (AGE) generated by the nonenzymatic covalent attachment of glucose to proteins, a diagnostic indicator of diabetes, also increase VEGF-A expression. AGE bovine serum albumin (BSA), but not nonglycated BSA, induces VEGF-A expression in a dose-dependent manner (Lu *et al.,* 1998; Yamagishi *et al.,* 1997). Glucose deprivation has also been shown to increase VEGF-A expression (Shosuke *et al.,* 1998; Shweiki *et al.,* 1995) and mRNA stabilization (Stein *et al.,* 1995). Therefore, lack of glucose control leading either to elevated or to reduced levels can result in the induction of VEGF-A expression. For example, AGEs are elevated in the ocular vitreous in proliferative diabetic retinopathy (Hirata *et al.,* 1997) and increase VEGF expression within the retina (Lu *et al.,* 1998). VEGF-A appears to be the primary angiogenic agent supporting retinal and choroidal neovascularization and diabetic retinopathy (Aiello *et al.,* 1994) and, perhaps, age-related macular degeneration (Kliffen *et al.,* 1997).

Hypoxia

Perhaps the most intriguing inducer of VEGF-A expression is hypoxia (Shweiki *et al.,* 1992). Decreased pO_2 has been long recognized to induce compensatory neovascular growth. Cultured cells can increase VEGF-A production from 10- to 50-fold by lowering the O_2 from 21 to 3% or less. Although detectable VEGF-A is not typically expressed by endothelial cells, it can be induced in hypoxia (Namiki *et al.,* 1995; Nomura *et al.,* 1995). Induction of VEGF expression is also seen in ischemic normal and cancerous tissues *in vivo.* Hypoxia is now known to increase VEGF-A production both by inducing transcription (Finkenzeller *et al.,* 1995; Levy *et al.,* 1995; Liu *et al.,* 1995) and by stabilizing its mRNA (Ikeda *et al.,* 1995; Shima *et al.,* 1995; White *et al.,* 1995) from a half-life of 30–45 min under normoxia to 6–8 hr under hypoxia (2% O_2). Induction of transcription presumably occurs through activation of 5′ DNA promoters and enhancers, whereas stability elements appear to reside in the 3′-untranslated region of VEGF-A mRNA. A functional 47-bp transcriptional, hypoxia-inducing factor-1 (HIF-1)-binding site is located nearly 1 kb 5′ of the VEGF-A transcriptional initiation site (Forsythe *et al.,* 1996). Hypoxia-stabilizing elements are located in the 3′-untranslated region (UTR) (Levy *et al.,* 1996b) within which are found three AU-rich sequences that form hypoxia-inducible RNA–protein complexes (Claffey *et al.,* 1998; Levy *et al.,* 1996a) containing the HuR protein (Levy *et al.,* 1998).

Other VEGF Family Members

Less is known of the functions of the more recently identified VEGF family members. Although none of these mammalian homologues appear to be as critical to the induction and maintenance of the vasculature as VEGF-A, they might be equally important for other crucial biologic activities.

PlGF and VEGF-B

The biologic function of the PlGF, which binds selectively to Flt-1, is not yet clear. PlGF is highly expressed not only in placenta (Cao *et al.,* 1997; Maglione *et al.,* 1993), but also in vascular endothelial cells (Yonekura *et al.,* 1999). PlGF typically exhibits little, if any, vascular endothelial cell mitogenic activity (Birkenhager *et al.,* 1996; DiSalvo *et al.,* 1995) consistent with the Flt-1 knockout phenotype. The function of the Flt-1 receptor is also somewhat enigmatic. Although it binds VEGF-A with even higher affinity than KDR, it does not appear to efficiently mediate a significant mitogenic response in most *in vitro* endothelial cell assays. The Flt-1-specific ligand PlGF has been observed to increase VEGF mitogenic activity *in vitro* so this receptor has been proposed to function as a decoy, sequestering low concentrations of VEGF that might otherwise stimulate KDR inappropriately (Park *et al.,* 1994). However, chimeric CSF-1 extracellular/VEGFR intracellular receptor transfectants provide a somewhat different interpretation. An intracellular KDR chimera mediates proliferation whereas a Flt-1 chimera does not. The Flt-1 chimera inhibited the activity of a cotransfected KDR chimera. Therefore, the cytoplasmic regions of Flt-1 appear to antagonize KDR responses (Rahimi *et al.,* 2000).

PlGF acting through Flt-1 can induce the migration of monocytes (Barleon *et al.,* 1996) and endothelial cell expression of procoagulant tissue factor (Clauss *et al.,* 1996). A chimeric Flt-1 in which the juxtamembrane region is replaced by the corresponding sequence from KDR confers endothelial cell migration but not proliferation activity (Gille *et al.,* 2000). VEGF-A/PlGF heterodimers, identified in tumor cells (DiSalvo *et al.,* 1995) and rhesus brochus epithelial cells (Cao *et al.,* 1996), can induce migratory and mitogenic activity in endothelial cells, albeit with lower specific activities than VEGF-A homodimers, and are angiogenic *in vivo* (Birkenhager *et al.,* 1996). Perhaps these heterodimers function by promoting the formation of KDR/Flt-1 receptor heterodimers. VEGF-B, also acting through Flt-1, can induce the expression of endothelial cell urokinase and plasminogen activator inhibitor-I, suggesting that it might have a role in the regulation of extracellular matrix degradation, cell adhesion, and migration (Olofsson *et al.,* 1998).

VEGF-C and VEGF-D

VEGF-C binds and activates lymphatic endothelial cell Flt-4 (Joukov *et al.,* 1996; Lee *et al.,* 1996) and drives lymphatic endothelial cell mitosis (Fitz *et al.,* 1997). The lymphatic system is involved primarily in the drainage of interstitial fluid, immune function, and inflammation. VEGF-C is present in T cells, lymphocytes, and platelets (Wartiovaara *et al.,* 1998). Although VEGF-C transcription is not induced by hypoxia, it can be increased by PDGF, EGF, and TGF-β (Enholm *et al.,* 1997) and by the proinflammatory cytokines IL-1α, IL-1β, and TNFα (Ristimak *et al.,* 1998). Overexpression of VEGF-C in the skin of transgenic mice causes lymphatic, but not vascular, endothelial cell proliferation and vessel enlargement (Jeltsch *et al.,* 1997). A homozygous mouse Flt-4 gene knockout is embryonically lethal with defective blood vessel development and fluid accumulation in the pericardial cavity (Dumont *et al.,* 1998). Primary human lymphoedema, a rare genetic disorder leading to swelling of the extremities, is correlated with mutations that inactivate the tyrosine kinase activity of Flt-4 (Karkkainen *et al.,* 2000). VEGF-C can acquire KDR-binding activity (Joukov *et al.,* 1996), along with corresponding functional increases in endothelial cell migration, proliferation, and vascular permeability (Joukov *et al.,* 1997) by the proteolytic removal of N- and C-terminal regions to generate a core VEGF receptor-binding homology domain similar to that illustrated in Fig. 4. The close homologue VEGF-D (Orlandini *et al.,* 1996), expressed in greatest abundance in lung, also binds to Flt-4 and can be activated proteolytically to bind KDR (Stacker *et al.,* 1999). Therefore, undefined proteolytic activation mechanisms can confer vascular angiogenic activity on these lymphangiogenic agents.

VEGF and Bone/Cartilage

Angiogenesis and Chondrogenesis/Osteogenesis

Both intramembranous and endochondral bone formations are associated with the formation of blood vessels, which leads to the recruitment of hematopoietic osteoclast–precursor cells as well as perivascular osteoblast–progenitor cells. Intramembraneous ossification is characterized by capillary ingrowth into a mesenchymal condensation of embryonic connective tissue cells, followed by differentiation of these mesenchymal cells into osteoblasts that secrete collagen and noncollagenous matrix proteins, resulting in mineralized bone matrix termed woven bone, which is then remodeled into lamellar bone.

Endochondral Osteogenesis

Although it has been assumed that angiogenesis is essential for osteogenesis, until recently the functional role of angiogenesis in osteogenesis, as well as molecular mechanisms involved in this process, was not well understood. In contrast to intramembranous ossification, which takes place mainly during development, endochondral bone formation occurs in development as well as in pathological osteogenesis such as fracture repair and ectopic ossification. Angiogenesis has been implicated in endochondral bone formation, where avascular cartilage is replaced by bone, thus becoming one of the most highly vascularized tissues. Endochondral osteogenesis is initiated by the condensation of mesenchymal cells that later differentiate into chondrocytes, which secrete cartilaginous matrix and form cartilage. As the cartilage area enlarges through cell proliferation and matrix deposition, chondrocytes become further differentiated. Compression and hypertrophy lead to calcified cartilage and apoptotic cell death. One of the earliest events that leads to replacement of calcified cartilage by mineralized bone matrix is the invasion of blood vessels from the metaphysis into calcified cartilage, resulting in the recruitment of cells involved in resorption of the calcified cartilage and deposition of bone matrix. Angiogenesis has also been implicated in pathological osteogenesis processes such as fracture repair (Ferguson *et al.,* 1999; Glowacki, 1998), ossification of articular cartilage (Fenwick *et al.,* 1999), distraction osteogenesis (Jazrawi *et al.,* 1998; Li *et al.,* 1999), and ectopic bone formation (Harada *et al.,* 1995).

A number of angiogenic factors are expressed in bone and cartilage, including FGFs (De Luca and Baron, 1999), members of the bone morphogenetic protein (BMP)/growth and differentiation factor (GDF) family (Bailon Plaza *et al.,* 1999; Carey and Liu, 1995; Sakou *et al.,* 1999), TGF-β (Serra *et al.,* 1999), IGF-I (Shinar *et al.,* 1993), EGF, PDGF, and CYR61 (Babic *et al.,* 1998). In addition, a number of antiangiogenic factors are also present in cartilage, such as thrombospondins, chondromodulin-I (Hiraki *et al.,* 1997), and developmental endothelial locus-1 (Hidai *et al.,* 1998), implicated in the avascular nature of cartilage. However, the role of these factors in angiogenesis in bone and cartilage is not clear.

Expression of VEGF-A in skeletal tissue and bone cells was first demonstrated *in vitro* in osteoblastic cells and *in vivo* in RNA isolated from bone tissue (Harada *et al.,* 1994). Abundant expression of VEGF-A mRNA and its protein were documented histologically in hypertrophic chondrocytes of adult rat tibiae, adult mouse tibiae (Gerber *et al.,* 1999), avian growth plate (Carlevaro *et al.,* 2000), and fetal human growth plate (Horner *et al.,* 1999). VEGF-A was also expressed in hypertrophic chondrocytes during fracture repair in mice (Ferguson *et al.,* 1999), as well as during ectopic osteogenesis in rats (Harada *et al.,* 1995), but was not observed in resting or proliferating chondrocytes. Expression of VEGF-A was also observed during chondrocyte differentiation *in vitro* in avian chondrocytes (Carlevaro *et al.,* 2000) and in rat chondrocytic cells. These expression patterns of VEGF-A, in combination with the well-documented role of VEGF and its receptors in angiogenesis, strongly implicate VEGF-A in angiogenesis and the blood vessel invasion, essential for endochondral ossification. A number of VEGF antagonists and anti-

bodies are being developed toward the suppression of tumor angiogenesis. One such protein, a chimera containing the three N-terminal extracellular Ig-like domains of soluble Flt-1 fused to an Fc fragment of IgG, was used in mice to address the role of VEGF in endochondral ossification (Gerber *et al.,* 1999; Harper and Klagsbrun, 1999). Treatment of 24-day-old mice with the soluble Flt-1 IgG chimera resulted in marked expansion of the hypertrophic chondrocyte zone and in disorganized blood vessels that failed to invade this region. Neutralization of VEGF action by soluble Flt-1 IgG also results in decreased trabecular bone formation and shortening of the femora, indicating the role of VEGF in endochondral ossification. However, the expression of genes associated with chondrocyte differentiation, i.e., type II and type X collagen, was not altered in these mice, suggesting that the expansion of the hypertrophic chondrocyte zone resulted from the increased life span of terminally differentiated chondrocytes rather than an alteration in the proliferation or maturation of chondrocytes (Gerber *et al.,* 1999; Harper and Klagsbrun, 1999).

The phenotype of the growth plate treated with soluble Flt-1 IgG resembles that of mice with a null mutation of MMP-9/gelatinase B, i.e., expansion due to delayed chondrocyte apoptosis and delayed vascularization and ossification (Vu *et al.,* 1998). MMP-9/gelatinase B is a matrix metalloproteinase highly expressed in TRAP-positive osteoclasts and chondroclasts. A similar growth plate phenotype has also been reported in mice with null mutation of MT1-MMP (Zhou *et al.,* 2000), supporting an essential role for these MMPs in the resorption of calcified cartilage, in neovascularization of calcified cartilage, and in endochondral ossification. In addition, conditional inactivation of VEGF-A alleles in chondrocytes was carried out using the Cre/loxP system in mice expressing Cre-recombinase under the control of the human type II collagen promoter (Haigh *et al.,* 2000). While most mice with deletion of a single VEGF-A allele in Cre-expressing cells died in uterus due to aberrant development of the dorsal aorta, few mice survived and developed an increased hypertrophic zone of the growth plate (Haigh *et al.,* 2000). A similar growth plate phenotype has also been reported in mice exclusively expressing VEGF-A_{120} (mouse isoforms are one amino acid residue shorter than the corresponding human forms) as a result of Cre/loxP-mediated deletion of exons 6 and 7, which encode VEGF-A_{164} and VEGF-A_{188} (Carmeliet *et al.,* 1999). Unlike VEGF-A (-/-) mice, these mice survive until the perinatal period and develop ischemic cardiomyopathy and a growth plate phenotype (Maes *et al.,* 2000).

Taken together, these findings indicate that VEGF-A, expressed in hypertrophic chondrocytes, plays an essential role in endochondral ossification, capillary invasion, chondrocyte apoptosis, and resorption of calcified cartilage by chondroclasts, which also require MMPs expression (Fig. 9).

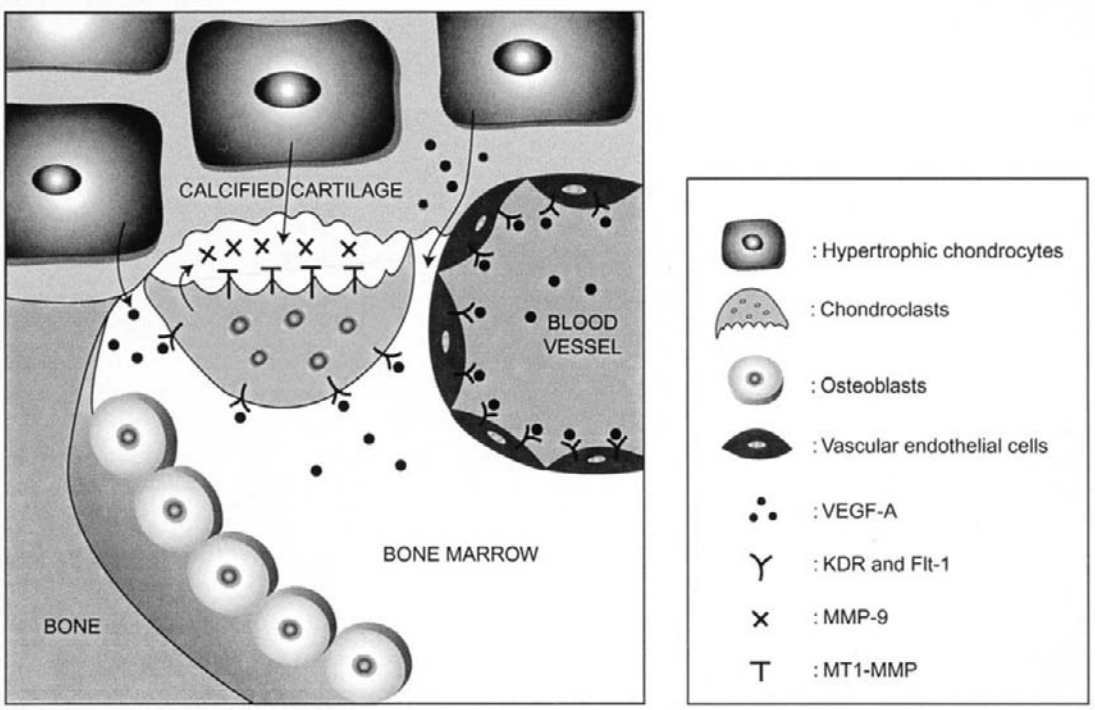

Figure 9 Role of VEGF-A in endochondral osteogenesis. VEGF-A released from hypertrophic chondrocytes induces capillary invasion to calcified cartilage, leading to the recruitment of chondroclasts that resorb calcified cartilage and osteoblasts that generate mineralized bone matrix. These actions of VEGF-A are also required for the death of hypertrophic chondrocytes. MMP-9 and MT1-MMP expressed in chondroclasts are essential for resorption of calcified cartilage as well as for capillary invasion and apoptosis of hypertrophic chondrocytes. VEGF-A may act directly on chondroclasts (and osteoclasts) to induce differentiation, survival, and migration.

Osteoblasts

In contrast to the well-documented role of VEGF-A expression in hypertrophic chondrocytes, a functional role for VEGF-A expression in osteoblasts has not yet been established. VEGF-A mRNA and protein are expressed *in vitro* in primary calvarial osteoblasts and in osteoblastic cell lines (Goad *et al.,* 1996; Harada *et al.,* 1994; Schlaeppi *et al.,* 1997; Steinbrech *et al.,* 1999; Wang *et al.,* 1996). Its expression is upregulated by prostaglandins E_2 and E_1, both inducers of osteogenesis, and is suppressed by dexamethasone, a negative regulator of osteogenesis (Harada *et al.,* 1994). In mouse and human osteoblastic cell lines, VEGF-A mRNA and its protein levels are also induced by other osteogenic factors, such as IGF-I (Goad *et al.,* 1996), TGF-β (Chua *et al.,* 2000; Saadeh *et al.,* 1999), 1,25(OH)$2D_3$ (Schlaeppi *et al.,* 1997; Wang *et al.,* 1996, 1997), endothelin-1 (Kozawa *et al.,* 2000), and bone morphogenetic proteins (Harada *et al.,* 1995; Yeh and Lee, 1999). Expression of VEGF-A is also upregulated by hypoxia via induction of hypoxia-inducible factor-1a, which could also mediate the upregulation of VEGF-A expression by IGF-I (Steinbrech *et al.,* 1999, 2000).

However, in contrast to these *in vitro* observations, analysis of VEGF expression *in vivo* in bone tissue failed to detect high levels of VEGF-A expression in osteoblasts. An experiment using a tail suspension hind limb unloading rat model showed that unloading results in reduction of VEGF expression and blood vessel number and area in tibiae (Barou *et al.,* 2000). Interestingly, mechanical loading rapidly induced angiogenesis (Jazrawi *et al.,* 1998) and the expression of VEGF-A mRNA in a distraction model in rats (unpublished information). Expression of VEGF-A mRNA in adult rat tibia diaphysis is induced rapidly by systemic treatment with PGE_2 (Machwate *et al.,* 1995), implicating the possible mediation of PGE_2 in this effect. Taken together, these observations suggest a possible role for VEGF-A and angiogenesis in bone metabolism changes induced by mechanical stress. Further detailed analyses of VEGF-A expression *in vivo* in osteoblasts, following application of these stimuli, as well as functional studies *in vivo* in animals, using tissue-selective gene targeting or neutralization of VEGF-A, are required to determine the role of VEGF-A and of angiogenesis in mechanical stress-induced bone metabolism and in bone remodeling (Parfitt, 2000).

Osteoclasts

There is increasing evidence for a role of VEGF-signaling pathways in hematopoietic cells. Targeted gene disruption of KDR indicates its potential role in hematopoiesis in addition to vasculogenesis (Shalaby *et al.,* 1997). Detailed *in vitro* analysis documented KDR as a marker for human postnatal hematopoietic cells (Ziegler *et al.,* 1999). In addition, monocyte/macrophage lineage cells are shown to express Flt-1, which could play a role in chemotactic responses (Barleon *et al.,* 1996; Clauss *et al.,* 1996). Expression of neurotropin-1, known to interact with $VEGF_{165}$ but not $VEGF_{121}$, was also reported in bone marrow stromal cells that support hematopoiesis (Tordjman *et al.,* 1999). A report in op/op osteopetrotic mice suggests a novel role for VEGF in osteoclasts derived from hematopoietic precursor cells (Niida *et al.,* 1999). op/op mice develop osteopetrosis due to the absence of the macrophage colony-stimulating factor (M-CSF) essential for osteoclastogenesis and for the generation of monocytes/macrophages (Yoshida *et al.,* 1990). The osteopetrotic phenotype of these mice is found only during their youth (rescuable by a single injection of M-CSF), suggesting the possible compensation by other growth factors or cytokines (Begg *et al.,* 1993). An injection of VEGF-A was found to result in osteoclast differentiation and osteopetrosis rescue in op/op mice (Niida *et al.,* 1999). In addition, neutralization of VEGF-A with either the soluble Flt-1–IgG chimera or the anti-VEGF-A antibody results in loss of osteoclasts in adult op/op mice or in young op/op mice after a single injection of M-CSF. Furthermore, in bone marrow cell cultures, VEGF-A, in combination with RANK ligand, induces the formation of osteoclast-like cells and their survival, indicating that VEGF-A can substitute for M-CSF to stimulate osteoclastogenesis and osteoclast survival (Niida *et al.,* 1999). A similar effect of VEGF-A on osteoclastogenesis has also been reported in a rabbit osteoclast culture system (Nakagawa *et al.,* 2000). Expression of both KDR and Flt-1 is found in osteoclasts isolated from bone tissue and *in vitro* in osteoclast-like cells (Gerber *et al.,* 1999; Nakagawa *et al.,* 2000; Niida *et al.,* 1999). Furthermore, PlGF, which interacts with Flt-1 but not with KDR, was as effective as VEGF-A in osteoclastogenesis in op/op mice, suggesting the involvement of Flt-1 in VEGF effects on osteoclasts (Niida *et al.,* 1999). Interestingly, in mice treated with the soluble Flt-1-IgG chimeric protein, there is a substantial reduction in the number of TRAP-positive chondroclasts at the cartilage–bone junction, suggesting the possible role of VEGF signaling in the recruitment and/or differentiation of chondroclasts essential for cartilage resorption (Gerber *et al.,* 1999) (Fig. 9).

Arthritis

Rheumatoid arthritis (RA) is characterized by chronic joint inflammation and infiltration by activated T cells and macrophages (Feldmann *et al.,* 1996; Feldmann and Maini, 1999). The overgrowth of synovial lesions results in the destruction of articular cartilage and bone. Angiogenesis is an indispensable process in the chronic proliferative synovitis and pannus formation in RA (Koch, 1998; Walsh, 1999). VEGF-A mRNA and protein are highly expressed in subsynovial macrophages and synovial-lining cells of inflammatory joints from RA patients (Ikeda *et al.,* 2000; Lu *et al.,* 2000; Nagashima *et al.,* 1995). Increased levels of VEGF-A protein were also found in synovial fluid, as well as in serum of RA patients, which may correlate with disease activity (Harada *et al.,* 1998; Maeno *et al.,* 1999; Pale-

olog *et al.,* 1998). A report on type II collagen-induced murine arthritis model showed that treatment with soluble Flt-1 linked to polyethylene glycol results in reduced joint inflammation and reduced bone and cartilage destruction (Miotla *et al.,* 2000), suggesting that blockage of VEGF activity could be beneficial in RA. Osteoarthritis (OA) is characterized by a progressive loss of articular cartilage, thickening of the trabeculare of the subchondral bone, and formation of new bone and cartilage, giving rise to osteophytes (McAlindon and Dieppe, 1989). Increased angiogenic activity was documented in articular cartilage from OA patients (Fenwick *et al.,* 1999), suggesting that vascularization could be part of the inflammation and ectopic endochondral ossification in avascular articular cartilage.

Summary

The discovery and initial characterization of the VEGF family of growth factors provide insight into the control of vascular and lymphatic angiogenesis. Vascular angiogenesis clearly contributes to the organization and remodeling of a variety of tissues, including bone. The importance of VEGFs to the growth, remodeling, and repair of bone could provide an important framework in which to appreciate the integrated control of vascular and bone biology.

CHAPTER 49

Transforming Growth Factor-β

L. F. Bonewald

Department of Medicine, Division of Endocrinology and Metabolism, University of Texas Health Science Center at San Antonio, San Antonio, Texas 78284

TGFβ Superfamily

TGFβ1 is the prototype and the founding molecule for the TGFβ superfamily. This family has grown to include more than 40 members, including TGFβ isoforms, activins and inhibins, Mullerian inhibitory substance, growth differentiation factors (GDFs), and an ever increasing number of bone morphogenetic proteins (BMPs). Members of this superfamily appear to mediate many key events in growth and development maintained evolutionarily from fruit flies to mammals. The actions of these proteins appear to be mediated through structurally similar serine/threonine kinase transmembrane receptors.

TGFβ isoforms consist of four distinct proteins: TGFβ1–3 and 5. Mammalian TGFβ1 and chicken TGFβ4 are products of homologous rather than duplicated genes (Burt and Jakowlew, 1992). TGFβ1–3 are expressed differentially in mammalian tissues, and each binds with different affinities to TGFβ receptors and appears to have slightly different biological effects (for review, see Centrella *et al.,* 1994). Greater homology exists between the mature regions as compared with the precursor regions, suggesting that the precursor regions may also provide distinct functions (Graycar *et al.,* 1989) (or the pro-peptides are under less selective pressure). BMPs more closely resemble proteins involved in differentiation during embryogenesis such as *Drosophila decapentaplegic* and Vg-1 than TGFβ. TGFβ will only induce new bone formation when injected in close proximity to bone. Unlike BMPs, TGFβ will not produce bone when injected into ectopic sites (Ozkaynak *et al.,* 1990).

Isoforms of TGFβ

The isoforms of TGFβ have been "lumped" together and their effects on bone generalized: however, the isoforms can have very different effects depending on tissue and receptor expression. This generalization must be kept in mind when reading this chapter. An excellent example of different, opposing, effects of the isoforms can be found in the cranial suture of the rat calvaria where removal of TGFβ-3 results in obliteration of the suture, but is prevented by removing TGFβ-2 (Opperman *et al.,* 1999). In the assays in which the various isoforms have been tested, small variations in biological effects have been observed (for review, see Centrella *et al.,* 1994), however, the dramatic differences in tissue distribution suggest specific functions for each isoform. For example, 80–90% of TGFβ in bone is the TGFβ1 isoform, however, the major form produced in kidney (approximately 50%) is TGFβ2 (Marra *et al.,* 1996) and prostate produces 30 to 70 times more TGFβ2 than 1 (Zhao *et al.,* 1997).

TGFβ isoforms are regulated differently. The promoter regions for TGFβ1, TGFβ2, and TGFβ3 show little similarity (Kim *et al.,* 1989; Malipiero *et al.,* 1990; Lafyatis *et al.,* 1990). TGFβ genes also appear to be regulated post-transcriptionally, which may account for the lack of correlation between mRNA expression and protein secreted from some cells. A 5′-untranslated region of the TGFβ1 gene appears to regulate the translation of TGFβ1 mRNA into protein (Kim *et al.,* 1992).

The various isoforms bind with different affinities to TGFβ receptors. The type II TGFβ receptor has a 100-fold

higher affinity for TGFβ 1 and 3 compared to TGFβ 2 (Lin *et al.,* 1992), whereas the endoglin receptor has much higher affinity for TGFβ 2 than for TGFβ 1 or TGFβ 3 (Cheifetz *et al.,* 1992), and the type III receptor has equal affinity for all three isoforms (Lopez-Casillas *et al.,* 1993). The exchange of amino acids 92–95 of TGFβ 1 for the corresponding amino acids of TGFβ 2 abolishes TGFβ 1 high-affinity binding to the type II receptor (Qian *et al.,* 1996). In a human colon carcinoma cell line that responds to TGFβ 2 but not TGFβ 1, TGFβ 2 but not TGFβ 1 bound to type I receptors (Zhou *et al.,* 1995). Investigators are now involved in unraveling the specificity of each isoform for each receptor by determining receptor- and ligand-binding sites (Burmester *et al.,* 1998).

The three-dimensional structure of the TGFβ1 and β2 isoforms has been determined and has served to be the prototype to determine the structure of the other members of the TGFβ superfamily. The TGFβ2 tertiary structure was determined by X-ray crystallography (Daopin *et al.,* 1992) and the structure of TGFβ1 by nuclear magnetic resonance imaging (Hinck *et al.,* 1996). The shape of TGFβ isoforms has been compared with an outstretched hand with curled fingers. Hydrophobic patches are on the "heel" of the "hand" and on the "fingertips." This is unlike most soluble proteins, which are spherical and have a hydrophobic core. When the two TGF monomers bind together to form the homodimer, the hydrophobic "heel" of one molecule touches the hydrophobic "fingers" of the other molecule. The central core of the hydrophobic molecule contains four molecules of water of unknown function. The other members of the TGFβ superfamily will probably contain this central core. Variable regions between the members of this superfamily appear to be at the tips of the "heel" of the molecule. The TGFβ receptors may bind through the back of the "hand." Several investigators are currently determining the tertiary structure of the receptors alone and bound to ligand. Analysis of the three-dimensional structure of the ligand and its receptors should lead to the production of agonists and antagonists for pharmaceutical use (Hoffman, 1992).

Results of Targeted Disruption of the TGFβ Gene or "KnockOut" Mice

Mice that have the targeted deletion of the genes for each TGFβ isoform have different phenotypes, again supporting the hypothesis that each isoform has specific functions. Interestingly, the deletion of a particular isoform of TGFβ in knockout animals does not appear to be compensated for by the other nondeleted isoforms. Targeted disruption of the TGFβ1 gene in mice results in death due to inflammatory disease (Boivin *et al.,* 1995; Kulkarni *et al.,* 1993; Shull *et al.,* 1992). These mice appear perfectly normal until after weaning when massive infiltration of lymphocytes and macrophages into several organs occurs. This leads to organ failure and death. However, the puzzling component of these studies was that the animals appeared normal until after weaning. The puzzle to the normal appearance and perinatal survival of TGFβ1 null mice was solved by Letterio *et al.* (1994). These investigators determined that TGFβ was being passed from the mother to pups through the placenta and also through breast milk. This resulted in maternal rescue of the TGFβ1 null embryos and newborn. These mice were the first example of a gene knockout experiment that was not equivalent to a protein knockout. To eliminate the effects of multifocal inflammation, TGFβ null deletions were created in severe combined immunodeficiency (SCID) mice (Diebold *et al.,* 1995). The longevity in these mice is increased fivefold, and inflammation is eliminated. T-cell marker expression, elevated during inflammation, such as major histocompatability complex class II and intercellular adhesion molecule I, is normal and cardiac cell proliferation is normal. Although inflammation is absent in immunodeficient TGFβ1 null mice and although they do survive into adulthood, they are 50–80% the size of their TGFβ1-expressing SCID littermates and show a lack of vigor and do not thrive. Therefore, it has been difficult to study the effects of a lack of TGFβ 1 on several developmental systems such as bone. However, these mice do have mineralization defects in their bones and teeth and are smaller than their normal siblings, indicating that TGFβ is important for normal bone development (D'Souza *et al.,* 1998; Geiser *et al.,* 1998).

Mice that lack the TGFβ 2 isoform have a wide range of developmental defects, including cranial defects, cardiac, lung, and urogenital defects (Sanford *et al.,* 1997). Mice lacking TGFβ3 show failure of the palatal shelves to fuse, which leads to cleft palate. No craniofacial abnormalities were observed, suggesting that TGFβ3 affects palatal shelf fusion by an intrinsic, primary mechanism (Proetzel *et al.,* 1995). These studies corroborate those of Brunet *et al.* (1995), who found that antibody and antisense oligonucleotides to TGFβ3 but not TGFβ1 or TGFβ2 prevented normal embryonic palate fusion in the mouse. Clearly, the three TGFβ isoforms play different roles in various tissues. Mice that lack the TGFβ type II receptor die *in utero* of a yolk sac hematopoiesis and vasculogenesis defect (Oshima *et al.,* 1996). These studies, utilizing targeted disruption of genes for TGFβ and receptor, emphasize the importance of these molecules during development.

TGFβs

TGFβ is a potent multifunctional cytokine whose major effects in the body appear to be as a regulator of cell growth, a stimulator of matrix production, and an inhibitor of the immune system. Early attempts to purify bone-derived growth factors resulted in the purification of TGFβ1 and TGFβ2 (for review, see Bonewald and Mundy, 1990). The discovery of large amounts of TGFβ in bone led to the discovery in numerous laboratories that TGFβ is a major player in bone remodeling. Agents important for new

bone formation or maintenance of bone mass appear to increase the amount of TGFβ in bone. For example, bones from ovariectomized rats have less TGFβ than normal rats (Finkelman *et al.,* 1991), vitamin D-deficient rats have less TGFβ than vitamin-repleted animals (Finkelman *et al.,* 1992), and studies using intermittent treatment with parathyroid hormone showing increased bone mass also show increased TGF β (Pfeilschifter *et al.,* 1990). The only other factor that appears to share this characteristic with TGFβ is insulin-like growth factor.

In Vitro Effects of TGFβ on Bone Cells

The bone remodeling process can be broken down arbitrarily into several stages. In the recruitment and chemotactic stage, the precursors for bone-forming cells are recruited to the site for future bone formation. After arriving, these cells will proliferate and then begin to differentiate, at which time the bone-forming cells begin to produce osteoid. The osteoid then becomes mineralized. TGFβ has dramatic effects on each of these stages of the bone remodeling process. TGFβ is a potent chemotactic factor that recruits a number of different cell types to sites of repair and inflammation but also recruits osteoblast precursors to sites of bone formation (Pfeilschifter *et al.,* 1990). The chemotactic epitope of TGFβ has been identified as residues 368 to 374 (Postlethwaite and Seyer, 1995). This synthetic peptide was shown to induce the chemotactic migration of neutrophils, monocytes, and fibroblasts. However, this peptide remains to be tested on osteoblast precursors.

In some osteoblast cultures, TGFβ will stimulate proliferation, whereas in others it will inhibit proliferation (for review, see Bonewald and Mundy, 1990). This is probably due to the stage of differentiation of the osteoblast population and the factors influencing experimental conditions. The major effect of TGFβ on the osteoblast is to cause this cell to differentiate and to become a matrix-producing cell. The two major functions of TGFβ are its effects on cell proliferation and matrix formation. Table I gives a list of proteins that are stimulated by TGFβ and a list of those that are inhibited. As can be seen from the list, proteins that are stimulated mainly appear to be matrix proteins and those that are inhibited appear to be proteases. When isolated calvaria are incubated with TGFβ *in vitro,* an increase in bone matrix formation and the number of osteoblasts is observed (Hock *et al.,* 1990).

Although TGFβ stimulates the formation of osteoid, it actually suppresses the formation of mineral in osteoid (for review, see Bonewald and Dallas, 1994). TGFβ will suppress the mineralization of rabbit chondrocytes and fetal rat calvarial cells. TGFβ also suppresses markers of the calcified matrix such as osteocalcin (see Table I). TGFβ inhibits osteocalcin expression in both fetal rat calvarial cells and ROS 17/2.8 cells and in $1,25D_3$-induced osteocalcin production by MG-63 cells. In *in vivo* models examining the effects of injections of TGFβ over murine calvaria (see below), it was only after the injections of TGFβ had ceased that the osteoid became mineralized. Therefore, once TGFβ has initiated new bone formation, it must be removed before mineralization can occur.

Table I TGFβ Is a Potent Stimulator of Matrix Formation[a]

Stimulates	Inhibits
Fibronectin	Procollagenase
Fibronectin receptor	Plasminogen activator
Collagen	Osteocalcin
Osteonectin	
Osteopontin	
Integrins (vitronectin receptor)	
Proteoglycans	
Decorin	
Tissue inhibitor metalloproteinases	
Plasminogen activator inhibitor	
Progelatinase (72 kDa)	
TGFβ	
LTBP	

[a] TGFβ stimulates the synthesis of matrix proteins and their receptors. TGFβ inhibits matrix degradation by increasing the production of protease inhibitors and decreasing the production of proteases (Roberts *et al.,* 1988). Not consistent with the inhibition of several proteases by TGFβ is the stimulation of progelatinase. As an inhibitor of mineralization, TGFβ also inhibits its marker, osteocalcin. TGFβ has autocrine effects and is a potent inducer of its very important regulatory molecule, the latent TGFβ binding protein (LTBP).

TGFβ generally has inhibitory effects on osteoclastic bone resorption. TGFβ appears to inhibit bone resorption by inhibiting the formation and activation of osteoclasts (for review, see Bonewald and Mundy, 1990). In bone systems where TGFβ stimulates resorption, this effect was shown to be mediated by the generation of prostaglandin by TGFβ (Tashjian *et al.,* 1985), possibly by the induction of prostaglandin synthase II in osteoblast cells (Pilbeam *et al.,* 1993). Therefore, TGFβ may act on osteoclast precursors to inhibit their proliferation and their formation and may inhibit the resorption process of mature cells by inducing cell death.

It has been shown that TGFβ may induce the apoptosis of mature osteoclasts (Hughes *et al.,* 1994). TGFβ has been shown to be responsible for apoptosis or programmed cell death in a number of tissues, such as liver, uterine epithelial cells, and hemopoietic cell lines, and will cause cell death of various tumor cell lines, such as prostate, liver, and kidney tumors (for review, see Bursch *et al.,* 1992). In the hemopoietic system, cytokines such as interleukin-6 act as positive regulators of cell growth, whereas TGFβ provides negative regulation in the form of programmed cell death (Sachs and Lotem, 1994). This may also be true as far as osteoclasts are concerned, as interleukin-6 also appears to be a positive regulator of osteoclasts (Ohsaki *et al.,* 1992).

Therefore, the function of TGFβ as an inducer of programmed cell death can be extended to bone with the specific target being the osteoclast.

However, to further justify calling TGFβ a multifunctional cytokine, TGFβ has also been shown to enhance osteoclast formation. TGFβ has been shown to enhance osteoclast formation in cultures of spleen cells and T lymphocytes (Horwood *et al.,* 1999), in marrow cultures cotreated with RANKL and M-CSF (Sells *et al.,* 1999), and to stimulate the formation of osteoclast-like cells in cultures of a human leukemia cell line, FLG 29.1(Fiorelli *et al.,* 1994).

In Vivo Effects of TGFβ on Bone

TGFβ will induce new bone formation if injected in close proximity to bone. Unlike bone morphogenetic proteins, TGFβ will not produce bone when injected into ectopic sites. The earliest *in vivo* experiments were performed using injection of TGFβ over the calvaria of mice (Mackie and Trechsel, 1990; Marcelli *et al.,* 1990; Noda and Camilliere, 1989). These studies showed conclusively that TGFβ stimulates new mineralized bone formation; however, whether these effects of TGFβ are mediated through prostaglandin are controversial. One study found no effect of indomethacin on TGFβ-induced new bone formation (Mackie and Trechsel, 1990), whereas one study saw a partial inhibition of new bone formation by indomethacin (Marcelli *et al.,* 1990). Soon after these studies were performed, it was shown that a single injection of TGFβ1 can induce bone closure of a nonhealing skull defect (Beck *et al.,* 1991). When TGFβ is combined with demineralized bone matrix, an acceleration of osteoinduction is observed (Kibblewhite *et al.,* 1993). The demineralized bone matrix used in this study has little ability to induce the synthesis of new bone by itself. However, in combination with TGFβ, an increase in the formation of trabecular bone is observed in conjunction with greater resorption of the demineralized bone matrix carrier. TGFβ has also been shown to initiate chondrogenesis and osteogenesis when applied to the rat femur (Joyce *et al.,* 1990b).

Systemic administration of TGFβ appears to stimulate cancellous bone formation in both juvenile and adult rats (Rosen *et al.,* 1994), in the nonload bearing rat (Machwate *et al.,* 1995), and in the aging mouse model (Gazit *et al.,* 1995). However, Kalu and co-workers (1993) did not find significant effects of TGFβ2 on the loss of cancellous bone after ovariectomy. Even though no significant effect was observed on bone loss, TGFβ2 did prevent the increase in TRAP(+)-multinucleated cells and caused a decrease in the number of trabecular osteoclasts. These studies suggest that bone loss in these different systems is mediated through different mechanisms and that TGFβ treatment may be more efficacious in some conditions of bone loss as compared to others. Perhaps in the ovariectomized rat model, resorption is accelerated greatly beyond the levels of formation so that TGFβ has little effect on bone loss.

Transgenic mice overexpressing active TGFβ 2 driven by the osteocalcin promoter have been described as osteoporotic (Erlebacher and Derynck, 1996), and mice overexpressing the dominant-negative TGFβ type II receptor driven by the same promoter have been described as osteopetrotic (Filvaroff *et al.,* 1997). These observations appear to contradict many of the observations concerning the function of TGFβ outlined in the previous paragraphs. However, one must take into consideration the following points when interpreting the role of TGFβ in bone based on the phenotype of these mice. (1) Transgenic animals do not represent a physiological, but a potentially pathological effect of TGFβ due to overexpression of active TGFβ. (2) Clearly, the expression of TGFβ must be tightly regulated. It must be readily available for on-site activation and then must be removed or inactivated. (3) Excess amounts of TGFβ actually inhibit mineralization. (4) TGFβ is thought to act as a coupling factor in bone to couple resorption with formation. If excess amounts of TGFβ are present, then bone remodeling is uncoupled. (5) The major isoform in bone is TGFβ1 not 2 and, as described earlier, the isoforms can have distinctly different affects on bone. (6) The osteocalcin promoter is expressed to a greater extent in mineralizing osteoblasts and osteocytes as compared to early osteoblasts (Mikuni-Takagaki *et al.,* 1995; Sims *et al.,* 1997). Therefore, overexpression of active TGFβ or the dominant- negative type II receptor in these animals is only occurring very late in osteoblast differention. TGFβ probably has its bone stimulatory effects in early phases of osteoblast differentiation. (7) The expression of osteocalcin, the TGFβ isoforms, and TGFβ type II receptor are clearly very different during bone formation and the mineralization process (Horner *et al.,* 1998). The type II receptor is not normally highly expressed during late stages of osteoblast differentiation. Together, these observations show that the regulation of TGFβ is critical in remodeling and disease. Bone disease can potentially result from an imbalance in TGFβ isoforms and their bioavailability.

TGFβ Receptors

Essentially all cells have receptors that specifically bind TGFβ (for reviews, see Heldin *et al.,* 1997; Hu *et al.,* 1998). Early studies using cross-linking techniques identified these receptors as type I, type II, and type III using band migration on SDS–PAGE (Cheifetz *et al.,* 1986; Segarini *et al.,* 1987; Wakefield *et al.,* 1987). The type I receptor gave a band ~65–70 kDa, the type II a band of 85–110 kDa, and the type III migrated as a diffuse band −200 kDa. These three major classes of receptors have been cloned (Franzen *et al.,* 1993; Lin *et al.,* 1992; Wang *et al.,* 1991). The type I and II receptors appear to be responsible for transducing intracellular signaling upon binding with TGFβ, whereas the type III receptor, now

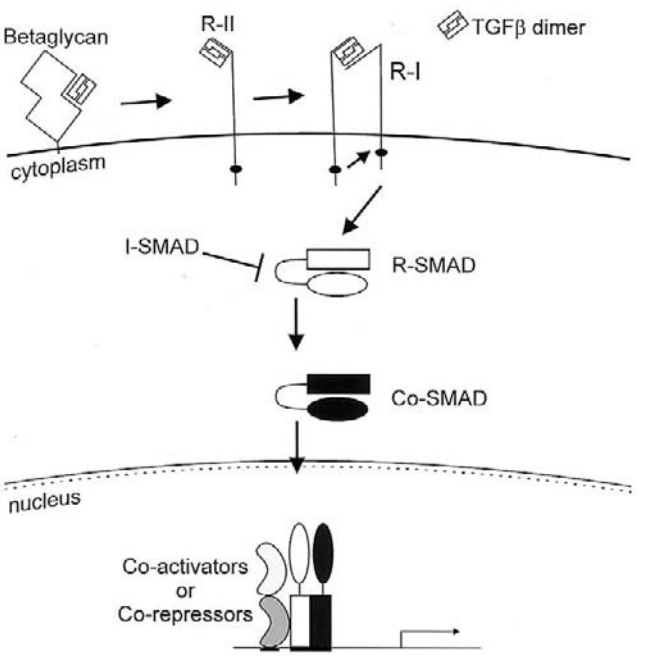

Figure 1 TGFβ receptor function and signaling mechanisms. Free TGFβ dimer is proposed to bind to the type II receptor or alternatively, β-glycan, also known as the type III receptor, presents cell surface-bound TGFβ to type II receptors. The β-glycan is displaced by the type I receptor for cell signaling to occur. The type II receptor is constitutively active. Following ligand binding, the type II receptor complexes with and activates the type I receptor. Instead of the simplified interactions as shown, the TGFβ receptors probably form large complexes. Data suggest that the type II receptor exists as a stable homodimeric complex. It is likely that the signaling TGFβ complex is a tetramer consisting of two type II chains and two type I chains. The type I receptor phosphorylates regulatory Smads, such as Smad-2 and -5. Inhibitory Smads (such as Smad-7) can block the interaction of the regulatory Smads with Smad-4, the major Co-Smad, which moves the complex to the nucleus. The specificity of the effects of TGFβ on the cell type is probably due to the composition of coactivators and/or corepressors present in the nucleus.

known as β-glycan, possesses only a short intracellular domain that does not appear to be involved in TGFβ signaling (Wang *et al.,* 1991). Although additional cell surface proteins that bind to TGFβ have been identified through cross-linking experiments (Centrella *et al.,* 1994; Massagueà, 1992), most attention has now been focused on type I–III receptors (see Fig. 1). The type III receptor is an integral membrane protein that is modified heavily by glycosaminoglycan groups, which probably accounts for its diffuse migration on gel electrophoresis. The nonglycosylated form of this receptor is still able to bind ligand. The type III receptor binds with equal affinity to the three TGFβ isoforms. It has been suggested that this receptor may function as a concentrating ligand before presentation to signal-transducing receptors type I and type II (Lopez-Casilles *et al.,* 1993; Massaguè *et al.,* 1990).

A considerable amount of time lapsed between the first cross-linking studies showing the presence of TGFβ receptors in 1985 and 1986 and determination of the actual signaling mechanism via serine/threonine kinase activity. Insight into the mechanism of signaling was provided when the type II activin receptor was cloned (Mathews and Vale, 1991). This receptor was identified as a transmembrane serine/threonine kinase. Since that time the cDNA cloning of various type I and type II receptors for TGFβ, activins, and BMPs has shown that all appear to be transmembrane serine/threonine kinases. It appears that the receptor signaling process for TGFβ is likely to serve as a model for the rest of the TGFβ superfamily. Both type I and type II receptors have short extracellular domains with a long cytoplasmic region that mainly consists of the kinase domain. The type I receptor also contains a conserved SGSGSGLP motif between the transmembrane domain and the kinase domain. These TGFβ receptors interact in both homomeric and heteromeric fashion.

Two systems have been proposed for the interactions of type I and type II receptors to promote TGFβ signaling. Wrana and colleagues (1994) proposed that TGFβ binds directly to the type II receptor, which is a constitutively active kinase. The bound TGFβ is then recognized by the type I receptor. These become a complex in which the type II receptor phosphorylates the type I receptor. Phosphorylation of the type I receptor is proposed to propagate signaling to downstream substrates. This signaling pathway is probably responsible for mediating the antiproliferative effects of TGFβ as well as effects on gene responses.

A second model proposes two distinct receptor-associated signaling pathways (Chen *et al.,* 1993). In this model, the type II receptor is required for signaling of growth inhibition. However, the second pathway is mediated through the type I receptor without signaling through the type II receptor as long as the extracellular domain of the type II receptor is present to provide ligand interaction with the type I receptor. This study was performed by producing a truncated type II receptor that could act as a dominant-negative mutant. This signaling through the type I receptor is responsible for the effects of TGFβ on extracellular matrix.

All three TGFβ receptor types appear to be expressed on osteoblasts, and the ratio and expression of these receptors can be modified by osteotropic factors. Studies on bone cells have been performed using cross-linking of radiolabeled TGFβ to the cell surface as initially performed by Segarini and co-workers (1989) where they described for the first time the presence of the three receptors on fetal rat osteoblasts. Subsequently, it was shown that parathyroid hormone (PTH) enhances the binding of TGFβ to all three receptors in fetal rat calvarial osteoblast-enriched cultures (Centrella *et al.,* 1988). This was in contrast to the effect of PTH on fibroblast-enriched cultures where PTH had no effect on TGF binding. Bone morphogenetic protein 2 (BMP 2) also appears to modulate the expression of TGFβ receptors (Centrella *et al.,* 1995b). In fetal rat calvarial osteoblast-like cells, the expression of type III and II receptors declined compared to the type I receptor in parallel with an increase in osteoblast-like activity. BMP 2 appears to accelerate this process in both osteoblast cultures and ROS 17/2.8 cells. Therefore, BMP 2 alters the TGFβ-binding profile in ways that are consistent with a differentiation

toward the osteoblast phenotype. This is in contrast to the effects of glucocorticoid on the TGFβ receptor profile where an increase in binding at type III sites is observed with a corresponding decrease in binding to type I and type II receptors (Centrella *et al.,* 1991). BMP 2 appears to override the effects of glucocorticoid on binding of TGFβ to receptors (Centrella *et al.,* 1995b). These studies, using BMP 2 and glucocorticoid on fetal rat calvarial cells, are in contrast to studies using the mouse mesenchymal stem cell line C3H-10T1/2 treated with retinoic acid, which predisposes these cells toward the osteoblast phenotype (Gazit *et al.,* 1993). In these studies, treatment with retinoic acid consistently decreased type III, type II, and type I receptor binding to TGFβ. The same effects were also observed using the rat cell line ROBC26. The authors suggested that downregulation of the TGFβ receptor might be an essential component of the osteoblast differentiation process.

Two separate TGFβ receptor signaling pathways are present in osteoblasts (Takeuchi *et al.,* 1995). Four clonal osteoblastic cell lines were examined that include MC3T3-E1 cells, MG-63, SaOS2, and UMR-106. Very different receptor profiles were observed with these cell lines. Both MC3T3 and MG-63 expressed all three receptor types. However, SaOS cells only expressed type I and type III and UMR-106 cells only expressed the type III receptor. These cells were examined for the effects of TGFβ on growth inhibition, proteoglycan synthesis, and fibronectin synthesis. Even though the SaOS cells lacked the type II receptor by cross-linking studies, they still responded to exogenous TGFβ with an increase in fibronectin synthesis. Even though the type II receptor did not bind to TGFβ, it was detectable by immunoprecipitation. Their data suggest that cells lacking signaling type II receptor escape the effects of TGFβ on proliferation and that the effect of TGFβ on fibronectin synthesis is under control of the type I receptor. Therefore, it is the combination of cell surface receptors for TGFβ that determines the response of osteoblasts to this cytokine.

TGFβ Signaling Pathways

An impressive amount of information concerning the intracellular events that follow the interactions between type I and type II receptors has been gained since 1996 (see Fig. 1). Direct substrates for the type I receptor appear to be Smad-2 and Smad-3, also known as receptor-activated Smads (R-Smads), whereas negative regulators of this interaction include Smad-6 and Smad-7, the inhibitory Smads (I-Smads) (Hayashi *et al.,* 1997; Imamura *et al.,* Hu *et al.,* 1998; de Castecker *et al.,* 2000). The discovery and naming of the Smads originated from studies of the dpp signaling pathway in *Drosophila* (Massague *et al.,* 1997). The Smads share structural homology through two domains called MH-1 and MH-2. These two regions are highly conserved evolutionarily. The MH-1 domain represses the MH-2 domain, which possesses constitutive transcription activity. It is proposed that the Smads associate as trimers through the MH-2 domain. Smad-2 or Smad-3 heterozygous mutant mice are viable, but the compound heterozygous Smad-2/Smad-3 mutant is lethal, suggesting a gene dosage effect and that the relative level of Smad-2 and -3 influences the nature of the TGFβ response (Weinstein *et al.,* 2000). Smad-2 and Smad-3 have been shown to interact with beta-tubulin and chemical disruption of tubular networks interferes with Smad2 binding to tubulin and activation of TGFβ signals. This suggests that the cytoskeleton is also involved in TGFβ signaling.

Smad-4, also called a common mediator (Co-Smad), appears to bring cytoplasmic Smad-2 and Smad-3 into the nucleus where together they can regulate the transcription of target genes (de Winter *et al.,* 1997) (see Fig. 1). Smad-4 was found to be homologous to a gene deleted in pancreatic carcinomas called "deleted in pancreatic cancer-4" or DPC-4 (Hahn *et al.,* 1996). A number of Smad-4-independent TGFβ responses have been identified (for review, see de Castecker *et al.,* 2000). These include Jun N-terminal kinase (JNK) and extracellular signal-related kinases (ERK) 1/2 mitogen-activated protein (MAP) kinase pathways. The potential exists for other co-Smads to be identified.

Other substrates for the type I receptor have been reported, which include FKBP12, WD40, and farnesyl transferase (see Hu *et al.,* 1998). However, the signaling function of these pathways is less clear than the Smad pathway. TGFβ has also been shown to activate a MAP-kinase pathway specified by the serine-threonine kinase TAK-1 (Yamaguchi *et al.,* 1995), and TGFβ has been implicated as well in G protein-mediated and ras-signaling pathways (for review, see de Castecker *et al.,* 2000). Because inhibitors of MAP kinases and p38 can clearly affect TGFβ signaling, Smads are not responsible for all TGFβ signaling.

Several transcription regulators and accessory proteins modulate TGFβ signaling. Negative modulators and inhibitors of the TGFβ signaling pathway include, in addition to the inhibitory Smads, the 5′TG 3′ interacting factor (TGIF), histone deacetylases (HDAC), Smad ubiquitination regulatory factor 1 (Smurf 1), calmodulin, a primary modulator of calcium signaling, and others (for more information, see Zimmerman and Padgett, 2000). Positive regulators include SARA, the Smad anchor for receptor activation (Tsukazaki *et al.,* 1998), that appears to function by bringing Smad-2 into close proximity with a cluster of residues in the kinase region of the type I receptor. Other SARA-like proteins may exist that bind to other Smads. Additional transcription activators include FAST proteins, AP-1 members, TFE3, a basic helix-loop-helix transcription factor that has been shown to cooperate with Smad-3 and -4, Polyoma virus enhancer-binding protein 2/core-binding factor factor (PEBP2/CBF), Olf-1/EBF associated zinc finger (OAZ), MSG1, CREB-binding protein (CBP)/p300, and others (for review, see Zimmerman and Padgett, 2000). Interestingly, the vitamin D nuclear receptor, VDR, interacts specifically with Smad-3. Activation of TGFβ signaling results in a Smad-3-mediated

enhancement of VDR-dependent transcription through the MH1 domain instead of the MH2 domain as is observed with other coactivators (Yanagi *et al.,* 1999; Yanagisawa *et al.,* 1999). This may have implications for bone growth and remodeling as TGFβ and $1,25(OH)_2D_3$ have been shown to synergistically increase alkaline phosphatase in primary human bone cells and the MG-63 osteoblast cell line (Wergedahl *et al.,* 1992; Bonewald *et al.,* 1992) This shows that TGFβ through Smad-3 is cooperatively enhancing VDR-regulated pathways.

Latency of TGFβ

TGFβ is secreted by cells in culture in biologically latent forms. Latent TGFβ can be activated *in vitro* by transient acidification or alkalinization or by the action of chaotropic agents (Gehron-Robey *et al.,* 1987; Lawrence *et al.,* 1985; Pircher *et al.,* 1986). Release of the mature TGFβ 25-kDa homodimer from the latent complex is necessary for TGFβ to exert its effects on target cells. TGFβ is the only growth factor known to be produced in a latent or inactive form (see Fig. 2).

The precursor or latency-associated peptide (LAP) is all that is necessary to confer latency. This latent complex, containing only LAP and the TGFβ homodimer, has been referred to as the "small latent complex" of 100 kDa. Approximately 50% of latent TGFβ made by bone cells is this form (Bonewald *et al.,* 1991), whereas other cell types produce little or none of this form. The small latent complex may have a unique function in bone by acting as a circulating, more readily activatable form.

Bone cells also produce the "large latent complex" as described in other cell types (Dallas *et al.,* 1995; Miyazono *et al.,* 1988; Tsuji *et al.,* 1990). The large latent complex contains a protein called the latent TGFβ-binding protein or

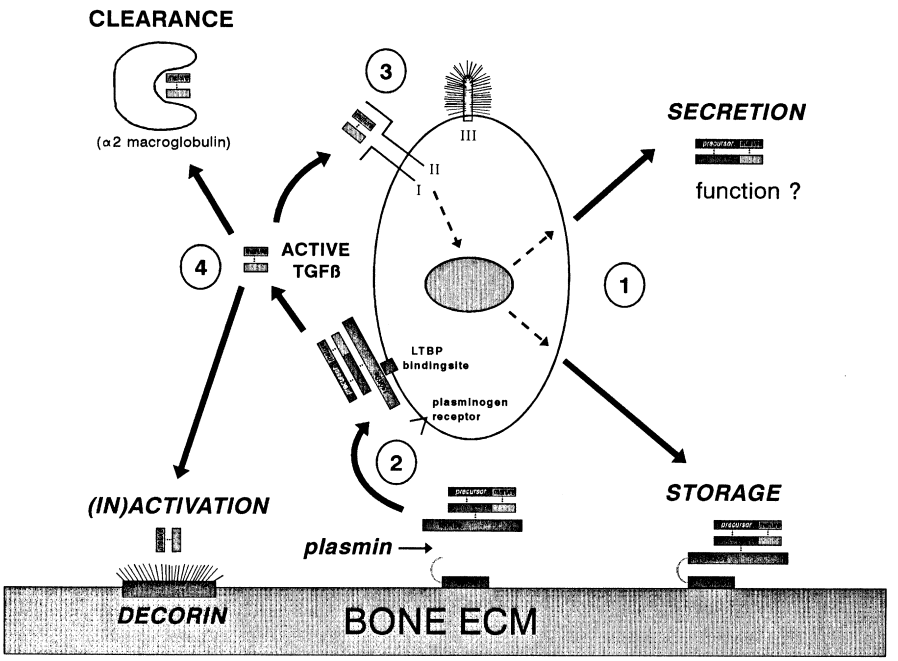

Figure 2 The osteoblast and TGFβ. The osteoblast produces latent TGFβ, can activate latent TGFβ upon proper stimulation, and can respond to TGFβ through specific receptors. Bone cells are unique in producing at least two latent forms of TGFβ (1): one that contains the TGFβ binding protein or LTBP and one that does not. The function of the complex lacking LTBP is unknown but perhaps it functions as a circulating form of latent TGFβ. In the complex containing LTBP, LTBP appears to direct the latent complex to bone for storage. Plasmin, a known matrix remodeling agent, will cause the release of latent TGFβ from the matrix by cleavage of the LTBP at a protease-sensitive hinge region (2). This plasmin-released complex appears similar to the platelet latent complex. It is proposed that binding sites exist on the cell surface for the cleaved LTBP, which can allow the tethered latent complex to be activated by cell surface-associated plasmin. Active TGFβ binds to the type II receptor, which in turn causes the association with the type I receptor (3). The type II receptor is a kinase that will activate the type I receptor, which in turn sends a signal to the nucleus. The type III receptor, known as β-glycan, is a proteoglycan that will bind TGFβ but does not appear to signal. TGFβ has an autocrine effect in that TGFβ will induce the production of its own mRNA in the form of latent TGFβ. Active TGFβ is removed from the circulation by association with α_2-macroglobulin (4) (O'Conner-McCourt and Wakefield, 1987). Other molecules are known to either activate or inactivate TGFβ. Decorin in the kidney inhibits TGFβ (Border *et al.,* 1992), but decorin in bone appears to maintain the activity of TGFβ (Takeuchi *et al.,* 1994). Thrombospondin appears to activate and maintain activity of TGFβ (Schultz-Cherry *et al.,* 1995).

LTBP-1 (see Fig. 3). This protein is truncated at the amino terminus in the latent complex produced by platelets (Wakefield *et al.,* 1987; Kanzaki *et al.,* 1990). We and others have shown that the nontruncated LTBP protein targets the small latent TGFβ to the matrix for storage (Dallas *et al.,* 1995; Taipale *et al.,* 1994). This protein does not confer latency to the complex.

Activation of Latent TGFβ

The earliest experiments examining the activation of latent TGFβ used dissociating agents such as acid, chaotropic agents, or heat treatment of conditioned media containing inactive TGFβ (Brown *et al.,* 1990). These were followed by experiments using recombinant small latent TGFβ to examine the activation process by proteases such as plasmin (Lyons *et al.,* 1990) or cells such as osteoclasts (Oreffo *et al.,* 1989). These experiments, using recombinant latent TGFβ, are more representative of the processing that occurs of the "small" latent complex. More attention has focused on the release and subsequent activation of the matrix-bound "large" latent TGFβ complex. Release and activation of matrix-bound latent TGFβ occur during matrix remodeling through the activity of proteases such as plasmin (Nunes *et al.,* 1997) and the cellular activity of cells such as bone-resorbing osteoclasts (Dallas *et al.,* 1997).

Several proteases have been implicated in the activation of latent TGFβ. The activation of LTGFβ in cocultures of endothelial cells and smooth muscle cells was shown to be due to the generation of plasmin (Sato *et al.,* 1990). Plasmin activates LTGFβ by proteolytically cleaving the precursor or LAP at multiple sites (Lyons *et al.,* 1990). Retinoids were found to increase the activation of LTGFβ in endothelial cells/smooth muscle cell cocultures by increasing membrane-associated plasminogen activator/plasmin levels (Kojima and Rifkin, 1993).

Several stimulated cell types have been shown to activate latent TGFβ, such as macrophages treated with interferon-γ (Twardzik *et al.,* 1990), with IgG or lipopolysaccharide (Schalch *et al.,* 1991), with mesenchymal cells treated with glucocorticoids (Rowley, 1992), with endothelial cells treated with fibroblast growth factor (Flaumenhaft *et al.,* 1992), and with cocultures of endothelial cells with pericytes or smooth muscle cells (Sato and Rifkin, 1989). Vascular smooth muscle cells treated with angiotensin II activate latent TGFβ (Gibbons *et al.,* 1992), and fetal fibroblasts treated with antiestrogens also produce active TGFβ (Colletta *et al.,* 1990). Keratinocytes treated with retinoic acid secrete active TGFβ2 (Glick *et al.,* 1989). Therefore, many cell types activate latent TGFβ, depending on whether other factors are present in the cellular environment.

Bone cells activate latent TGFβ, but through different mechanisms (see Fig. 3). Human osteoblast-like cells treated with glucocorticoids activate latent TGFβ (Oursler *et al.,* 1993). Parathyroid hormone-treated osteoblast-like cells, UMR-106-01 cells and neonatal mouse calvarial cells, appear to activate latent TGFβ using the plasminogen activator system (Yee *et al.,* 1993). Isolated avian osteoclasts upon treatment with retinol will activate latent TGFβ (Oreffo *et al.,* 1989), but this activation was shown not to be due to plasmin (Bonewald *et al.,* 1996). Oursler (1994) showed that avian osteoclast-like cells isolated using an antibody that recognizes the 121F antigen, a protein related to superoxide dismutase, will produce and activate latent TGFβ. No significant inhibition of latent TGFβ activation was observed using a series of protease inhibitors, including those that block plasmin, although a combination of five protease inhibitors significantly blocked activation. It has been shown that one of the mechanisms whereby osteoclasts can activate latent TGFβ is through matrix metalloproteinases (MMPs)(Dallas *et al.,* 1997). Both MMP-9 and MMP-2 have been shown to activate latent TGFβ (Yu and Stamenkovic, 2000).

A noncellular mechanism has been described in which latent TGFβ is activated by extracellular organelles called matrix vesicles (Boyan *et al.,* 1994). Matrix vesicles found in osteoid are associated with matrix calcification. Alone, these organelles have no effect on latent TGFβ; however, upon pretreatment of these organelles with $1,25(OH)_2D_3$, both recombinant latent TGFβ1 and recombinant latent TGFβ2 are activated. Matrix vesicles have been shown to contain proteases, such as plasminogen activator, and therefore one of the nongenomic effects of $1,25D_3$ on the membranes of these organelles may be the release of TGFβ-activating proteases.

Thrombospondin, a glycoprotein involved in cell growth, adhesion, migration, and angiogenesis, will activate latent TGFβ (Schultz-Cherry *et al.,* 1995). In cell-free systems, thrombospondin activates both small and large latent TGFβ (Murphy-Ullrich *et al.,* 1992; Schultz-Cherry *et al.,* 1994). Activation was shown to be a two-step process. The first process involves the actual binding of latent TGFβ to thrombospondin, and the second step involves the release of active TGFβ. The sequences of thrombospondin responsible for these two activities were identified and synthetic peptides made that would either block the binding of TGFβ to thrombospondin or prevent activation of the molecule. Peptides interfering with the first function (GGWSHW) or those interfering with the second function (KRFK) may have potential therapeutic uses where TGFβ activity requires modulation, such as in wound healing or fibrotic scar formation.

It has been suggested that TGFβ-1 null mice and thrombospondin-1 null mice share similar abnormalities (Crawford *et al.,* 1998). When thrombospondin-1 null mice were treated with a peptide that mimics the thrombospondin activation of TGFβ, several organ abnormalities reverted back to wild type. Synthetic peptide, KRFK, made to a repeat in thrombospondin, can activate latent TGFβ by cleaving LAP (Schultz-Cherry *et al.,* 1995), and an antagonist peptide, LSKL, can prevent this activation. Investigators suggest that thrombospondin may be the best physiological activator of latent TGFβ, even more so than the plasmin/plasminogen-activator system described by Flaumenhaft and co-workers (1992, 1993; Kojima and Rifkin,

1993). It remains to be determined if this is true for all organ systems, especially bone.

Proteases other than plasmin will activate latent TGFβ. Elastase will cleave matrix-bound latent TGFβ, but will not activate the small latent complex. Whereas both MMP-9 and MMP-2 activate latent TGFβ, only MMP-9, but not MMP-2, will cleave LTBP-1. Prostate-specific antigen will specifically activate latent TGFβ-2 but not latent TGFβ-1, nor will it release matrix-bound latent TGFβ (Zhao *et al.,* 1997). This is the first example of isoform-specific activation. Release of latent TGFβ from the matrix through the cleavage of LTBP-1 does not necessarily result in the activation of latent TGFβ (Dallas *et al.,* 1994, 1995). Cleavage of LTBP may be a means of releasing latent TGFβ that can then be available for activation at a site distant from the storage site. Plasmin will activate small latent TGFβ, but much lower concentrations (10- to 100-fold less) will release matrix-bound latent TGFβ, suggesting that a more physiological function of plasmin is to release the latent complex from the matrix rather than to activate the soluble forms.

Latent TGFβ-Binding Protein (LTBP)

TGFβ may be unique among growth factors because of its association with the protein LTBP (Figs. 2 and 3). The function of LTBP may not only be to target or deliver latent TGFβ to the matrix, but also to provide a vehicle for its release from the matrix and to target the modified released latent complex to the cell surface for activation. Additionally, and independent from its association with TGFβ, LTBP appears to function as a structural extracellular matrix protein required for new bone formation (Dallas *et al.,* 1995). The relationship between TGFβ and LTBP could represent an intricate system for regulating the actions of this multifunctional growth factor.

LTBP appears to be a structural extracellular matrix protein involved in the formation of large fibrillar structures in the extracellular matrix of bone cells (Dallas *et al.,* 1995). Both antibodies and antisense oligonucleotides to LTBP will inhibit the formation of bone-like nodules by fetal rat calvarial cells. The fibrillar structures found in these cultures contain LTBP complexed with the small latent TGFβ and free LTBP not complexed to TGFβ. These fibrillar structures also contain fibrillin-1. In long bones *in vivo,* LTBP-1 and fibrillin colocalized to the surface of newly forming osteoid and bone (Dallas *et al.,* 2000). The presence or composition of other proteins within these fibrils is not known. Plasmin cleaves LTBP at a protease-sensitive hinge region, which leaves the 60-kDa amino terminus of the LTBP in the matrix and releases the latent complex containing a 130-kDa cleaved fragment of LTBP similar in composition to that described for platelets. This latent complex appears to be targeted to the cell surface for activation by plasmin (see Fig. 3.)

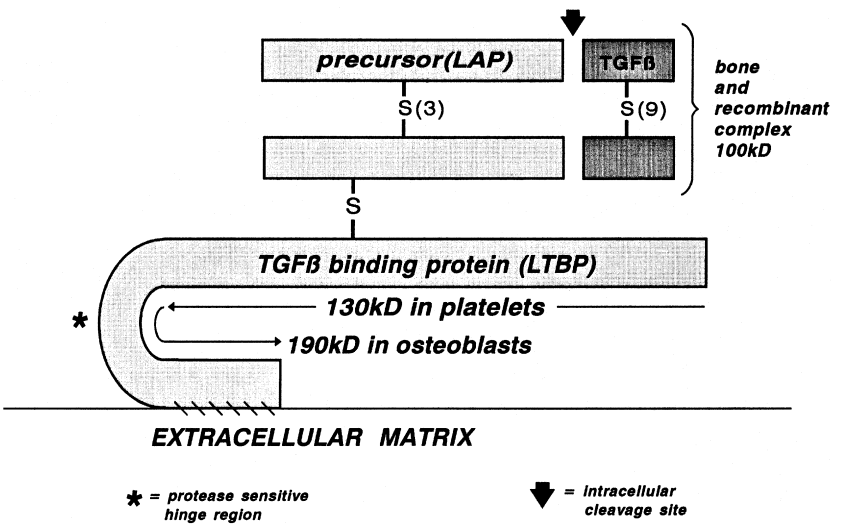

Figure 3 Various forms of latent TGFβ. Various forms of latent TGFβ are produced by different cell types. Bone cells produce the 100-kDa latent complex, which lacks the TGFβ binding protein or LTBP. This 100-kDa complex appears to be identical to the recombinant material secreted by transfected Chinese hamster ovary cells. Platelets produce the 100-kDa complex covalently associated through disulfide bonds with a truncated form of LTBP of 130 kDa. Bone cells also make the latent complex in which the 100-kDa latent TGFβ is covalently attached to a 190-kDa LTBP. In all latent complexes, the mature TGFβ homodimer must be dissociated from the precursor to become biologically active. LTBP is not necessary for processing or secretion of latent complex in bone cells and it does not confer latency to the complex. LTBP appears to direct the latent complex to the matrix for storage. LTBP itself forms fibrillar structures in the matrix. Latent TGFβ can be released from the matrix through the action of plasmin on the matrix-bound latent complex. LTBP contains a protease-sensitive hinge region through which this occurs.

Mutations in LTBP may result in connective tissue disorders. Sequence analysis of LTBP reveals a number of features characteristic of matrix or adhesion molecules, such as 16 epidermal growth factor-like repeats, an RGD sequence, putative calcium-binding domains, and an 8 amino acid motif identical to the cell-binding domain of β2 laminin (Kanzaki *et al.,* 1990; Tsuji *et al.,* 1990). Several of these features are shared with the fibrillin family of extracellular matrix proteins in addition to a novel cysteine repeat motif that is unique to the fibrillin family (Maddox *et al.,* 1989; Rosenbloom *et al.,* 1993; Sakai *et al.,* 1986; Zhang *et al.,* 1994). Fibrillins are major components of connective tissue microfibrils. Marfan syndrome and related disorders of the cardiovascular and skeletal system have been linked to mutations in genes for the fibrillin family of extracellular matrix proteins of which LTBP appears to be a new member (Dietz *et al.,* 1991; Lee *et al.,* 1991; Lonngvist *et al.,* 1994; Maslen *et al.,* 1991; Milewicz *et al.,* 1992). Women with Marfan's syndrome have increased osteopenia, which may predispose them to hip fracture (Kohlmeier *et al.,* 1995). Marfan-like connective tissue and skeletal disorders for which no current explanation is available or of unknown etiology may be due to mutations in members of the LTBP family.

To date, four LTBP genes have been isolated containing 15–19 EGF-like repeats: three novel eight cysteine (8-Cys) repeats and a "hybrid domain" that shares homology with the EGF-like and eight cysteine repeats (for review, see Taipale *et al.,* 1988). Many extracellular matrix proteins contain EGF-like repeats that mediate noncovalent protein–protein interactions, but only LTBPs and fibrillins contain the 8-Cys domains that mediate covalent interactions. The third 8-Cys repeat in LTBP-1 and -3 efficiently binds all three TGFβ isoforms through the latency-associated peptide: LTBP-4 has much weaker binding and LTBP-2 and the fibrillins 1 and 2 do not bind at all (Saharinen and Keski-Oja, 2000). LTBP-2 shares 41% homology with LTBP-1 and has very similar overall structural homology (Moren *et al.,* 1994). LTBP-3 shares 38% homology with LTBP-1, is produced by MC3T3-E1 osteoblast cells, and forms a complex with the TGFβ1 precursor (Yin *et al.,* 1995). It was suggested that LTBP-3 may be an early marker of osteoblast differentiation. This supports the observation of Dallas *et al.* (1995, 2000) showing that LTBP-1 is expressed very early in fetal rat calvarial cell culture and in the periosteal layer of developing bone. This new family of LTBP-like molecules may have important functions in bone formation.

Deletion of LTBP-2 appears to be a neonatal lethal (Shipley *et al.,* 2000). One other LTBP other than LTBP-1, LTBP-3, has been shown to be made by bone cells, specifically by MC-3T3 E1 cells (Yin *et al.,* 1995). The expression of LTBP-3 in *Xenopus* is found in the skull and notochord (Quarto *et al.,* 1999). Rifkin and co-workers (1999) have successfully deleted the gene for LTBP-3 in mice. These mice have a short snout, bossy forehead, closed parietal suture, short long bones, and overgrown incisors, probably because the snout is shortened. The gene deletions for LTBP 1 and 4 have not yet been accomplished.

Role of TGFβ in Bone Cancer Metastasis

TGFβ normally functions as a tumor suppressor. Mice that have a haploinsufficiency for TGFβ are more susceptible to tumorigenicity (Tang *et al.,* 1998). Acquisition of resistance to TGFβ growth inhibition obviously plays a major role in the progression to malignancy, as cancer cells are less susceptible to growth inhibition by TGFβ than normal cells (Fynan and Reiss, 1993). This resistance can be due to mutations and/or deletions in any component of the TGFβ receptor signaling pathway, as described by Sherr and colleagues (1996). In addition to mutations in receptors and signaling molecules, resistance to TGFβ can be due to the low expression of receptors and induction of TGFβ resistance by growth factors or viral transforming proteins and can occur at levels beyond the TGFβ signaling pathway, such as mutations in cell cycle regulators such as Rb, p15, p21, and p300/CBP, all targets of TGFβ (for review, see Taipale *et al.,* 1998).

TGFβ can support cancer growth by suppressing the immune system while simultaneously stimulating normal support cells to secrete growth factors for cancer cells. In the case of bone metastatic breast cancer, TGFβ can induce the production of the bone-resorbing factor parathyroid hormone-related peptide (PTHrp), which in turn stimulates osteoclastic bone resorption, thereby releasing growth factors, including TGFβ from the bone matrix (Guise *et al.,* 1996; see also Chapter 61). This creates a "vicious" cycle of events that sustains and supports growth of the breast cancer. Neutralizing PTHrp decreases osteoclastic bone resorption and tumor burden in bone. Guise and co-workers (1996) showed that a neutralizing monoclonal antibody to PTHrp(1-34) inhibits the development of breast cancer metastases, MDA-MB-231 cells, to bone in the nude mouse model. Similar results have been obtained with lung cancer cells (Iguchi *et al.,* 1996). MCF-7 breast cancer cells do not express PTHrp and do not metastasize to bone: however, when stably transfected with a vector carrying the gene for PTHrp, these cells do metastasize to bone (Thomas *et al.,* 1999), indicating that PTHrp is a bone metastatic factor.

TGFβ stimulates the production of PTHrp in several tumor types (for review, see Chirgwin and Guise, 2000). Because bone contains other growth factors (such as the IGFs, FGFs, PDGFs, and BMPs), these were tested for stimulation of PTHrp production by MDA-MB-231 cells. Only TGFβ stimulated PTHrp production (Yin *et al.,* 1999). These investigators also stably transfected the TGFβ type II dominant receptor in MDA-MB-231 cells and found considerably less bone destruction and less tumor burden. Expression of a constitutively active TGFβ type II receptor reversed the dominant-negative blockade, resulting in increased PTHrp production, enhancement of osteolytic bone metastasis, and decreased survival (Yin *et al.,* 1999). Introduction of cDNA

for PTHrp constitutively driven by the CMV promoter increased PTHrp production and accelerated the development of osteolytic bone metastases greatly. In these cells, TGFβ appears to be signaling through both the Smad pathway as described earlier and the p38 MAPkinase pathway downstream of TAK1 to regulate PTHrp production (Kakonen *et al.,* 2000). Thus, TGFβ receptor activation is important for the development and progression of osteolytic bone metastases.

Activation of latent TGFβ may also play a role in tumor invasion and angiogenesis. Yu and Stamenkovic (2000) have shown that cell surface-localized matrix metalloproteinase-9 activates TGFβ, thereby promoting tumor growth and invasion. Because many cancers express the matrix metalloproteinses, it will be important to determine if these play a role in bone metastasis.

In addition to the mechanisms described earlier, the loss of LTBP-1 expression or regulation may also be associated with malignancy. LTBP-1 expression is lost in malignant prostatic cells (Eklov *et al.,* 1993), gastrointestinal carcinomas (Mizoi *et al.,* 1993), and SV40-transformed fibroblasts (Taipale and Keski-Oja, 1996). Loss of LTBP-1 and thereby the loss of targeting of latent TGFβ to the extracellular matrix may be another mechanism whereby transformed cells escape regulation by TGFβ. It is not known if this is true for tumors that metastasize to bone.

Role of TGFβ in Osteoporosis

TGFβ may play a role in osteoporosis in humans. Low bone mass has been shown to be the most important risk factor for the development of osteoporotic fractures. Women in Denmark with a variant form of TGFβ-1 have low bone density and an increased susceptibility to osteoporosis (Langhdahl *et al.,* 1997). This variant is caused by a one base deletion in the intron sequence 8 bases prior to exon 5 in the TGFβ1 gene, which theoretically would result in less TGFβ1. This variant was also associated with increased bone turnover in both osteoporotic and normal women. However, this association with increased susceptibility to osteoporosis was not associated with peak bone mass, bone growth, early postmenopausal bone loss, or response the hormone replacement therapy (HRT) (Langhdahl *et al.,* 1997). This variant of TGFβ may be influencing susceptibility to osteoporotic fractures through other mechanisms than regulation of peak bone mass. Yamada and co-workers (1988) have found a polymorphism of the TGFβ1 gene that is a determinant of bone mass and is a susceptibility factor for osteoporosis. A substitution of thymidine at position 29 to a cytosine resulted in a proline for leucine substitution at amino acid 10. This polymorphism was found to be associated with higher peak bone mass in both males and females, and the thymidine-containing allele was an independent risk factor for osteoporosis in Japanese women. Of course in both of the studies, the target of the TGFβ is unknown.

Animal studies support a role for TGFβ in osteoporosis. Decreased TGFβ mRNA expression and decreased deposition of TGFβ occur in bones from ovariectomized rats (Finkelman *et al.,* 1992). Osteopenia in old male mice was due to reduced TGFβ (Gazit *et al.,* 1988). These investigators found less TGFβ stored in the matrix of long bones from these aged mice compared to young mice and less TGFβ produced by marrow osteogenic cells. The osteoprogenitors from aging mice are more responsive to TGFβ, and bone formation was stimulated by injections of TGFβ into these animals. This study supports previous studies showing that TGFβ is an important bone growth factor. Systemic administration of TGFβ 2 has been shown to prevent bone loss due to immobilization in rats (Machwate *et al.,* 1995).

It has been speculated that estrogen may partially maintain bone mass through TGFβ and that raloxifene maintains bone mass through the induction of TGFβ3 expression (Yang and Termine, 1994). The TGFβ3 promoter appears to contain a region that is positively regulated by raloxifene but that is unrelated to ERE-like sequences. Apparently this region can be activated by both estrogen and raloxifene, despite the fact that it does not have the conventional characteristics of an estrogen receptor.

Summary

The drive and determination to discover osteoinductive factors were responsible for the discovery of the TGFβs and other members of this superfamily in bone. However, with their discovery has come the challenge of unraveling their function in bone and the challenge to control the use and delivery of these factors. Nature has developed a surprisingly complex system of regulation—from latency and activation of the TGFβ molecule to an intricate system of receptors and a vast array of regulatory molecules that either enhance or inhibit the activity of this factor. Greater understanding of TGFβ, its effects, and its regulation is necessary to apply this information for potential clinical use. The challenge continues.

CHAPTER 50

Bone Morphogenetic Proteins

Vicki Rosen and John M. Wozney
Genetics Institute, Cambridge, Massachusetts 02140

Introduction

The idea that the remarkable regenerative capacity of bone resided within bone itself came from the pioneering work of Urist (1965), who described the isolation of a bone inductive extract from adult bone and demonstrated the ability of this extract to induce new endochondral bone formation at ectopic sites in rodents. Much effort went into the characterization of this extract, which Urist called bone morphogenetic protein (BMP), but it was not until the genes responsible for the bone inductive activity were cloned using recombinant DNA methods that our understanding of the exact nature of the signals involved in bone formation began to take shape (Celeste *et al.,* 1990; Kingsley, 1994a; Luyten *et al.,* 1989; Ozkaynak *et al.,* 1990, 1992; Sampath and Reddi, 1981; Sampath *et al.,* 1987, 1991; Urist *et al.,* 1973; Wang *et al.,* 1988, 1990; Wozney *et al.,* 1988). We now recognize that BMPs are part of a large multigene family, the transforming growth factor β (TGF-β) superfamily, whose members are related to each other by relative degrees of sequence similarity but that possess a wide-ranging number of biological functions (Kingsley, 1994b; Rosen and Thies 1992; Fig. 1).

Members of the BMP subfamily show an identifying pattern of seven conserved cysteine residues in the mature, carboxy-terminal portion of the protein, which is where BMP activity resides. Mature BMP proteins are synthesized as larger precursor molecules that are processed to approximately 30,000 molecular weight dimers before their secretion from the cell.

Members of the BMP family initiate their cellular action by binding to transmembrane serine/theronine kinases known as type I and type II receptors. These closely related proteins are composed of a short cysteine-rich extracellular domain, a single transmembrane-spanning domain, and an intracellular domain with serine and theronine kinase regions (Franzen *et al.,* 1993; Lin *et al.,* 1992). BMPs can bind to both type I and type II receptors alone with low affinity (Liu *et al.,* 1995). High-affinity binding of BMPs is only achieved when both receptors are present. The same BMP can bind more than one type II receptor, which in turn can interact with different type I receptors. The nature of the signal seems to be dependent on the composition of the receptor complex and on the specificity of the type I receptor kinase (see Chapter 48).

Once secreted, the availability of BMPs for receptor interactions is mediated by the presence of extracellular antagonists that appear to bind to BMP proteins and prevent their subsequent interaction with BMP receptors. These include noggin for BMP-2, -4, -7, and GDF5 and 6, chordin for BMP-2, -4, and -7, follistatin for BMP-2, -4, -7, and BMP-11/GDF11, and gremlin for BMP-2, -4, and GDF5 (Dionne *et al.,* 2001; Gamer *et al.,* 1999; Gazzero *et al.,* 1998; Pereira *et al.,* 2000; Piccolo *et al.,* 1996). While the role for extracellular BMP antagonists in development is clear, how these same antagonists affect BMP signaling in the adult skeleton is only beginning to be investigated.

The osteogenic capacity of many BMPs has been proven by implanting individual pure recombinant BMPs in the rat ectopic assay, a measure of *de novo* osteoinduction, and using this stringent criteria, BMP-2, BPMs-4 through 7, and BMP-9 have been shown to be bone inductive molecules (Celeste *et al.,* 1992, 1994; D'Alessandro *et al.,* 1991; Gitelman *et al.,* 1994; Wozney *et al.,* 1988). In addition, heterodimeric forms of BMPs exist and several exhibit an enhanced bone inductive ability (Aono *et al.,* 1995; Israel *et al.,* 1996). In each case, the BMP protein acts to initiate the cascade of biological events known as endochondral bone formation, in which mesenchymal stem cells lay down a cartilaginous structure that is then resorbed and replaced by bone (Reddi, 1981) .

The following sections describe current thinking on the utility of BMPs as therapeutic agents and discuss how these

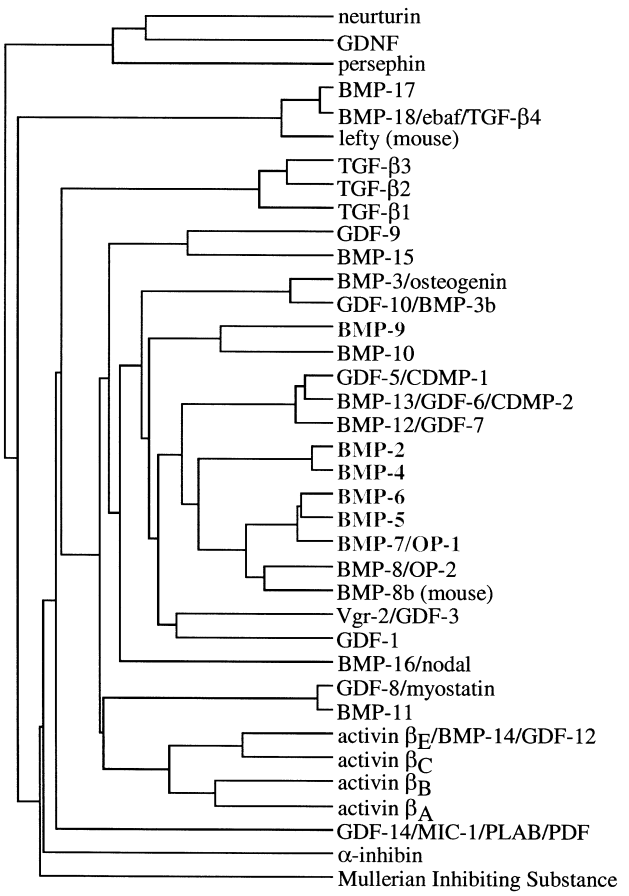

Figure 1 Relationships of BMP/TGF-β gene family members shown as a comparison of their amino acid identities from the first conserved cysteine residue. Osteogenic BMPs are shown in gray. Figure was generated using the GCG program PileUp.

efforts are based on our understanding of the role of BMPs in formation of the embryonic skeleton and maintenance of bone mass in adults.

Therapeutic Applications of Bone Morphogenetic Proteins

Potential therapeutic applications for BMPs are wide ranging and include (1) replacement for bone grafting materials in orthopedic settings, (2) replacing bone grafts for dental applications, and (3) enhancing fixation of prosthetic metal implants. While only small amounts of the osteoinductive BMPs are needed to produce substantial amounts of bone, delivery of these potent molecules must be highly controlled, and BMPs are typically applied with a matrix or carrier. The matrix then aids in defining the shape and volume of the bone being induced and results in the retention of BMP at the site of application long enough for the cellular response to the protein to be initiated. Matrices can be composed of a variety of substances, and the physical form of the material can be optimized for the particular therapeutic application. Materials most commonly studied include collagen (the primary structural protein component of bone and many other tissues), hyaluronic acid, allograft (either mineralized or demineralized), calcium phosphate materials (hydroxyapatite or tricalcium phosphate), and synthetic polymers such as polylactide or poly (lactide-co-glycolide).

Applications of BMPs in Orthopedic Surgery

Large segmental long bone defect models have been extensively utilized to evaluate the osteoinductive potential of BMPs. Advantages of these models include their inability to heal spontaneously (hence, they are "critical-sized"), ease of radiographic evaluation of the bone-induction process, and the ability to unequivocally evaluate the histologic and biomechanic properties of the induced bone. For example, both rhBMP-2 and BMP-7/OP-1 have been shown to heal large defects in species including rats, rabbits, dogs, and monkeys (reviewed in Rosen and Wozney, 2000). These studies have substantiated the potent osteoinductive capacity of these BMPs. In addition, they have demonstrated that the bone induced by BMP intimately associates with the preexisting surrounding bone and remodels consistent with its location (i.e., in response to the biomechanic environment), assuming the biomechanic properties appropriate for the anatomic site. Interestingly, the bone is only formed in the area where the BMP implant was placed, and appears to be self-limiting. This is likely to be due to removal of the inductive substance from the site, as well as upregulation of inhibitory molecules in response to the factor.

Spinal fusion procedures currently utilize large amounts of autogenous bone graft and hence provide an opportunity to evaluate BMPs as a bone graft substitute. RhBMP-2 and BMP-7/OP-1 have been tested successfully in preclinical animal models of both intertransverse process and interbody (in conjunction with interbody fusion cage devices) fusion. For example, rhBMP-2 has been shown to yield successful spinal fusions in rabbit, dog, and monkey models by radiographic, mechanic, and histologic criteria (Boden *et al.,* 1996; David *et al.,* 1999; Sandhu *et al.,* 1995; Sandhu, 1996; Schimandle *et al.,* 1995;). In these studies, BMPs appear to perform equal to, or superior to, autograft. In some cases, fusions form earlier and with higher frequency when BMP is used. Clinical studies utilizing BMPs in spinal fusion applications are ongoing. A small (14 patient) study has been published in which rhBMP-2 was compared to autograft in interbody spinal fusions (Boden *et al.,* 2000). Similar to the preclinical studies, the fusion rate and frequency induced by BMP were at that of autograft. This suggests a significant medical benefit of the use of BMP, as the additional operative procedure of autograft harvest (and associated morbidity) is avoided.

Fracture Repair

Because BMPs are likely physiologic mediators of fracture repair, they are attractive potential therapeutics when insufficient repair process occurs, and perhaps even to

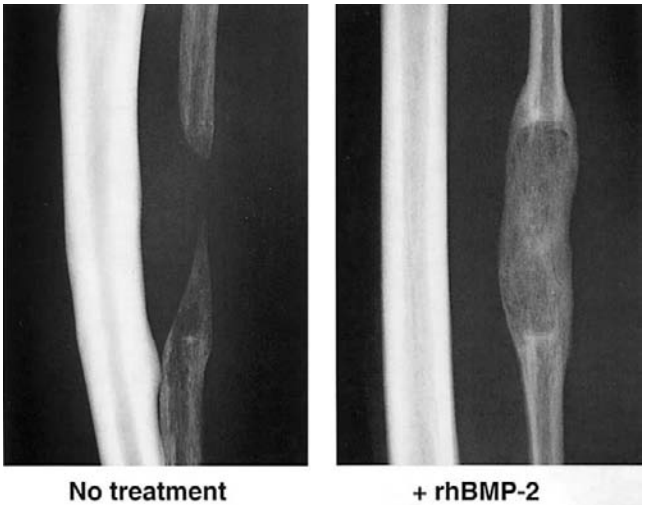

Figure 2 Healing of a critical-sized segmental defect in monkeys by rhBMP-2. Two-centimeter full-thickness defects were created in the fibulae of cynomolgous monkeys. Defects were implanted with rhBMP-2 with a calcium phosphate cement (right) or left untreated (left). Radiographs detail healing after 16 weeks. Note complete regeneration of bone in the rhBMP-2-treated defect compared with minimal bone formation in the untreated control.

accelerate fracture repair. Several animal studies have demonstrated the ability of BMP-2 and BMP-7/OP-1, with or without carriers, to accelerate fracture repair in rabbit, goat, and dog models (Bouxsein *et al.,* 1999; Popich *et al.,* 1997; Turek *et al.,* 1997; Welch *et al.,* 1997). For example, BMP-2 was shown to decrease the time to healing by 35–50% in a rabbit osteotomy model, as assessed by biomechanic criteria. Interestingly, histologic analysis suggested that the addition of exogenous BMP both increased the amount of fracture callus present and accelerated the maturation of the callus, i.e., its conversion from a soft cartilaginous callus to a bridging bony callus (Fig. 2).

Clinical studies have also been performed with BMPs as therapeutics for fracture repair. RhBMP-2/OP-1 combined with a particulate bone matrix carrier has been evaluated in established tibial nonunions. An additional study has evaluated rhBMP-2 with a collagenous sponge carrier in acute tibial fractures. While initial reports on these studies appear promising, full publications on the results of these studies are not available at the time of this writing.

Dental and Craniofacial Applications of BMP Therapeutics

In the dental area, there is a need for bone regeneration to fill tooth extraction sockets and replace bone lost due to periodontal disease. In addition, augmentation of the alveolar bone that has decreased in volume with age is required for the placement of dental implants and subsequent dental restoration. Preclinical studies have documented the ability of BMPs to regenerate large segmental defects in the jaws of rats, dogs, and monkeys, suggesting that BMP has substantial potential for the augmentation of alveolar bone (Boyne *et al.,* 1996; Toruimi *et al.,* 1991). Augmentation of maxillary bone by rhBMP-2 has been shown in goat and monkey models, following implantation in the maxillary sinus (Hanisch *et al.,* 1997a; Margolin *et al.,* 1998; McAllister, 1998; Nevins *et al.,* 1996). In addition, vertical augmentation of mandibular bone by rhBMP-2 has been shown in dog models (Cochran *et al.,* 1999; Hanisch *et al.,* 1997b; Sigurdsson *et al.,* 1997). In both settings, the bone appears to behave as native bone and to support placement and osseointegration of dental implants. These studies have led to a series of clinical studies evaluating rhBMP-2, in combination with a collagen sponge matrix, to augment alveolar bone, including in sinus floor augmentation procedures (Boyne *et al.,* 1997). In these studies, bone, induction was observed by CT scans by 16 weeks after implantation of the BMP. Histologic analysis of core biopsies of the induced bone, taken at the time of implant placement (approximately 6 months postapplication), confirmed the formation of normal bone with extensive vascularization. As predicted from the animal studies, the new bone is capable of supporting placement of dental implants and remodels consistent with the biomechanic forces placed on it. Preliminary studies with OP-1 in sinus floor augmentation procedures have yielded mixed results, with variable amounts of bone induction and some inflammation, perhaps associated with the carrier matrix material (Groeneveld *et al.,* 1999; van den Bergh *et al.,* 2000).

The inflammatory process associated with periodontal disease results in the loss of bone surrounding teeth, as well as the loss of attachment structures. Thus, successful treatment of this condition requires not only regeneration of bone, but also tissues such as cementum and the periodontal ligament. Interestingly, the application of single BMPs, including both BMP-7/OP-1 and BMP-2, has been shown to regenerate periodontal tissues in canine and monkey models (Giannobile *et al.,* 1998; Ishikawa *et al.,* 1994; Ripamonti *et al.,* 1996; Sigurdsson *et al.,* 1995; Wikesjo *et al.,* 1999). Clinical studies with BMPs for periodontal regeneration are also being carried out, although publications on these studies are limited.

BMP Gene Therapy

Gene therapy entails the vectoring of a gene into cells which then synthesize the protein product desired. The gene of interest may be introduced using either just DNA or a vectoring system such as a virus. The gene may be introduced directly into the body, or into cells that are infected *ex vivo,* and then reintroduced into the body. One of the major challenges of this therapy is the continued expression of the transgene; expression typically decreases rapidly with time. Because only transient expression of a BMP is necessary (and desirable) to result in bone induction, it provides a special opportunity for gene therapy. Adenoviral vectors carrying a BMP gene (BMP-2 , BMP-7, or BMP-9) have been used directly in animal models to enhance fracture and

create spinal fusions (Alden *et al.,*1999; Baltzer *et al.,* 2000; Franceschi *et al.,* 2000; Helm *et al.,* 2000; Musgrave *et al.,* 1999).

Bone marrow mesenchymal cells or cell lines have also been infected *ex vivo* with BMP-carrying adenoviral vectors (Lieberman *et al.,* 1998, 1999; Mason *et al.,* 2000; Riew *et al.,* 1998). Upon reintroduction into animals, these cells then have been shown to induce bone and repair both bone and cartilage defects. Finally, direct application of DNA consisting of a BMP gene construct has been shown to enhance long bone repair in a rat model (Fang *et al.,* 1996). Together, these studies suggest the potential for use of BMP-based gene therapies. The technical difficulties and safety considerations with current gene therapy modalities need to be carefully considered relative to the traditional application of the BMP proteins.

BMP Biology

Progress in the therapeutic utility of BMP has been paralleled by increases in our understanding of the roles of individual BMPs during formation of the embryonic skeleton and in the role endogenous BMPs play in skeletal homeostasis in adults.

Role of BMPs on Formation of the Embryonic Skeleton

Localization of BMPs to developing skeletal structures provides primary evidence for the roles of these proteins in skeletal patterning and skeletal cell differentiation. Data obtained from *in situ* hybridization studies confirm that transcripts for BMP-2 through BMP-7, and GDF5–7 are all present in the developing embryo at sites and times consistent with their involvement in mesenchymal condensation and cartilage differentiation (reviewed in Gamer and Rosen, 2000).

While many of the upstream signals that control the expression of individual BMPs at specific sites still need to be defined, data from many laboratories suggest that BMPs, fibroblast growth factors (FGFs), and sonic hedgehog (Shh) interact in a hierarchial way to pattern limb skeletal elements (Bitgood and McMahon, 1995; Laufer *et al.,* 1994; Niswander and Martin, 1993). BMP-2 and -4 transcripts are found in the apical ectodermal ridge (AER) and the zone of polarizing activity (ZPA), two important signaling centers (Lyons *et al.,* 1990) that define limb patterning. At these locations, BMP-2 and -4 are thought to act downstream of FGF and Shh signals. Unfortunately, mice carrying null mutations for BMP-2 or BMP-4 die early in embryogenesis before limb patterning occurs (Winnier *et al.,* 1995; Zhang and Bradley, 1996), providing us with little information on specific roles for BMP-2 and -4 in the early limb.

BMP-7 (OP-1) is expressed in the early limb bud in a manner consistent with involvement in early limb formation. Mice lacking BMP-7 survive until birth and display only mild limb skeleton abnormalities (Dudley *et al.,* 1995; Luo *et al.,* 1995). The absence of a strong skeletal phenotype in BMP-7 knockouts may be due to the ability of BMPs to compensate for each other, and BMP-2 and -4 are still present in the limbs of BMP-7 null mice (Dudley and Robertson, 1997). Data from mice carrying null mutations for both BMP-7 and BMPRIB support the idea that BMPs have overlapping functions in skeletal development (Yi *et al.,* 2000).

A clear example of BMPs directing the differentiation of specific skeletal structures is in the GDF5 null mouse, which exhibits a brachypodism phenotype. bp/bp mice display shortening of the long bones of the appendicular skeleton, reduction in the number of digits in the paws, and misshapen bones in both the front and hind feet (Gruneberg and Lee, 1973; Storm *et al.,* 1994). In these mice, expression of GDF5 transcripts normally occurs at all sites where skeletal malformations take place. The lack of GDF5 signals results in failure of joint morphogenesis between individual bones and in alterations in the size and shape of the mesenchymal condensations themselves. These changes are paralleled in humans where mutations in the GDF5 gene result in joint dysmorphogenesis at sites where GDF5 is normally expressed, and in this instance the skeletal anomalies can be directly related to the expression pattern of GDF5 (Polinkovsky *et al.,* 1997; Thomas *et al.,* 1997; Weinstein *et al.,* 2000).

BMP-6 expression appears to mark chondrocytes actively undergoing hypertrophy, and misexpression experiments using the chick limb have established a temporal relationship between the expression of BMP-6 and Indian hedgehog (Ihh) in chondrocyte hypertrophy and replacement by bone (Vortkamp *et al.,* 1996). It is surprising then that BMP-6 null mice appear to have normal skeletons at birth, suggesting that BMP-6 is not required for endochondral ossification to occur (Solloway *et al.,* 1998).

In the axial skeleton, BMP-5 appears to play a central role in formation of the cartilaginous structures of the outer ear, the sternum, and the ribs. Mice lacking a functional BMP-5 gene display the short ear (se) phenotype, with characteristic defects in each of these structures (King *et al.,* 1994). These defects are evident early in skeletal development, as condensations that give rise to affected structures are altered in size and shape. BMP-5 transcripts can also be found in other skeletal elements where no effect of the loss of BMP-5 is observed (Kingsley *et al.,* 1992). Here, the presence of other osteogenic BMPs may compensate for the absence of BMP-5.

The ability to remove specific BMPs and observe skeletal development in mice has clarified the role of BMP-3 in the skeleton. Much historical information on BMP-3 exists; it is the most abundant BMP in bone matrix, and highly purified osteogenic fractions from bone, named osteogenin by Reddi, display bone inductive activity (Luyten *et al.,* 1992; Sampath *et al.,* 1987). However, efforts to show that recombinant BMP-3 induces bone formation have been unsuccessful (Takao *et al.,* 1996). Most surprisingly, examination of the phenotype of BMP-3 null mice revealed that

the loss of BMP-3 during embryogenesis does not affect skeletal patterning, as the size, shape, and location of all skeletal elements appear normal (Daluski *et al.,* 2001). Adult BMP-3 null mice display increased bone density, with a trabecular volume twice that of wild-type littermates at 5–6 weeks of age. While the cellular basis for this phenotype is currently under investigation, preliminary data suggest that BMP-3 can antagonize BMP-2 activity by acting through the activin receptor pathway to modulate BMP-2-mediated transcriptional events. Careful evaluation of the role of BMP-3 in adult bone should help determine the usefulness of modulating endogenous levels of BMP-3 for regulation of bone mass.

GDF11, a recently described BMP family member, is expressed during mouse embryogenesis in a pattern consistent with its involvement in skeletal patterning and differentiation (Gamer *et al.,* 1999; Nakashima *et al.,* 1999). While GDF11 protein shows no osteoinductive activity in the rat ectopic assay (K. Cox, personal communication), mice lacking functional GDF11 exhibit extensive axial skeletal patterning defects, as well as palate abnormalities. This mutant skeletal phenotype is thought to be due to broad homeotic transformation of vertebrae to more anterior developmental fates, resulting in additional lumbar and thoracic vertebrae and the complete absence of a tail (McPherron *et al.,* 1999). Detailed analysis of GDF11 transcripts in the chick limb show that it is highly expressed in limb bud mesenchyme, but is excluded from the central core of prechondrogenic condensations. Ectopic addition of GDF11 to developing limbs results in foreshortening of the limbs through inhibition of both chondrogenesis and myogenesis (Gamer *et al.,* 2000). These observations suggest additional roles for BMP-like molecules as negative regulators of skeletal patterning.

Tooth formation also appears to be BMP mediated, and specific BMPs have been localized in early dental epithelium, in dental mesenchyme, and finally during terminal differentiation of both odontoblasts and ameloblasts (Thesleff *et al.,* 1995; Thesleff and Nieminen, 1996; Vanio *et al.,* 1993).

In addition to the examination of BMP expression, localization of BMP receptors has provided us with clues to BMP responsive cell types during skeletal development. In the chick, BMPRIB is expressed in precartilaginous condensations, whereas BMPRIA is expressed at low levels throughout the limb mesenchyme, with higher levels seen in regions of cell fate specification in the posterior distal aspect of the limb (Kawakami *et al.,* 1996; Zou *et al.,* 1997). At later stages, BMPRIA is highly expressed in the prehypertrophic chondrocytes (Zou *et al.,* 1997). The BMP type II receptor is also found in precartilaginous condensations, as well as in the AER and interdigitial mesenchyme (Kawakami *et al.,* 1996). Studies with dominant-negative and constitutively active BMP receptors in chick have revealed critical roles of BMP signaling in chondrogenesis and skeletal patterning (Enomoto-Iwamoto *et al.,* 1998; Zhou and Niswander, 1996). In addition, data from studies in which BMPRIB has been inactivated in mice show that significant receptor function overlap exists and that loss of BMPRIB results in small alterations in skeletal structures, suggesting that BMPRIB has broadly overlapping functions with other BMP receptors during skeletal development (Baur *et al.,* 2000; Yi *et al.,* 2000).

Developmental analysis of the function of BMP antagonists suggests that they guard against BMP activity during formation of the skeleton. Inactivation of the noggin gene in mice results in hyperplasia of cartilage condensations and failure of joint formation (Brunet *et al.,* 1998). This phenotype is reminiscent of that seen in humans with missense mutations in noggin. Both proximal symphalangism and multiple synostosis syndrome, autosomal-dominant disorders, are characterized by joint fusion caused by the union of two individual bones (Gong *et al.,* 1999). Gain-of-function studies in the chick limb have also shown that too much noggin blocks BMP activity and inhibits normal skeletal chondrogenesis (Capdevila *et al.,* 1998; Pathis *et al.,* 1999). *In vitro* studies using primary fetal osteoblasts have shown that BMP-2 induces noggin expression in target cells, creating a negative feedback loop, which tightly controls BMP activity (Gazzerro *et al.,* 2000).

The physiological role of other BMP antagonists such as chordin, follistatin, and members of the Dan family in skeletal patterning and skeletal cell differentiation has also suggested that these proteins act to dampen BMP activity at sites where it is expressed (Gamer and Rosen, 2000).

Osteogenesis in the Adult Skeleton

While determination of the size, shape, and location of skeletal elements is an embryonic event, the adult skeleton undergoes continuous turnover, a process known as bone remodeling. Removal of existing bone and its replacement by new bone is carried out in a highly controlled manner and requires the differentiation of both osteoblasts and osteoclasts from precursors located in the bone marrow environment (Manolagas and Jilka, 1995). The exact nature of the signals that control remodeling remains to be established, but it is likely that both osteoblast and osteoclast precursors are affected by systemic and local signals and by mechanical stimulation (Rodan, 1998).

BMPs have been proposed to be the local signals that induce commitment of mesenchymal stem cells resident in bone marrow into osteoprogenitors and osteoblasts (Abe *et al.,* 2000; Manolagas and Weinstein, 1999). Several lines of evidence make this hypothesis an attractive one. Much data exist to show that BMPs are present in bone matrix in a form that allows for their release or presentation to marrow stromal cells, cells that can differentiate into osteoblasts in response to BMPs (Rosen *et al.,* 1996). Osteoblasts have also been shown to synthesize and secrete BMPs both *in vitro* and *in vivo,* suggesting that once BMPs initiate MSC differentiation, a positive feedback loop is created, allowing for the production of additional BMP signals (Suzawa *et al.,* 1999). The BMP antagonists noggin and gremlin are

present in bone and are made by osteoblasts (Gazzarro *et al.,* 1998; Pereira *et al.,* 2000), suggesting that local activation of MSC may be highly controlled. It has also been reported that BMP-1, the procollagen C propeptide, is able to release BMPs from collagenous matrix, providing another way that endogenous BMPs may be made available in a site-specific manner during the remodeling process (Wardle *et al.,* 1999). Finally, bone formation and bone resorption during remodeling may be linked through BMPs, as BMPs are thought to regulate the transcription of several osteoblast-specific transcription factors, which in turn may regulate transcription of RANK ligand, a signal important for the differentiation of hematopoietic progenitors into osteoclasts (Manolagas and Weinstein, 1999). If this is the case, BMPs may be involved in every step of the remodeling process.

These tantalizing links between BMPs and bone remodeling have become the focus of much research and may lead to new therapeutic approaches to osteopenia. Of fundamental importance in designing treatments that utilize site-specific activation of endogenous BMPs is the identification of which BMPs are available to affect bone remodeling and which cell types at each step of the remodeling process are the targets of these signals. Once the BMPs necessary for remodeling are identified, it will be necessary to determine whether factors that are known to change the balance in remodeling toward formation or resorption do so through effects on these BMPs. *In vitro* studies have shown that estrogens and glucocorticoids, two agents known to affect remodeling, increase BMP-6 synthesis by osteoblasts (Boden *et al.,* 1997; Ricard *et al.,* 1998). However, mice in which the BMP-6 gene has been removed through homologous recombination in ES cells have no apparent skeletal defects and do not develop osteopenia, suggesting that BMP regulation of remodeling is likely to be complex (Solloway *et al.,* 1998).

It will also be of great interest to determine whether the decrease in MSC present in bone marrow that occurs with aging is related to the changes in levels of specific BMPs found in bone matrix in older animals (D'Ippolito *et al.,* 1999). If BMPs are required for MSC survival, as well as MSC differentiation, changing the BMP content of bone matrix and bone marrow may have important clinical benefits. A hint that this may be the case has been provided by the production of transgenic mice in which noggin, a potent BMP antagonist, is overexpressed using the bone-specific osteocalcin promoter. These mice have osteopenia and are prone to fracture, suggesting that a reduction in osteogenic BMPs available to the postnatal skeleton reduces overall bone formation and bone healing (Devlin *et al.,* 2000).

New bone formation also occurs in the adult skeleton during the process of fracture repair, when osteoblast precursors resident in marrow and periosteum differentiate into osteoblasts in a highly regulated manner (Rosen and Thies, 1992). BMPs have been shown to be present at fracture repair sites, and several lines of evidence support the role of BMPs in this process. First, all of the cell types that synthesize new bone during fracture healing have been shown to be targets for BMPs *in vitro* and to possess BMP receptors *in vivo* (Bostrom *et al.,* 1995). In addition, immunohistochemical identification of BMP-2 and -4 at the fracture site in rats suggests that BMPs may be released from bone matrix at the time of fracture and are then able to act on target cells in the area or recruit cells to the fracture site, where they differentiate into osteoblasts (Nakase *et al,* 1994). Alternatively, BMPs may be synthesized by osteoblasts resident in bone and activated by other cytokines released during the fracture healing process. While we still do not know which BMPs are absolutely required for fracture repair, data from the *short ear mouse,* a naturally occurring null for BMP-5, show that mice lacking BMP-5 have a reduced capacity to repair rib fractures as adults (Green, 1958). The availability of animal models in which specific BMPs, BMP receptors, and BMP antagonists have been removed should allow us to address this issue and to begin to understand what regulates endogenous BMP production during fracture healing.

Another circumstance in which the adult skeleton produces new bone is during distraction osteogenesis, a method of bone lengthening that takes advantage of the inherent capacity of bone to repair after breaking (Paley, 1988). In a clinically controlled setting, the bone to be lengthened is broken and the two opposing ends are increasingly separated from each other over the course of days or weeks. The end result of this engineered trauma is bone regeneration tailored to the distance of bone separation (Yasui *et al.,* 1997). We are just beginning to understand the molecular and cellular events that form the basis of distraction osteogenesis, and from these initial studies, it seems likely that BMPs are important mediators of bone formation at the distraction site. Data demonstrate temporal and spatial localization of mRNAs for BMPs in a rat model of distraction osteogenesis and link the mechanical stress/tension needed for successful distraction osteogenesis with BMP gene expression (Sato *et al.,* 1999). It is likely that mechanical forces influence BMP gene expression at sites of distraction osteogenesis through a yet to be understood process and that BMPs are components of the complex signals required during several stages of the repair. The precise link between mechanical stress and BMP gene expression remains to be discovered, as do the other signaling pathways that must interact with BMPs to produce the cascade of events that results in temporally delayed bone formation. Understanding what regulates the temporal differences in bone formation seen between distraction osteogenesis and normal fracture healing, that are thought to be BMP-mediated events, should provide insight into how BMPs affect the rate of repair.

Data from Mundy *et al.* (1999) identified statins as a class of previously unknown bone anabolic agents. Preliminary studies suggest that statins promote bone formation *in vivo* by specifically activating the BMP-2 promoter in osteoblasts and osteoprogenitor cells. These findings provide the rationale for the development of systemic agents

that would promote bone formation via activation of BMP-2 transcription at skeletal sites, creating a new therapeutic modality for osteoporosis.

CHAPTER 51

Bone Morphogenetic Protein Receptors and Actions

Kohei Miyazono

Department of Molecular Pathology, Graduate School of Medicine, University of Tokyo, Tokyo 113-0033, Japan; and Department of Biochemistry, The JFCR Cancer Institute, Tokyo 170-8455, Japan

Introduction: BMPs

Bone morphogenetic proteins (BMPs) were originally identified as proteins that induce the formation of bone and cartilage tissues when implanted at ectopic sites in rats (Wozney *et al.,* 1988; Reddi, 1998). *In vitro,* BMPs have potent effects on the regulation of growth and differentiation of chondroblast and osteoblast lineage cells. Moreover, BMPs have been shown to be multifunctional cytokines with a wide range of biological activities in various cell types, including epithelial cells, mesenchymal cells, monocytes, and neuronal cells (see Chapter 50).

BMPs belong to a larger superfamily, known as the transforming growth factor-β (TGF-β) superfamily, which includes TGF-βs, activins and inhibins, and Müllerian inhibiting substance (MIS). More than a dozen molecules have been identified in the BMP subfamily; these can be classified into several subgroups based on similarities in structure and function. BMP-2 and BMP-4 are highly similar and form one subgroup (BMP-2/4 group). BMP-5, BMP-6, BMP-7 (also termed osteogenic protein-1; OP-1), and BMP-8 (OP-2) form another subgroup (OP-1 group). Growth/differentiation factor-5 (GDF-5, also termed cartilage-derived morphogenetic protein-1, CDMP-1), GDF-6 (CDMP-2, also termed BMP-13), and GDF-7 (BMP-12) belong to a third subgroup (GDF-5 group) (Fig. 1) (Kawabata and Miyazono, 2000). Most of the members of the BMP-2/4 and OP-1 groups have been shown to induce formation of bone and cartilage tissues *in vivo,* whereas those of the GDF-5 group induce cartilage and tendon-like tissues. In contrast, certain other BMPs appear not to induce formation of bone and cartilage tissues *in vivo.* Myostatin (also termed GDF-8) plays a central role in muscle formation, but probably not in bone formation.

In this chapter, mechanisms for the signal transduction by BMPs, mainly those in the BMP-2/4, OP-1, and GDF-5 subgroups, are described and compared to the TGF-β signaling system. Although the signaling mechanisms of serine/threonine kinase receptors and Smads have been intensively studied in invertebrates, i.e., in *Drosophila* and *C. elegans* (Zimmerman and Padgett, 2000), BMP signaling pathways in mammals will be the principal focus of this chapter.

BMP Receptors

Serine/Threonine Kinase Receptors

Members of the TGF-β superfamily bind to two distinct types of serine/threonine kinase receptors, termed type I and type II receptors (Heldin *et al.,* 1997). Both type II and type I receptors are essential for signal transduction. TGF-β and activin ligands bind to type II receptors independently of type I receptors, whereas type I receptors can bind these ligands only in the presence of type II receptors. In contrast, BMPs weakly bind to type II receptors independently of type I receptors, but their binding affinity is dramatically increased when both types of receptors are present (see below) (Liu *et al.,* 1995; Rosenzweig *et al.,* 1995). The type II receptor transphosphorylates the type I receptor, which transmits intracellular signals.

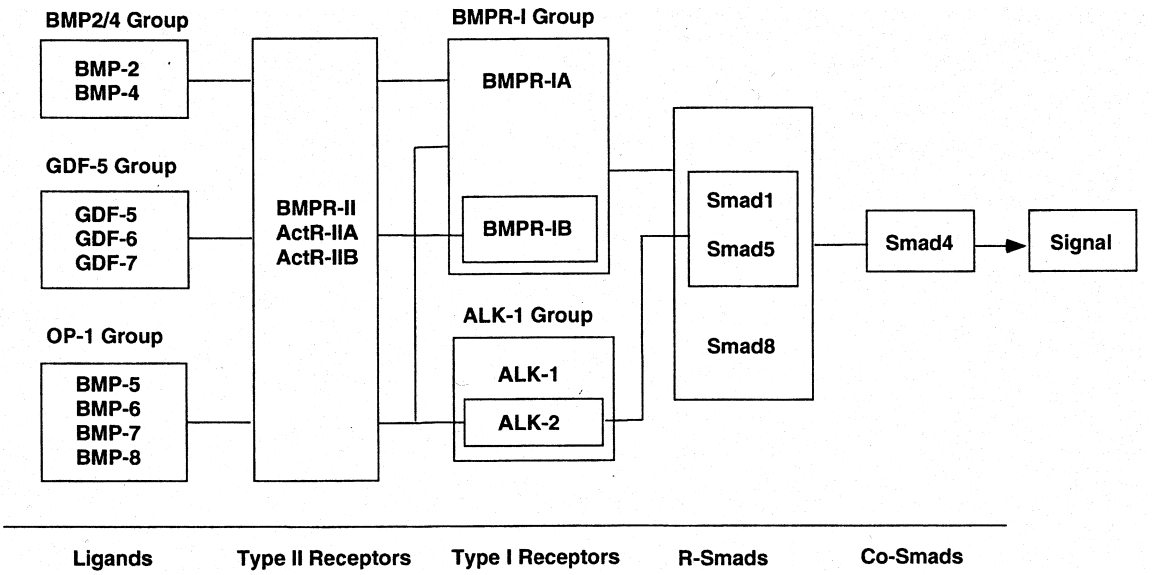

Figure 1 Relationships between BMPs, type II and type I receptors, and Smad proteins in signal transduction. Among the receptors of the ALK-1 group, only ALK-2 serves as a receptor for the BMPs in the OP-1 group. Similarly, BMPR-IB, but not BMPR-IA, preferentially functions as a type I receptor for GDF-5. Of the BMP-R-Smads, Smad1 and Smad5 are activated by ALK-2, whereas all three BMP-R-Smads are activated by BMPR-IA and BMPR-IB.

The structures of the type I and type II receptors are schematically shown in Fig. 2A. They have a relatively short extracellular domain, a single membrane-spanning domain, and an intracellular domain containing a serine-/threonine kinase domain. The extracellular domains have several conserved cysteines, which are important for the formation of characteristic three-dimensional structures (Greenwald *et al.,* 1999; Kirsch *et al.,* 2000a). In addition to the serine/threonine kinase domain, the intracellular domains of type I receptors, but not those of type II receptors, have a characteristic GS domain (glycine and serine-rich domain) located N-terminal to the serine/threonine kinase domains. In the kinase domain, type I receptors have a characteristic structure, denoted L45 loop, between kinase subdomains IV and V. The C-terminal tails of type I receptors are very short (less than 9 amino acids), whereas those of type II receptors are more than 24 amino acids long. The C-terminal tail of BMPR-II is much longer (530 amino acids) than other type II receptors. Although the functional importance of the C-terminal tail of BMPR-II is unknown, mutations in this domain have been found in some patients with familial primary pulmonary hypertension (PPH) (see below) (IPPH Consortium, 2000; Deng *et al.,* 2000).

BMP Type I Receptors

Seven type I receptors, termed activin receptor-like kinases (ALKs) 1 through 7, have been identified in mammals. ALKs can be classified into three subgroups, i.e., the BMPR-I group, the ALK-1 group (Fig. 1), and the TβR-I group (Kawabata and Miyazono, 2000). ALK-3 and ALK-6 are very similar to each other (BMPR-I group), and are also denoted BMP type IA and type IB receptors (BMPR-IA and BMPR-IB), respectively. The kinase domains of BMPR-IA and BMPR-IB have 85% amino acid sequence identity. Functional differences between the intracellular domains of BMPR-IA and BMPR-IB have not been determined. ALK-5, ALK-4, and ALK-7 are structurally similar to each other (TβR-I group), and ALK-5 and ALK-4 serve as TGF-β and activin type I receptors (TβR-I and ActR-IB), respectively. Ligands for ALK-7 have not yet been identified. ALK-1 and ALK-2 are structurally similar to each other (ALK-1 group), and they are distantly related to the other type I receptors. ALK-1 is highly expressed in endothelial cells and binds TGF-β in these cells (Oh *et al.,* 2000). ALK-2 is a type I receptor for certain BMPs, including BMP-6 and BMP-7 (ten Dijke *et al.,* 1994; Macías-Silva *et al.,* 1998; Ebisawa *et al.,* 1999). Despite the low degree of similarity between the receptors of the ALK-1 group and those of the BMPR-I group, they transduce similar intracellular signals.

BMPR-IA is expressed in various types of cells, including human foreskin fibroblasts, MC3T3-E1 osteoblasts, C2C12 myoblasts, and ROB-C26 osteoprogenitor cells (ten Dijke *et al.,* 1994; Nishitoh *et al.,* 1996; Ebisawa *et al.,* 1999). ALK-2 is also widely expressed in various cells, including human foreskin fibroblasts, MC3T3-E1 cells, and C2C12 cells. In contrast, expression of BMPR-IB is restricted to certain cell types, including ROB-C26 cells and glioblastoma cell lines.

Members of the BMP family bind with different affinities to BMPR-IA, BMPR-IB, and ALK-2, overexpressed in mammalian cells. Under physiological conditions, BMP-2 and BMP-4 bind to BMPR-IA and BMPR-IB (ten Dijke *et al.,* 1994). In contrast, BMP-6 and BMP-7 bind strongly

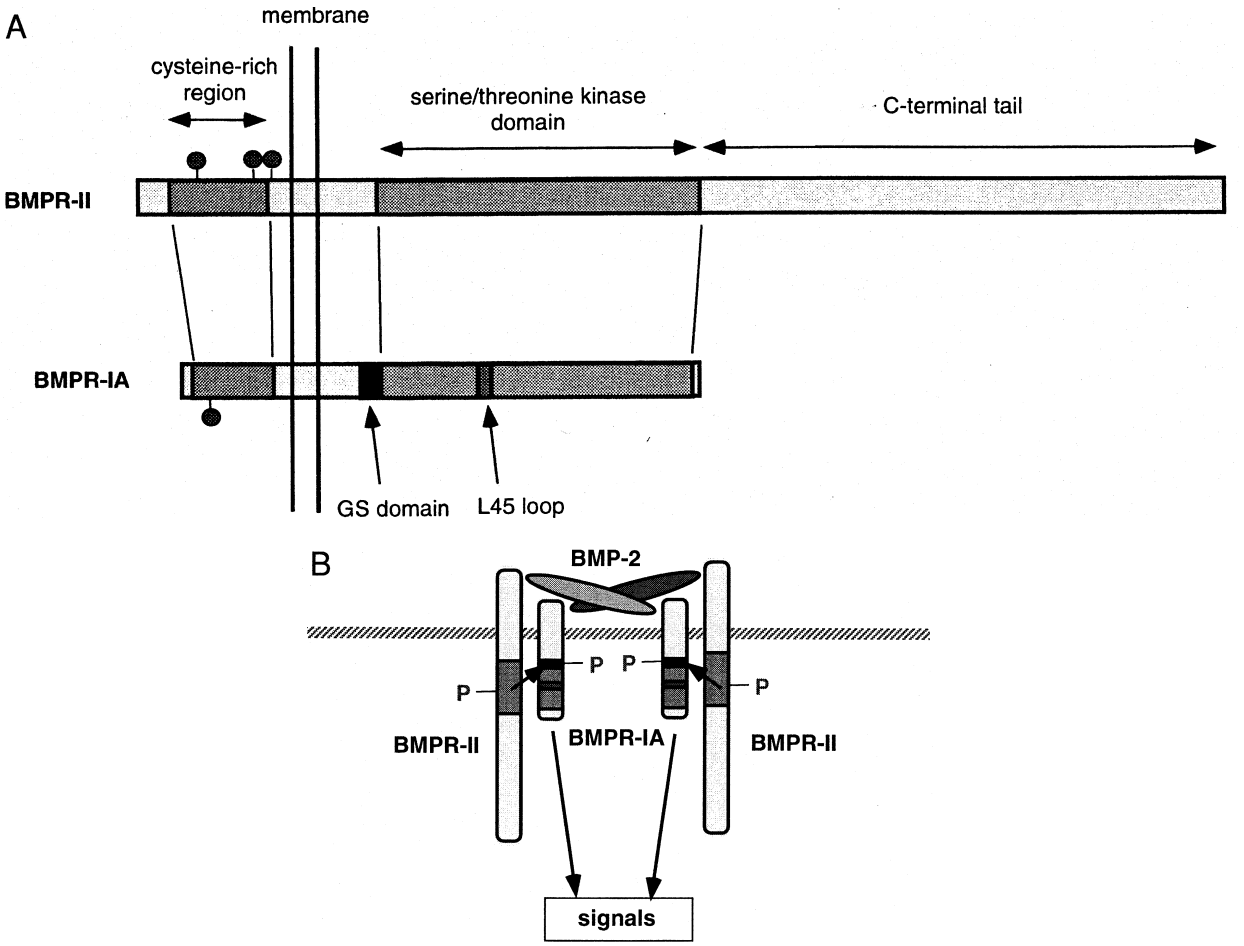

Figure 2 BMP type II and type I receptors. (A) Structure of BMPR-II and BMPR-IA. ActR-IIA and ActR-IIB have similar structures, but shorter C-terminal tails than BMPR-II. BMPR-IB and ALK-2 have overall structures similar to that of BMPR-IA. Closed circles indicate N-glycosylation sites. (B) BMP-2 has an elongated structure, and binds to BMPR-IA and BMPR-II through wrist and knuckle epitopes, respectively. BMPR-II transphosphorylates the GS domain of BMPR-IA, and BMPR-IA kinase transduces intracellular signals.

to ALK-2, and weakly to BMPR-IB (Ebisawa *et al.,* 1999). GDF-5 preferentially binds to BMPR-IB, but not to other receptors (Nishitoh *et al.,* 1996). In addition to members of the BMP family, MIS binds to BMPR-IB together with its specific type II receptor, MISR-II (Gouédard *et al.,* 2000). Thus, BMP type I receptors are shared by certain other members of the TGF-β superfamily. Although ALK-2 was originally identified as a type I receptor for activin (ActR-I), under physiological conditions it functions as a receptor for BMPs but not for activins.

Truncated forms of BMPR-IA and BMPR-IB, lacking the intracellular domains, or kinase inactive forms with mutations in the ATP-binding sites, have been widely used to study the functions of BMPs. BMPs induce differentiation of C2C12 cells into osteoblast-like cells, but in the presence of the truncated form of BMPR-IA, cells fail to become osteoblasts, differentiating instead into mature myocytes (Namiki *et al.,* 1997). In chick limbs, BMPs induce apoptosis in interdigital tissues, since truncated forms of BMPR-IA and BMPR-IB induce web formation in these regions (Zou and Niswander, 1996; Yokouchi *et al.,* 1996).

The two unique structures in the intracellular domain, i.e., GS domain and L45 loop, are observed only in type I receptors, but not in type II receptors. Mutations in the GS domains (see below) lead to constitutive activation of type I receptors. The constitutively active BMP type I receptors, including those of the BMPR-I group and the ALK-2 group, stimulate osteoblast differentiation *in vitro* (Fujii *et al.,* 1999). The L45 loop located between kinase subdomains IV and V of type I receptors is most important for the determination of intracellular signaling.

BMP Type II Receptors

Three receptors, i.e., BMPR-II, ActR-IIA, and ActR-IIB, serve as type II receptors for BMPs. BMPR-II is specific for BMPs, whereas ActR-IIA and ActR-IIB are shared by activins and BMPs. In contrast to type I receptors, these type II receptors appear to bind most BMPs.

Two alternatively spliced variants of BMPR-II have been identified (Rosenzweig *et al.,* 1995; Liu *et al.,* 1995). The long form of BMPR-II is composed of 1038 amino

acids, and includes the long C-terminal tail rich in serines and threonines. The short form lacks the long C-terminal tail, but its expression is rare in most tissues. The long and short versions have been reported to be functionally indistinguishable in *Xenopus* assays (Ishikawa *et al.,* 1995); however, nonsense mutations in the C-terminal tail have been found in some patients with familial PPH, suggesting that this region plays an important role in signaling activity (IPPH Consortium, 2000; Deng *et al.,* 2000).

BMPR-II binds ligands only weakly by itself, but its ligand-binding affinity is increased in the presence of type I receptors. ActR-IIA and ActR-IIB bind activins and BMPs, but the binding affinities of ActR-IIA/IIB to BMPs are lower than those to activins (Yamashita *et al.,* 1995). ActR-IIA/IIB binds activins with high affinity in the absence of type I receptors. Similar to BMPR-II, however, ActR-IIA/IIB binds BMPs with high affinity only in the presence of type I receptors (Rosenzweig *et al.,* 1995; Liu *et al.,* 1995).

BMPR-II and ActR-IIA/IIB are widely expressed in various tissues. BMPR-II is expressed in skeletal muscle, heart, brain, and lung, and plays an important role in mesoderm formation during early embryogenesis (Beppu *et al.,* 2000).

Molecular Mechanism of BMP Receptor Activation

BMP Binding to Receptor Extracellular Domains

The extracellular domains of BMP type I receptors interact with ligands even in the absence of type II receptors. Since a soluble form of BMPR-IA lacking the transmembrane and intracellular domains binds BMPs in the absence of type II receptors, it may be useful as an antagonist of BMPs (Natsume *et al.,* 1997). The binding affinity of BMP-2 for soluble BMPR-IA is about 1 nM, and that of BMPR-IB is about 11 nM (Kirsch *et al.,* 2000b). In contrast, binding affinities for the extracellular domains of BMPR-II and ActR-IIA are only 100 and 50 nM, respectively.

Two receptor-binding motifs have been identified in BMP-2 (Kirsch *et al.,* 2000b) (Fig. 2B). A large epitope 1 (termed "wrist epitope") is a high-affinity binding site for BMPR-IA, and a smaller epitope 2 (termed "knuckle epitope") is a low-affinity binding site for BMPR-II. The wrist epitopes from both monomers contribute to binding to BMPR-IA, whereas the knuckle epitope from only one monomer is involved in the binding to BMPR-II. The wrist and knuckle epitopes are very closely located to each other, possibly facilitating interaction between BMPR-IA and BMPR-II in activation of the receptor kinases. Interestingly, certain BMP-2 mutants in the knuckle epitope (Ala-34 and Leu-90), but not in the wrist epitope, function as antagonists of BMP-2, since these mutants bind to BMPR-IA with the wrist epitope, but fail to interact with BMPR-II through the mutated knuckle epitope.

The extracellular domain of ActR-IIA has a structure termed three-finger toxin fold, composed of three pairs of β-strands projecting from the palm domain with a conserved scaffold of disulfide bridges (Greenwald *et al.,* 1999). The extracellular domains of ActR-IIA and BMPR-IA have very similar three-dimensional configurations but with some differences (Kirsch *et al.,* 2000a). The BMPR-IA extracellular domain consists of two β-sheets and one α-helix (helix α1); the latter is missing in ActR-IIA, and may serve as a key element in type I receptors for specific ligand-binding.

Activation of Serine/Threonine Kinases

Small fractions of type II and type I receptors are present as preexisting homodimers as well as heterodimers on the cell surface in the absence of ligand stimulation (Gilboa *et al.,* 2000). All BMP receptors form oligomers, including type II/type I heteromers (BMPR-II/BMPR-IA and BMPR-II/BMPR-IA) and type II/type II and type I/type I oligomers (BMPR-II/BMPR-II, BMPR-IA/BMPR-IA, BMPR-IB/BMPR-IB, and BMPR-IA/BMPR-IB). Ligand binding increases significantly receptor hetero- and homooligomerization, except for BMPR-II homodimers. Receptor oligomerization may also induce conformational alterations of these receptor molecules.

The type II receptor kinase is constitutively active in the absence of ligand. Upon ligand binding, the type II receptor kinase transphosphorylates the GS domain of type I receptor, resulting in the activation of type I receptor kinases (Fig. 2B). The intracellular substrates are then activated by the type I kinase (Wrana *et al.,* 1994).

Phosphorylation of the GS domain is a critical event in signal transduction by the serine/threonine kinase receptors. Crystallographic analysis of the intracellular domain of TβR-I revealed that the inactive conformation of the TβR-I kinase is maintained by physical interaction between the GS domain, the N-terminal lobe, and the activation loop of the kinase (Huse *et al.,* 1999). Upon phosphorylation of the GS domain by TβR-II, the receptor is converted to an active conformation. Mutations of Thr-204 in TβR-I and the corresponding Gln in BMP type I receptors to acidic amino acids (Asp or Glu) lead to constitutive activation of the type I receptors (Wieser *et al.,* 1995). The constitutively active type I receptors transmit intracellular signals in the absence of ligands or type II receptors, indicating that type I receptors are a downstream component of the type II receptor signaling pathways and that they determine the specificity of the intracellular signals. However, truncation of the C-terminal tail of BMPR-II was found in some familial PPH patients, suggesting that yet unidentified signals may be transduced through BMPR-II (IPPH Consortium, 2000; Deng *et al.,* 2000).

FKBP12 is a binding protein for immunosuppressants such as FK506 and rapamycin. It binds to the Leu–Pro sequence in the GS domain of type I receptors, and negatively regulates the activity of type I receptors (Wang *et al.,*

1996; Chen *et al.,* 1997). FKBP12 thus prevents spontaneous activation of type I receptors by type II receptors.

The L45 loop of the N lobe in the type I receptor protrudes from the kinase domain (Huse *et al.,* 1999) and specifically interacts with intracellular substrates, e.g., Smads (Feng and Derynck, 1997). Amino acid sequences of the L45 loop are conserved in each type I receptor subgroup, but diverge between different subgroups. The L45 loop of the BMPR-I group is more similar to that of the TβR-I group than that of the ALK-1 group; however, receptors of the BMPR-I and ALK-1 groups activate a similar set of Smads, while those of the TβR-I group activate a distinct set of Smads.

PSEUDORECEPTOR: BAMBI

Xenopus BAMBI is a pseudoreceptor for serine/threonine kinase receptors with a high degree of sequence similarity to the human *nma* gene product (Onichtchouk *et al.,* 1999). BAMBI/Nma is structurally related to type I serine/threonine kinase receptors, but the former does not have the intracellular domain. BAMBI stably interacts with various type I and type II receptors and inhibits signaling by these receptors. Since the expression of BAMBI and *nma* is induced by BMP and TGF-β (Onichtchouk *et al.,* 1999; Akiyoshi *et al.,* 2001), BAMBI/Nma may regulate BMP/TGF-β signaling via a negative feedback loop.

Mutations of BMP Receptors *in Vivo*

During embryogenesis, BMPR-IA is ubiquitously expressed, while expression of BMPR-IB is more limited. In adult tissues BMPR-IB is observed only in brain. BMPR-IB and BMPR-IA are expressed in glioblastoma (Yamada *et al.,* 1996), and their expression correlates very well with the malignancy grade. Since BMPs induce differentiation of neuroepithelial cells into astrocytes, BMPs may play an important role in preventing the progression of this tumor.

BMPs play essential roles during embryogenesis, and mice lacking BMP-2 or BMP-4 exhibit defects in mesoderm formation during early embryonic stages. Similarly, gene targeting of *BMPR-IA* or *BMPR-II* leads to defects in mesoderm formation. Homozygous *BMPR-IA* mutant mice die by E9.5 due to defects in mesoderm formation during gastrulation (Mishina *et al.,* 1995). *BMPR-II* null mice also die by E9.5, and their phenotype is very similar to that of *BMPR-IA*$^{-/-}$ mice (Beppu *et al.,* 2000).

BMPR-IB-deficient mice are viable, but exhibit short limbs and abnormal digit cartilage, similar to *GDF-5* null mice (Baur *et al.,* 2000; Yi *et al.,* 2000). Analysis of *GDF-5*; *BMPR-IB* double mutant mice revealed that GDF-5 is a physiological ligand for BMPR-IB *in vivo,* although other receptors may also be involved in the GDF-5 signaling pathway. In addition, analysis of *BMP-7*; *BMPR-IB* double knockout mice revealed that BMP-7 and BMPR-IB may act in part in overlapping pathways.

Some, but not all, *ActR-IIA*-deficient mice exhibit hypoplasia of the mandible and other skeletal abnormalities (Matzuk *et al.,* 1995). Defects in the reproductive system and decrease in the secretion of follicle stimulating hormone (FSH) are also observed in these mice. *ActR-IIB* null mice exhibit complicated cardiac defects, and abnormalities in lateral asymmetry and vertebral patterning (Oh and Li, 1997). ActR-IIA and ActR-IIB also play important roles in the formation of the endocrine pancreas (S. K. Kim *et al.,* 2000).

Primary pulmonary hypertension is characterized by stenosis of precapillary pulmonary arteries. Proliferation of endothelial cells and smooth muscle cells is observed in the pulmonary arteries of PPH and leads to high pulmonary artery pressure. Familial PPH occurs as an autosomal dominant disorder with reduced penetrance. Mutations in the *BMPR-II* gene are found in some familial PPH patients (IPPH Consortium, 2000; Deng *et al.,* 2000). Mutations can be observed in various regions of this gene, including the extracellular domain, transmembrane domain, intracellular domain, and even the C-terminal tail. BMP signaling may thus play an important role in the maintenance of vascular integrity in the pulmonary arteries.

Intracellular Signaling

Signaling by Smad proteins

STRUCTURE OF SMADS

Three Classes of Smads Smads are the major signal transducers for the serine/threonine kinase receptors (Heldin *et al.,* 1997; Miyazono *et al.,* 2000). Activated type I receptor kinases phosphorylate receptor-regulated Smads (R-Smads). R-Smads then form a complex with common-partner Smads (Co-Smads) and translocate to the nucleus. The oligomeric Smad complexes regulate the transcription of target genes through interaction with various transcription factors and transcriptional coactivators or corepressors. Inhibitory Smads (I-Smads) negatively regulate the action of R-Smads and/or Co-Smads.

Eight different Smads have been identified in mammals. They can be classified into three subclasses as described above, i.e., R-Smad, Co-Smad, and I-Smad. R-Smads are subdivided into those activated in BMP signaling pathways (BMP-R-Smads) and those in TGF-β/activin signaling pathways (TGF-β-R-Smads). BMP-R-Smads include Smad1, Smad5, and Smad8, while Smad2 and Smad3 are TGF-β-R-Smads. Smad4 is the only Co-Smad in mammals, shared by both the BMP and the TGF-β/activin signaling pathways. Smad6 and Smad7 are I-Smads. Smad1 and Smad5 have been shown to induce the differentiation of C2C12 myoblasts into osteoblasts, a process facilitated by the addition of Smad4 (Fujii *et al.,* 1999). Moreover, osteoblast differentiation by Smad1/5 is facilitated upon nuclear translocation of R-Smads induced by ligand or receptor activation.

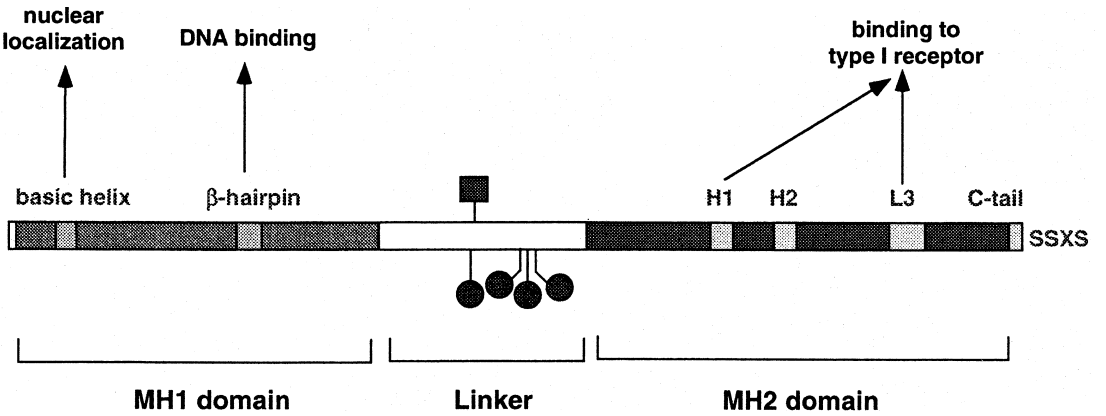

Figure 3 Structure of R-Smads. Helix 2 (H2) and the C-terminal region are important for specific interaction with DNA-binding protein FAST1, but other portions of R-Smads may also be able to interact with various DNA-binding proteins. Circles in the linker region indicate the PXS/TP (or S/TP) motif, and the square indicates the PY motif.

Smads have highly conserved N- and C-terminal regions termed Mad homology (MH) 1 and MH2 domains, respectively, which are bridged by a linker region of variable length and amino acid sequence (Fig. 3). MH2 domains are found in all three classes of Smads, whereas MH1 domains are conserved only in R-Smads and Co-Smads. The N-terminal regions of I-Smads highly diverge from those of the other Smads. R-Smads also have a characteristic Ser-Ser-Val/Met-Ser sequence (SSXS motif) at the C-terminal ends. The SSXS motif is phosphorylated by the type I receptors, resulting in the activation of R-Smads for signaling.

Smad1, Smad5, and Smad8 are structurally highly similar to each other, and the functional differences between them are unknown. However, Smad1 and Smad5, but not Smad8, are activated by BMP-6 and BMP-7 (Ebisawa *et al.,* 1999), whereas all three BMP-R-Smads are activated by BMP-2 (Aoki *et al.,* 2001). It has been reported that Smad1 and Smad5 are activated by TGF-β in certain cell types (X. Liu *et al.,* 1998); however, it is currently unknown whether activation of Smad1/5 occurs directly by TβR-I or through other receptors (e.g., ALK-1).

MH2 Domain The MH2 domain, composed of about 200 amino acids, have various important functions. It is responsible for (1) interaction with receptors, (2) binding to SARA (Smad anchor for receptor activation), (3) oligomer formation with other Smads, (4) interaction with various DNA-binding proteins, and (5) transcriptional activation. In the absence of receptor activation, the MH2 and MH1 domains physically interact with each other, and repress each other's function. Upon phosphorylation of the SSXS motif by receptors, this interaction is eliminated, and R-Smads become activated.

A region composed of 17 amino acids, termed the "L3 loop," protrudes from the surface of the molecule and interacts with the L45 loop of type I receptors (Chen *et al.,* 1998; Shi *et al.,* 1997; Wu *et al.,* 2000). The amino acid sequences of the L3 loop are conserved in BMP-R-Smads and in TGF-β-R-Smads, but diverge between these two groups. In addition to the L3 loop, the α-helix H1 in the MH2 domain, composed of eight amino acids, is also required for the interaction of BMP-R-Smads with type I receptors of the ALK-1 group (Chen and Massagué, 1999). The α-helix H2 and the C-terminal tail of the MH2 domain of R-Smads may interact with specific DNA-binding proteins and determine the specificity of the downstream signaling pathways (Fig. 3).

MH1 Domain The MH1 domains, composed of approximately 130 amino acids, are responsible for (1) binding to specific DNA sequences, (2) interaction with certain DNA-binding proteins, (3) nuclear translocation, and (4) repression of the function of MH2 domains. The direct-DNA binding of Smads occurs through an 11-amino-acid "β-hairpin loop," which protrudes from the surface of the molecule (Shi *et al.,* 1998). Although the structure of the β-hairpin loop is conserved in R-Smads and Co-Smad in mammals, only Smad4 and Smad3 bind to the characteristic Smad-binding element (AGAC or GTCT sequence) (Zawel *et al.,* 1998). In contrast, BMP-R-Smads bind to the AGAC/GTCT sequence only weakly and bind instead to the GCCGnCGC sequence with relatively high affinity (Kim *et al.,* 1997; Kusanagi *et al.,* 2000). Smad1 was shown to bind to the GCAT motif in the *Xenopus Xvent.2B* promoter (Henningfeld *et al.,* 2000).

The C-terminal half of α-helix 2 in the MH1 domain, located N-terminal to the β-hairpin loop, is rich in basic residues (Lys-40-Lys-Leu-Lys-Lys; termed "basic helix") (Shi *et al.,* 1998). The basic helix of R-Smads, but not that of Co-Smad, serves as a nuclear localization signal through interacting with importin β (Xiao *et al.,* 2000a,b).

Linker Region The linker regions of R-Smads contain four copies of PXS/TP (or S/TP) motifs which are phosphorylated by MAP kinases (Kretzschmar *et al.,* 1997). When these motifs are phosphorylated, R-Smads become unable to translocate into the nucleus.

The PPXY sequence (known as the PY motif) interacts with proteins containing WW domains. A PY motif is found

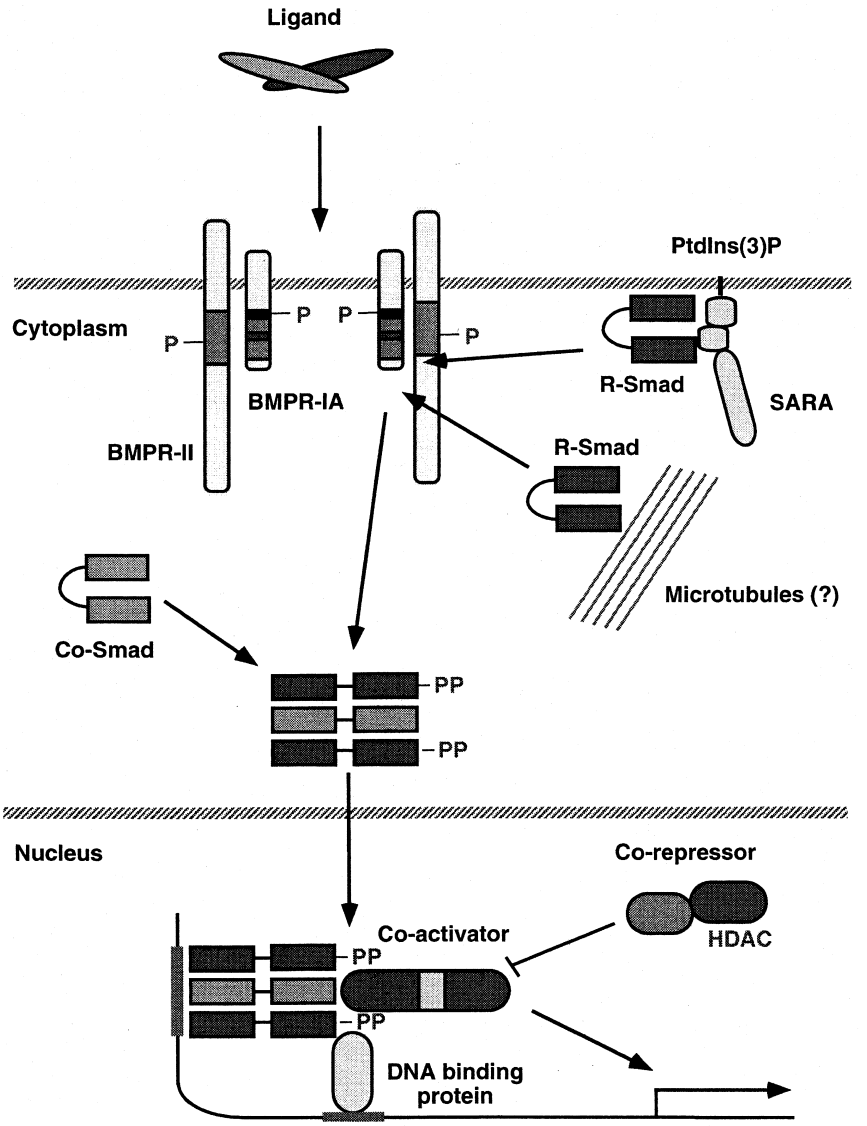

Figure 4 Mechanism of activation of Smad signaling pathway. R-Smads exist in the cytoplasm through interaction with membrane anchoring protein SARA. TGF-β-R-Smads have been shown to interact with microtubules, but it is not known whether BMP-R-Smads also interact with the microtubular network. Transcriptional corepressors inhibit the transcription induced by transcriptional coactivators, but transcriptional corepressors that specifically interact with BMP-R-Smads have not been identified.

in all Smads except Smad4 and Smad8. Smurf1, a member of the Hect family of E3 ubiquitin ligases, interacts with Smad1 and Smad5 through the PY motif, and degrades them in a ligand-independent manner (Zhu *et al.,* 1999).

An alternatively spliced variant of Smad8, lacking 37 amino acids in the linker region, has been observed (Watanabe *et al.,* 1997). Whether there is a functional difference between the long and short versions of Smad8 remains to be determined.

SMAD SIGNALING IN THE CYTOPLASM

R-Smads exist in the cytoplasm bound to membrane-associated proteins or to microtubules (Fig. 4). Although a Smad2/3-interacting protein SARA (Smad anchor for receptor activation) has been identified (Tsukazaki *et al.,* 1998), SARA-like molecule(s) that anchor BMP-R-Smads to the cell surface or intracellular membranes have not been identified. β-Tubulin interacts with Smads 2, 3, and 4 (Dong *et al.,* 2000), but interaction of BMP-R-Smads to the microtubular network has not been demonstrated.

SARA contains a phospholipid interaction domain, termed the FYVE domain, which targets SARA to the plasma membrane. SARA presents R-Smads to type I receptors, and facilitates their activation (Tsukazaki *et al.,* 1998). R-Smads transiently interact with and become phosphorylated by activated type I receptors. The interaction between type I receptors and R-Smads is determined by the L45 loop of type I receptors and L3 loop and α-helix H1

of the MH2 domains of R-Smads (Fig. 3) (Wu *et al.,* 2000). Phosphorylation occurs at the last two serine residues in the SSXS motif of the R-Smads. R-Smads then form heteromeric complexes with Co-Smads, possibly composed of two molecules of R-Smads and one molecule of Co-Smad (Kawabata *et al.,* 1998).

Nuclear translocation of R-Smads occurs independently of Co-Smads, whereas Co-Smads require R-Smads for nuclear translocation (Watanabe *et al.,* 2000). The basic helix in the MH1 domains of R-Smads is masked in unstimulated cells; after activation by the type I receptors, the basic helix is exposed, and interacts with importin β, leading to nuclear translocation of R-Smads (Xiao *et al.,* 2000a,b). Isolated MH2 domains are also actively transported into the nucleus, although the mechanisms by which this occurs remain to be determined (L. Xu *et al.,* 2000).

SMAD SIGNALING IN THE NUCLEUS

In the nucleus, Smads regulate transcription of target genes through (1) direct binding to specific DNA sequences, (2) interaction with other DNA-binding proteins, and (3) recruitment of transcriptional coactivators and/or corepressors (Fig. 4).

Instead of the characteristic GTCT/AGAC sequence specific for Smad3 and Smad4, BMP-R-Smads bind to a GC-rich sequence (GCCGnCGC motif) found in the promoter region of *Smad6* (Isihida *et al.,* 2000). Although direct DNA-binding of Smads is important for transcriptional activation of certain genes, it is not required for other genes.

Smads interact with various DNA-binding proteins, and this interaction may be a critical event in the exhibition of specific effects of TGF-β and BMPs in different types of cells. Although many DNA-binding proteins, including FAST1, AP-1 complex, TFE3, Sp1, and vitamin D receptor, interact with TGF-β-R-Smads, only several DNA-binding proteins have been reported to interact with BMP-R-Smads. Runx is a family of transcription factors that regulate various biological events, including hematopoiesis and osteogenesis. Three mammalian isoforms of Runx, Runx1 through -3, have been identified. Mice lacking the *Runx2* gene (also termed Cbfa1 or polyomavirus enhancer binding protein-αA; PEBP2αA) exhibit complete loss of bone formation. BMP-R-Smads physically interact with Runx2 upon activation by BMP receptors (Hanai *et al.,* 1999; Zhang *et al.,* 2000). Runx2 and BMP-R-Smads cooperatively activate the transcription of target genes, and facilitate the osteoblast differentiation of osteoprogenitor cells. Runx thus functions as a nuclear target of Smads in specific tissues.

OAZ is a DNA-binding protein containing 30 zinc-finger domains. OAZ interacts with BMP-R-Smads in response to BMP-2 stimulation, and activates the transcription of *Xvent.2* through direct DNA-binding (Hata *et al.,* 2000). OAZ has also been shown to be a transcriptional partner of Olf-1/EBF in olfactory epithelium and pre-B lymphocytes. OAZ is thus a transcription factor with dual functions, utilizing distinct clusters of zinc-fingers for the BMP-Smad pathway and Olf signaling pathway.

Zinc-finger transcription factors of the Gli family play an important role in hedgehog signaling. A C-terminally truncated version of Gli3, but not the full-length Gli protein, interacts with Smads 1 through 4 (F. Liu *et al.,* 1998). This interaction occurs in the absence of ligands, and dissociation occurs upon ligand stimulation. Since the C-terminally truncated Gli3 is observed in Pallister–Hall syndrome and polydactyly type A, the biological significance of the Smad–Gli3 complex is an important question to be answered.

In addition to the transcription factors that positively regulate the transcription of target genes, certain DNA-binding proteins act as transcriptional repressors in the absence of BMP/TGF-β stimulation, and this repression may be relieved after interaction with Smads upon ligand stimulation (Miyazono *et al.,* 2000). A homeodomain protein Hoxc-8 binds to the promoter region of the *osteopontin* gene and represses its transcription. Upon BMP stimulation, Smad1 interacts with Hoxc-8, which then dissociates from the DNA-binding element (Shi *et al.,* 1999). Another homeodomain protein, SIP1, a member of the δEF1/Zfh family (Verschueren *et al.,* 1999), has been suggested to repress the expression of the *brachyury* gene in a fashion similar to Hoxc-8. SIP1 interacts with all R-Smads; whether SIP1 acts as a target for BMP-R-Smads under physiological conditions remains to be determined.

p300 and CBP (CREB binding protein) have histone acetyl transferase (HAT) domains, which upregulate gene transcription by loosening nucleosomal structure and by increasing the accessibility to the general transcription machinery. p300 and CBP interact with various transcription factors; they interact with Smad1, -2, and -3 upon ligand stimulation and enhance Smad-dependent transcription of target genes (Miyazono *et al.,* 2000; Massagué and Wotton, 2000). SNIP1, a nuclear protein with forkhead-associated (FHA) domain, interacts with Smads 1, -2, and -4 (R. H. Kim *et al.,* 2000). SNIP1 inhibits complex formation between Smad4 and p300, and suppresses the transcriptional activation induced by TGF-β.

Transcriptional co-repressors, including TGIF, c-Ski, and SnoN, recruit histone deacetylases (HDACs) to Smad complexes (Miyazono, 2000). In contrast to p300/CBP, they induce nucleosomal condensation, and consequently repress the transcription of target genes. TGIF, c-Ski, and SnoN preferentially interact with TGF-β-R-Smads. However, c-Ski represses BMP signaling *in vivo* (Wang *et al.,* 2000).

TARGET GENES FOR BMPS

In contrast to the TGF-β/activin signaling system, target genes regulated by BMP-R-Smads have not been fully determined. *Tlx-2* is a target gene for BMPs. *Tlx-2* is a homeobox gene related to human *Hox11* and is expressed in the primitive streak of mouse embryos (Tang *et al.,* 1998). *Xvent.2* is another BMP-target gene, which is also a homeobox gene and mediates the effects of BMP-4 in *Xenopus* embryos (Candia *et al.,* 1997). Smad6 and Smad7 in mammals and Daughters against Dpp (Dad) in *Drosophila* are induced by BMP signaling. BMP-R-Smads directly activate

transcription from the *Smad6* promoter (Ishida *et al.,* 2000) and from the *Xenopus Xvent.2* promoter (Henningfeld *et al.,* 2000). *Id* gene products are negative regulators of basic helix–loop–helix transcription factors, including MyoD. *Id1* through *-3* are immediate–early response targets of BMPs in embryonic stem cells (Hollnagel *et al.,* 1999). Transcription of the *osteopontin* gene is regulated by BMPs through direct binding of Hoxc-8 to a specific DNA-binding element (Shi *et al.,* 1999).

REGULATION OF SMAD SIGNALING

I-Smads I-Smads, i.e., Smad6 and Smad7, function as antagonists of R-Smad/Co-Smad signaling (Fig. 5). I-Smads interact with type I receptors activated by type II receptors through their MH2 domains. Unlike R-Smads, however, they do not dissociate from type I receptors, and thus prevent the activation of R-Smads (reviewed in Miyazono *et al.,* 2000). Smad6 has also been reported to form a complex with Smad1 and compete with Smad4 for oligomer formation. As a third mechanism, Smad6 has been reported to interact with a transcription factor Hoxc-8, and thereby inhibit the interaction between Smad1 and Hoxc-8 and repress the transcription of the *osteopontin* gene induced by Smad1 (Bai *et al.,* 2000). Smad7 inhibits both TGF-β and BMP signaling, whereas Smad6 preferentially represses BMP, but not TGF-β or activin, signaling.

In mammalian cells, Smad7 is located in the nucleus, and exported to the cytoplasm upon TGF-β stimulation (Itoh *et al.,* 1998). The mechanism and functional importance of the nuclear export of Smad7 are unknown. Smad6 is diffusely expressed in both the cytoplasm and the nucleus. Whether Smad6 is also exported to the cytoplasm remains to be determined.

Expression of I-Smads is regulated by various stimuli, including growth factors, mechanical stress, interferon-γ, and NF-κB signaling (reviewed in Miyazono, 2000). Most

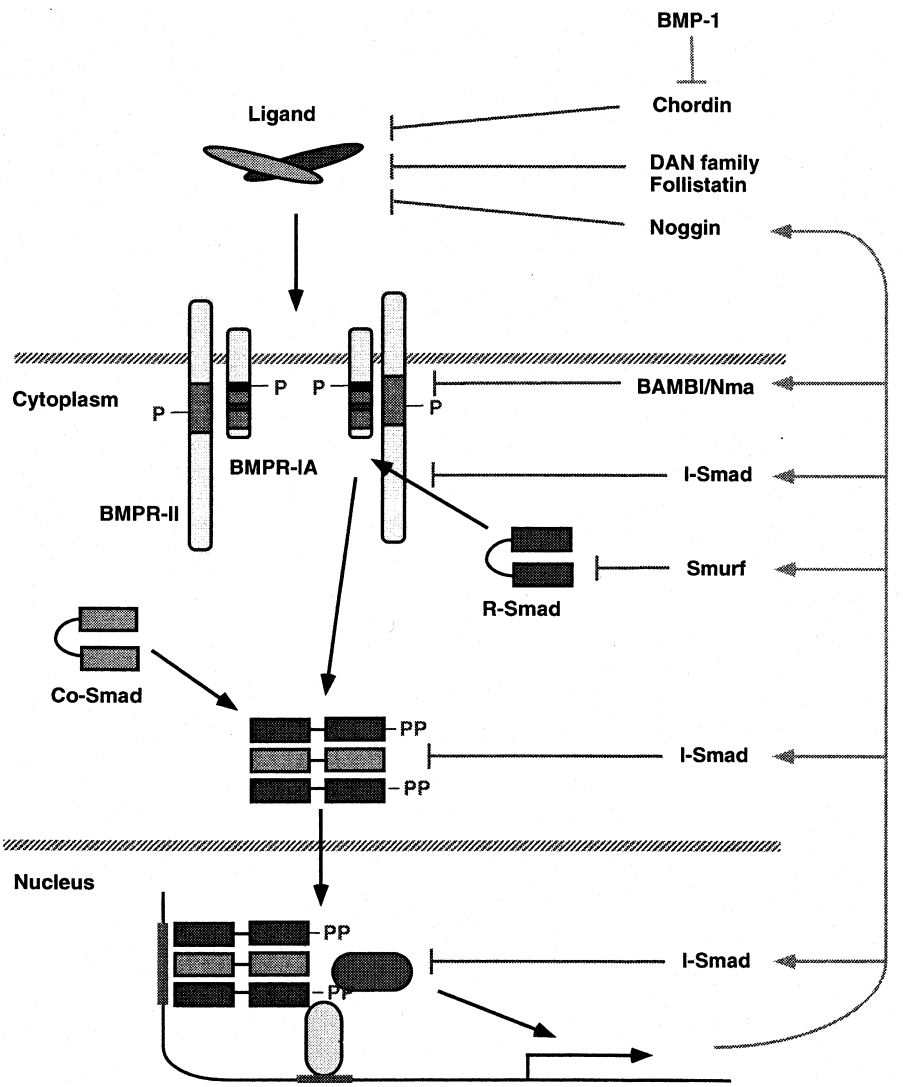

Figure 5 Regulation of BMP signaling pathways. BMP signaling is negatively regulated by extracellular antagonists, pseudoreceptor BAMBI/Nma, E3 ubiquitin ligase Smurf, and I-Smads. Expression of these regulatory molecules is induced by BMP or TGF-β signaling.

importantly, expression of I-Smads is strongly induced by TGF-β/activins and BMPs; transcription of Smad7 and Smad6 has been shown to be induced by direct effects of TGF-β-R-Smads and BMP-R-Smads, respectively (Nagarajan *et al.,* 1999; Ishida *et al.,* 2000). R-Smad/Co-Smad and I-Smad thus form a negative feedback loop for regulation of TGF-β superfamily signaling.

Proteasome-Dependent Degradation of Smads R-Smads are degraded by the ubiquitin–proteasome pathway in ligand-independent and ligand-dependent fashions (Miyazono, 2000). Protein ubiquitination is triggered by E1 ubiquitin-activating enzyme, E2 ubiquitin-conjugating enzyme, and E3 ubiquitin-ligases. Of these, E3 ligases are most important for specific recognition and degradation of target proteins. Smurf1 is a Hect family E3 ligase that interacts with BMP-R-Smads. This interaction occurs between two copies of the WW motif in Smurf1 and the PY motif in the linker region of BMP-R-Smads (Zhu *et al.,* 1999). Smurf1 degrades BMP-R-Smads in a ligand-independent fashion. Since Smurf1 may regulate the cellular pool of BMP-R-Smads, cells become more sensitive to TGF-β/activins than to BMPs in the presence of large amounts of Smurf1.

After nuclear translocation and transcriptional activation, R-Smads may be degraded by the ubiquitin-proteasome pathway (Lo and Massagué, 1999; Fukuchi *et al.,* 2001). This ligand-dependent degradation of R-Smads may be important for irreversible termination of TGF-β/BMP signaling.

Cross-Talk with Other Signaling Pathways BMP signaling is regulated negatively and positively by various signaling pathways, including MAP kinase and STAT pathways. The Erk MAP kinase pathway is activated by peptide growth factors. Erk phosphorylates the serines and threonines in the PXT/SP (or T/SP) motif, four copies of which are present in the linker regions of R-Smads. R-Smads phosphorylated by Erk are unable to translocate into the nucleus, and thus signaling by BMPs and TGF-β is inhibited by peptide growth factors through the action of Erk MAP kinase (Kretzschmar *et al.,* 1997).

Leukemia inhibitory factor (LIF) and BMP-2 synergistically induce astrocytic differentiation of neuroepithelial cells (Nakashima *et al.,* 1999). LIF activates STAT3 through gp130 and JAKs, and BMP-2 activates BMP-R-Smads. Although direct interaction between STAT3 and BMP-R-Smads is not observed, they are indirectly associated through binding to p300, which results in cooperative transcriptional activation of target genes.

IN VIVO ABNORMALITIES ASSOCIATED WITH *SMAD* GENES

Smad4 null mice die before E7.5 with gastrulation defects and an abnormal visceral mesoderm, which are similar to the phenotypes of *BMP-4*- and *BMPR-IA*-deficient mice (Sirard *et al.,* 1998). Mutations of the human *Smad4/DPC4* gene are frequently found in pancreatic cancer, biliary tract cancer, metastatic colon cancer, and juvenile polyposis (reviewed in Miyazono *et al.,* 2000). Homozygotic loss of the *Smad4* gene together with *Apc* mutations results in progression of intestinal tumors (Takaku *et al.,* 1998). *Smad4* heterozygous mice develop gastric polyposis 6–12 months after birth, which eventually progresses to gastric cancer as a result of loss of heterozygosity (Takaku *et al.,* 1999; X. Xu *et al.,* 2000).

Smad5-deficient mice exhibit abnormalities in angiogenesis with dilated vessels and decreased number of smooth muscle cells surrounding vessels (Yang *et al.,* 1999; Chang *et al.,* 1999). The phenotype of *Smad5*-null mice is similar to that of the *ALK-1* null mice as well as those of *TGF-β-*, *TβR-II-*, or *endoglin*-deficient mice. Since ALK-1 binds TGF-β in endothelial cells and activates BMP-R-Smads (Oh *et al.,* 2000), Smad5 might be a major signal transducer for TGF-β in endothelium. Smad5 is also required for development of left–right asymmetry (Chang *et al.,* 2000).

Smad6-null mice exhibit cardiac defects with abnormal valve formation and outflow tract septation (Galvin *et al.,* 2000). Some *Smad6*-null mice survive through adulthood, but exhibit aortic ossification and elevated blood pressure, indicating that Smad6 is required for development and homeostasis of the cardiovascular system.

Other Signaling Pathways

In addition to the Smad pathways, BMP-2 and GDF-5 have been shown to activate the p38 MAP kinase pathway (Iwasaki *et al.,* 1999; Nakamura *et al.,* 1999; Kimura *et al.,* 2000). The p38 MAP kinase activated by BMPs induces neurite outgrowth from PC12 pheochromocytoma cells, chondrocyte differentiation of ATDC5 mouse teratocarcinoma cells, and apoptosis in mouse hybridoma MH60 cells. Erk MAP kinases have also been shown to be activated by BMP-2 in certain cells. These non-Smad pathways activated by BMPs may play important roles in modulation of effects of Smads on cellular proliferation and differentiation.

TAK1 has been reported to act as a downstream component of BMP and TGF-β and activate the SAPK/JNK and p38 MAP kinase pathways. BMPR-IA directly interacts with XIAP, which activates TAB1-TAK1. However, activation of TAK1 by TGF-β or BMPs may occur only under certain conditions; under physiological conditions, TAK1 may serve as a downstream target of interleukin-1 (Ninomiya-Tsuji *et al.,* 1999).

Extracellular Regulators of BMPs

BMP Antagonists

The biological activities of BMPs are tightly regulated by extracellular antagonists (Fig. 5). A wide variety of extracellular antagonists of the TGF-β superfamily exist, and are divided into two different types: those that directly bind ligands (ligand-binding antagonists) and others that compete with ligands for binding to specific receptors (pseudoligand-type antagonists) (Miyazono, 2000). Lefty-1, Lefty-2, and

zebrafish Antivin are typical pseudoligand-type antagonists, which interfere with binding of Nodal and activin-like factors to activin type II receptors; however, it is unknown whether Lefty-1/Lefty-2/Antivin block the activity of BMPs *in vivo.*

Most of the antagonists of BMPs are ligand-binding type antagonists, including Noggin, Chordin, Cerberus and its related proteins, and Follistatin (Miyazono, 2000; Massagué and Chen, 2000). Cerberus and its related proteins, including Gremlin, Caronte, and DAN, contain a conserved cystine-knot motif, and are collectively referred to as the DAN family. BMP antagonists other than those of the DAN family do not exhibit structural similarity to each other.

These BMP antagonists have distinct expression profiles and different affinities with various BMP isoforms. Noggin antagonizes BMP-2, BMP-4, and GDF-6 efficiently, but BMP-7 less efficiently. Caronte functions as an antagonist of BMP-4, BMP-7, and Nodal. Noggin competes with Cerberus, Gremlin, and DAN for binding to BMP-2, indicating that the binding sites in BMPs are shared by these antagonists (Hsu *et al.,* 1998). Cerberus binds to several cytokines, including BMPs, nodal-like factors, and Wnt, through independent binding sites in its molecule (Piccolo *et al.,* 1999). Follistatin is a potent antagonist of activins, but also antagonizes certain BMPs both *in vitro* and *in vivo.*

Limb development is regulated by various BMP antagonists, including Noggin, Chordin, Gremlin, and Follistatin (McMahon *et al.,* 1998; Merino *et al.,* 1999). Noggin is also involved in hair-follicle induction. In *Xenopus* embryos, Noggin and Chordin are expressed in Spemann's organizer and induce neural tissues and dorsalize ventral mesoderm. These BMP antagonists may thus play a central role in the formation of morphogen gradients during early embryogenesis.

Certain BMP antagonists may exert their effects through a negative feedback loop. Expression of Noggin is induced by BMPs in osteoprogenitor cells (Gazzero *et al.,* 1998). Other cytokines, including TGF-β, also induce expression of Noggin, indicating that expression of BMP antagonists is regulated by BMP signaling itself, as well as through crosstalk of signals.

BMP-1 Is a BMP Activator

BMP-1 does not belong to the TGF-β superfamily, but is a procollagen C-proteinase that cleaves procollagens and induces accumulation of extracellular matrix (Kessler *et al.,* 1996). BMP-1 homologs are present in *Drosophila* (*Tolloid*) and in *Xenopus* (*Xolloid*); studies of Tolloid and Xolloid suggest that BMP-1 may be an activator of BMPs, since it releases active BMPs from inactive complexes by cleavage of Chordin (Piccolo *et al.,* 1996; Marques *et al.,* 1997).

Conclusion

BMPs play multiple roles in various tissues including bone, cartilage, neurons, heart, kidney, and lung. Signaling by BMPs is transduced by serine/threonine kinase receptors and Smad proteins. BMP signaling is tightly regulated by various mechanisms including extracellular antagonists, pseudoreceptors, and I-Smads. BMPs thus exhibit a diverse array of biological activities in various tissues. Further understanding of the BMP signaling pathways can aid the pharmacological regulation of biological activities of BMPs in various tissues.

CHAPTER 52

Colony-Stimulating Factors

Introduction

Between bone and bone marrow exists a close anatomical relationship, and several lines of evidence suggest a reciprocal interaction between the two tissues. On the one hand, bone marrow contributes the precursors of the cells that provide the cellular basis of bone remodeling. The bone resorbing cell, the osteoclast, stems from a hemopoietic progenitor, the colony-forming unit granulocyte/macrophage (CFU-GM) (Hagenaars *et al.,* 1991; Hattersley *et al.,* 1991a; Kurihara *et al.,* 1990). The bone-forming cell, the osteoblast, and the osteocyte are derived from mesenchymal progenitors of the marrow stromal fibroblasts, the colony-forming unit fibroblasts (CFU-F) (Owen, 1985; Owen and Friedenstein, 1988).

On the other hand, bone seems to exert a positive influence on hemopoiesis. In developing bone, osteoclasts resorb and invade the calcified cartilage rudiment. As a result, the primitive marrow cavity is formed and hemopoiesis is initiated. Cells of the osteoblastic lineage control osteoclast recruitment and activity through synthesis of factors acting directly on progenitors and mature osteoclasts (Chambers, 1992; Suda *et al.,* 1995; Yasuda *et al.,* 1998). This way osteogenic cells are essential for the process of invasion of the bone rudiment by osteoclasts and endothelia and the consequent establishment of hemopoiesis.

Bone cells may support hemopoiesis by providing factors essential for hemopoiesis. In marrow, multipotential hemopoietic stem cells proliferate and differentiate into lineage-restricted hemopoietic progenitors that eventually give rise to the terminally differentiated cells of the myeloid series. This progression occurs under the influence of macromolecules called colony-stimulating factors (CSFs) (Metcalf, 1984). The CSFs are glycoproteins initially characterized by their ability to stimulate *in vitro* the clonal proliferation of hemopoietic multipotential stem cells and/or mono- or bipotential progenitors in semisolid (agar or methylcellulose) medium. In some cases, however, CSFs are also able to commit hemopoietic cells to a single myeloid lineage. In addition, they may also induce the functional activity of mature, specialized myeloid cells and maintain their survival. This group of CSFs includes interleukin-3 (IL-3, also named multi-CSF), granulocyte/macrophage-CSF (GM-CSF), granulocyte-CSF (G-CSF), and CSF-1 (also named macrophage-CSF, M-CSF).

CSFs are ideal candidate factors for being synthesized by osteogenic cells to modulate locally, as described above, both osteoclast recruitment and marrow hemopoiesis. In this chapter, we shall exclusively describe the role of CSFs in modulating osteoclast development and activity. Other cytokines and interleukins have been shown to have intrinsic and/or synergistic effects on general hemopoiesis and/or osteoclast development. However, these factors were not identified originally based on their capacity to induce clonal proliferation of hemopoietic cells and for this reason they are not considered as CSFs. Their role in the local control of bone cell physiology is extensively described in other chapters of this book.

Colony-Stimulating Factor-1

Colony-stimulating factor-1 (CSF-1), also called macrophage colony-stimulating factor, was originally described as the growth factor for cells of the mononuclear phagocyte system (MNPS) and for osteoclasts. The cytokine binds to a single class of high-affinity cell-surface receptors that are encoded by the proto-oncogene c-*fms* and belong to the

receptor tyrosine kinase family. Expression of c-*fms* is considered a marker for the cells of the MNPS (Felix *et al.,* 1994; Stanley, 1994). Within this chapter, the effects exerted by the cytokine on the cells of this lineage as well as the mechanisms involved will be discussed.

Molecular Biology and Biochemistry of CSF-1

CSF-1 is the product of a single-copy gene, localized in humans on chromosome 1 and in mice on chromosome 3. Size and structure of the gene, spanning ≈120 kb and containing 10 exons, 8 of which encode translated sequences, are well conserved among the species. Several transcripts, derived from a common RNA precursor by alternative splicing, encode either a secreted or a membrane-bound form of the cytokine.

Transcripts encoding the secreted or the membrane-bound form of CSF-1 differ in alternative usage of exon 6 sequences encoding amino acid sequences responsible for posttranslational processing of the protein. Besides a transmembrane domain, present in all transcripts, exon 6 encodes a stretch of amino acids containing a proteolytic cleavage site, which is hydrolyzed to release the N-terminal peptide from the transmembrane domain. This process occurs within the secretory vesicles of the cells, and the cleavage product is rapidly secreted by exocytosis. In the absence of the proteolytic cleavage site, the protein remains anchored in the membrane and, after fusion of the secretory vesicles with the cell membrane, becomes exposed on the cell surface, from where it is slowly released (for review, see (Sherr and Stanley, 1990)).

All translation products contain an amino-terminal signal peptide of 32 amino acids. Furthermore, a hydrophobic 23-amino-acid region is followed by a charged "stop transfer" sequence, characteristic for many membrane-spanning proteins. The CSF-1 peptide is cotranslationally glycosylated and remains integrated in the membrane of the endoplasmic reticulum, the amino-terminal end facing the lumen. In the Golgi, the protein is O-glycosylated and the N-linked carbohydrate molecules are further processed. The secreted forms of the cytokine can be further modified by the attachment of a glycosaminoglycan side chain.

The CSF-1 precursor protein for the secreted cytokine is synthesized as a 554-amino-acid precursor, which is processed to yield a disulfide-linked homodimer of 223 amino acids per chain. The membrane-bound form of CSF-1 is synthesized as a 256-amino-acid precursor protein, which, in turn, is processed to a homodimer of 150 amino acids per chain.

Expression and Regulation of CSF-1

Several groups have demonstrated the essential role of CSF-1 in the formation of osteoclasts (Felix *et al.,* 1990a; Kodama *et al.,* 1991; Wiktor-Jedrzejczak *et al.,* 1990; see Chapter 7). The involvement of the cytokine in the regulation of acute bone resorption, however, is much less defined. The main question is whether CSF-1 constitutes an essential component of the hemopoietic microenvironment, essential but not exerting regulatory functions, or whether the cytokine is involved in the acute regulation of bone resorption and is modulated by osteotropic hormones and cytokines. The regulation of the biological activity of CSF-1 is further complicated by the fact that the cytokine is synthesized either as a secreted or as a membrane-bound molecule (Stanley, 1994). Whether the two molecular forms of the growth factor exert different biological actions or whether the difference is merely based on spatial distribution is yet an open question. The membrane-bound form of CSF-1 is more efficient *in vitro* than soluble CSF-1 in promoting osteoclast formation (Takahashi *et al.,* 1991a). This may be attributed to the proximal relationship of other membrane-associated factors that influence osteoclastogenesis, namely receptor activator of NF-κB ligand (RANKL; see Chapter 7).

CSF-1 has been shown to be produced constitutively by mesenchymal cells, among them osteoblasts, and by activated macrophages *in vitro* (Stanley, 1994). The secretion is stimulated by parathyroid hormone (PTH), IL-1, and tumor necrosis factor (TNF)-α (Felix *et al.,* 1989; Sato *et al.,* 1986; Shiina-Ishimi *et al.,* 1986; Weir *et al.,* 1993). In contrast, expression of the cytokine is tightly controlled *in vivo.* Thus, the expression of CSF-1 is dramatically increased in mice during early pregnancy (Bartocci *et al.,* 1986), where CSF-1 is induced by 17β-estradiol and progesterone in uterine glandular epithelial cells (Daiter *et al.,* 1992; Pollard *et al.,* 1987). In bone, expression of CSF-1 is correlated temporally and spatially with osteoclast formation and bone resorption (Hofstetter *et al.,* 1995). Together, these observations suggest that the expression of CSF-1 is tightly controlled under physiological conditions. Despite these observations, relatively little is known concerning the regulation of the expression of CSF-1 by hormones and cytokines *in vivo.* As mentioned above, estrogen deficiency, through the induction of the synthesis of IL-1 and TNF-α by marrow cells may induce the expansion of a subpopulation of stromal cells high in CSF-1 production (Kimble *et al.,* 1996). These increased levels of CSF-1 support the formation of osteoclasts, causing the osteopenia. The levels of CSF-1 were also reported to be elevated after injections of lipopolysaccharide (LPS) into mice (Roth *et al.,* 1997), and by this mechanism, the mobilization and activation of mononuclear phagocytes in the inflammatory response is facilitated.

Further evidence for the regulation of the expression of CSF-1 was provided by *in vitro* studies on organ or cell cultures. In organ cultures of fetal rat long bones, PTH and PTH-related peptide (PTHrP) were shown to induce an increase in bone resorption (Weir *et al.,* 1996). By using models of bone resorption that are dependent on the formation of new (fetal metacarpals) or on the activation of existing osteoclasts (fetal radii), it was possible to distinguish the effect of CSF-1 on recruitment (proliferation, differentiation) and on osteoclast activity.

Since CSF-1 is synthesized as a membrane bound and as a secreted molecule, it has been speculated that these molecular forms may exert different biological activities or may be of different efficiencies in their biological actions (Takahashi *et al.,* 1991a). Subsequently it was shown that the cell surface form of CSF-1 is sufficient to induce the formation of osteoclasts from bone marrow cells (Yao *et al.,* 1998). This implies the possibility that the two molecular forms are differentially regulated. Indeed, various groups described hormones, e.g., PTH, 1,25$(OH)_2$ vitamin D_3, and dexamethasone, cytokines such as TNF-α, or mechanical stimuli such as pressure to stimulate expression of the membrane-bound form of CSF-1 while the synthesis of the secreted molecule is not affected (Rubin *et al.,* 1997, 1998, 1996; Yao *et al.,* 1998). Since the different forms of CSF-1 are encoded by different mRNAs that are derived from a common hnRNA precursor by differential splicing, the regulation of the expression of membrane-bound and secreted CSF-1 occurs at the posttranscriptional level. The mechanisms that allow for this regulation, however, are as yet not known.

A considerable effort was devoted to elucidate the transcriptional control of CSF-1 expression. When the partial promoter of the murine CSF-1 gene was cloned, it was found to contain consensus sequences for a number of different transcription factors (Harrington *et al.,* 1991). From cell culture studies it has become evident that TNF-α is most effective in regulating CSF-1 expression in cells of the osteoblast lineage. An important signal transduction pathway induced by TNF-α involves the members of the NF-κB family of transcription factors. The importance of NF-κB family members in bone metabolism was evident when double knockout mice, deficient in the NF-κBs p50 and p52, expressed an osteopetrotic phenotype, caused by an absence of osteoclasts (Iotsova *et al.,* 1997). The requirement for NF-κB in CSF-1 expression was demonstrated using osteoblastic cells derived from p50 knockout mice. These cells failed to react to treatment with TNF-α by increasing the synthesis of CSF-1, as is the case in osteoblasts from wild-type controls (Yao *et al.,* 2000). Somewhat contradictory, however, was the finding that the NF-κB consensus sequence of the CSF-1 promoter was not critically involved in the stimulation of CSF-1 expression by TNF-α (Isaacs *et al.,* 1999; Rubin *et al.,* 2000). In stromal ST-2 cells, inactivation of NF-κB still allowed for TNF-α-induced expression of the cytokine. Removal of the NF-κB consensus sequence increased basal expression of CSF-1, but still allowed further stimulation by TNF-α. Thus it is clear that NF-κB transcription factors are critically involved in osteoclastogenesis and also that exposure to TNF-α induces the synthesis of CSF-1, but the interrelationship of the two is not yet understood. Another transcription factor that was shown to be involved in the transcription of the CSF-1 gene was AP-1 (Konicek *et al.,* 1998). Most important was the finding that the expression of the cytokine in different cell types is governed by common and by cell-type-specific *trans*-acting factors, allowing for a tight temporal and spatial regulation. As mentioned above, however, presently it is still not clear whether CSF-1 is involved in the acute regulation of bone resorption or whether the growth factor acts as a constitutive component of the hemopoietic microenvironment. Support for the latter results from recent studies in which IL-1, IL-3, IL-6, IL-7, IL-10, GM-CSF, G-CSF, bFGF, and TGF-β did not effect CSF-1 expression by cultured human bone marrow stromal cells (Besse *et al.,* 2000).

CSF-1 in Postmenopausal Osteoporosis

CSF-1, together with RANKL (also known as osteoclast differentiation factor [ODF], osteoprotegerin ligand [OPGL], stromal osteoclast forming activity [SOFA], TNF superfamily 11 [TNFSF-11], and TNF-related activation-induced cytokine [TRANCE]) (Anon, 2000), is one of the two essential growth factor for osteoclasts (Quinn *et al.,* 1998; see Chapter 7). It was not clear, however, whether CSF-1 would contribute in a critical way to the observed bone loss under conditions of estrogen deficiency, and many studies focused on its role in the bone loss induced by estrogen deficiency. Estrogen has been shown in one culture system of osteoblast-like cells to stimulate the synthesis of osteoprotegerin (OPG), a decoy receptor for RANKL (Hofbauer *et al.,* 1999, 2000), and to suppress signal transduction through RANK (receptor activator of NF-κB) (Shevde *et al.,* 2000). It was more difficult to elucidate the regulation of CSF-1 expression by estrogen.

Several years ago it was reported that peripheral blood monocytes from osteoporotic women (Pacifici *et al.,* 1987) or from women after oophorectomy (Pacifici *et al.,* 1991) secrete elevated levels of IL-1 and TNF-α. An increase in the production of these cytokines, and their critical role in increased bone loss, was confirmed in various animal studies (Kimble *et al.,* 1997; Kitazawa *et al.,* 1994; Pacifici *et al.,* 1987; Srivastava *et al.,* 1995). CSF-1 was first implicated in bone loss after estrogen deficiency, when it was found that after ovariectomy, a subpopulation of stromal cells developed that synthesized increased levels of CSF-1 (Kimble *et al.,* 1996). This stimulation was brought about by the action of the monocyte products IL-1 and TNF-α on stromal cells. Further studies on the mechanism of action of IL-1 and TNF-α on the expression of CSF-1 demonstrated a role for the early response gene *egr-1*. Under estrogen deficiency, *Egr-1* becomes phosphorylated. In its phosphorylated state, *Egr-1* cannot interact with the transcription factor SP-1, causing an excess of free SP-1 to stimulate CSF-1 production via the SP-1 site in the CSF-1 promoter (Srivastava *et al.,* 1998). In mice deficient in *Egr-1,* bone turnover is high, but estrogen deficiency fails to stimulate bone resorption further (Cenci *et al.,* 2000a), again demonstrating the role of the transcription factor in the upregulation of CSF-1 expression.

The above-described studies on the effect of estrogen deficiency on CSF-1 expression do not take into account the possibility that the expression of the two main molecular forms, membrane bound versus secreted, may be affected as

well. Indeed it was shown in cultures of human bone marrow cells (Sarma *et al.,* 1998) and in ovariectomized rats (Lea *et al.,* 1999) that the expression of the membrane-bound form of CSF-1 was increased under conditions of estrogen deficiency, an effect that was reversed by treatment with estrogen.

In the recent past, the cross-talk between cells of the immune defense and bone has been shown to be very important, in particular in a disease like rheumatoid arthritis. Thus, activated T cells were shown to secrete RANKL *in vitro* and to support osteoclast formation (Horwood *et al.,* 1999) and *in vivo* (Kong *et al.,* 1999). Most interesting, osteoclastogenesis induced by T cells is counteracted by interferon-γ, another T-cell product (Takayanagi *et al.,* 2000). This T-cell–bone connection, however, is not only important in inflammatory and immunologic situations, but has been shown to be relevant in estrogen deficiency as well. Thus, not only cells of the monocyte/macrophage lineage may mediate the effect of estrogen deficiency on bone by the production of TNF-α and IL-1, but T lymphocytes contribute to bone loss through the synthesis of TNF-α as well (Cenci *et al.,* 2000b). The critical role of T cells in this process was further underlined by the fact that bone wasting is not observed in athymic *nu/nu* mice (Cenci *et al.,* 2000b) and in Rag1 mice that are deficient in both T and B lymphocytes (Spanopoulou *et al.,* 1994).

The Role of CSF-1 in the Formation of Osteoclasts

Animals defective in the production of growth factors represent ideal models for investigating the effects of these proteins during development and function of organs and cells. One such model is the murine osteopetrotic mutant strain *op,* which is devoid of biologically active CSF-1 (Felix *et al.,* 1990b; Wiktor-Jedrzejczak *et al.,* 1990), the defect being caused by a point mutation within the coding region of the CSF-1 gene (Yoshida *et al.,* 1990). The phenotype of *op/op* mice is characterized by a virtual absence of osteoclasts (Marks and Lane, 1976). Treatment of these animals with daily injections of recombinant human CSF-1 induced osteoclast formation and bone resorption, proving that the deficiency in CSF-1 is indeed the cause of the osteopetrosis in *op* mice (Felix *et al.,* 1990a; Kodama *et al.,* 1991).

The dependence of osteoclast formation on CSF-1 was further corroborated in organ and in cell culture systems. In cultures of ^{45}Ca-prelabeled fetal metatarsals, CSF-1 stimulated osteoclastogenesis and release of ^{45}Ca. This effect was blocked by irradiation of the bone rudiments, indicating an action of CSF-1 on proliferating osteoclast precursors. No effect on bone resorption by the cytokine was observed in cultured fetal radii, in which bone resorption depends on the activation of mature osteoclasts (Corboz *et al.,* 1992). This data suggests an effect of CSF-1 on recruitment of osteoclasts rather than on the activation of mature cells. In cultures of ^{45}Ca-prelabeled fetal metatarsals from *op/op* mice, CSF-1 alone had a slight effect only on the release of ^{45}Ca. Bone resorption was stimulated, however, when the rudiments were cultured in the presence of CSF-1 plus PTH and $1,25(OH)_2D_3$ (Morohashi *et al.,* 1994). Thus, in this system, CSF-1 was required but not sufficient for the formation of osteoclasts. The process of osteoclast formation may be initiated by CSF-1 inducing the proliferation of osteoclast precursors. PTH and $1,25(OH)_2D_3$ presumably acted on osteoblast/stromal cells to induce RANKL expression.

In vitro, osteoclasts are formed in cocultures of osteoblasts or stromal cells and hemopoietic precursor cells in the presence of $1,25(OH)_2D_3$ (Takahashi *et al.,* 1988). Cocultures of hemopoietic precursors and osteoblastic cells from *op/op* or +/? littermates gave rise to osteoclasts, when the mesenchymal cells as the source for CSF-1 were derived from phenotypically normal +/? animals. When the osteoblasts were derived from *op/op* animals, osteoclast formation was observed upon addition of high concentrations (up to 100 ng/ml) of exogenous CSF-1 only. In these experiments, it was irrelevant whether the hemopoietic precursor cells were derived from *op/op* or +/? animals, respectively (Takahashi *et al.,* 1991a).

The coculture system can be divided into an early phase in which proliferation of osteoclast precursors takes place and a late phase of differentiation and fusion. While $1,25(OH)_2D_3$ is essential only during the second phase of the culture, CSF-1 was found to be required during the proliferation and differentiation/fusion phases (Tanaka *et al.,* 1993). Neutralizing antibodies against GM-CSF did not affect osteoclast formation. Precursor cells grown in the presence of GM-CSF or interleukin-3, however, are capable of forming osteoclasts in coculture with osteoblasts (Takahashi *et al.,* 1991b). These cytokines may therefore support proliferation of early precursors, but are not able to replace CSF-1 at later stages of development. Somewhat contradictory was the finding that fusion of osteoclast precursors in long-term bone marrow cultures is not blocked by anti-CSF-1 antibodies, demonstrating the independence of this step in osteoclast formation from the cytokine (Biskobing *et al.,* 1995).

The notion that the late stages of osteoclast formation and of bone resorption are independent of the presence of CSF-1 was supported by some *in vivo* data. To induce osteoclast formation in osteopetrotic *op/op* mice, a single injection of the growth factor proved to be sufficient (Kodama *et al.,* 1993). This observation allows the conclusion that CSF-1 is essential to initiate proliferation of early osteoclast precursors, while the later steps of differentiation and fusion may be governed by other factors (see Chapter 7).

Data similar to those obtained with the *op/op* mouse were obtained with the osteopetrotic rat *tl* mutant. Phenotypically, *tl* rat and *op/op* mice are similar, in both cases osteopetrosis being caused by the virtual absence of osteoclasts. Furthermore, in both mutants, a reduction of femoral, peritoneal, and pleural macrophages was observed. Since the *tl* rat was not cured by marrow transplantation, and since the increase in CSF-1 activity after treatment with endotoxin was substantially smaller in sera from *tl/tl* rats than in sera from

phenotypically normal littermates, it was proposed that the osteopetrosis in *tl/tl* rats is also due to CSF-1 deficiency. Indeed, upon injection of CSF-1 into *tl/tl* rats, osteoclastogenesis was induced and bone resorption was restored (Marks *et al.,* 1992). Furthermore, osteoclast formation was induced in neonatal metatarsals from *tl/tl* rats when cultured in the presence of CSF-1, PTH, and $1,25(OH)_2D_3$ (Peura and Marks, 1995), as was described previously for the murine *op/op* mutant (Morohashi *et al.,* 1994).

Expression of the CSF-1 Receptor in Bone

Osteoclast precursors and mature osteoclasts are among the target cells for CSF-1, since these cells were shown to contain transcripts encoding the receptor (Hofstetter *et al.,* 1992; Weir *et al.,* 1993), as well as to bind the cytokine (Hofstetter *et al.,* 1995).

Expression of c-*fms* is reliant on the transcription factor PU.1 (DeKoter *et al.,* 1998). PU.1 controls the development of granulocytes, macrophages, and B and T lymphocytes. Granulocytic precursors deficient in PU.1 cannot differentiate with CSF-1 due to the lack of c-*fms* expression, and hence the PU.1 null mice do not have osteoclasts and are osteopetrotic (Tondravi *et al.,* 1997).

The identification of RANKL will further aid in the identification of signaling pathways involved in osteoclast formation and the potential for cross-talk between c-*Fms* and RANK signaling. RANKL and CSF-1 alone are sufficient to differentiate hemopoietic cells to osteoclasts and many studies have now been performed in stromal cell-free systems. However, the search for a cell line with the potential to differentiate to a *bona fide* osteoclast is still paramount to address many fundamental questions for osteoclast formation, differentiation and activation. The RAW264.7 cells have been recognized as a potential cell line that fulfils many of the functions of the osteoclast following differentiation in response to RANKL (Burgess *et al.,* 1999). However, a degree of caution must be exercised with this cell line. This cell line is CSF-1 independent and it is not known whether the independence is provided by a mutated c-*fms* allowing constitutively active receptor signaling or is a consequence of dysregulation of other control mechanisms. Due to the CSF-1-independent nature of this cell line, effects of agents determined for this cell line should be confirmed in other hemopoietic cell lines, such as C7 (Miyamoto *et al.,* 1998) or in populations of hemopoietic cell populations.

While CSF-1 action on osteoclast precursors is clearly established, the effect on mature osteoclasts is less clear. The resorptive activity of disaggregated osteoclasts on bone slices was inhibited by exogenously added CSF-1 (Hattersley *et al.,* 1988). Further analysis revealed that, besides supporting survival of mature osteoclasts, CSF-1 acts as a chemotactic agent and induces spreading and migration in these cells (Fuller *et al.,* 1993; see Chapter 7). As a consequence, reducing the proportion of resorbing cells inhibited total resorptive activity. By this mechanism, CSF-1 would regulate both the quantity and the spatial pattern of resorption. Strengthening this hypothesis is the observation that in fetal rat long bones in culture, addition of antibodies against CSF-1 led to an increase of PTH-stimulated bone resorption (Weir *et al.,* 1996).

Biological Effects of the Molecular Forms of CSF-1

As has been described above, osteoblasts and hypertrophic chondrocytes express CSF-1 *in vivo.* These cells are in close proximity to osteoclast precursors and mature osteoclasts, which express binding sites for the cytokine. These findings suggest that locally produced and acting forms of the growth factor might modulate bone resorption by regulating osteoclastic development and activity.

CSF-1 is synthesized either as a rapidly secreted molecule, a portion of which is posttranslationally modified to a proteoglycan (Price *et al.,* 1992; Suzu *et al.,* 1992), or as a membrane-bound protein. The proteoglycan form, shown to bind to collagen type V, could be integrated in the extracellular matrix and has been shown to be present in bone (Ohtsuki *et al.,* 1993, 1995). This proteoglycan, together with the membrane-bound CSF-1, can confer a locally restricted biological action. *In vitro,* osteoblasts have been shown to synthesize each of these various molecular forms of the growth factor (Felix *et al.,* 1996). However, little is known yet about the biological activities of the different forms of the cytokines as well as the regulation of their expression.

Recent studies concentrated on the regulation of the various molecular forms of CSF-1 by bone active hormones and cytokines. In primary murine osteoblasts, $1,25(OH)_2D_3$ increased the levels of transcripts encoding the membrane-bound and the secreted forms of the cytokine, respectively (Rubin *et al.,* 1996). Also PTH and TNF-α were found in human osteoblast-like cells to increase all CSF-1 transcripts (Yao *et al.,* 1998). Thus, no specific regulation of either the membrane-bound or the secreted molecular forms of the cytokine has yet been demonstrated.

Accumulating evidence suggests that the molecular forms of CSF-1 exert distinct biological effects on their respective target cells. Injections of the cytokine into *op/op* animals did not completely reverse the osteopetrotic phenotype; a residual subepiphyseal osteosclerosis persisted (Sundquist *et al.,* 1995). Furthermore, CSF-1 injections into *op/op* animals restore some populations of tissue macrophages, while others were only partially or not at all responsive (Cecchini *et al.,* 1994). These results indicate that circulating CSF-1 cannot fully replace endogenous cytokine production. This may be due to limited access to the sites where CSF-1 is required or to the possibility that production and efficiency of membrane- and matrix-bound and secreted CSF-1 may differ at various sites. Furthermore, new roles for CSF-1 were indicated when the membrane-bound molecule was found to not only act as a growth factor, but to mediate intracellular signal transduction (Zheng *et al.,* 2000).

The data obtained using the coculture of osteoblasts and spleen cells point in the same direction. Only high

concentrations of CSF-1 were able to support osteoclast formation when the osteoblasts were derived from *op/op* animals, suggesting that soluble CSF-1 may not be the most efficient molecular form of the cytokine to support this process (Takahashi *et al.,* 1991a).

Resolution of the Osteopetrotic Phenotype in *op/op* Mice

Osteopetrotic *op/op* mice undergo an age-dependent hemopoietic recovery (Begg *et al.,* 1993; Marks and Lane, 1976; Wink *et al.,* 1991). After 6 weeks of age, an increase in the marrow space available for hemopoiesis is observed, and at 22 weeks of age, marrow cavity and cellularity were comparable with normal. Since the gene encoding CSF-1 is mutated in the *op/op* strain, the recovery cannot be due to an age-dependent expression of this factor, suggesting osteoclast formation via a CSF-1 independent regulatory pathway. However, based on the complex posttranscriptional processing of CSF-1 transcripts, an incompletely penetrant phenotype, due to a leaky mutation causing a delay of normal development, cannot be excluded (Hume and Favot, 1995). If, on the other hand, CSF-1 would be partially redundant, a candidate growth factor to replace CSF-1 may be GM-CSF, although cytokine production, besides CSF-1, is not impaired in *op/op* mice (Felix *et al.,* 1995; Wiktor-Jedrzejczak *et al.,* 1990). Injections of GM-CSF alone did not reverse the osteopetrotic phenotype in *op/op* animals (Wiktor-Jedrzejczak *et al.,* 1994), but when GM-CSF was injected together with IL-3, the osteopetrosis was corrected (Myint *et al.,* 1999). Furthermore, bone resorption and hemopoietic recovery proceeded with the same kinetics in *op/op* mice and in GM-CSF/CSF-1 double knockout animals (Nilsson *et al.,* 1995), negating an essential role of GM-CSF in the recovery process. Thus, the formation of osteoclasts and the reconstitution of bone resorption in growing *op/op* animals require proliferation, differentiation, and activation of macrophages and osteoclasts by alternative pathways, independent of CSF-1 and GM-CSF. Although CSF-1 and RANKL both are essential growth factors for cells of the osteoclast lineage (Quinn *et al.,* 1998), in *op/op* mice, the formation of osteoclasts can proceed without CSF-1, albeit with lower efficiency.

VEGF and TGF-β in the Formation of Osteoclasts

A step toward the elucidation of the mechanisms leading to the resolution of the osteopetrotic phenotype in *op/op* mice was recognized when a single injection of vascular endothelial growth factor (VEGF) was found to resolve the osteopetrotic phenotype in *op/op* mice (Niida *et al.,* 1999). The authors suggest that VEGF is produced in *op/op* mice at levels sufficient for the survival and functioning of mature osteoclasts, but not for the recruitment of these cells at maximal levels, resulting in an osteopetrotic phenotype that is resolved with time. The hypothesis for a potential role of VEGF in the regulation of bone resorption was further strengthened by the finding that the factor acts chemotactically on osteoclasts and their precursors (Engsig *et al.,* 2000). Since VEGF is synthesized by hypertrophic chondrocytes (Gerber *et al.,* 1999), is integrated in the extracellular matrix of bone and cartilage, and can be released by metalloproteinases (Bergers *et al.,* 2000), VEGF seems to be suited to act as a growth factor for the cells of the osteoclastic lineage.

Another factor gaining interest as a growth factor for osteoclasts is transforming growth factor-β (TGF-β). The effect of TGF-β on the formation of osteoclasts and on bone resorption has been controversial, with stimulatory and inhibitory effects being described. An essential role of TGF-β in the inhibition of bone resorption by estrogen was suggested when it was found that inhibition of bone resorption by estrogen *in vivo* and *in vitro* was due to the induction of apoptosis in osteoclasts by the factor (Hughes *et al.,* 1996). Recent data, however, demonstrated the ability of TGF-β to enhance the formation of osteoclasts. The factor prevents osteoclast precursors to become irreversibly committed to the macrophage lineage in the presence of CSF-1. In the presence of TGF-β, the cells retain their potential to differentiate into osteoclasts in response to RANKL (Fuller *et al.,* 2000; Sells Galvin *et al.,* 1999). The three factors CSF-1, TGF-β, and RANKL may therefore fulfil specific roles in the formation of osteoclasts, CSF-1 supporting proliferation, differentiation, and survival of hemopoietic precursors, TGF-β blocking the precursors developing into macrophages, and RANKL inducing the cells to develop into mature osteoclasts. On the mature cells, the actions of the three cytokines vary—TGF-β causing apoptosis, CSF-1 supporting survival and migration and RANKL being required for survival and activation (Jimi *et al.,* 1999).

The differential actions of TGF-β to be inhibitory in cocultures, yet stimulatory in RANKL- and CSF-1 treated hemopoietic cultures indicated that the inhibitory actions of TGF-β might result from its actions on the osteoblast. Indeed this appears to be so. TGF-β acts to increase osteoblast OPG production while decreasing RANKL production (Quinn *et al.,* 2001; Takai *et al.,* 1998). The independence of OPG involvement to inhibit osteoclast formation was demonstrated using cocultures established from osteoblasts and hemopoietic cells from OPG null mice. In such cultures, TGF-β was still inhibitory and recombinant RANKL could rescue osteoclast formation, although osteoclast formation was not equivalent to cultures that had not been treated with TGF-β.

Although GM-CSF alone does not reverse the osteopetrotic phenotype in *op/op* mice, the cytokine nevertheless plays an essential role in the development of parts of the mononuclear phagocytic system. Some populations of macrophages are normal at birth and during life in *op/op* mice and are not affected by injections of CSF-1 (Cecchini *et al.,* 1994). These monocytes, which are involved in inflammatory and immune responses, appear to depend on GM-CSF rather than CSF-1 (Naito *et al.,* 1991;

Wiktor-Jedrzejczak *et al.,* 1992). Macrophages involved in organogenesis and tissue turnover (osteoclasts might be included in this group) require the presence of CSF-1 for their development and survival. Absence of CSF-1 blocks development of precursor cell populations at an early stage of differentiation.

The fact that deficiency in CSF-1 leads to a lack of both macrophages and osteoclasts suggest the presence of a common precursor requiring CSF-1 for proliferation and/or differentiation. Only later do these cells reach a branching point after which they are committed to differentiate into macrophages or osteoclasts. Mice deficient in c-*Fos,* a component of the dimeric transcription factor activator protein AP-1, express an osteopetrotic phenotype caused by the absence of osteoclasts, as is the case for *op* mice (Wang *et al.,* 1992). In these animals, however, macrophages are normal or even more numerous than normal. The c-*Fos* protein subsequently was shown to be an essential regulator of osteoclast-lineage determination (Grigoriadis *et al.,* 1994). Since only osteoclasts are affected by the lack of c-*Fos,* the precursors are already committed to develop into osteoclasts at the time they require the transcription factor. Thus, they are beyond the branching point separating the differentiation pathways of the macrophage and osteoclast lineages. Subsequently, it was shown that RANKL induces the expression of *Fra-1* in a c-*Fos*-dependent manner, thereby establishing a link between RANK signaling and the defect in c-*fos* knockout mice. Further transfection of *Fra-1,* unlike c-*fos,* into osteoclast precursor cells increased osteoclast formation (Owens *et al.,* 1999). This suggested that *Fra-1* may be limiting in osteoclast formation or that it fulfills roles distinct from those of c-*Fos.*

Effects of CSF-1 on Mature Osteoclasts and Signal Transduction

The effects exerted by CSF-1 on macrophages are extensively studied, as are the mechanisms involved in signal transduction in these cells. Ligand activation of the receptor kinase serves as the proximal signal that eventually elicits the mitogenic response. CSF-1 is required during the G1 phase of the cell cycle for mononuclear cells to enter S phase, but the growth factor is not necessary during S, G2, and M phases. Withdrawal of the growth factor induces the cells to enter a quiescent state and leads to cell death. In osteoclasts CSF-1 induces, as in macrophages, cell spreading. The cytokine increases migration of osteoclasts, this way decreasing the number of resorbing cells and as a consequence decreasing total resorptive activity (Fuller *et al.,* 1993). In addition to inducing migration of osteoclasts, CSF-1 induces the fusion of mature cells as well (Amano *et al.,* 1998). In summary, CSF-1 supports proliferation, differentiation, fusion, and survival of progenitors and mature osteoclasts. The cytokine, however, does not activate the bone resorptive activity of the mature cells (Jimi *et al.,* 1999).

Upon binding of CSF-1 to c-*Fms,* the receptor dimerizes noncovalently and autophosphorylates by activation of its intrinsic tyrosine kinase activity (Hamilton, 1997). After phosphorylation, a number of intracellular proteins can bind to the receptor, propagating specific signal cascades and cellular responses. Subsequently, the receptor becomes internalized, dephosphorylated, multiubiquinylated, and degraded (Lee *et al.,* 1999; Wang *et al.,* 1999).

As mentioned above, binding of CSF-1 induces cell spreading both in macrophages and in osteoclasts. This effect is brought about by cytoskeletal rearrangements, involving c-*Src*-dependent tyrosine phosphorylation (Insogna *et al.,* 1997) and translocation of phosphatidylinositol-3-kinase (PI-3K) from the cytoplasm to the cell membrane (Grey *et al.,* 2000; Palacio and Felix, 2001). Although the spreading can be blocked by the specific PI-3K inhibitor wortmannin (Amano *et al.,* 1998), deficiency in the monocyte specific PI-3K isoform PI-3Kγ does not affect the bone phenotype (Hirsch *et al.,* 2000). In c-*src*-deficient mice, which are characterized by an osteopetrotic phenotype due to an osteoclastic failure to form a ruffled border (Boyce *et al.,* 1992), the autophosphorylation of c-*Fms* is not affected, while the phosphorylation of an as yet unidentified protein of 85–90 kDa is significantly reduced, suggesting an abnormal phosphorylation of down-stream targets (Insogna *et al.,* 1997).

Other signal transduction pathways induced by CSF-1 involve *Cbl* (Lee *et al.,* 1999; Ota *et al.,* 2000), which is important for degradation of c-*Fms.* Furthermore, mitogen-activated protein kinases and phosphatases (Lee and States, 2000; Valledor *et al.,* 1999) are activated, finally leading to regulation of cell cycle progression by cyclins (Dey *et al.,* 2000). This short summary of signal transduction pathways induced by CSF-1 upon binding to c-*Fms* indicates the complexity of signaling that is required for the fulfilment of the multiple roles the growth factor exerts on the cells of the osteoclast lineage.

Interleukin-3 (IL-3: Multicolony-Stimulating Factor)

IL-3, which is also called multicolony-stimulating factor, has the broadest target specificity for any of the known cytokines. IL-3 can stimulate proliferation and differentiation of basophils, erythroid cells, macrophages, mast cells, megakaryocytes and neutrophils. It induces primitive pluripotential stem cells to proliferate and differentiate to erythroid and myeloid cells.

IL-3 is a glycoprotein and is produced in high amounts by activated T lymphocytes, raising the possibility of its involvement in rheumatoid arthritis or other autoimmune diseases affecting bone.

The receptor for IL-3 is a member of the hemopoietin receptor superfamily. The receptors for IL-3, IL-5, and GM-CSF are heterodimeric and each uses a common β chain. The α chains of these receptors confer specificity for their cognate ligand, although the affinities for the ligand–α chain interaction are low. The common β chain for

these receptors has no affinity for the ligands and is responsible for signal transduction following ligand binding to the α chain and recruitment of the β chain. In humans only one common β chain has been described, while in the mouse the β chain has been duplicated such that it carries two copies that are over 95% identical. The murine β chains appear to be redundant and can compensate for each other if mutated (Nishinakamura *et al.,* 1995). Although the receptor activation results in signal transduction and JAK/STAT activation (Bagley *et al.,* 1997; Woodcock *et al.,* 1997), the ability of IL-5 to internalize along with its receptor (Jans *et al.,* 1997) raises the potential that other members of this family (IL-3 or GM-CSF) might undergo a similar process.

The expression of IL-3 by osteoblasts is well documented (Birch *et al.,* 1993; Bost *et al.,* 2000; Walsh *et al.,* 2000); however, little is known of the action of IL-3 on osteoblasts. IL-3 has been demonstrated to have no effect of osteoblast proliferation or in the production of NO synthase (Riancho *et al.,* 1995; Stock *et al.,* 1998).

Because of the ability of IL-3 to stimulate the proliferation and differentiation of hemopoietic stem cells, it would be expected that IL-3 would affect osteoclast formation. Any action of IL-3 on hemopoietic stem cells would cause the proliferation of basophils, erythroid cells, macrophages, mast cells, megakaryocytes, neutrophils, and osteoclasts. IL-3 has been reported to induce murine bone marrow cells to differentiate into osteoclasts (Barton and Mayer, 1989; Hattersley and Chambers, 1990), and a neutralizing antibody to IL-3 inhibited this differentiation (Barton and Mayer, 1989). In contrast to these findings, IL-3 also can inhibit this process (Shinar *et al.,* 1990) and has no direct effects on mature osteoclasts to regulate resorptive activity (Barton and Mayer, 1990).

Granulocyte-Macrophage Colony-Stimulating Factor (GM-CSF)

Biochemistry of GM-CSF

The principal role of GM-CSF consists in the stimulation of the growth of granulocytes and macrophages, although the cytokine may modulate osteoclastogenesis as well (see below). GM-CSF is synthesized by a number of different cell types, including endothelial cells, fibroblasts, macrophages, osteoblasts, stromal cells, and T lymphocytes. Cross species GM-CSF is not well conserved, with human and murine sharing only 56% amino acid identity and each is unable to substitute for the other to confer biological activity. GM-CSF contains two potential N-linked glycosylation sites, and both murine and human GM-CSF is glycosylated, although glycosylation is not required for activity.

The GM-CSF receptor, like that of IL-3, is a heterodimer composed of an α and a β chain; the β chain is common for both IL-3 and GM-CSF. GM-CSF can bind to the α chain with low affinity; however, signal transduction is conferred by the β chain. Upon binding the α chain, the β chain is recruited and the relatively low-affinity GM-CSF–α chain interaction is converted to one of a high-affinity state, permitting signal transduction. Several cellular targets of GM-CSF-induced tyrosine phosphorylation have been identified, including the β chain, JAK2, MAP kinase, raf, shc, and STAT5A, and STAT5B (Mui *et al.,* 1995a,b).

Much information has been gained on the action of GM-CSF since the production of GM-CSF-deficient and GM-CSF receptor β chain-deficient mice. Further, resolution of the interacting amino acids of GM-CSF with a neutralizing antibody has shed light on the topology of the receptor binding site of the β chain of the GM-CSF receptor (Rossjohn *et al.,* 2000). It is anticipated that the structure of the ligand–receptor complex would be solved in the immediate future.

GM-CSF Actions in Bone

In response to lipopolysaccharide, PTH, or TNF-α, GM-CSF production by osteoblasts is enhanced (Felix *et al.,* 1991). T lymphocytes on exposure to IL-18, a cytokine whose expression is elevated in mature osteoblasts, demonstrate enhanced GM-CSF production (Udagawa *et al.,* 1997). The contribution of locally produced GM-CSF to bone remodeling and turnover is controversial (see below), and the activity of GM-CSF on osteoblasts is unknown.

The effects of granulocyte-macrophage colony-stimulating factor (GM-CSF) on osteoclast formation vary considerably according to the culture system employed. The addition of GM-CSF to murine cocultures, where the hematopoietic cells were pretreated with GM-CSF before being cultured with normal osteoblastic cells, stimulates osteoclast formation (Takahashi *et al.,* 1991b). Furthermore, in cells derived from human subjects, a combination of GM-CSF, IL-1, and IL-3 has been reported to stimulate the formation of multinucleated cells from $CD34^+$, stromal cell antigen negative ($Stro\text{-}1^-$) cells (Matayoshi *et al.,* 1996). Annexin II, a calcium-dependent phospholipid binding protein, induces osteoclast formation and bone resorption (Takahashi *et al.,* 1994). The mechanism by which Annexin II increases osteoclast formation involves the production of GM-CSF by T cells in response to Annexin II, followed by the expansion of the CFU-GM stem cells (Menaa *et al.,* 1999). Although these data suggest that GM-CSF may well enhance osteoclast formation, its actions are not independent of CSF-1 and GM-CSF can not substitute for CSF-1 to facilitate osteoclast formation. In cocultures of spleen cells from wild-type mice with primary osteoblast derived from *op/op* mice, neither GM-CSF nor IL-3 supported osteoclast formation (Hattersley *et al.,* 1991b). While injection of GM-CSF in *op/op* mice was able to compensate in part for the absence of CSF-1 in the development of macrophages, it was unable to play a similar role in osteoclast differentiation (Wiktor-Jedrzejczak *et al.,* 1994). The effects of GM-CSF in *op/op* mice was restricted to stimulating macrophages participating in immune defense,

but was without action on resident tissue macrophages, which are dependent on CSF-1 (Wiktor-Jedrzejczak *et al.,* 1994). These differential effects suggest the existence of at least two populations of macrophages, one dependent on GM-CSF and the other on CSF-1 (Cecchini *et al.,* 1994; Wiktor-Jedrzejczak *et al.,* 1992).

GM-CSF has also been reported to inhibit osteoclast formation *in vitro* using a variety of assay systems. GM-CSF was found to dose-dependently inhibit osteoclast formation in murine coculture assays of primary osteoblasts with spleen cells (Gillespie and Horwood, 1998; Horwood *et al.,* 1998; Udagawa *et al.,* 1997), in murine spleen cultures stimulated with RANKL and CSF-1 (as described in Chapter 7; Quinn *et al.,* 1998)), and in human peripheral blood monocyte cultures treated with RANKL and CSF-1 (Quinn *et al.,* 1998). The effects of GM-CSF action were limited to the first 3 days of coculture of primary osteoblasts with spleen cells, indicative of GM-CSF action during the proliferative phase of osteoclast formation.

When GM-CSF was exogenously added to murine bone marrow culture, it suppressed osteoclast-like cell formation induced by $1,25(OH)_2D_3$. These effects were abrogated by the addition of neutralizing anti-GM-CSF antibodies (Hattersley and Chambers, 1990). Both mouse and human osteoclast formation, supported by SaOS-4/3 cells that express the PTH/PTHrP receptor, were inhibited by either adding an antibody against M-CSF or by adding GM-CSF (Matsuzaki *et al.,* 1999). Dexamethasone, a glucocorticoid implicated in osteoclast formation, inhibits endogenous production of GM-CSF in murine bone marrow culture, consistent with GM-CSF acting as a negative regulator of osteoclast formation (Shuto *et al.,* 1994). Human osteosarcoma cell lines, MG-63 and SaOS-2, both produce G-CSF and GM-CSF and osteoblasts were suggested to play a central role in the hemopoietic microenvironment as basal producers of these cytokines (Taichman and Emerson, 1996).

The differentiation of human blood monocytes/macrophages in response to CSF-1 or GM-CSF is starting to be addressed at the molecular level using serial analysis of gene expression (Hashimoto *et al.,* 1999). Of note, monocyte-derived chemokine and prostaglandin synthases were induced in response to CSF-1. Quite surprisingly, CSF-1 and GM-CSF induced the expression of legumain, an asparaginyl endopeptidase, that has been shown to inhibit osteoclast formation (Choi *et al.,* 1999). The ability of CSF-1 to promote osteoclast formation, as well as potentially inhibit this process by the induction of an inhibitor, provides a further mechanism for exquisite control for this process.

Although GM-CSF does not permit the formation of osteoclasts, it is probably not a true inhibitor of the process but is involved in macrophage lineage commitment more than permitting osteoclast differentiation.

Consistent with a role for local GM-CSF production, interleukin-18 (IL-18) was found to be a potent inhibitor of osteoclast formation *in vitro.* IL-18 enhances the production of both IFN-γ and GM-CSF, both of which are potent inhibitors of osteoclast formation (Gillespie and Horwood, 1998; Udagawa *et al.,* 1997). IL-18 was shown to be expressed by mature osteoblastic cells and to enhance the production of GM-CSF by T cells (Horwood *et al.,* 1998; Udagawa *et al.,* 1997). In turn, the T cell-derived GM-CSF was sufficient to inhibit osteoclast formation, as was demonstrated using cultures using cells from GM-CSF null or GM-CSF receptor null mice. Thus, GM-CSF production by osteoblast/stromal cells, T cells, or fibroblastic cells may influence osteoclast formation.

Although the *in vitro* data demonstrating that GM-CSF can alter osteoclast formation is quite compelling, there is little *in vivo* data indicating a central role for GM-CSF to either enhance or inhibit osteoclast formation during normal bone turnover. Null mice for either GM-CSF, GM-CSF receptor, IL-18, or interleukin-1 β converting enzyme, which is responsible for processing IL-1 and IL-18, display normal bone architecture (Kuida *et al.,* 1995; Nishinakamura *et al.,* 1995; Robb *et al.,* 1995; Stanley *et al.,* 1994; Takeda *et al.,* 1998) and display no evidence of osteoporosis or osteopetrosis. This differs markedly from what would be predicted from the *in vitro* data. However, in pathological conditions such as arthritis the IL-18/GM-CSF pathway may have a profound effect in the establishment of arthritis and ultimately the bone destruction associated with this condition. The involvement of GM-CSF or IL-18 in collagen-induced arthritis (CIA) has been demonstrated in GM-CSF-deficient (Campbell *et al.,* 1998) or IL-18-deficient (Wei *et al.,* 2001) mice, respectively. GM-CSF or IL-18 null mice develop markedly reduced incidence or severity (hyperplasia, infiltration and bone erosion) of arthritis compared with their respective heterozygous or wild-type mice. While administration of GM-CSF or CSF-1 exacerbates synovial hyperplasia, joint inflammation, and bone erosion (Bischof *et al.,* 2000). Such findings argue that the proinflammatory roles of IL-18 or GM-CSF are responsible for the enhanced severity of arthritis observed in these CIA models. Since IL-18 can induce the expression of both GM-CSF and IFN-γ, the contribution of each of these to the onset and development of arthritis is not known. Recent data, however, suggests that IFN-γ production in arthritis may protect the bone by counteracting the excess synthesis of RANKL by activated T cells (Takayanagi *et al.,* 2000). Further, evidence is accumulating for GM-CSF- or IFN-γ-independent actions of IL-18 that are particularly evident in the presence of IL-12. IL-18 with IL-12 act in synergy to inhibit osteoclast formation *in vitro,* and this occurs independently of GM-CSF or IFN-γ action (Horwood *et al.,* 2001). As with the conflicting observations derived from *in vitro* studies with GM-CSF and IL-18 relative to the severity of arthritis seen in CIA in GM-CSF or IL-18 deficient mice, IL-12 and IL-18 coadministration promotes arthritis in mice with established CIA (Gracie *et al.,* 1999; Leung *et al.,* 2000). Additionally, anti-IL-12 therapy alone, or in combination with anti-TNF-α, suppresses murine collagen-induced arthritis (Butler *et al.,* 1999). This probably results from the proinflammatory roles of IL-12 and IL-18, both of

which have been reported to enhance synovial hyperplasia and increase cellular infiltration when administered in the murine CIA model (Leung *et al.,* 2000).

The only animal model in which IL-18 has been shown to have a protective role to prevent bone loss is a mouse model of breast cancer metastasis to bone. IL-18 administration reduced osteolysis and hypercalcemic effects of MDA-MB-231 cells following intracardiac delivery and subsequent metastasis in bone (Nakata *et al.,* 1999). Given that IL-18 acts on T lymphocytes to promote IFN-γ and GM-CSF production and that GM-CSF can be a potent inhibitor, it is tempting to speculate that IL-18-induced GM-CSF inhibits osteoclast formation, resulting in reduced osteolysis and hypercalcemia, in a manner akin to the *in vitro* situation. It has been established that breast cancer cell cytokines such as PTHrP facilitate osteoclast formation by enhancing and inhibiting osteoblastic RANKL and OPG production, respectively (Thomas *et al.,* 1999; see Chapter 61). Thus the activation and inhibition of osteoclast formation/activity is a complex one in pathological conditions where unique interrelationships among hemopoietic cells, osteoblasts, breast cancer cells, stromal cells and cells of the immune system become apparent. The relative contribution of CSFs in the maintenance, proliferation, differentiation, and cellular responses of each of these cell types needs to be considered to determine their ultimate role in modifying the skeleton.

Granulocyte Colony-Stimulating Factor (G-CSF)

Biochemistry of G-CSF

Granulocyte colony-stimulating factor (G-CSF) is principally involved in the regulation of neutrophil function and their maturation. G-CSF is a glycoprotein of ~25 kDa, and the human and murine forms are 73% identical in their primary amino acid sequence and cross-react biologically. Activated macrophages, endothelial cells, fibroblasts, and osteoblasts produce G-CSF.

The G-CSF receptor is a member of the hemopoietic growth growth-factor receptor family. Its structure resembles that of the leukemia inhibitor factor (LIF), IL-6, and oncostatin, M receptors and gp 130. Unlike these receptors which function as heterodimers or heterotrimers, the active form of the G-CSF receptor is as a homodimer.

Effects of G-CSF on the Functions of Osteoblasts and Osteoclasts

Several reports document effects of G-CSF to enhance osteoclast formation *in vivo;* however, there is little indication that G-CSF has a direct effect on osteoclastogenesis *in vitro.* Hemopoietic cells treated with G-CSF *in vitro* differentiate along the granulocyte lineage, and do not commit to the osteoclast lineage. However, when osteoclast progenitors established under myeloid and lymphoid conditions were treated with G-CSF, expansion of osteoclast colony-forming units was noted (Lee *et al.,* 1997). Support for such a role for G-CSF *in vivo* results from administration of G-CSF to mice, and transgenic mice overexpressing G-CSF (Takahashi *et al.,* 1996; Takamatsu *et al.,* 1998). G-CSF administration in animal models (mouse and rat) resulted in osteoporosis, as a consequence of two mechanisms — dramatically increased osteoclast numbers and reduced bone formation (Soshi *et al.,* 1996; Takamatsu *et al.,* 1998). Similarly, osteoporosis/osteopenia is frequently described in patients with congenital neutropenia treated with G-CSF (Bishop *et al.,* 1995; Yakisan *et al.,* 1997). It is unknown whether the osteoporosis/osteopenia in these patients directly results from G-CSF therapy or is a consequence of the neutropenia. Anabolic steroid and bisphosphonate therapy in one such patient resulted in increased bone mass (Bishop *et al.,* 1995).

Although osteoblasts synthesize G-CSF, the action of G-CSF on osteoblast function is not extensively documented. Rats administered with G-CSF resulted in inhibition of endosteal bone formation, while periosteal formation was unaffected (Soshi *et al.,* 1996). This may be attributed to the excessive number of granulocytes being produced in the endosteum, or differential actions of G-CSF on these osteoblastic populations.

Conclusions

In the recent past, our understanding of the recruitment and the activation of osteoclasts have vastly improved. Animal and cell culture models helped to identify critical steps in the regulation of the differentiation pathway from the hemopoietic precursor cell to the mature osteoclast and to understand the interplay of factors collaborating in the regulation of bone resorption. In this chapter, the contribution of CSFs to the formation and activation of osteoclasts has been reviewed.

Hemopoietic cells are the principal targets of CSFs, and as such the principal bone cell type affected by CSF action is the osteoclast. The exquisite modulation of osteoclast formation, differentiation, and activation is fundamental for the process of bone resorption. Each of the CSFs, i.e., CSF-1, GM-CSF, IL-3, and G-CSF, is expressed by osteoblasts and may impinge upon osteoclast differentiation. Each CSF exerts its unique effects on the proliferation, differentiation, activation, and survival of hemopoietic cells. The interplay between these factors, along with other cytokines and growth factors, will ultimately dictate proliferation, differentiation, lineage commitment, and apoptosis of the target cells.

The osteoblast is often considered the "CSF factory of bone" due to its ability to produce CSF-1, a critical factor to the proliferation and survival of the osteoclast. The fundamental role of CSF-1 in osteoclast formation was recognized as a consequence of the *op* mouse, which is devoid of functional CSF-1. In these mice, osteoclast formation does not

occur and as a consequence the mice are osteopetrotic. The osteopetrotic phenotype was almost completely reversed by CSF-1 administration, inducing the formation of osteoclasts and restoration of bone resorption. However, a subepiphyseal osteosclerosis persisted, suggesting that the soluble form of CSF-1 does not account for all the biological effects of the cytokine. Several growth factors have been described to coexist as secreted and membrane-bound molecules (stem cell factor, RANKL, TNF-α), and it is probable that these molecular forms fulfil specific biological roles.

Treatment of osteopetrotic op mice with a combination of GM-CSF and IL-3 or with VEGF could restore the bone defect associated with CSF-1 deficiency. Thus it has become evident that the lack of CSF-1 can be compensated for by other factors. It is not clear, however, whether the combination of GM-CSF and VEGF administration to *op* mice could fully restore the CSF-1 functions. It is unlikely that these agents when combined would fully rescue the *op*/*op* phenotype; however, combined they should rectify peripheral macrophage development and enhance osteoclast formation, although hitherto unrecognized phenotypes may develop.

The demonstration that osteoclast formation and survival is dependent upon the action of CSF-1, and that osteoclasts express *c-fms,* provides substantial evidence that osteoclasts and macrophages are derived from common precursors. Consistent with this, osteoclasts can be derived from macrophage-rich populations or macrophage-like cell lines such as RAW264.7 or C7. Such a common progenitor (CFU-GM) would differentiate in response to G-CSF or CSF-1 to a CFU-G or CFU-M progenitor, respectively (Fig. 1, see also color plate). The CFU-G progenitor is considered to be the precursor for myeloblasts and neutrophils, while monocytes, macrophages and osteoclasts would be derived from the CFU-M progenitor. However, we need to be mindful of the potential for plasticity between these different pathways.

Although CSF-1 and RANKL are crucial for osteoclast development, their action cannot be considered in isolation. Both CSF-1 and RANKL are widely distributed (Kartsogiannis *et al.,* 1999; Stanley, 1994) and this should facilitate osteoclast formation in a nonrestrictive manner. Indeed fibroblasts from a variety of organs have the capacity to support osteoclast formation and in a number of pathologies multinucleate TRAP expressing cells have been reported at sites distal to bone (Quinn *et al.,* 2000). Thus, appropriately primed hemopoietic cells juxtaposed to RANKL- and CSF-1-expressing cells or exposed to membrane shed forms may have the potential to differentiate along the osteoclast linage. Such an assumption requires that inhibitors of osteoclast formation (see Chapter 7) are abundant at these sites. Thus crucial to the development of osteoclasts at extraskeletal sites, is the presence of active CSF-1 and RANKL. Excess OPG, the decoy receptor for RANKL, at such sites would retain cells to differentiate along the macrophage pathway. Conversely, appropriate combinations of CSFs may permit cells to be maintained as a stem cell population to differentiate along other lineages such as granulocytes or macrophages. A striking example for

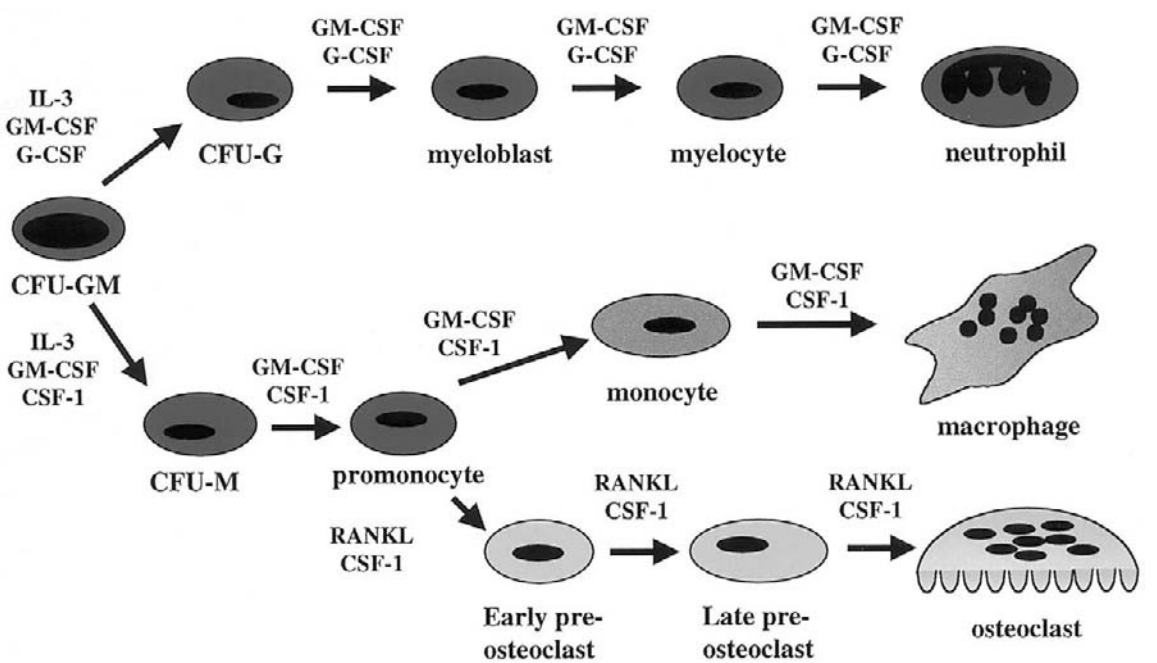

Figure 1 The lineage of osteoclasts. Osteoclasts, macrophages, and neutrophils potentially arise from a common stem cell known as the granulocyte-macrophage colony forming unit (CFU-GM). Differentiation toward a myelocyte and neutophil is dependent upon the action of G-CSF and GM-CSF. The initial pathway of osteoclast differentiation from the macrophage colony-forming unit (CFU-M) is identical to that of the monocyte/macrophages, but the final pathway is different and diverges from that of the monocytes. Both macrophage and osteoclast differentiation pathways are dependent upon the action of CSF-1. (See also color plate.)

this hypothesis is the possible role of TGF-β in the formation of osteoclasts. Marrow cells, in the presence of CSF-1 and TGF-β are maintained in their capacity to develop into osteoclasts upon exposure to RANKL, while in the absence of TGF-β, the cells loose their responsiveness to RANKL and become committed to the macrophage lineage.

Similar control mechanisms also may well exist in bone to facilitate coupled bone formation and bone resorption. Cytokines and growth factors are produced by cells in bone and may act as the soluble form via the extracellular fluid, but they may also be integrated into the extracellular matrix and act as "homing" molecules or regain their biological activity after release. In this context, some cytokines may contribute constitutively to the microenvironment suitable for cell differentiation and/or survival, while others are acutely regulated and direct cell development along specific pathways.

The activities of the CSFs in the bone microenvironment, in concert with other factors, would thus permit maintenance of appropriate cell numbers for each hemopoietic lineage.

The previously hypothesized but undocumented role of T- and B-lymphocytes and fibroblastic cells in normal bone remodeling in estrogen deplete and replete states, and in pathological bone remodeling are being characterized. The contribution of CSFs expressed by these cells, as well as other factors that may modulate osteoclast formation or activity needs to be considered. This is particularly true for pathologies such as prostate and breast cancer metastases to bone and rheumatoid arthritis. Since prostate and breast cancers produce CSF-1, both would be predicted to provide an environment for osteolysis. Prostate cancers and some breast cancers have the propensity to develop osteoblastic/osteosclerotic metastasis; however, osteolysis is a prerequisite for the subsequent growth of the metastases.

In rheumatoid arthritis, the T lymphocyte has a pivotal role in the establishment and onset of arthritis. Coupled with the production of RANKL by activated T cells, is a concomitant production of a number of CSFs that may provide a conducive environment for osteoclast formation. Simultaneously with the production of osteoclastogenic factors and cytokines, T cells have been shown to secrete factors inhibiting the formation of osteoclasts as well. The cytokine and/or CSF production by T lymphocytes is most certainly augmented by further production of cytokines and growth factors from synovial fibroblasts that become hyperplastic.

The identification of RANKL/OPG/RANK pathway to control osteoclast differentiation has permitted the expansion of experimental cell systems used to address osteoclast formation and facilitated a means to identify new control mechanisms. However, appropriately primed hemopoietic cells could predispose and commit osteoclasts to the action of RANKL or TNF-α. The interdependence of TNF-α with RANKL for osteoclast formation have recently been highlighted (Lam *et al.,* 2000). The requirement of TNF-α priming of hemopoietic cells prior to RANKL exposure shows parallels with the actions of TGF-β.

Future research will undoubtedly focus on the process of osteoclast formation and the cross-talk between the osteoclast-inductive pathways in response to RANKL and CSF-1 signaling. How do inhibitory agents impinge upon CSF-1 signaling? What is the relative contribution of CSFs from cellular sources during cancer or immuno-induced osteolysis? Is CSF-1 production modulated prior to or during osteoporosis? However the most important issue to address in this context is the molecular basis for the interrelationship and interdependence of the various cells in the bone microenvironment in their ability to influence bone remodeling.

CHAPTER 53

Local Regulators of Bone

IL-1, TNF, Lymphotoxin, Interferon-γ, IL-8, IL-10, IL-4, the LIF/IL-6 Family, and Additional Cytokines

Mark C. Horowitz and Joseph A. Lorenzo

Departments of Orthopaedics and Rehabilitation, Yale University School of Medicine, New Haven, Connecticut 06520; and the Department of Medicine, The University of Connecticut Health Center, Farmington, Connecticut 06032

The bone remodeling cycle is highly regulated by a variety of factors (i.e., hormones, cytokines, growth factors, and physical force). These are produced both locally and systemically and act in concert to direct local rates of bone turnover. Recent studies of the mechanisms regulating bone remodeling have concentrated on the role of cytokines since these factors appear to have crucial roles in both normal and pathologic bone cell function. A variety of cytokines that were originally identified by their ability to regulate immune and hematopoietic cells are believed to be produced in the bone microenvironment either spontaneously or in response to specific stimuli. It has become apparent that during both health and disease, the production of cytokines by cells in the bone microenvironment and the responses of bone cells to these cytokines are regulated in a highly ordered manner. It is hypothesized that the spectrum of cytokines that are produced in bone defines the responses of bone cells to a particular state and predicts the subsequent development of normal or pathologic bone remodeling. Diseases of bone where cytokines are believed to play an important role include osteoporosis, Paget's disease, and the effects of malignancy on bone. Studies of the production of cytokines in bone and the responses of bone cells to these cytokines may provide insights into the mechanisms that regulate the development of these diseases and could lead to new therapies for these conditions. The following is a broad overview of the actions of a number of cytokines on bone and the mechanisms by which bone cells respond to these cytokines.

Effects of Interleukin-1 on Bone

Interleukin-1 (IL-1) is a multifunctional cytokine with a wide variety of activities. It is a family of two active peptides (IL-1α and IL-1β) that are encoded by two separate gene products. Both forms of IL-1 have identical activities and potencies (Dinarello, 1991). IL-1 is the first polypeptide mediator of immune cell function that was shown to regulate bone resorption (Gowen *et al.,* 1983; Lorenzo *et al.,* 1987) and formation (Canalis, 1986), and it is the major activity that had previously been identified as osteoclast activating factor (OAF) (Dewhirst *et al.,* 1985). IL-1 is the most potent stimulator of bone resorption yet identified (Lorenzo *et al.,* 1987). It also increases prostaglandin synthesis in bone (Lorenzo *et al.,* 1987), an effect that may account for some of its resorptive activity since prostaglandins themselves are potent resorption stimuli (Klein and Raisz, 1970). The ability of IL-1 to stimulate bone resorption *in vivo* and *in vitro* requires that inducible nitric oxide synthase be present (Van't Hof *et al.,* 2000). Like a variety of other resorption stimuli, IL-1 increases receptor activator of nuclear factor κB ligand (RANKL) production in stromal/osteoblastic cells (Hofbauer *et al.,* 2001) by a mechanism that may require STAT3 activation (O'Brien *et al.* 1999). It also paradoxically stimulates OPG production in a human osteosarcoma cell line (Vidal *et al.,* 1998) and it directly enhances the resorptive activity of mature osteoclasts (Jimi *et al.,* 1999) by a mechanism that may involve activation of nuclear factor κB (NF-κB) (Miyazaki *et al.,* 2000).

Osteoclast-like multinucleated giant cell formation in cultured bone marrow is stimulated by IL-1 through a prostaglandin-dependent mechanism (Akatsu *et al.,* 1991). Hence, IL-1 may be involved in the differentiation of osteoclasts from hematopoietic progenitor cells, and this appears to be an additional mechanism by which it regulates bone resorption. IL-1 is a potent bone resorption stimulus *in vivo* (Sabatini *et al.,* 1988). Its effects on bone formation appear to be mainly inhibitory (Canalis, 1986), although it does stimulate DNA synthesis in both bone organ cultures and primary cultures of human bone cells (Canalis, 1986; Gowen *et al.,* 1985).

IL-1 is produced by bone organ cultures. However, the cells responsible for this production are not clearly identified (Lorenzo *et al.,* 1990b). It appears that both hematopoietic and mesenchymal/osteoblastic cells can produce IL-1 and its production is enhanced when both cell types are cocultured together (Haynes *et al.,* 1999). Macrophages are a likely source of IL-1 in bone marrow (Horowitz *et al.,* 1989), and osteoblast-like cells from human adult bone can also produce IL-1β *in vitro* (Keeting *et al.,* 1991).

A natural inhibitor to IL-1 has been identified (Arend *et al.,* 1990). This peptide, IL-1 receptor antagonist (IL-1ra), is an analog of IL-1 that binds but does not activate IL-1 receptors. IL-1ra blocks the ability of IL-1 to stimulate resorption and PGE_2 production in bone organ cultures (Seckinger *et al.,* 1990). Increased release of IL-1ra has recently been shown in the conditioned medium of cultured peripheral blood monocytes (PBM) from either normal or osteoporotic postmenopausal women when levels are compared with cultures of PBM from premenopausal women or postmenopausal women who are treated with estrogen (Pacifici *et al.,* 1993).

There are two known receptors for IL-1, type I and type II (Dinarello, 1993a,b). All known biologic responses to IL-1 appear to be mediated exclusively through the type I receptor (Sims *et al.,* 1993). Postreceptor signaling through the type I receptor involves sphingomyelin breakdown and production of ceramide (Kolesnick and Golde, 1994) in addition to activation of NF-κB (Jimi *et al.,* 1996). The type II IL-1 receptor appears to have little or no agonist activity rather it functions as a decoy receptor that prevents the activation of IL-1 type I receptor (Colotta *et al.,* 1993). In addition, type II IL-1 receptor can be released and circulate in serum as a soluble binding protein that inhibits IL-1 interactions with the type I receptor (Dinarello, 1993a,b). Type II IL-1 receptor may also synergize with IL-1ra to inhibit activation of the type I IL-1 receptor by IL-1 (Burger *et al.,* 1995).

Production of IL-1 appears to be involved in the development of osteoporosis. Increased IL-1 bioactivity has been found in the conditioned medium of PBM from some patients with a high-turnover form of this disease (Pacifici *et al.,* 1987). One group has found that *in vivo* estrogen treatment reduced the amount of IL-1 that was released from cultured PBM (Pacifici *et al.,* 1989). However, not all studies have confirmed this finding (Hustmeyer *et al.,* 1993; Stock *et al.,* 1989). In a related study, greater bone resorbing activity was found in lipopolysaccharide (LPS)-stimulated, PBM-conditioned medium from ovariectomized women than in PBM-conditioned medium from premenopausal or estrogen treated postmenopausal women (Cohen-Solal *et al.,* 1993). Neutralization studies showed this activity to result from both IL-1 and tumor necrosis factor (TNF)-α production *in vitro.* Measurements of IL-1 in the serum of pre- and postmenopausal women have produced conflicting results. One study showed that IL-1 levels were increased 30 days after ovariectomy (Fiore *et al.,* 1994), but others failed to find a correlation between serum IL-1α, IL-1β, or IL-1ra levels and indices of bone turnover in either pre- or postmenopausal women (McKane *et al.,* 1994) or between osteoporotic women and normals (Khosla *et al.,* 1994). Because modulation of cytokine production and/or responses in the bone marrow microenvironment may be the key mechanism by which estrogens modulate bone cell function, recent studies have focused on the ability of estrogen withdrawal to regulate IL-1 production in bone marrow. Increased production of a number of cytokines including IL-1α has also been identified in the conditioned medium of bone marrow cultures from postmenopausal women who had discontinued estrogen replacement within 1 month compared with similar studies of premenopausal controls (Bismar *et al.,* 1995). Two groups have demonstrated in mice that IL-1α biologic activity in bone marrow serum increases after ovariectomy but levels of IL-1α protein do not (Miyaura *et al.,* 1995; Kawaguchi *et al.,* 1995).

In vivo administration of IL-1ra inhibited the bone loss that occurred in ovariectomized rats (Kimble *et al.,* 1994). This effect was most pronounced after 4 weeks and was much less at earlier times. In addition, treatment of mice for 2 weeks after ovariectomy with IL-1ra decreased the ability of marrow cell cultures to form osteoclasts *in vitro* and inhibited the excretion of pyridinoline cross-links (a marker of *in vivo* bone resorption) (Kitazawa *et al.,* 1994).

IL-1 has also been implicated as one mediator of the hypercalcemia that accompanies some forms of cancer. Production of IL-1 occurs in myeloma cells that are cultured *in vitro* (Carter *et al.,* 1990) and correlates with their ability to stimulate bone resorption and hypercalcemia *in vivo.* In addition, the uncoupling of bone resorption and bone formation, which is characteristic of the lytic bone lesions in myeloma, is reproduced by local *in vivo* infusions of IL-1 (Boyce *et al.,* 1989).

Effects of Tumor Necrosis Factor on Bone

Like IL-1, TNF is a family of two related polypeptides (α and β) that are products of separate genes (Beutler and Cerami, 1986; Paul and Ruddle, 1988). TNF-α and -β have similar biologic activities and are both potent stimulators of bone resorption (Bertolini *et al.,* 1986; Lorenzo *et al.,* 1987) and inhibitors of bone collagen synthesis (Bertolini *et al.,* 1986; Canalis, 1987).

In vivo, TNF-α injections increased the serum calcium of mice (Tashjian *et al.,* 1987), and similar effects were seen with TNF-β (Garrett *et al.,* 1987). In a more detailed study, Chinese hamster ovary (CHO) cells that were genetically engineered to release large amounts of active TNF-α peptide were injected into nude mice (Johnson *et al.,* 1989). These animals became hypercalcemic within 2 weeks. Bone histomorphometry demonstrated a 10-fold increase in the number of osteoclasts in their bones compared with controls (animals injected with CHO cells that contained an empty vector). In addition, the percentage of the bone surface undergoing active resorption was similarly increased in animals receiving the TNF-producing cells.

The effects of TNF on resorption appear to be mediated by its effects on osteoclasts since osteoclast number increased after TNF treatment of bones (Johnson *et al.,* 1989) and because resorption stimulated by TNF was inhibited by calcitonin (Stashenko *et al.,* 1987). Like IL-1, TNF-stimulated induction of osteoclast-like cells formation in bone marrow culture (Pfeilschifter *et al.,* 1989) is mediated by increases in RANKL expression (Hofbauer *et al.,* 1999). However, in addition to increasing RANKL expression TNF also stimulates osteoprotegerin (OPG) in osteoblastic cell models (Hofbauer *et al.,* 1998). There is currently a controversy as to whether TNF can stimulate osteoclast formation from precursor cells in the absence of RANKL. Some authors have demonstrated this activity (Kobayashi *et al.,* 2000; Azuma *et al.,* 2000). However, others have found TNF to directly stimulate the differentiation of osteoclast precursor cells into osteoclasts only in the presence of RANKL (Lam *et al.,* 2000). The synergistic effects of TNF on RANKL-mediated osteoclastogenesis are mediated by activation of the TNF-receptor 1 (p55) (Zhang *et al.,* 2000)

In bone organ cultures, TNF stimulates DNA synthesis (Canalis, 1987). However, in an osteoblast-like osteosarcoma cell line, ROS 17/2.8, TNF did not stimulate DNA synthesis but did inhibit collagen synthesis (Nanes *et al.,* 1989). Furthermore, addition of hydroxyurea, an inhibitor of DNA synthesis, to primary rat osteoblast-enriched cultures did not alter the inhibitory effects of TNF on collagen synthesis (Centrella *et al.,* 1988). Hence, the effects that TNF has on cell replication do not appear linked to its effects on collagen synthesis. *In vitro,* TNF directly inhibits the differentiation of osteoblast precursor cells into mature osteoblasts (Gilbert *et al.,* 2000). This effect appears to involve production of nitric oxide and peroxynitrite (Hikiji *et al.,* 1997, 2000). Osteoblast apoptosis (programmed cell death) can also be stimulated by TNF (Jilka *et al.,* 1998) and this response also may be mediated by nitric oxide production (Damoulis and Hauschka, 1997).

In contrast to the inhibitory effects that continuous treatment with TNF has on collagen synthesis in bone, transient treatment with TNF for 24 hr causes a rebound increase in collagen synthesis in primary cultures of osteoblast-like cells from rat calvaria (Centrella *et al.,* 1988). Posttranscriptional regulation of message translation may also be involved in the effects that TNF has on collagen synthesis (Centrella *et al.,* 1988). TNF-α is produced by human osteoblast-like cell cultures (Gowen *et al.,* 1990) and its production is stimulated by IL-1, GM-CSF, and lipopolysaccharide but not by PTH, $1,25(OH)_2$ vitamin D_3, or calcitonin. Like RANKL, effects of TNF on osteoblastic cells are mediated by stimulation of NF-κB activity (Ali *et al.,* 1999; Yao *et al.,* 2000).

As with IL-1, TNF binds to two cell surface receptors, the TNF receptor 1 or p55, and the TNF receptor 2 or p75 (Fiers, 1993). In contrast to IL-1, both receptors transmit biologic responses. There appear to be interactions between the TNF receptor 1 and TNF receptor 2 (Tartaglia *et al.,* 1993), and for many responses, activation of both receptors is necessary to produce a full biologic effect (Vandenabeele *et al.,* 1995). However, some effects can be induced by selective activation of either receptor (Sheehan *et al.,* 1995). Mice deficient in the TNF receptor 1 and TNF receptor 2 have been made by ES cell knockout techniques (Rothe *et al.,* 1993; Erickson *et al.,* 1994). These animals appear healthy and breed normally, but lack normal immune responses and apoptotic mechanisms.

Estrogens are reported to modulate TNF production *in vitro* in human osteoblast cultures by one group (Rickard *et al.,* 1992). However, another group failed to find an effect of estrogen treatment on TNF protein production in human osteoblast-like cell cultures (Chaudhary *et al.,* 1992). Spontaneous production of TNF in cultured peripheral monocytes from women who had recently undergone ovariectomy was increased compared with levels from cells that were assayed preovariectomy (Pacifici *et al.,* 1991). As mentioned above, bone-resorbing activity in LPS-stimulated peripheral blood monocyte-conditioned medium (CM) is increased in cultures from postmenopausal women when compared with CM from premenopausal or postmenopausal women that were treated with estrogen and this effect relies on TNF in the CM to some degree (Cohen-Solal *et al.,* 1993). Kimble *et al.* (1994) found that like the effect of *in vivo* administration of IL-1ra, treatment of mice with soluble TNF receptor, an inhibitor of TNF action, reduced the ability of ovariectomy to decrease bone mass (Kimble *et al.,* 1995a). Interestingly, the most potent inhibition of the effects of estrogen withdrawal on bone mass was seen in rats that were treated with both IL-1ra and soluble TNF receptor. In a related study, it was demonstrated that mice overexpressing soluble TNF receptor 1, which binds TNF and inhibits its action, did not have increased bone loss after ovariectomy (Ammann *et al.,* 1995). Recently, mice lacking mature T-lymphocytes were found to not lose bone mass after ovariectomy and this effect appeared to be related to T-lymphocyte-mediated production of TNF (Cenci *et al.,* 2000).

TNF-β has been implicated as one cause of the effects that hematological malignancies have on bone (Garrett *et al.,* 1987). A tumor cell line was established from a patient with multiple myeloma who had developed hypercalcemia and osteolytic bone lesions. This cell line was found to contain detectable steady-state levels of TNF-β mRNA and to produce TNF-β *in vitro.* Furthermore, an antibody to TNF-β blocked some but not all of the *in vitro* bone resorbing activity that was present in the conditioned

medium from these cells and from other established myeloma cell lines. Like IL-1, TNF stimulates bone resorption while inhibiting bone formation and mimics the *in vivo* responses of bone to hematological malignancy (Bertolini *et al.,* 1986).

TNF has also been linked to the resorptive effects that nonhematologic malignancies have on bone. In one report, a squamous carcinoma cell line was shown to release a factor that stimulated monocyte cultures to produce TNF-α. This tumor did not itself produce TNF. However, implantation of the tumor into nude mice stimulated bone resorption, hypercalcemia, and leukocytosis that were reversed by a specific anti-TNF-α antibody (Yoneda *et al.,* 1991).

Effects of Interferon-γ on Bone

Interferon (IFN)-γ is another regulatory cytokine with a wide variety of biologic activities. *In vitro* IFN-γ was first shown to inhibit resorption (Gowen and Mundy, 1986; Peterlik *et al.,* 1985). This effect appears to be more specific for the response to IL-1 and TNF since lower concentrations of IFN-γ inhibit the maximum activity of these factors compared with resorption stimulated by PTH or $1,25(OH)_2$vitamin D_3 (Gowen *et al.,* 1986). The actions of IFN-γ on *in vitro* resorption appear to be mediated by its effects on osteoclast progenitor cells. IFN-γ inhibits the ability of $1,25(OH)_2$ vitamin D_3, parathyroid hormone (PTH), IL-1, and RANKL to stimulate the formation of osteoclast-like cells in cultures of human bone marrow (Takahashi *et al.,* 1986; Fox and Chambers, 2000). This effect is mediated at least in part by the ability of IFN to stimulate degradation of TRAF-6 (Takayanagi *et al.,* 2000), an intermediate in RANK signaling (Wong *et al.,* 1999).

IFN-γ is also known to inhibit other hematopoietic functions including erythropoiesis (Mamus *et al.,* 1985). However, it does not affect the resorptive activity of mature osteoclasts (Hattersley *et al.,* 1988). IFN-γ can synergistically augment IL-1 or TNF stimulated nitric oxide (NO) production by cultured osteoblasts (Ralston *et al.,* 1995). NO appears to be a biphasic regulator of osteoclast-mediated bone resorption that stimulates at low concentrations and inhibits at high concentrations (Ralston *et al.,* 1995). It is possible that part of the inhibitory effects of IFN-γ on IL-1- and TNF-mediated resorption results from effects on NO synthesis. IFN-γ together with IL-1 or TNF synergistically stimulates NO production to high levels in bone, which inhibits osteoclast-mediated resorption by inducing apoptosis of osteoclast progenitors and inhibiting osteoclast activity (Van't Hof and Ralston, 1995).

The *in vitro* effects of IFN-γ on collagen synthesis are also inhibitory. In bone organ culture, IFN-γ decreases both collagen and noncollagen protein synthesis (Smith *et al.,* 1987). This effect was not dependent on prostaglandin synthesis (Smith *et al.,* 1987). The effects of IFN-γ on collagen synthesis in the osteoblast-like ROS 17/2.8 cell line are similar to those seen in organ cultures (Nanes *et al.,* 1989).

IFN-γ also inhibits DNA synthesis in bone organ cultures (Smith *et al.,* 1987), in human cultured bone cells with osteoblast characteristics, and in the ROS 17/2.8 cells (Nanes *et al.,* 1989). It also inhibits the stimulatory effects that TNF and IL-1 have on cell replication in bone cultures (Smith *et al.,* 1987) and that TNF has in human osteoblast-like cells (Gowen *et al.,* 1988) and the ROS 17/2.8 osteosarcoma cell line (Nanes *et al.,* 1989). Effects of IFN-γ on osteoblast function appear to involve nitric oxide production (MacPherson *et al.,* 1999).

The effects of IFN-γ on bone *in vivo* are markedly different from its actions *in vitro.* In rats, ip injection of IFN-γ for 8 days induced osteopenia (Mann *et al.,* 1994). In patients who have osteopetrosis and produce defective osteoclasts, administration of IFN-γ stimulates bone resorption and appears to partially reverse the pathology of the disease. These effects are possibly due to the ability of IFN-γ to stimulate osteoclast superoxide synthesis (Key *et al.,* 1992, 1995) or osteoclast formation *in vivo* (Vignery *et al.,* 1990).

Additional Cytokines That Are Produced in Bone or Have Effects on Bone Cell Function

A variety of additional cytokines have been shown to either be produced by bone cells or to have effects on bone cell function. Interleukin-8 (IL-8) and monocyte chemotactic peptide-1 (MCP-1) are members of the chemokine family of cytokines, which is named for the ability of its members to direct the migration of cells to sites of inflammation. Both are produced in bone cells in a regulated manner (Chaudhary and Avioli, 1995; Takeshita *et al.,* 1993; Zhu *et al.,* 1994). More than 20 different chemokines have been described. In addition to IL-8 and MCP-1, these include macrophage inflammatory proteins 1α, 1β, and 2 (MIP-1α, MIP-1β, and MIP-2) and RANTES (Regulated on Activation Normal T-cell Expressed and Secreted) (Horuk, 1994). All contain four conserved cysteine residues and are classified into two categories depending on whether the first two conserved cysteine residues are separated by an intervening amino acid (CXC) or not (CC). IL-8 is a member of the CXC chemokine group while MCP-1 belongs to the CC group. IL-8 has specific neutrophil chemotactic activity. It is produced by human osteoblast-like cells, the human osteosarcoma cell line MG-63, human bone marrow stromal cells and human osteoclasts (Chaudary and Avioli, 1995; Chaudary *et al.,* 1992; Rothe *et al.,* 1998). Production of IL-8 in these cells was augmented by treatment with either IL-1 or TNF and was synergistically increased by their combination. Dexamethasone decreased the production of IL-8 in the cells in response to treatment with IL-1 or TNF. However, *in vitro* estrogen treatment had no effect.

MCP-1, which was originally called JE in mice, is a potent monocyte chemoattractant that is produced by stimulated osteoblasts (Zhu *et al.,* 1994). Like IL-8, IL-1 and TNF strongly stimulated its production in human and murine

osteoblastic cells (Takeshita *et al.,* 1993; Zhu *et al.,* 1994; Graves *et al.,* 1999).

The function of IL-8 and MCP-1 in bone remains to be defined. However, MCP-1 does not appear to be involved in regulating the development or activity of osteoclasts since it did not stimulate the maturation of osteoclast-like cells in bone marrow cultures (Zhu *et al.,* 1994) nor did it affect bone resorption rates in organ cultures (Williams *et al.,* 1992) or in isolated osteoclasts that were cultured on bone slices (Fuller *et al.,* 1995). However, it is possible that it regulates the migration of a common monocyte-osteoclast progenitor cell from the blood or bone marrow to sites of osteoclast development at the bone surface.

Of the other members of the chemokine family that have been examined for their effects on bone cells, MCP-1α and IL-8 were found to stimulate the motility but suppress the resorptive rate of isolated osteoclasts while MIP-1β, MIP-2, and RANTES were without effect (Fuller *et al.,* 1995). However MIP-1α is a potent stimulator of bone resorption that may be involved in the effects of multiple myeloma on bone (Choi *et al.,* 2000).

Interleukin 4, 10, and 13 are members of a group of locally acting factors that have been termed inhibitory cytokines (Burger and Dayer, 1995). These proteins modulate the biosynthesis of proinflammatory cytokines and regulate the production of proinflammatory cytokine antagonists that either bind but do not activate cytokine receptors (IL-1ra) or prevent binding of active cytokines to receptors by forming complexes in solution (soluble type 2 IL-1 receptor or soluble TNF receptors). IL-10 is produced by TH2 cells as well as other cell types including stimulated monocytes. In bone marrow cell cultures, which express a variety of proteins characteristic of osteoblasts including alkaline phosphatase, type I collagen, and osteocalcin, treatment with IL-10 suppressed the production of osteoblastic proteins and prevented the onset of mineralization (Van Vlasselaer *et al.,* 1993). IL-10 also inhibits the formation of osteoclast-like cells in bone marrow cultures without affecting macrophage formation or the resorptive activity of mature osteoclasts (Owens *et al.,* 1996). The inhibitory effects of IL-4 on osteoclastogenesis appears to involve tyrosine phosphorylation of specific intracellular proteins (Hong *et al.,* 2000). *In vitro* both IL-4 and IL-13 inhibit bone resorption by suppressing prostaglandin production in osteoblasts (Onoe *et al.,* 1996). In addition, they have been identified as chemoattractants for osteoblasts *in vitro* (Lind *et al.,* 1995).

Effects of IL-4 on Bone

IL-4 is a 19-kDa pleotropic cytokine secreted by activated TH2 cells and mast cells (Howard *et al.,* 1982). Its major functions include the growth and survival of T helper cells, the activation and growth of B cells, increased expression of class II MHC molecules, and the inhibition of macrophage function (Hart *et al.,* 1989; Stuart *et al.,* 1988). Although IL-4 is not a member of the LIF/IL-6 subfamily of cytokines, it uses a two-chain plasma membrane-expressed receptor similar in many ways to the LIF and IL-11 receptors. Ligand binds to the 140-kDa IL-4 receptor, which is a single polypeptide chain of 800 amino acids that confers both specificity and determines signaling (Idzerda *et al.,* 1990). The IL-4 receptor heterodimerizes with the γ common chain of the IL-2 receptor to form a complete receptor (Russell *et al.,* 1993). Binding of IL-4 results in the phosphorylation on tyrosine of cellular substrates. The IL-4 receptor has no intrinsic kinase activity. As is the case for the LIF receptor, Jak1 and Jak3 are tyrosine phosphorylated in response to IL-4, as is Stat 6 (Witthuhn *et al.,* 1994). Jak3 associates with the γ common chain, suggesting that the IL-4 receptor-specific chain associates with Jak1. It is assumed that the phosphorylation of cellular substrates is mediated by the Jak kinases. IL-4 binding does cause the tyrosine phosphorylation of ligand specific substrates such as insulin receptor substrates 1 and 2. Activation of these unique substrates is likely to be part of how different ligands confer specific activities to their targets.

IL-4 appears to inhibit bone remodeling. In organ culture, IL-4 antagonized the resorption inducing activity of IL-1, tumor necrosis factor, 1,25-dihydroxyvitamin D_3, and prostaglandin E2 (PGE2) without affecting basal resorption (Watanabe *et al.,* 1990). As mentioned previously, IL-4 inhibits macrophage function. Osteoclasts are in the macrophage lineage, suggesting that at least one of the targets for IL-4 are mature osteoclasts or more likely osteoclast precursors. Addition of IL-4 to cultures of bone marrow cells (source of osteoclast precursors) and stromal cells causes the inhibition of osteoclastogenesis (Shioni *et al.,* 1991). In this system, osteoclastogenesis induced by PTH, PTH-related peptide (PTHrP), 1,25-dihydroxyvitamin D_3, IL-1, and PGE2 was inhibited by the addition of IL-4 (Lacey *et al.,* 1995). Using this same system, bone marrow macrophages were substituted for unfractionated bone marrow cells with similar results, suggesting that the target for the IL-4 inhibitory activity was the osteoclast precursor. Recently, the effects of IL-4 on osteoclastogenesis were demonstrated to occur through direct actions on the peroxisome proliferator-activated receptor gamma 1 (Bendixen *et al.,* 2001).

In vivo bone resorption in mice that were transplanted with a PTHrP- and IL-1-secreting tumor was inhibited by continuous infusions of IL-4 (Nakano *et al.,* 1994). In addition, IL-4 delivery by adenovirus vector was shown to suppress RANKL and IL-17 production and prevent bone resorption in an *in vivo* collagen induced arthritis mouse model (Lubberts *et al.,* 2000). At least part of this inhibitory effect could be related to the ability of IL-4 to block local prostaglandin synthesis in bone cells (Kawaguchi *et al.,* 1996, Onoe *et al.,* 1996). Further evidence for the role that IL-4 may play in the control of bone remodeling is provided by IL-4-overexpressing transgenic mice (Lewis *et al.,* 1993). These mice have pronounced cortical thinning in the long bones and vertebrae. Although IL-4 overexpressing mice have normal numbers of osteoclasts, their function appeared altered as measured by a decrease in TRAP activity. Interestingly, these animals have

a marked reduction in bone formation. Both the number of cells lining the bone surface and the function of these cells was decreased. IL-4 treatment also decreased bone turnover in ovariectomized mice (Okada *et al.,* 1998).

Hence, osteoblasts, as well as osteoclasts, appear to be a target of IL-4. IL-4 induces the secretion of macrophage colony-stimulating factor (M-CSF) from the murine osteoblast-like cell line MC3T3-E1 as well as primary osteoblasts in a dose-dependent manner (Lacey *et al.,* 1994). MC3T3 cells express IL-4 receptors that can be upregulated by treatment with 1,25-dihydroxyvitamin D_3 (Lacey *et al.,* 1993). Primary human osteoblast-like cells and the human osteosarcoma MG-63 also express IL-4 receptors (Riancho *et al.,* 1993; Ueno *et al.,* 1992). Furthermore, IL-4 stimulated the proliferation of human osteoblast-like cells *in vitro* as well as their expression of alkaline phosphatase

Additional Cytokines

Interleukin-7 stimulates both B and T-lymphopoiesis. *In vivo* injection of IL-7 into mice leads to increased osteoclast formation and bone loss by a mechanism that requires T-lymphocyte production of resorptive cytokines (Miyaura *et al.,* 1997; Weitzmann *et al.,* 2000). In addition IL-7 receptor deficient mice have increased bone mass compared to wild-type controls (Miyaura *et al.,* 1997). Interleukin 12 is a regulator of immune responses that stimulates T-lymphocytes to produce an unknown cytokine, which inhibits osteoclast formation either alone or in synergy with interleukin 18 (Horwood *et al.,* 2001). Interleukin 15, which shares many activities with IL-2, was shown in one report to enhance the differentiation of osteoclast precursor cell toward mature osteoclasts (Ogata *et al.,* 1999). Interleukin 17 is a product of activated T-lymphocytes and has been shown to enhance osteoclastogenesis in two reports (Kotake *et al.,* 1999; Van bezooijen *et al.,* 1999). In one report IL-17-mediated increases in osteoclast numbers in bone marrow-osteoblast cocultures were dependent on prostaglandin synthesis (Kotake *et al.,* 1999) while in the other they were seen only in cultures that were also treated with TNF (Van bezooijen *et al.,* 1999). Interleukin 18 is produced by osteoblastic cells (Udagawa *et al.,* 1997) and inhibits osteoclast formation in cocultures of spleen and osteoblastic cells through its ability to stimulate granulocyte-macrophage colony-stimulating factor (GM-CSF) production in T-lymphocytes (Horwood *et al.,* 1998).

Effects of the LIF/IL-6 Subfamily of Cytokines on Bone

Abundant data have accumulated demonstrating that the LIF/IL-6 subfamily of cytokines has important effects on the regulation of the normal and pathologic remodeling cycles. These factors are related based on sequence homology, chromosome location, and receptors (Rose and Bruce 1991). This subfamily is composed of leukemia inhibitory factor (LIF), oncostatin-M (OSM), IL-6, IL-11, ciliary neurotrophic factor (CNTF), and cardiotrophin-1 (CT-1). The data known about these cytokines as they relate to bone is variable. Information is known about which bone cells secrete LIF and IL-6. Receptor expression for all of the cytokines is better described and some of the biological consequences of that binding are known. More data is known about LIF, OSM, and IL-11, less is available on CNTF and CT-1, and substantial information is known about IL-6 and its receptors (Bellido *et al.,* 1997; Elias *et al.,* 1995; Girasole *et al.,* 1994; Horowitz *et al.,* 1994; Jay *et al.,* 1996). Although information is available about the receptors for these cytokines and some of the downstream events that occur following ligand binding in skeletal cells, it is more recently that the signal transduction pathways used by these cytokines has begun to be elucidated (Bellido *et al.,* 1994, Horowitz *et al.,* 1996; Levy *et al.,* 1996). These cytokines may interact with their receptors in two settings, both of which can result in signal transduction. The first and more conventional setting is when ligand binds to its appropriate plasma membrane expressed receptor component. This interaction initiates receptor component assembly, culminating in a functional receptor capable of transmitting a signal to the interior of the cell. This form of ligand–receptor interaction can occur for all of the cytokine subfamily members. The second setting, which involves the interaction between ligand and soluble receptor, is limited to specific members of the subfamily (IL-6, IL-11, and CNTF).

Originally known as differentiation inducing factor, LIF is a pleotropic cytokine exerting multiple effects in bone. Its effects on bone resorption *in vitro* are variable and, like other members of the group, depend on the model system that is used. LIF is secreted as a diffusible molecule and in an immobilized form associated with the extracellular matrix as a result of alternate promoter usage, again suggesting an important developmental control mechanism (Rathjen *et al.,* 1990). LIF mRNA is found in various rodent and human immortalized cell lines and primary fetal rat calvarial cells (Marusic *et al.,* 1993). It induces bone resorption in cultured mouse calvaria via a prostaglandin-mediated mechanism (Reid *et al.,* 1990). However, in fetal rat and mouse long bone cultures it inhibits resorption (Lorenzo *et al.,* 1990a; Van Beek *et al.,* 1993). Mice injected with a hematopoietic cell line overexpressing LIF developed cachexia and increased bone turnover with marked bone formation (Metcalf and Gearing, 1989). LIF can either potentate or inhibit the expression of alkaline phosphatase and type I collagen synthesis depending on the cells or assay used, suggesting a role for LIF in osteoblast development (Lorenzo, 1991). Addition of LIF to fetal rat calvarial cell cultures results in inhibition of bone nodule formation (Malaval *et al.,* 1995). LIF had variable effects on osteoblast-like cell proliferation. LIF had no effect on the proliferation of the human osteosarcoma cell line MG-63, induced a 40% increase in proliferation in murine MC3T3-E1 cells and had no effect on authentic murine calvarial osteoblasts (Bellido *et al.,* 1997). The addition of LIF to MC3T3-E1 cells inhibited apoptosis induced by either serum

starvation or addition of TNF (Jilka *et al.,* 1998). Treatment of MC3T3-E1 cells with PTH results in the increased transcription of LIF and IL-6 but not 14 other cytokines including IL-1, GM-CSF, and TGFβ-1 (Greenfield *et al.,* 1993) Similarly, treatment of a rat osteosarcoma cell line with PTH resulted in IL-6 secretion (Horowitz *et al.,* 1990). This suggests that some of the effects of PTH may be mediated by LIF and PTH (Grey *et al.,* 1999). Because murine osteoblasts respond to LIF, they must express cell surface receptors. LIF induced signal transduction in nonskeletal cells results in protein tyrosine phosphorylation.

Therefore, appropriate substrates should also be phosphorylated in bone cells. Treatment of the murine osteoblast cell line MC3T3-E1 with LIF results in tyrosine phosphorylation of Jak1, Jak2, gp130, and what appears to be the LIFR (Lowe *et al.,* 1995). The fact that osteoblasts respond to LIF and secrete LIF indicate that it is a true autocrine growth factor. However, few data are available on the effects of LIF on primary human osteoblast-like cells, effects which may be particularly important because osteoblast-like cells derived from patients 60 years and older fail to respond to LIF as measured by the induction of phosphoproteins (M.Horowitz unpublished observation). Whether this reflects an intrinsic unresponsiveness in these cells or is related to other processes is unknown. It is tantalizing to speculate that if this failure was age related, it could account for the onset of osteopenia and possibly osteoporosis. This idea is supported by the observation that mice rendered LIFR negative by homologous recombination develop severe osteopenia with increased osteoclastic activity (Ware *et al.,* 1995).

OSM, which is structurally similar to LIF, is a 28-kDa glycoprotein originally isolated from media of PMA stimulated U937 human histiocytic leukemia cells (Zarling *et al.,* 1986). OSM is secreted by phytohemagglutinin-stimulated T cells, lipopolysaccharide activated monocytes, and cell cultures from AIDS-related Kaposi's sarcoma for which OSM is a growth factor. OSM mRNA is also found in bone marrow cells. Its expression in bone, however, is currently unknown. OSM, like LIF, induces murine osteoblasts to proliferate and secrete matrix proteins and, of the family members, it is the most potent stimulator of IL-6 (Jay *et al.,* 1996, Bellido *et al.,* 1997). However, it inhibits alkaline phosphatase activity and bone resorption (Jay *et al.,* 1996). OSM has also been reported to inhibit the proliferation of MG-63 cells (Bellido *et al.,* 1997). Anti-Fas antibody induced apoptosis in MG-63 cells was inhibited by OSM (Jilka *et al.,* 1998). OSM activation of MG-63 cells leads to transcriptional activation of the p21WAF1,CIP1,SDI1 gene which has been shown to be important in protecting against apoptosis and could explain the anti-apoptotic effects of OSM (Gorospe *et al.,* 1997; Wang *et al.,* 1996). Transgenic mice that overexpress bovine OSM develop osteopetrosis (Malik *et al.,* 1995). Although the overall syndrome is similar to the picture seen in the LIF overexpressing mice, it does not have the associated increase in bone resorption. In fact, the osteopetrosis seen in both the LIF- and the OSM-overexpressing mice is just the opposite picture to that seen in the LIFR knockout mice. Human OSM induces tyrosine phosphorylation in both primary human and mouse osteoblast-like cells. Three JAK family members (Jak1, Jak2, and Tyk2) are tyrosine phosphorylated in response to OSM in calvarial osteoblastic cells, a response similar to that observed in nonskeletal cells (Levy *et al.,* 1996). However, human osteoblast-like cells express a number of additional phosphoproteins in the 150- to 200-kDa range not found in the mouse. These differences may be due to the mouse cells' use of the LIFR+gp130 and the alternate receptor, or of the OSM-specific receptor (OSMR)+gp130 complex vs the human cells' use of only the OSM-specific receptor, because human cells do not express the LIFR (Gearing and Bruce, 1992; Rose *et al.,* 1994). These data suggest that differences exist between the ability of these ligands to bind and activate osteoblasts and the complexity may be increased by differences in species and age.

The newest member of the LIF/IL-6 family is CT-1, a 21.5-kDa protein originally isolated from differentiated mouse embryonic stem (ES) cells (Pennica *et al.,* 1995a). The amino acid sequence of CT-1 is similar to LIF (24% homology) and CNTF (19% homology). mRNA for CT-1 is expressed in heart, liver, and kidney with less in brain and none in spleen. Its expression in bone is currently unknown. CT-1 is a potent inducer of myocyte hypertrophy, as are LIF, IL-11, and OSM, while IL-6 and CNTF are much less effective. CT-1 is inactive in the B9 assay (detects IL-6) and inhibits the differentiation of mouse ES cells (Pennica *et al.,* 1995b). CT-1 binds the LIFR directly and requires gp130 to effect signal transduction (Pennica *et al.,* 1995b). No α component of the receptor has been identified. Based on the receptor component composition, CT-1 should activate osteoblasts. Addition of CT-1 to calvarial osteoblastic cultures induces numerous tyrosine phosphorylated proteins in a time-dependent manner (M. Horowitz, unpublished observation). Because CT-1 uses the LIFR+gp130, it seems reasonable that the defects observed in heart development in the gp130 knock-out mouse are due, at least in part, to the failure of CT-1 to function. CT-1 must also be considered a candidate, as are LIF and OSM, for the cytokines contributing to the maintenance of normal bone remodeling which is profoundly altered in the LIFR knockout mice.

The second setting for the interaction of ligand and receptor is restricted to IL-6, CNTF, and IL-11 by the ability of their receptors to be cleaved from the membrane and function in soluble form (sIL-6R, sCNTFR, and sIL-11R). It is these α components that confer a level of specificity to the interaction of ligand and cell. Soluble receptor can bind ligand, forming a complex which can interact with the appropriate β subunits to trigger signaling. Addition of premixed sIL-6R plus IL-6 to murine calvarial osteoblasts results in their activation. This indicates that for IL-6 this interaction can occur in solution. This interaction can also occur on the cell membrane, as is the case for IL-11 and CNTF interacting with their receptor on calvarial osteoblasts. This is due to the presence of the α components for IL-11 and CNTF being expressed on the cell membrane

while the IL-6 α component is absent. This type of interaction may induce signal transduction in cells which would not normally be responsive to these cytokines due to lack of the appropriate α components on their membrane surface. It is thought that the major effect of IL-6 is its colony-stimulating activity on osteoclast precursors (Roodman, 1992). This is an important issue since estrogen inhibits cytokine induced IL-6 secretion by bone cells and osteoclastogenesis (Girasole *et al.,* 1992). Antibodies to IL-6 or estrogen blocked the increased formation of osteoclasts in ovariectomized mice (Jilka *et al.,* 1992). However, Tamura has reported that IL-6 does not directly induce osteoclast formation in coculture experiments (Tamura *et al.,* 1993). This failure can be overcome by the addition of sIL-6R. IL-11, OSM, and LIF (OSM>IL-11>LIF) all directly induce osteoclast formation in this system. Because of the design of the studies, the target of the cytokines could not be determined. However, treatment of primary mouse osteoblast cultures with IL-11 resulted in the upregulation of RANKL gene expression (Yasuda *et al.,* 1998). Increased RANKL expression would explain the increase in osteoclast formation in coculture induced by all four cytokines. We have shown that IL-6 does not directly induce tyrosine phosphorylation in primary mouse or human osteoblasts, but this failure can be overcome by the addition of sIL-6R (Horowitz *et al.,* 1994). However, it has been demonstrated that treatment of murine osteoblastic cells with dexamethasone induced a marked increase in IL-6 receptor expression (Udagawa *et al.,* 1995). This suggests that osteoblastic cells may be the target for IL-6 under the appropriate conditions. Therefore, the target cell in bone for IL-6 remains ambiguous. The ambiguity over the role of IL-6 in bone is heightened by the differences reported in the ability of IL-6 to induce bone resorption (Ishimi *et al.,* 1990, al-Humidan *et al.,* 1991). Because osteoblasts secrete IL-6, it is possible that IL-6 may function as an autocrine or paracrine factor, but this could only occur in the presence of sIL-6R or an increase in cortisol levels. The fact that other members of the subfamily also induce osteoclast formation supports our hypothesis that these factors play an important role in the regulation of bone remodeling. Although the LIFR has no α component, LIFR can be detected in the circulation (Layton *et al.,* 1992). Unlike the agonist effect of sIL-6R+IL-6, sLIFR+LIF may have an antagonistic effect (Gearing, 1993). Whether this is due to α vs β receptor component usage or downstream events is unknown. Equally unknown is the effect of sLIFR+LIF on bone cells.

IL-11 is a 23-kDa stromal cell derived cytokine which causes the maturation of hematopoietic precursor cells (Quesniaux *et al.,* 1993). The IL-11-specific receptor is 24% homologous with the IL-6R, suggesting that it also occurs in soluble form (Hilton *et al.,* 1994). IL-11, unlike IL-6, appears to function in the estrogen replete state to induce osteoclast formation and bone resorption and therefore may regulate normal remodeling (Girasole *et al.,* 1994). We have demonstrated that IL-11 is secreted by primary human osteoblasts and induces tyrosine phosphorylation in primary mouse osteoblasts (Elias *et al.,* 1995; Horowitz *et al.,* 1994). This suggests that unlike IL-6, but like LIF, IL-11 is a true autocrine factor for osteoblasts. This is supported by our demonstration that IL-11 induces IL-6 secretion by primary osteoblastic cells (Horowitz *et al.,* 1994). The IL-11 receptor, which is 32 and 30% identical by amino acid composition to the CNTF and IL-6 receptors, respectively, is expressed by day 9 in the developing embryo (Neuhaus *et al.,* 1994). The highest expression is in mesenchymal cells, particularly in regions containing chondro and osteo progenitors. However, no IL-11R mRNA was detected in mature osteoblasts, chondroblasts, odontoblasts, or osteocytes. This suggests that IL-11R is a marker of early bone development. MC3T3-E1 cells treated with IL-11 resulted in the phosphorylation of Jak1, Stat1, and Stat3, the inhibition of cellular proliferation, and stimulation of alkaline phosphatase activity (Shih *et al.,* 2000).

One way in which these ligands are related is by the use of a common receptor. This receptor is composed of multiple components and expression of different components allows the cell to discriminate between ligands. Therefore, a clear understanding of how this receptor functions cannot be separated from the significance of how multiple ligands sharing a common receptor regulate cell function. The receptor is composed of a set of proteins which are assembled in a defined order and which have specific functions. However, the members of the subfamily utilize different combinations of the receptor components. Each subfamily member appears to possess at least three receptor binding sites. The first site binds the α component of the receptor. The receptors for IL-6, IL-11, and CNTF have ligand binding α components while the receptors for OSM, LIF, and CT-1 lack this component (Davis *et al.,* 1991).

The other two binding sites on the ligand are required for interaction with the β1 and β2 components of the receptor. The β1 component is a transmembrane protein which forms a complex with the ligand and the α component, or with the ligand alone if the α component is absent. The β1 component has been found in the receptor of all subfamily members that have been examined. However, it is not necessarily the same molecule for every member. OSM, CNTF, and CT-1 use the same β1 molecule that was originally identified for LIF, known as LIFRβ or LIFR (Gearing *et al.,* 1992). LIFR is now known to be the low-affinity receptor for LIF (Fig. 1).

The β2 component has been identified as gp130. GP-130 was originally identified as a signal transducer for IL-6 and is now known to be a common and obligatory component of the receptor for all of the cytokines in the subfamily and is required for signal transduction (Ip *et al.,* 1992). GP-130 has been referred to as a high-affinity converting subunit. An example of this is cell activation with LIF, an event which requires LIF, LIFR, and gp130. LIF can bind LIFR and transmit a suboptimal signal. However, the presence of gp130 allows for high-affinity binding, optimal signal transduction, and cell activation. With the exception of

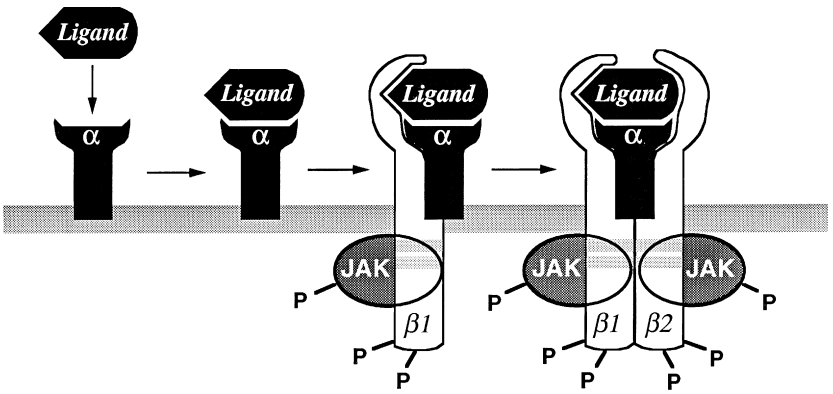

Figure 1 LIF/IL-6 cytokine receptor with component assembly including ligand, α component, β1 component, β2 component (gp130), and JAK kinase. P indicates tyrosine phosphorylation sites; cross-hatched portion in β components represents box 1 and 2 regions where JAK kinase is associated.

OSM, it appears that gp130 is the last member of the receptor components to bind the ligand and form the completed and functional receptor. As can be seen in Table 1, CNTF, LIF, OSM, and CT-1 use the LIFR subunit as the β1 component and gp130 as the β2 component. IL-6 and IL-11 use two gp130 molecules. Like LIF, OSM uses gp130 as a high-affinity converting subunit. However, unlike LIF, OSM binds gp130 preferentially. OSM may also use the OSM alternate receptor (OSMR), which is similar in structure to LIFR (32% homology) and requires gp130 for signaling (B. Mosley *et al.,* 1996). The OSMR is expressed on primary murine calvarial osteoblasts (Horowitz *et al.,* 1996). LIF does not bind the OSMR (Fig. 2).

It has been demonstrated in nonskeletal cells that signal transduction stimulated by this subfamily of cytokines is mediated by tyrosine kinases. With respect to bone cells, two major examples can be cited to demonstrate the importance of tyrosine phosphorylation in bone remodeling. Both examples involve altered bone remodeling due to genetic defects in some aspect of the process involving tyrosine phosphorylation. The first, as demonstrated by the *op/op* mouse, has a defect in the secretion of biologically active M-CSF, which can no longer signal through its receptor, c-*fms,* a receptor tyrosine kinase (Yoshida *et al.,* 1990). The second example involves c-*src,* a nonreceptor tyrosine kinase whose gene deletion by homologous recombination, like the *op/op* defect, results in osteopetrosis (Soriano *et al.,* 1991).

Table I Cytokine Receptor Composition

	Subunits		
Cytokine (ligand)	α	β1	β2
IL-6	IL-6R	None	gp130
IL-11	IL-11R	None	gp130
LIF	None	LIFR	gp130
OSM	None	LIFR	gp130
OSM	None	OSMR	gp130
CNTF	CNTFR	LIFR	gp130
CT-1	None	LIFR	gp130

The JAK family (Janus or just another kinase) are associated with the receptors for the LIF/IL-6 subfamily and other cytokines including interferon-γ, erythropoietin, growth hormone, IL-3, and GM-CSF (Silvennoninen *et al.,* 1993). The JAK family presently includes five members, Jak1–4 and Tyk2, which range in size from 130 to 137 kDa. In mammals Jak1, Jak2, Jak3, and Tyk2 are used. These kinases can be distinguished from other nonreceptor tyrosine kinases in that they have no SH2 or SH3 (*src* homology) domains and contain two catalytic domains, one being the classical kinase domain and the second a kinase-related domain which is nonfunctional (Firmbach-Kraft *et al.,* 1990; Wilks *et al.,* 1991). Different JAK kinases are activated depending on cell type and ligand bound and may phosphorylate different substrates, representing a second level of discrimination by the cell (Stahl, 1994).

The LIF/IL-6 subfamily of cytokines use Jak1, Jak2, and Tyk2. IL-12 uses a gp130-related receptor but not gp130 itself. Cytokines whose receptors are homodimers such as growth hormone, prolactin, erythropoietin, and thrombopoietin use Jak2. Signal transduction is initiated by ligand binding to its receptor which causes receptor multimerization and an apparent conformational change in the receptor complex allowing for activation of the associated JAK kinases and phosphorylation of three groups of proteins. The first group includes the β chains of the receptor (LIFR, gp130, and OSMR). Second, the kinase itself becomes phosphorylated. The third group includes a family of cytoplasmic proteins. In both skeletal and nonskeletal cells some of these cytoplasmic proteins are transcription factors belonging to the STAT family (signal transducers and activators of transcription). In addition to the STAT proteins, a group of adaptor proteins (i.e., Shc) may also become phosphorylated on tyrosine. Tyrosine phosphylation of Shc is important because it pro-

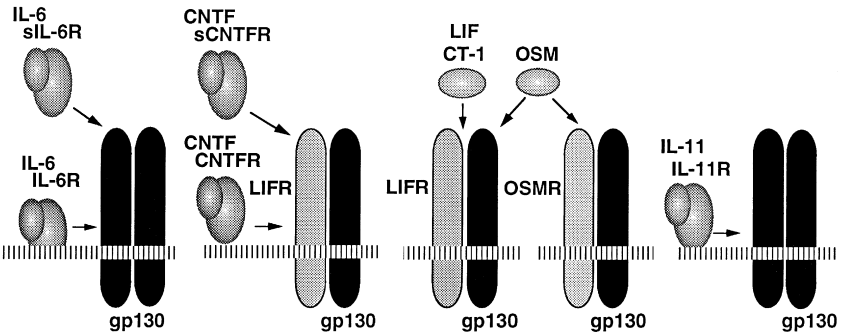

Figure 2 Receptor composition of the LIF/IL-6 family of cytokines.

vides the bridge between activated receptor chains and the mitogen activated protein kinase (MAPK) pathway. Phosphorylated tyrosine residues and their flanking amino acids on the cytoplasmic domains of the receptor chains form docking sites where proteins like the STATs, Shc, and protein tyrosine phosphatases bind and become phosphorylated (Stahl *et al.,* 1995). These proteins recognize the phosphorylated tyrosine through their SH2 domains. Because the JAKs autophosphorylate, their phosphorylated tyrosines may also serve to dock additional proteins. JAK-deficient mice have been generated with multiple phenotypes (Neubauer *et al.,* 1998; Parganas *et al.,* 1998; Rodig *et al.,* 1998). Jak1-deficient mice show perinatal lethality, are small at birth, have defects in lymphopoiesis but not myelopoiesis and fail to respond to the LIF/IL-6 subfamily of cytokines. Jak2 deficiency results in embryonic lethality due to the absence of erythropoiesis. Loss of Jak3 results in a SCID-like syndrome (Park *et al.,* 1995; Thomis *et al.,* 1995). Apparently, the skeletons of these mice have not been examined.

At the present time, six members of the STAT family have been described (Darnell *et al.,* 1994). Once phosphorylated, these proteins homo- or heterodimerize and translocate to the nucleus, by an unknown mechanism, and bind appropriate DNA sequences, resulting in gene transcription (Shuai *et al.,* 1993). A DNA promoter site in genes activated by IL-6 is similar to the IFN-γ-activated site (GAS) which mediates transcriptional induction of IFN-γ responsive genes (Pearse *et al.,* 1993). Nonskeletal cells treated with IL-6 tyrosine phosphorylate Stat1 or related proteins with subsequent binding to GAS and IL-6 sites (Bonni *et al.,* 1993; Sadowski *et al.,* 1993). CNTF induces phosphorylation of STAT proteins with subsequent translocation to the nucleus (Bonni *et al.,* 1993). Because CNTF, as well as other family members, activates early response genes, a comparison of promoter sequences was developed as a potential target sequence for STAT proteins. When nuclear extracts from CNTF-treated cells (nonskeletal) were incubated with oligonucleotides to the STAT protein recognizing sequence, binding occurred as detected by DNA–protein mobility-shift assay. This binding did not occur in the absence of CNTF and could be blocked (super shift) by the addition of anti-p91 (anti-Stat1α) (Bonni *et al.,* 1993). At present, only limited data are available relating to phosphorylation of cytosolic transcription factors and subsequent gene activation in bone cells. We have shown by immunoprecipitation that OSM induces tyrosine phosphorylation of both Stat1α and Stat3 in primary mouse osteoblastic cultures (Levy *et al.,* 1996). Stat1α and Stat3 are also phosphorylated in MC3T3 cells in response to LIF (Lowe *et al.,* 1995). Expression of a dominant negative Stat3 in a stromal/osteoblastic cell line that normally supports osteoclastogenesis results in the failure of those cells to further support osteoclast formation (O'Brien *et al.,* 1999). The inhibition of osteoclastogenesis by the dominant negative Stat3 occurs following stimulation by OSM, IL-6+sIL-6R, and IL-1 but not by parathyroid hormone or 1,25-dihydroxyvitamin D3. In the same system the dominant negative Stat3 blocked the ability of OSM or IL-6+sIL-6R to induce expression of RANKL, indicating an important role for Stat3 in gp130-mediated osteoclast formation. Stat3-deficient mice have a severe defect in development and die early in fetal life (Takeda *et al.,* 1997). A conditional knockout of Stat3 has been developed (Takeda *et al.,* 1998). These mice demonstrate the importance of Stat3 in IL-2, IL-6, and IL-10 signaling. Their bone phenotype(s), if any, have not been reported. Although the data are extremely limited at present, CNTF appears not to play a major role in bone cell activation. Of the family members, CNTF is the poorest at inducing IL-6 secretion from primary cultured osteoblastic cells (Horowitz *et al.,* 1994). However, CNTF did induce cell proliferation, increase alkaline phosphatase activity, and induce IL-6 secretion in MC3T3 cells (Bellido *et al.,* 1995). One pathway that has been shown to be activated by tyrosine phosphorylation in nonskeletal cells is Ras, a small GTP-binding protein that functions to relay signals to a group of kinases referred to as mitogen-activated protein kinases (MAPKs) or extracellular signal-regulated kinases (ERKs) (Bollag and McCormick, 1991). Activation of the MAPK cascade leads to the stimulation of transcription factors resulting in specific biological consequences. In nonskeletal cells it is known that OSM and IL-6 phosphorylate and activate MAPK (Amaral *et al.,* 1993, Kumar *et al.,* 1994). Our data show induction of a 43- to 45- kDa phosphorylated protein in human and mouse osteoblasts following OSM stimulation, which we have recently shown is MAPK (Horowitz and Levy, 1995). Tyrosine kinase pathways are linked to the Ras signaling pathway via Grb2, a small adaptor protein that contains domains referred to as src homology

(SH2 and SH3), which are involved in protein–protein interactions. Grb2 associates with the guanine nucleotide exchange factor for Ras, SOS (the mammalian homolog of the *Drosophila* son of sevenless gene product), via interactions between its SH3 domain and proline-rich sequences in SOS. These Grb2–SOS complexes then associate with tyrosine kinase receptors through binding of the SH2 domain of Grb2 to tyrosine residues in growth factor receptors that become phosphorylated following ligand binding and cellular activation. The tripartite complex of receptor/Grb2/SOS aids in translocating SOS from the cytoplasm to the plasma membrane where it is placed in close proximity to its target, Ras, converting Ras from the GDP to the biologically active, GTP-bound state. Another adaptor protein, Shc, contains an SH2 domain which has been shown to bind to tyrosine phosphorylated receptors in nonskeletal cells (Pelicci *et al.,* 1992). Shc also contains an additional phosphotyrosine binding domain (PTB) which is capable of interacting with other phosphorylated proteins (Kavanaugh and Williams, 1995). Subsequent to cytokine binding, Shc becomes tyrosine phosphorylated and can interact with phosphorylated cytokine receptors, thereby enabling its interaction with Grb2 and activation of the Ras pathway. OSM stimulation of human osteoblasts results in tyrosine phosphorylation of Shc (Horowitz and Levy, 1995). The presence of tyrosine phosphorylated MAPK supports the idea that family members may be stimulating the Ras pathway as well as the JAK/STAT signaling pathway. The tyrosine kinases that are responsible for phosphorylating Shc upon cytokine stimulation may be members of the JAK family or other cytoplasmic tyrosine kinases such as the src-family of tyrosine kinases.

As with other types of cytokine signaling, it is as important, if not more so, to turn off the signaling cascade as it is to turn it on. This can be accomplished by the activation, through phosphorylation on tyrosine residues, of protein tyrosine phosphatases. Once activated these proteins dephosphorylate other phosphorylated proteins, in particular tyrosine kinases resulting in deactivation. As mentioned previously, protein tyrosine phosphatases dock to phosphorylated tyrosine residues on the cytoplasmic domains of the cytokine receptor through their SH2 domains, resulting in phosphorylation of the phosphatase. Although there is clear evidence that protein tyrosine phosphatases are activated in response to the LIF/IL-6 family of cytokines (PTPase, Shp1) little if any direct data is available as to whether this negative regulation occurs in bone cells (Stahl *et al.,* 1995). In addition to the negative regulatory activity of phosphatases, a new family of proteins has been recently identified that can inhibit JAK-STAT signaling. The first member of this family (CIS/CIS1) inhibited the signaling of IL-3 and erythropoietin (Yoshimura *et al.,* 1995). A second member of the family was identified and is referred to as JAB (JAK binding protein), SOCS1 (suppressor of cytokine signaling), or SSI-1 (STAT-induced STAT inhibitor) (Endo *et al.,* 1997; Naka *et al.,* 1997, Starr *et al.,* 1997) and is a negative regulator of IL-6 signaling. At present seven members of this family have been identified. In some cases (JAB and CIS3) inhibit the kinase activity by directly binding to the JAKs and in others cases (CIS/CIS1) the STATs are inhibited. Thus ligand binding results not only in activation of the signaling pathway, but also in its inactivation by a negative feedback loop. Whether this family of proteins downregulates cytokine activation in bone cells remains to be determined.

CHAPTER 54

Prostaglandins and Bone Metabolism

Carol C. Pilbeam,[*] John R. Harrison,[†] and Lawrence G. Raisz[‡]

[*]University of Connecticut Center on Aging, [†]Department of Orthodontics, and [‡]Division of Endocrinology, University of Connecticut Health Center, Farmington, Connecticut 06030

Introduction

In the 30 years since prostaglandin E_2 (PGE_2) was first shown to stimulate cyclic AMP production and resorption in bone organ cultures, ample evidence has accumulated that prostaglandins (PGs) and other eicosanoids have important physiologic and pathologic roles in skeletal metabolism. However, an understanding of these roles has been complicated by the fact that PGs have dual effects in most test systems and that little is known about the skeletal production of PGs *in vivo.* This chapter will summarize current knowledge on the regulation of PG production in bone and the effects of PGs and other eicosanoids on bone resorption and formation.

PG Production

Metabolic Pathways

Eicosanoids are oxygenated 20-carbon fatty acids derived from polyunsaturated eicosatrienoic, eicosatetranoic (arachidonic), and eicosapentanoic ("fish oil") fatty acids. The predominant precursor is arachidonic acid (AA), cleaved from phospholipids in the lipid bilayer of cells. There are three major families of eicosanoids, as shown in Fig. 1: (1) prostanoids (PGs and thromboxane), synthesized via the cyclooxygenase pathway; (2) leukotrienes, lipoxins, and hydroxy-fatty acids, synthesized via the lipoxygenase pathway; and (3) epoxy and omega derivatives, synthesized via the cytochrome P-450-dependent epoxygenase pathway (Capdevila *et al.,* 2000; Smith, 1989). Eicosanoids are "local hormones" and are synthesized in most tissues. They generally circulate at low levels (less than 1 nM) in the plasma, concentrations below those at which they are normally able to elicit responses (Smith 1989). PGs have been the eicosanoids most studied in bone because they are highly expressed in osteoblastic cells and can have marked effects on both bone resorption and formation.

The production of PGs involves three major steps: (1) hormone- or stress-activated mobilization of AA; (2) conversion of AA to prostaglandin endoperoxide H_2 (PGH_2); and (3) conversion of diffusible PGH_2 by tissue-specific isomerases and reductases to PGE_2, PGD_2, $PGF_{2\alpha}$, prostacyclin (PGI_2), and thromboxane. The committed step in the conversion of AA to PGs is catalyzed by a bifunctional enzyme which converts free AA to PGG_2 in a cyclooxgenase reaction followed by reduction of PGG_2 to PGH_2 in a peroxidase reaction (Smith *et al.,* 1996). This enzyme, formally named prostaglandin endoperoxide H synthase or prostaglandin G/H synthase (PGHS), is popularly called cyclooxgygenase (COX) in reference to its first function. At higher AA concentrations than expected to occur naturally (≤ 2 μM), COX can also exhibit some lipoxygenase activity (Thuresson *et al.,* 2000). Although synthesis of eicosanoids is predominantly dependent on enzymatic metabolism of free AA, nonenzymatic free-radical-induced peroxidation of free or esterified AA can give rise to natural products that are isomeric with PGs and leukotrienes, called isoprostanes and isoleukotrienes (Morrow and Roberts, 1997; Rokach *et al.,* 1997). These products may be important in inflammation.

The individual PG synthases are differentially distributed in tissues and have been thought to influence PG production largely by determining the predominant type of prostanoid

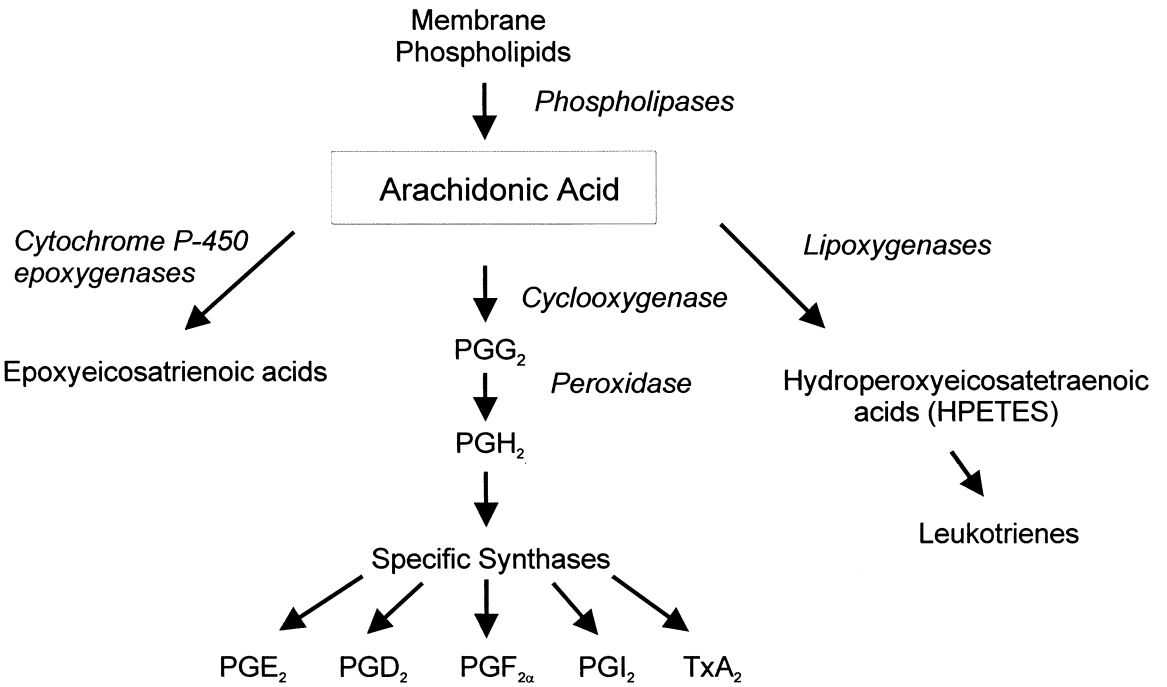

Figure 1 Diagram of the three major families of eicosanoids derived from arachidonic acid: prostanoids (PGs and thromboxane); (2) leukotrienes, lipoxins, and hydroxy-fatty acids; and (3) products of the cytochrome P-450-dependent epoxygenase pathway. The cyclooxygenase reaction that converts arachidonic acid to PGG_2 and the peroxidase reaction that subsequently converts PGG_2 to PGH_2 are both carried out by prostaglandin G/H synthase (PGHS), also called cyclooxygenase (COX).

synthesized in a particular tissue. However, PGD and PGE synthases have recently been cloned, and studies have shown that their expression in a single tissue may be regulated by a variety of factors, including fluid shear stress and interleukin-1 (IL-1) (Forsberg *et al.,* 2000; Pinzar *et al.,* 2000; Taba *et al.,* 2000). As more is learned about these synthases, they are likely to become important targets for drug therapy aimed at manipulating specific PGs.

Two Isoforms for COX

There are two enzymes for COX, COX-1 and COX-2, encoded by separate genes. COX-1 is expressed at relatively stable levels in most tissues and is considered to be "constitutive," while COX-2 is generally expressed at very low levels in most tissues but can be induced to high levels by multiple factors (Herschman 1994; Smith *et al.,* 1996; Williams and DuBois, 1996). COX-2 was initially identified as a phorbol ester-inducible primary response or immediate–early gene (TIS10) in murine 3T3 cells (Kujubu *et al.,* 1991) and a v-*src*-inducible gene product in chicken fibroblasts (Xie *et al.,* 1991). The human COX-2 gene has about 80% homology with the chicken and murine genes (Hla and Neilson 1992). The COX-1 gene is about 22 kb long with 11 exons, while the COX-2 gene is approximately 8 kb long with 10 exons (Fletcher *et al.,* 1992; Kraemer *et al.,* 1992). The gene for COX-2 lacks an intron that encodes a hydrophobic region in the amino-terminus of COX-1 protein but contains an extra sequence that encodes an 18-amino-acid insert in the carboxy-terminal region of COX-2 protein, as well as a longer 3′ untranslated region with multiple AUUUA sequences which have been associated with rapid degradation of mRNA. COX-1 and COX-2 are about 60% identical at both amino acid and nucleic acid levels. Both COX-1 and COX-2 are homodimeric (72 kDa/subunit), heme-containing glycoproteins (Smith *et al.,* 1996). Although some studies have suggested differences in cellular locations of the two enzymes, other studies find both enzymes to be located similarly on the inner and outer membranes of the nuclear envelope and on the lumenal surface of the contiguous endoplasmic reticulum (Smith *et al.,* 1996; Spencer *et al.,* 1998). Unlike many membrane proteins which have a transmembrane domain, COX-1 and COX-2 are anchored only to one leaflet of the lipid bilayer through the hydrophobic surfaces of amphipathic helices (Smith *et al.,* 1996).

Although COX-1 and COX-2 have essentially the same catalytic mechanisms, they appear to be independently functioning biosynthetic pathways. This is due in part to the differential regulation of their expression but may also involve differential substrate utilization and differential association with specific PG synthases. Because COX-1 is generally constitutively expressed while COX-2 is inducible, it was hypothesized that COX-2 is responsible for acute PG responses associated with inflammation and pain, while COX-1 produces those prostanoids needed for ongoing "housekeeping" functions, including maintenance of renal blood flow, platelet aggregation, and gastric cytoprotection. This hypothesis led to

the development of highly selective inhibitors of COX-2 activity, such as rofecoxib and celecoxib, for treatment of pain and inflammation associated with such diseases as arthritis (Golden and Abramson 1999; Marnett *et al.,* 1999). These agents cause fewer gastric ulceration and bleeding problems than nonselective NSAIDs.

The roles of COX-1 and COX-2 are probably more complex than originally conceived. Mice in which either the COX-1 or the COX-2 gene is disrupted have been engineered (Dinchuk *et al.,* 1995; Morham *et al.,* 1995; Langenbach *et al.,* 1995, 1999). COX-1-deficient mice survive normally, have no gastric pathology, show less indomethacin-induced gastric ulceration than wild-type mice, and have a reduced inflammatory response to exogenous AA but not to phorbol ester. As expected, COX-1-deficient mice have reduced platelet aggregation. COX-2-deficient mice have progressive renal disease which may limit their life span, and they have normal inflammatory reactions to both AA and phorbol ester. COX-1-deficient female mice have delayed parturition. COX-2-deficient females are infertile, with multiple failures in female reproductive processes, including ovulation (absence of corpora lutea), fertilization, implantation, and decidualization, none of which are due to deficiency of gonadotrophins or ovarian hormones (Lim *et al.,* 1997). Disruption of either COX-1 or COX-2 has been shown to be associated with reduced intestinal tumorgenesis in Min mice (Chulada *et al.,* 2000). These studies demonstrate that COX-2 can be a mediator of pathologic processes but has physiologic functions as well. To make matters more complicated, recent studies suggest that induction of COX-2 may also play an important role in the repair of damaged gastric and colonic mucosa (Colville-Nash and Gilroy 2000).

Substrate for COX

Phospholipase A_2 (PLA_2) enzymes catalyze the hydrolysis of membrane phospholipids, releasing free fatty acids and lysphospholipids. More than 10 mammalian PLA_2 enzymes have been identified. At least two classes of PLA_2 enzymes play important roles in prostanoid generation—cytosolic PLA_2 ($cPLA_2$) and the group II secretory PLA_2 ($sPLA_2$) enzymes (Balsinde *et al.,* 1999; Chaminade *et al.,* 1999; Murakami *et al.,* 1997a). $cPLA_2$, with a molecular mass of 85 kDa, is specific for AA release. $cPLA_2$ is constitutively expressed in the cytoplasm of cells, is activated at micromolar concentrations of Ca^{2+} in stimulated cells, and, after activation, translocates to the nuclear and endoplasmic recticulum membranes. $sPLA_2$ enzymes, with molecular mass of 14 kDa, nonselectively release fatty acids from the *sn*-2 position of phospholipids and require millimolar Ca^{2+} concentrations for activation. $sPLA_2$ enzymes can be induced by proinflammatory agents. After secretion, $sPLA_2$ enzymes can hydrolyze phospholipids in cell membranes or in microvesicles shed from activated cells or possibly act via specific membrane receptors (Lambeau and Lazdunski 1999). Two $sPLA_2$ enzymes, types IIA and V, have been shown to be the major contributors to PG production (Bingham *et al.,* 1999; Sawada *et al.,* 1999). These two enzymes have different cellular locations but may be able to compensate for each other since some mouse strains, such as C57Bl/6 mice (and the MC3T3-E1 osteoblastic cells derived from them), naturally lack type IIA $sPLA_2$.

COX-1 and COX-2 may be functionally coupled to the different phospholipases (Balsinde *et al.,* 1998; Naraba *et al.,* 1998; Reddy and Herschman, 1996, 1997), but the relationship is complex. Similar to the COX enzymes, phospholipases have both constitutive and inducible members. There is cross-talk between the phospholipases, with studies showing that $sPLA_2$ activation requires previous $cPLA_2$ activation (Balsinde *et al.,* 1998; Fujishima *et al.,* 1999) and vice versa (Hernandez, *et al.,* 1998). Moreover, PGs themselves can enhance COX-2 and $cPLA_2$ expression (Murakami *et al.,* 1997b; Pilbeam *et al.,* 1994). It is not surprising, therefore, that both $cPLA_2$ and $sPLA_2$ enzymes have been implicated in both the "immediate" and "delayed" phases of stimulated PG generation associated with constitutively expressed COX-1 and inducible COX-2 activities, respectively (Murakami *et al.,* 1997a).

PG Receptors

G-protein Receptors

Much of the complexity of PG effects on skeletal tissues may be attributable to the fact that there are multiple transmembrane G-protein-coupled receptors to which PGs can bind and which can produce different effects through different signaling pathways. For PGE_2 itself there are four classes of receptors. The EP_1 receptor acts largely by increasing calcium entry and phosphatidyl inositol turnover and has been implicated in mineralized nodule formation (Fujieda *et al.,* 1999) and the induction of c-*fos* and c-*jun* (Suda *et al.,* 2000), as well as IL-6 and COX-2 (Kozawa *et al.,* 1998; Suda *et al.,* 1998). The EP_2 and EP_4 receptors, both of which activate adenylyl cyclase, have been the most extensively studied. Both receptors appear to be involved in regulation of osteoblast function, including the ability of these cells to induce osteoclast formation, based on experiments with knockout animals and selective agonists, which are described below. There are limited studies of PGE_2 effects on chondrocytes, which suggest that the EP_1 and EP_2 receptor pathways may be involved in regulating proliferentiation and differentiation of these cells as well (Del Toro *et al.,* 2000; Sylvia *et al.,* 2000). The EP_3 receptor acts largely by inhibiting cyclic AMP production and has not been shown to have a specific role in bone. However, there are alternative transcripts of this receptor which can act through other signal transduction pathways (An *et al.,* 1994).

The PGI_2 or IP receptor has not been extensively studied, but PGI_2 is produced by bone cells and selective agonists for this receptor have been shown to stimulate bone resorption (Conaway *et al.,* 1986). Studies suggest the existence of both PGE_2 and PGI_2 receptors on bone cells (Khanin *et al.,*

1999; Zaman *et al.,* 1997), and one recent study demonstrated IP receptors in mouse osteoblastic MC3T3-E1 cells induced by tumor necrosis factor (TNF)-α (Wang *et al.,* 1999). Finally there is evidence for a $PGF_{2\alpha}$ receptor (FP) pathway in bone, which may act through a protein kinase C (PKC) pathway to induce COX-2 (Pilbeam *et al.,* 1994), inhibit collagen synthesis (Fall *et al.,* 1994), and activate the MAP kinase pathway (Hakeda *et al.,* 1997). Additional pathways through PGD_2 or thromboxane A receptors have not been identified.

Peroxisome Proliferator-Activated Receptors (PPARs)

PPARs are members of the nuclear receptor family of transcription factors that are important in lipid metabolism and may have a variety of effects on cellular function. Three major subtypes, α, γ, and δ, have been described, reviewed in Greene *et al.* (2000). Upon ligand binding, PPARs form heterodimeric complexes with retinoid X receptors and bind to PPAR response elements, attracting coactivators and other proteins, to mediate gene transcription. PPARγ is expressed in bone marrow stromal cells and might play a role in determining adipocyte versus osteoblastic differentiation from a common stem cell (Gimble *et al.,* 1998). PPARγ has a wide array of potential ligands, including arachidonic acid, NSAIDS at high concentrations, some lipoxygenase metabolites, and a metabolite of PGD_2, 15-deoxy-Δ^{12-14} PGJ_2. Metabolites of the lipoxygenase pathway have also been reported to bind PPARα (Greene *et al.,* 2000). PPARδ has recently been reported as the receptor mediating the effects of PGI_2 that are essential for embryo implantation in the mouse (Lim *et al.,* 1999), demonstrating the first functional role for this receptor. However, the importance of naturally occurring PGD_2 metabolites or other endogenous ligands as activators of PPARs is still unclear.

Regulation of PG Production in Osteoblasts

Stimulation of PG Production

Early studies using complement-sufficient antisera which contain antibodies to rodent cell surface antigens showed that this serum could increase resorption of fetal rat long bones by stimulating endogenous PG production (Raisz *et al.,* 1974). Subsequently, a large number of agonists were found to increase bone PG production, including many regulators of bone metabolism. Prostanoids produced by bone cells include PGE_2, $PGF_{2\alpha}$, and 6-keto-$PGF_{1\alpha}$, the metabolite of PGI_2, as well as some PGD_2 and thromboxane (Feyen *et al.,* 1984; Raisz *et al.,* 1979). Among the factors which stimulate PG production in bone are mediators of inflammatory processes, such as interleukin-1 (IL-1) (Sato *et al.,* 1986) and TNF-α (Tashjian *et al.,* 1987); multifunctional regulators of cell growth and differentiation, such as transforming growth factor (TGF)-α and -β (Hurley *et al.,* 1989; Sumitani *et al.,* 1989; Tashjian *et al.,* 1985); systemic calcium-regulating hormones, such as parathyroid hormone (PTH) (Pilbeam *et al.,* 1989) and $1,25(OH)_2D_3$ (Klein-Nulend *et al.,* 1991); and mechanical loading of bone (Cheng *et al.,* 1997; Lanyon, 1992; Rawlinson *et al.,* 1991; Reich and Frangos, 1993). Thyroid hormone (Klaushofer *et al.,* 1995), platelet-derived growth factor (PDGF) (Tashjian *et al.,* 1982), bradykinin (Ljunggren *et al.,* 1991a), and thrombin (Ljunggren *et al.,* 1991b) can also stimulate PG production in osteoblasts.

Importance of COX-2 Expression for Stimulated PG Responses

Most commonly used osteoblastic cell models constitutively express COX-1 and, except for ROS 17/2.8, which expresses only COX-1 (Pilbeam *et al.,* 1997b), can be induced to express COX-2, as shown in Fig. 2. Induction of COX-2 in osteoblastic cells appears to be necessary for most stimulated PG responses (Fig. 2). Agonists shown to induce COX-2 in osteoblastic cells include cytokines—IL-1 (Harrison *et al.,* 1994; Kawaguchi *et al.,* 1994, 1996; Min *et al.,* 1998; Pilbeam *et al.,* 1997a), TNF-α (Kawaguchi *et al.,* 1996), and IL-6 (Tai *et al.,* 1997); growth factors—TGFα (Harrison *et al.,* 1994; Pilbeam *et al.,* 1997a), TGF-β (Pilbeam *et al.,* 1993, 1997a), and basic fibroblast growth factor (FGF-2) (Kawaguchi *et al.,* 1995a); systemic hormones—PTH (Kawaguchi *et al.,* 1994; Tetradis *et al.,* 1997) and $1,25(OH)_2$ vitamin D_3 (Okada *et al.,* 2000a); and fluid shear stress or mechanical loading (Forwood *et al.,* 1998; Klein-Nulend *et al.,* 1997; Pavalkon *et al.,* 1998). Serum is also a potent stimulator of COX-2 expression and PG production in cultured osteoblasts (Pilbeam, Kawaguchi *et al.,* 1993) (Fig. 2).

In many osteoblastic cell cultures (Pilbeam *et al.,* 1994), in contrast to bone organ cultures (Kawaguchi *et al.,* 1994, 1996), little PGE_2 is produced despite induction of COX-2 expression unless serum is present or AA is added, suggesting that substrate availability is limiting. Some agonists, such as TGF-β (Pilbeam *et al.,* 1997a) and PDGF (Chen *et al.,* 1997), stimulate more PGE_2 production in serum-free cultures of osteoblasts than other agonists, probably secondary to their effects on phospholipases. PDGF has been shown to activate $cPLA_2$ in osteoblasts (Chen *et al.,* 1997).

Autoamplification of PG Responses by PGs

$PGF_{2\alpha}$ was found to increase PGE_2 production in organ culture, thereby enhancing the resorptive effects of PGE_2 (Raisz *et al.,* 1990). It was subsequently shown that many PGs induce COX-2 expression and can, therefore, amplify PG responses to other agonists (Kawaguchi *et al.,* 1994; Pilbeam *et al.,* 1994). Cyclic AMP (cAMP) increases COX-2 expression and PG production, and PGs increase cAMP production which could provide the basis for a positive feedback system (Raisz *et al.,* 1990; Oshima *et al.,* 1991; Tetradis *et al.,* 1996, 1997). However, PGs also induce COX-2 expression

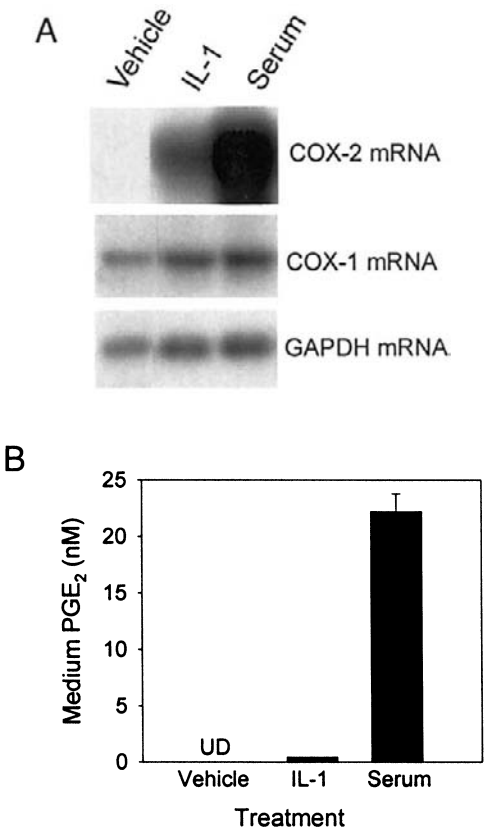

Figure 2 Induction of cyclooxygenase-2 (COX-2) and PGE_2 production by interleukin-1 (IL-1) and freshly added serum in murine osteoblastic MC3T3-E1 cells. Cells were grown to confluence and serum deprived for 24 hr before treatment for 3 hr with vehicle, IL-1 (10 ng/ml), or fetal calf serum (10%). Methods are as described in Pilbeam *et al.,* (1997a). (A) Total RNA was extracted and Northern analysis performed. COX-2 mRNA was not detectable in control cultures but was markedly induced by IL-1 and serum. There was little effect on cyclooxygenase-1 (COX-1) mRNA. mRNA levels for the housekeeping gene glyceraldehyde 3-phosphatase dehydrogenase (GAPDH) are shown to assess RNA loading. (B) PGE_2 levels were measured by radio-immunoassay ($n = 3$ wells per group). PGE_2 was undetectable (UD) in the medium of vehicle-treated cultures.

through PKC pathways (Pilbeam *et al.,* 1994; Takahashi *et al.,* 1994). This amplifying mechanism could be important in sustaining production of PGs in cell and organ cultures, in mediating the prolonged effects of short periods of impact loading or mechanical strain in skeletal tissue, and in prolonging effects of cytokines in inflammatory diseases.

Transcriptional Regulation of COX-2

In osteoblasts, COX-2 behaves like an immediate–early gene in response to most agonists, with the induction of mRNA expression being rapid, transient, and independent of new protein production (Min *et al.,* 1998; Kawaguchi *et al.,* 1995a; Pilbeam *et al.,* 1993, 1997a). In murine osteoblastic cells transfected with murine COX-2 promoter–luciferase reporter constructs, the 371 bp of the 5′-flanking COX-2 gene proximal to the transcription start site is adequate to mediate transcriptional induction by many of the agonists discussed above (Harrison *et al.,* 2000; Kawaguchi *et al.,* 1995a; Okada *et al.,* 2000b; Pilbeam *et al.,* 1997a; Tetradis *et al.,* 1997; Wadleigh and Herschman, 1999). *Cis*-acting sequences in this region shown to mediate effects on COX-2 expression in osteoblastic cells include a cyclic AMP response element (CRE) (Okada *et al.,* 2000b; Wadleigh and Herschman 1999), an activator protein-1 (AP-1 or Fos/Jun) binding site (Okada *et al.,* 2000b), and CCAAT enhancer binding protein (C/EBP) sites (Harrison *et al.,* 2000; Wadleigh and Herschman, 1999; Yamamoto *et al.,* 1995).

To study the transcriptional regulation of COX-2 *in vivo,* we generated mice transgenic for -371/+70 bp of the COX-2 5′-flanking DNA fused to a luciferase reporter (Freeman *et al.,* 1999). When these mice were injected with lipopolysaccharide (LPS), a potent inflammatory mediator, COX-2 mRNA and luciferase activity were induced in multiple tissues. The LPS induction of both luciferase activity and of endogenous COX-2 mRNA in calvarial bone was among the highest of all the tissues sampled, including brain, colon, heart, lung, and uterus. In freshly isolated tissues from mice injected with LPS, we have consistently found Northern analyses for COX-2 mRNA levels to show higher levels of expression of COX-2 in bone than in bone marrow (unpublished data). Hence, although PGs produced by other cell types interfacing with bone, such as macrophages and vascular endothelial cells, may influence bone cell differentiation and function, the converse may also be true—that osteoblasts are an important source of PGs which may influence neighboring cells in the bone marrow and in the vascular network.

Inhibition of PG Production

Glucocorticoids have been shown in many studies to be potent inhibitors of stimulated PG production, and their anti-inflammatory actions are thought to be due in part to this inhibition. Prior to the identification of COX-2, glucocorticoids were thought to work predominantly through interference with release of AA release. It is now clear that glucocorticoids have a major inhibitory effect on the inducible COX-2 mRNA and protein expression which accounts for the majority of their effects on PG production in bone and other tissues (Kawaguchi *et al.,* 1994; Pilbeam *et al.,* 1993). We have found that retinoic acid is a potent transcriptional inhibitor of COX-2 gene expression and PG production in osteoblasts (Pilbeam *et al.,* 1995). The cytokines IL-4 and IL-13 also inhibit COX-2 expression and PG production in bone organ and cell cultures (Kawaguchi *et al.,* 1996; Onoe *et al.,* 1996).

Nonsteroidal anti-inflammatory drugs (NSAIDs), such as indomethacin and aspirin, inhibit PG production by competing directly with AA for binding to the cyclooxygenase catalytic site. Hence, NSAIDs will not inhibit isoprostane or leukotriene production. NSAIDs are widely used to study the role of endogenous PGs, but it should be remembered that NSAIDs can have multiple effects in addition to inhibiting COX activity (Paik *et al.,* 2000). Until recently, most available NSAIDs inhibited both COX-1 and COX-2 activity.

NS-398 is the first selective NSAID to become widely available for *in vitro* and animal studies. In rodent osteoblastic cells, NS-398 at a concentration of 0.01 μM was selective for inhibition of COX-2 activity; however, at concentrations of 0.1 and 1 μM, NS-398 also inhibited COX-1 activity by 60 and 85%, respectively (Pilbeam *et al.,* 1997b). Hence, the selectivity of NS-398 was lost at higher doses.

As noted above, PGs themselves can induce COX-2 expression and, hence, NSAIDs can also decrease COX-2 expression by reducing PG-mediated autoamplification. Other agents reported to inhibit PG production in bone cells are vitamin K_2 (Hara *et al.,* 1993) and interferon-γ (Peterlik *et al.,* 1985).

Regulation of PG Production by Estrogen

Estradiol can decrease stimulated PG production in cultured murine calvaria (Pilbeam *et al.,* 1989). However, this effect of estrogen on PG production is not mediated through changes in COX-1 or COX-2 transcription (Pilbeam, unpublished data). Cytokine activity is hypothesized to increase with estrogen withdrawal *in vivo* (Kimble *et al.,* 1995), and cytokine-stimulated PG production by osteoblasts may be increased. PG production by calvaria cultured briefly from ovariectomized rats was increased, and this effect was reversed by estradiol administration *in vivo* (Feyen and Raisz 1987). Marrow supernatants from ovariectomized mice stimulated more bone resorption in calvarial cultures than supernatants from estrogen-replete mice, and this increase was mediated by increased PG production secondary to increased COX-2 expression (Kawaguchi *et al.,* 1995b; Miyaura *et al.,* 1995). The induction of COX-2 expression was secondary to increased IL-1α activity in the supernatants and was reversed by *in vivo* treatment of the ovariectomized mice with estradiol (Kawaguchi *et al.,* 1995b). The role of endogenous PGs in bone loss due to sex hormone deficiency is unclear. Partial reversal of bone loss by an NSAID in ovariectomized rats has been reported, but the effect was not sustained (Kimmel *et al.,* 1992). However, it may not have been possible to produce a sustained inhibition of COX-2 activity with nonselective NSAIDs at tolerated concentrations.

Role of PGs in Bone Resorption

PGs and Resorption in Organ Culture

Early work on the effects of PGs on bone resorption showed that PGs of the E series are the most potent activators, with an effective concentration range of 1 nM to 10 μM (Klein and Raisz, 1970; Raisz and Martin, 1983). $PGF_{2\alpha}$ is less effective than PGE_2, stimulating resorption at concentrations of 0.1 μM and above, and the ability of $PGF_{2\alpha}$ to stimulate resorption is partly dependent upon induction of PGE_2 (Raisz *et al.,* 1990). PGI_2 can also stimulate resorption, while PGD_2 is ineffective. Many factors that stimulate PG production also stimulate resorption in organ culture, and the resorption stimulated by such factors can be mediated in part by PG production (Akatsu *et al.,* 1991; Stern *et al.,* 1985; Tashjian *et al.,* 1982, 1987). However, the dependence of resorption in organ culture on stimulated PG production is quite variable (Pilbeam *et al.,* 1996), and some potent stimulators of PGE_2, such as PTH, do not exhibit PG-dependent resorption in these systems (Pilbeam and Raisz, unpublished data).

PG Effects on Osteoclast Formation and Differentiation *in Vitro*

PGE_1 and PGE_2, but not $PGF_{2\alpha}$, stimulate osteoclast formation in marrow cultures (Collins and Chambers, 1991; Kaji *et al.,* 1996). In contrast to organ culture resorption studies, studies in marrow culture consistently demonstrate a dependence of osteoclast formation on stimulated PG production. Agonists reported to stimulate PG-dependent osteoclast formation in marrow cultures include IL-1 (Akatsu *et al.,* 1991; Lader and Flanagan, 1998; Sato *et al.,* 1996), TNF-α (Lader and Flanagan, 1998), PTH (Inoue *et al.,* 1995; Sato *et al.,* 1997), 1,25 $(OH)_2$ D_3 (Collins and Chambers 1992), IL-11 (Girasole *et al.,* 1994; Morinaga *et al.,* 1998), IL-6 (Tai *et al.,* 1997), IL-17 (Kotake *et al.,* 1999), phorbol ester (Amano *et al.,* 1994), and FGF-2 (Hurley *et al.,* 1998). TGF-β enhances 1,25 $(OH)_2D_3$-stimulated osteoclastogenesis at low concentrations by a PG-dependent mechanism, but inhibits at higher concentrations (Shinar and Rodan, 1990). The PG enhancement of stimulated osteoclast formation in marrow culture may reflect the increased formation of new osteoclastic precursors, while stimulated resorption in organ culture may be more dependent on activation of a pool of available osteoclastic precursors.

The formation of mature bone-resorbing osteoclasts requires a contact-dependent interaction with cells of the osteoblastic lineage (Suda *et al.,* 1999). The molecule mediating this interaction, originally cloned as receptor activator of NF-κB (RANK) ligand or RANKL (Anderson *et al.,* 1997), is identical to TNF-related activation-induced cytokine (TRANCE) (Wong *et al.,* 1997). Subsequently, RANKL was also found to be identical to osteoclast differentiating factor (ODF) and to be a ligand for osteoprotegerin (OPG), a decoy receptor for RANKL, and is, therefore, also called OPGL (Yasuda *et al.,* 1998). Osteoblastic cells produce both RANKL and OPG, as well as macrophage colony-stimulating factor (M-CSF), also required for osteoclastogenesis, while osteoclastic cells express RANK. Induction of RANKL has been shown to be essential for resorption by PGE_2 (Tsukii *et al.,* 1998).

In Vitro Studies Using COX-2 Null Mice

COX-2 is the isoenzyme responsible for the PG enhancement of stimulated osteoclastogenesis. In marrow cultures from mice in which both alleles for COX-2 have been disrupted (COX-2 $-/-$ mice), osteoclast formation stimu-

lated by $1,25(OH)_2D_3$ or PTH was reduced 60–70% compared to wild-type (+/+) cultures (Okada *et al.,* 2000a). PGE_2 production was markedly reduced in marrow cultures from COX-2 −/− mice compared to cultures from wild-type mice, and decreased osteoclastogenesis in COX-2 −/− cultures was completely reversed by addition of PGE_2 to the cultures. Heterozygous COX-2 +/− marrow cultures had levels of osteoclast formation and PGE_2 production intermediate to those in COX-2 +/+ and COX-2 −/− cultures. Treatment of normal cultures with COX inhibitors (indomethacin and NS-398) mimicked the results observed in cultures from COX-2 −/− mice. The reduced response to $1,25\ (OH)_2D_3$ and PTH in COX-2 −/− cultures was associated with reduced expression of RANKL by osteoblasts, and this reduction could also be reversed by addition of PGE_2. There was no consistent difference in the expression of OPG, which inhibits osteoclastogenesis, in COX-2 −/− cultures compared to COX-2 +/+ cultures. There was no effect of disruption of both COX-1 alleles on stimulated PG production or osteoclastogenesis. We have found similar results for osteoclastogenesis stimulated by FGF-2 and IL-1 (Pilbeam, unpublished data), suggesting that PGs produced by COX-2 are necessary for *in vitro* osteoclastogenesis in response to multiple agents.

In addition to acting on osteoblastic cells to increase RANKL, PGs may also act on osteoclastic progenitors among the hematopoietic cells to influence the formation and activity of osteoclasts. Osteoclasts can be formed in spleen cultures, which contain osteoclast precursors but no osteoblasts, if the cultures are treated with M-CSF and soluble RANKL to replace the need for supporting osteoblastic cells. PGE_2 has been shown to enhance the combined effects of RANKL and M-CSF to stimulate osteoclast formation in spleen culture systems (Wani *et al.,* 1999). In such a system, we found that osteoclast formation was reduced 50% when spleen cells came from COX-2 −/− mice compared to cells from COX-2 +/+ mice (Okada *et al.,* 2000a). This reduction was due to increased expression of granulocyte-macrophage colony-stimulating factor (GM-CSF), an inhibitor of osteoclast formation in these cultures. GM-CSF may act by diverting progenitor cells into the macrophage pathway that might otherwise differentiate into osteoclasts. Hence, PGs can enhance osteoclastogenesis by acting on osteoclast supporting cells to increase RANKL and on hematopoietic cells to decrease GM-CSF. Putative effects of PGE_2 on osteoclast formation are schematically summarized in Fig. 3.

PG Effects on Isolated Osteoclast Activity

Paradoxically, when added to isolated osteoclasts *in vitro,* PGE_2 transiently inhibits bone resorption (Fuller and Chambers 1989). A similar transient inhibition of bone resorption and lysosomal enzyme release in mouse calvarial bone cultures by PGs has also been observed (Lerner *et al.,* 1987).

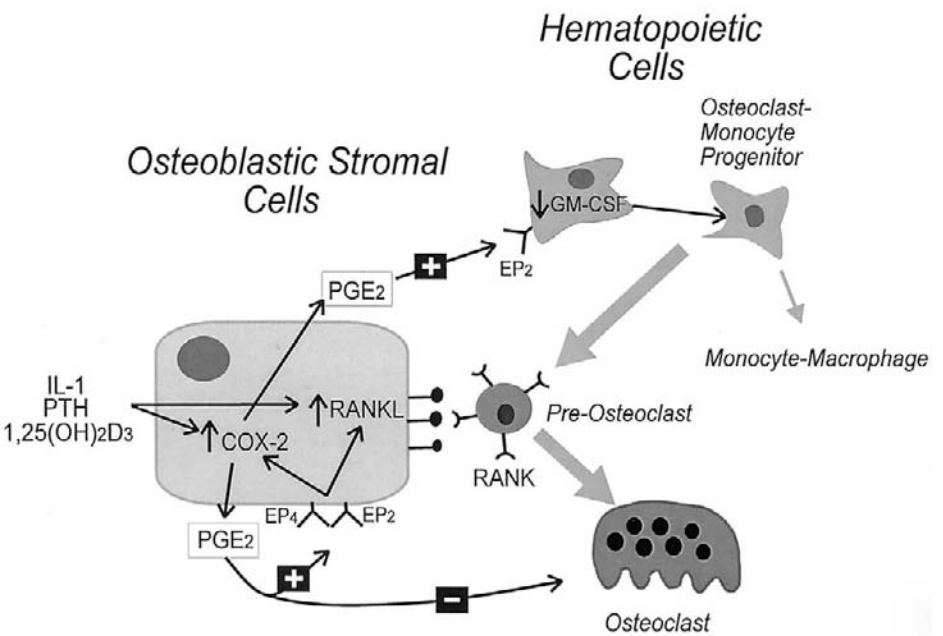

Figure 3 Schematic diagram of the putative roles for PGs in bone resorption. PGs have positive effects on formation of osteoclasts but may inhibit osteoclastic activity. Osteoblastic stromal cells express both COX-2 and RANKL. Interaction of RANKL with RANK, which is expressed by osteoclastic precursor cells, is required for precursor cells to differentiate into mature osteoclasts. COX-2-derived PGs stimulate the expression of RANKL and enhance the stimulation of RANKL by other agonists. PGs may also act on hematopoietic cells to inhibit GM-CSF expression, resulting in increased entrance of progenitor cells into the osteoclastic differentiation pathway. PGs can have a transitory inhibitory effect on the activity of isolated mature osteoclasts.

This inhibitory effect may be due to a direct activation of adenylate cyclase in osteoclasts, thereby mimicking the effect of calcitonin to inhibit osteoclast function. The physiologic relevance of this transient inhibition is unknown.

In Vivo Studies

Little is known about the role of PGs in bone resorption *in vivo.* A role for PGs in bone resorption might be most evident when resorption is stimulated, and the ability to generate new osteoclasts from osteoclastic precursors becomes the factor limiting the rate of resorption. In this regard, the prolonged *in vivo* resorption response to IL-1 was found to depend on PGs (Boyce *et al.,* 1989). *In vivo* injection of IL-1 above the calvaria in mice for 3 days was shown to stimulate PG-independent resorption when mice were sacrificed 24 hr after the last injection. However, resorption continued for 3–4 weeks after the IL-1 injections were stopped, and this resorption was PG-dependent.

Clearly, COX-2 is not required for basal levels of bone resorption since COX-2 −/− mice do not develop osteopetrosis (Okada *et al.,* 2000a). To study the role of COX-2 in acute resorption *in vivo,* we injected PTH at high dose above the calvaria of COX-2 −/− mice and their wild type +/+ littermates (Okada *et al.,* 2000a). This protocol has been shown to result in localized resorption at the site of injection which is reflected by systemic hypercalcemia (Zhao *et al.,* 1999). After 3 days of injection, PTH caused hypercalcemia in the COX-2 +/+ mice but not in the COX-2 −/− mice. Hence, the absence of COX-2 limits the maximal resorption response to PTH *in vivo* as well as *in vitro.*

PG Receptors and Bone Resorption

Recent studies of cells and tissues from EP receptor knockout animals and studies using selective EP receptor agonists have added further complexity to our understanding of PGE_2 stimulation and inhibition of bone resorption. Osteoclast formation in bone marrow cultures and mixed cultures of osteoblasts and spleen cells was found to be impaired when cells from either EP_2 or EP_4 knockout animals were used (Li *et al.,* 2000; Sakuma *et al.,* 2000). These studies confirmed earlier results using selective EP agonists and antagonists (Ono *et al.,* 1998). While both EP_2 and EP_4 are involved in the PGE_2 effects on the osteoblastic support cells for osteoclastogenesis, EP_2 is also involved in the effects of PGE_2 on hematopoietic precursors (Fig. 3). Spleen cells from EP_2 knockout animals showed an impaired osteoclastogenic response when treated with M-CSF, RANKL, and PGE_2 (Li *et al.,* 2000). Resorption studies using cultured calvaria from EP_4 knockout animals showed an impaired resorptive response to PGE_2 (Miyaura *et al.,* 2000). The inhibitory effect of PGE_2 on osteoclast activity may also involve both the EP_4 and EP_2 receptors (Mano *et al.,* 2000).

Role of PGs in Bone Formation

Studies in cell and organ culture have indicated that PGs can have both stimulatory and inhibitory effects on bone formation. On the other hand, *in vivo* studies in rats have constantly demonstrated a potent anabolic effect. PGs can increase both periosteal and endosteal bone formation in the rat and produce substantial increases in bone mass, similar to the effects of PTH (Jee and Ma 1997; Lin *et al.,* 1994; Suponitzky and Weinreb, 1998). Similar anabolic effects can be seen in fetal rat calvarial organ cultures, in which PGE_2 can stimulate both cell replication and differentiation (Woodiel *et al.,* 1996). The most consistent anabolic effect is seen in cultures designed to study osteoblastic differentiation. In marrow stromal cell and primary calvarial cell cultures, PGE_2 stimulates the formation and differentiation of osteoblastic colonies (Flanagan and Chambers 1992; Scutt and Bertram 1995). In addition, PGE_2 given *in vivo* enhances osteoblastic differentiation in explanted marrow stromal cells (Weinreb *et al.,* 1997). Moreover, marrow stromal cells or primary calvarial cells cultured from COX-2 −/− mice have markedly delayed osteoblastic differentiation compared to cells from COX-2 +/+ mice (Okada *et al.,* 2000c). The receptor pathway for this anabolic effect is not yet fully elucidated. Based on early studies with selective agonists in rat calvarial organ culture and marrow cell culture, a role for the EP_2 receptor was suggested, but subsequent studies in marrow cultures support the possibility of mediation by the EP_4 receptor (Weinreb *et al.,* 1999).

At high concentrations, PGs can inhibit collagen synthesis in cell and organ culture (Fall *et al.,* 1994). This inhibitory effect appears to occur largely via transcriptional inhibition of collagen and to be mediated by the FP receptor rather than an EP receptor. Hence, similar to their effects on the osteoclast lineage, PGs can enhance the differentiation of osteoblastic progenitors but can inhibit the function of mature osteoblasts.

Little is known about the role of endogenous PGs *in vivo.* We have done preliminary studies on mice with one (+/−) or both (−/−) alleles for the COX-2 gene disrupted and their wild-type littermates (+/+) (Okada *et al.,* 2000c). Comparing 3-month-old female COX-2 −/− and +/+ mice, with no differences in body weight or serum creatinine, there was a 9.0% ($P < 0.05$) decrease in tibial bone mineral content (BMC) and a 10% ($P = 0.05$) decrease in femoral BMC of −/− mice compared to +/+ mice ($n = 4$). Histomorphometric analyses of the proximal tibiae of 2-month-old mice ($n = 4$) showed decreases of 40 and 15% ($P < 0.05$) in trabecular bone volume (TBV) and mineral apposition rate (MAR), respectively, in heterozygous COX-2 +/− mice compared to COX-2 +/+ mice. There were small decreases in percentage osteoclast surface and osteoclast number in COX-2+/− mice which were not significant. In femurs from 6-month-old female mice ($n = 3–4$), there was no significant difference in TBV between COX-2 +/− and +/+ mice, but there was a 34% decrease in MAR and 42% decrease in osteoclast number per bone surface

($P < 0.01$) in COX-2 +/− mice compared to +/+ mice. These studies suggest that bone formation may be reduced more than bone resorption as a result of COX-2 deficiency.

Role of PGs in the Effects of Mechanical Loading on Bone

Many studies have suggested that PGs may mediate some of the effects of mechanical loading on bone. Orthodontic movement of teeth stimulates PG production, and endogenous PGs enhance the rate of tooth movement, presumably as the result of PG-stimulated bone turnover (Giunta *et al.,* 1995; Grieve *et al.,* 1994; Kehoe *et al.,* 1996; Saito *et al.,* 1991). Mechanical loading of bone explants can increase PG production and result in new bone formation (Cheng *et al.,* 1997; Lanyon, 1992; Rawlinson, *et al.,* 1991). Loading induced new bone formation *in vitro,* in an isolated avian ulna preparation (Pead and Lanyon 1989), and *in vivo,* in externally loaded tail vertebrae of rats (Chow and Chambers 1994), was blocked with inhibitors of PG production. In humans, *in situ* microdialysis showed a 2.5–3.5-fold increase in the release of PGE_2 in the tibial metaphysis after loading (Thorsen *et al.,* 1997).

How mechanical loading is coupled to cellular responses in bone is unknown, but fluid flow is thought to play a role in the response to physiologic loading (Hillsley and Frangos, 1993; Piekarski and Munro, 1977; Turner *et al.,* 1994). Small displacements in the mineralized matrix of bone are hypothesized to generate interstitial fluid flow in the lacunar–canalicular network. Fluid shear stress (force per unit area) is exerted in the direction of the flow on membranes of cells lining the surfaces. Osteocytes which contact each other and the osteoblasts lining the mineralized matrix via gap junctions are thought to be the main strain sensing network (Kufahl and Saha, 1990).

Osteoblasts and osteocytes subjected to fluid shear stress produce PGs (Klein-Nulend *et al.,* 1997; Pavalko *et al.,* 1998; Reich and Frangos 1993). When osteoblastic cells are subjected to fluid flow, there is an early release of PGE_2 followed by a more sustained production. The early PG production is likely to be due to release of arachidonic acid converted to PGs by the constitutively expressed COX-1, while the sustained PG production is due to induction of COX-2 (Klein-Nulend, *et al.,* 1997; Pavalko *et al.,* 1998). Using MC3T3-E1 cells stably transfected with a COX-2 promoter–luciferase reporter construct and calvarial cells from mice transgenic for this construct, we have shown that fluid shear stresses as low as 0.1 dynes/cm^2 rapidly induce new COX-2 gene transcription and that the induction is dependent on the mitogen-activated protein signaling pathway that activates ERK 1 and 2 (Wadhwa *et al.,* 2000). This transcriptional activation may be mediated by a combination of C/EBP-β, CRE, and AP-1 *trans*-acting sites (Ogasawara *et al.,* 2000).

Less is known about the role of COX-2 *in vivo* in the response to loading. The increase in endosteal bone formation following a single short period of bending applied to rat tibiae was prevented by a selective COX-2 inhibitor (NS-398) (Forwood 1996). However, an immunohistochemistry study by the same group reported increases in COX-1 as well as COX-2 protein in osteocytes in the tibial bone of rats following 4-point bending, with sparse expression of COX-2 relative to COX-1 (Forwood *et al.,* 1998).

Role of PGs in Inflammatory Bone Loss

PG production is frequently found to be increased in inflammatory processes, such as rheumatoid arthritis (Crofford *et al.,* 1994). In a study of acute inflammation in the rat footpad induced by carrageenan, COX-2 expression was elevated, and selective inhibition of COX-2 activity inhibited edema and hyperalgesia (Seibert *et al.,* 1994). Because of the association of COX-2 derived PG production with inflammation and because PGs are potent stimulators of bone resorption, it is often assumed that COX-2 derived PGs contribute to the bone loss and cartilage destruction associated with inflammatory diseases. There are some studies showing that NSAIDs decrease alveolar bone loss in peridontitis to support this conclusion (Howell *et al.,* 1991; Jeffcoat *et al.,* 1993). However, other agents which are elevated in inflammatory diseases, such as cytokines, are themselves potent inducers of bone resorption independent of their effects on PG production. In addition, cytokines can inhibit bone matrix proteins independently of cytokine-induced PG production (Rosenquist *et al.,* 1996). As discussed above (under Role of PGS

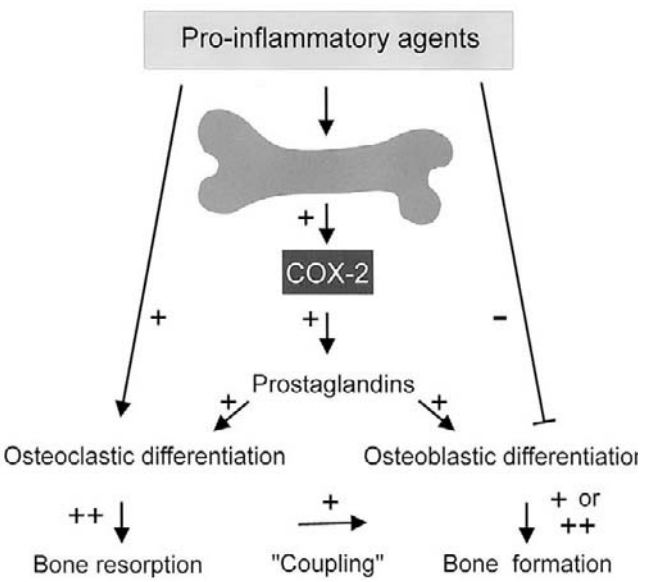

Figure 4 Diagram of the potential effects of PGs on bone turnover in inflammation. Inflammatory mediators, such as IL-1 and TNF, induce COX-2 expression and PG production. These inflammatory mediators also have direct effects on bone to stimulate resorption and inhibit formation. The induced PGs might enhance or prolong the stimulatory effects on resorption but might counter the inhibitory effects on osteoblastic formation.

in Bone Resorption, subsection titled *In Vivo* Studies), PGs produced by proinflammatory agents may prolong the resorption responses to these agents, particularly if PGs play an important role in maintaining or replenishing the pool of differentiated osteoclasts. Nevertheless, it is possible that the ability of PGs to stimulate osteoblastic differentiation might have a compensatory effect (Fig. 4).

It is interesting to note that some studies have suggested that COX-2 metabolites are proinflammatory only during the early stages of an inflammatory response; and, at later times, COX-2 generates a different set of PGs, the cyclopentenone PGs, which have anti-inflammatory effects (Gilroy *et al.,* 1999). Although these PGs include putative ligands for the PPARs, such as 15-deoxy-Δ^{12-14} PGJ_2, it is thought that the anti-inflammatory effects are more likely to occur through a PPAR-independent pathway (Gilroy *et al.,* 1999).

Effects of NSAIDS on Bone in Humans

Effects of NSAIDs on Bone Mineral Density (BMD) in Humans

Only a few studies have examined the effects of NSAIDs on BMD in animals or humans. In a study of postmenopausal women 65 years of age or older, there was no significant difference found in N-telopeptide cross-link excretion, a marker of bone resorption, between self-reported users of NSAID or aspirin compared to nonusers (Lane *et al.,* 1997). In a similar cohort, the use of aspirin or NSAID was found to be associated with small but significant increase in hip and spine BMD, but there was no clinically significant protective effect on risk for fracture (Bauer *et al.,* 1996). In a study of older women from Rancho Bernardo, California, the regular use of propionic acid NSAIDs (ibuprofen, naproxen, ketoprofen), but not acetic acid NSAIDs (indomethacin, diclofenac, sluindac, tolmetin), was associated with higher BMD at multiple skeletal sites (Morton *et al.,* 1998). When women with self-reported osteoarthritis were excluded, significantly higher BMD was observed in the hip in propionic acid NSAID users. Those who concurrently used estrogen and priopionic acid NSAIDs had the highest BMD at all sites.

There are no published studies examining the effects of selective COX-2 inhibitors on BMD. It seems likely that continuous inhibition of COX-2 activity might not have been attained in studies with nonselective NSAIDs because the frequent administration and high doses necessary to inhibit COX-2 activity might produce toxic side effects. Moreover, nonselective NSAIDs *in vitro* can have biphasic effects — low concentrations can increase, rather than decrease, PG production (Lindsley and Smith, 1990; Raisz *et al.,* 1989). Hence, studies with the new selective inhibitors of COX-2, which have fewer limiting gastrointestinal or bleeding side-effects at doses which effectively inhibit COX-2, may help to clarify the role of PGs in bone metabolism.

Other Effects of NSAIDs on Bone in Humans

Nonselective NSAIDs have been used to examine effects of PGs after orthopedic surgical procedures. Heterotropic ossification is a complication of hip arthroplasty that can adversely affect the outcome. Several studies have shown that perioperative treatment with aspirin or other NSAIDs can prevent this complication (Kienapfel *et al.,* 1999; Neal *et al.,* 2000; Nilsson and Persson, 1999), suggesting that the problem is caused by PG-mediated bone formation. Because PGs may enhance the bone remodeling needed for fracture healing, there is concern that NSAIDs might adversely affect fracture healing. Studies suggest that NSAIDs can inhibit repair of fractured femurs (Altman *et al.,* 1995; Reikeraas and Engebretsen, 1998) and spinal fusions (Dimar *et al.,* 1996) in rats and the fixation of implants in femora of rabbits (Jacobsson *et al.,* 1994), while exogenously applied PGs can stimulate callus formation in rabbits (Keller *et al.,* 1993). Ultrasound stimulation can enhance bone healing, and studies have suggested both that ultrasound acts by decreasing PG production (Sun *et al.,* 1999) and by stimulating COX-2 induction and associated PG production (Kokubu *et al.,* 1999).

Leukotrienes and Bone

Compared with the products of the COX pathway, little is known about the products of 5-lipoxygenase pathway in bone. Most studies have examined effects on bone resorption. 5-Lipoxygenase products have been shown to stimulate bone resorption in neonatal mouse organ cultures. Leukotrienes and hydroxyeicosatetraenoic acids (HETEs) can affect resorption in a biphasic manner, with low doses stimulating and high doses inhibiting resorption (Meghji *et al.,* 1988). Maximal stimulation of resorption by leukotriene B_4 (LTB_4), LTC_4, LTE_4, and 5-HETE occurred at 10 pM, while 12-HETE and LTD_4 required 100 pM and 10 nM, respectively. The effects of LTB_4, C_4, and 12-HETE were partially inhibited by indomethacin, suggesting some mediation by PGs. A cell line established from giant cell tumors of bone produced an activity which stimulated bone resorption in organ culture and stimulated isolated osteoclasts to form resorption lacunae on dentine (Gallwitz *et al.,* 1993). This activity was identified as 5-HETE and a peptidoleukotriene, either LTC_4, $-D_4$, or $-E_4$. Commercially available LTC_4/LTD_4 and 5-HETE stimulated bone resorption in neonatal mouse calvariae and pit formation by isolated rat osteoclasts (Gallwitz *et al.,* 1993). Peptidoleukotrienes were also shown to stimulate isolated avian osteoclasts to form resorption lacunae (Garcia *et al.,* 1996a). These authors reported that LTD_4 receptors are present on avian osteoclasts. LTB_4, a more stable lipoxygenase product, increased bone resorption and osteoclast numbers in mice when injected locally above the calvariae and stimulated resorption in mouse calvarial organ cultures (Garcia *et al.,* 1996b). LTB_4 also stimulated isolated rat osteoclasts to form resorption lacunae with greater potency than

the peptidoleukotrienes, LTD_4 and LTE_4. Isolated avian osteoclasts also express both high and low-affinity LTB_4 receptors and LTB_4 can increase TRAP activity and pit formation by these osteoclasts (Flynn *et al.,* 1999).

Much less is known about the effects of leukotrienes on osteoblasts, but recent evidence suggests that leukotrienes may inhibit bone formation. 5-HETE and LTB_4 inhibited BMP-2-induced bone formation in mouse calvarial organ culture and blocked the formation of mineralized nodules in response to BMP-2 and dexamethasone in fetal rat calvarial cell culture (Traianedes *et al.,* 1998). Consistent with an inhibitory role of leukotrienes on bone formation, 5-lipoxygenase null mice were reported to have increased cortical bone thickness (Bonewald *et al.,* 1997).

Summary

PGs are abundant in bone and are potent regulators of bone cell function. Osteoblasts produce PGs, and this production is highly regulated by local and systemic factors. Stimulated production of PGs by osteoblasts requires both the induction of COX-2 expression and the availability of arachidonic acid substrate. PGs are complex, potent regulators of bone cell function *in vitro.* Recent studies indicate that COX-2 overexpression is associated with tumorigenesis (Williams *et al.,* 1999), suggesting that PGs can function as general regulators of cell replication and/or apoptosis. PGE_2, which may be the most important local eicosanoid in skeletal regulation, can stimulate or inhibit both bone resorption and formation. *In vitro,* PGE_2 can stimulate the differentiation of both osteoblasts and osteoclasts, and the net balance of these two effects under physiologic or pathologic conditions *in vivo* is not yet clear. The physiologic importance of the inhibitory effects of PGs on collagen production by osteoblasts and on the activity of mature osteoclasts is unknown. Some of the complexity of PG actions on bone can be explained by the multiplicity of receptors for PGs. There are at least four distinct receptors for PGE_2 with differential signaling pathways that have not yet been fully elucidated. Further studies are needed to clarify the specific pathways of PGs action in bone. Once this is accomplished, it may be possible to identify therapeutic applications of manipulating PGs in skeletal disorders.

Acknowledgments

Nitric Oxide

General

Nitric oxide (NO) is a gas radical that is enzymatically produced by the oxidation and cleavage of one of the terminal nitrogen atoms of the amino acid L-arginine. The reaction is dependent on electrons donated by the cofactor NADPH, requires oxygen, and yields L-citrulline as a coproduct. Nitric oxide is involved in a variety of physiological and pathophysiological processes including vasodilatation, neurotransmission, and the killing of various pathogens and in the genesis of inflammatory diseases. These broad-ranging actions of NO are determined largely by the site of NO synthesis, the rate of NO synthesis, and how much is generated and by the nature of the environment into which it is released. The reactivity of NO is influenced in particular by the presence of reactive oxygen intermediates and the activity of anti-oxidant defense systems (Moncada and Higgs, 1993; Knowles and Moncada, 1994; Gross and Wolin, 1995).

A family of three related enzymes, the NO synthases (NOS), regulates the synthesis of NO. These are characterized as a neuronal form (type 1; nNOS) originally isolated from brain (Bredt and Snyder, 1990), an endothelial form (type 3; eNOS) originally isolated from bovine aortic endothelial cells (Pollock *et al.,* 1991), and an inducible form (type 2; iNOS) originally isolated from murine macrophages (Xie *et al.,* 1992). Both eNOS and nNOS are expressed constitutively and are characterized by highly regulated, rapid but low-output NO production that has a tonic, physiological function (Moncada and Higgs, 1993; Knowles and Moncada, 1994). Conversely, iNOS is generally not present or active under normal physiological conditions but can be induced in a number of different cell types in response to infection, inflammation, or traumatic injury (Moncada and Higgs, 1993; Knowles and Moncada, 1994; Gross and Wolin, 1995). In contrast to the constitutive enzymes, iNOS expression is induced over several hours requiring transcription of mRNA and *de novo* protein synthesis. Once activated iNOS is capable of sustained generation of NO over many hours, which in some circumstances can lead to localized production of high levels of NO (Gross and Wolin, 1995). In these circumstances NO can exacerbate the inflammatory response as seen in septic shock and can also contribute to localized cell and tissue damage (Gross and Wolin, 1995).

Although nNOS, eNOS, and iNOS catalyze the same reaction, generating NO from L-arginine, they are distinct enzymes, each the product of separate genes, that share only 50–60% homology and each subject to widely differing mechanisms of regulation. Some of the general characteristics of NOS isoenzymes are presented in Table I. All three isoforms exhibit a bidomain structure containing consensus sequences for binding several cofactors along the C-terminal domain, including NADPH, FAD, FMN, and calmodulin. The arginine-binding site is retained within the N-terminal domain, which also contains a heme group and a consensus site for binding tetrahydrobiopterin. All cofactors are required for full activity and in their native, catalytically competent state, all three isoforms are homodimers (Griffith and Stuehr, 1995). The constitutive NOS enzymes are also

Table I General Molecular and Biochemical Characteristics of NOS Enzymes and their Association with Bone

	nNOS, NOS I	iNOS, NOS II	eNOS, NOS III
Molecular weight (kDa)	160 ~260 Homodimer (active form)	130 ~260 Homodimer (active form)	135 ~260 Homodimer (active form)

dependent on mobilization and intracellular Ca^{2+} availability. Comparisons of sequence homologies reveal that NOS enzymes bear resemblance to just one other known mammalian enzyme, cytochrome P450 reductase (CPR), sharing around 60% sequence similarity along their C-terminal domain (Bredt *et al.,* 1991; Griffith and Stuehr, 1995). This has been instrumental in elucidating the catalytic mechanism of NOS showing that the C-terminal domain, like CPR, is essentially an electron transporter. Bound calmodulin then acts as gate to regulate flow of electrons from the C-terminal domain to the N-terminal domain where they are donated to the heme group and their energy is used to drive the generation of NO (Griffith and Stuehr, 1995). While the C-terminal domains of NO synthase isoenzymes are very similar the N-terminal domains demonstrate some variations. Most notably, eNOS possesses consensus sequences for myristoylation/palmitoylation at its N-terminus and is important in determining its subcellular trafficking, locating the enzyme to membranes and in particular the caveolae (Garcia-Cardena *et al.,* 1996).

Other important aspects of NO biology include the molecular regulation of NO synthases. For the purposes of this review we need only consider mechanisms of eNOS and iNOS regulation. The molecular regulation of iNOS is particularly complex and occurs at several sites in the gene expression pathway with both transcriptional and posttranscriptional mechanisms (Ganster and Geller, 2000). Expression of iNOS can be induced by various "proinflammatory" cytokines including tumour necrosis factor alpha (TNF-α), interleukin 1-beta (IL-1β), and interferon-gamma (IFN-γ) and the effects of these inductive stimuli are mediated by the NF-κB and Jak-STAT signaling pathways (Ganster and Geller, 2000). Downregulators of iNOS expression include glucocorticoids such as dexamethasone which inhibits cytokine-induced iNOS mRNA at the transcriptional level (Ganster and Geller, 2000). The cytokine TGF-β has been shown to downregulate iNOS expression at the posttranscriptional level by inducing instability in iNOS mRNA. There is also evidence for a negative feedback loop whereby NO downregulates iNOS gene expression as well as inhibits the activity of iNOS protein (Ganster and Geller, 2000).

While the eNOS gene is considered to be constitutively expressed there are number of factors that exert positive or negative effects on the level of expression. The activity of eNOS is stimulated by a number of agonists including estrogen, vascular endothelial growth factor (VEGF), and shear stress and involves activation of various signaling pathways particularly those resulting in mobilization of intracellular Ca^{2+} and phosphorylation of eNOS (Gratton *et al.,* 2000). It is also clear that in addition to stimulating the activity of eNOS protein, shear stress, estrogen, VEGF, as well as TGF-β and fibroblast growth factor (FGF), upregulate eNOS expression at the level of transcription. Conversely, TNF-α and hypoxia downregulate eNOS gene expression by inducing instability in eNOS mRNA (Kleinert *et al.,* 2000).

NO Signaling

Biological Chemistry of NO

Although NO might be regarded as chemically very simple, its biochemistry in biological systems is often complex and this accounts in part for the wide range of biological

processes that are influenced by NO. Nitric oxide is probably the representation of several related species including its higher oxides and derived oxidants. For the purpose of this review it is necessary to consider only the NO-derived oxidant peroxynitrite with all other actions generalized as NO.

Despite its varied reactivities, NO is eventually oxidized to nitrite and nitrate in biological systems. In aqueous buffers and culture conditions nitrite is the principal oxidation product of NO (Ignarro *et al.,* 1993), whereas *in vivo* NO is in general almost completely oxidized to nitrate and excreted. These "end products" have proved to be useful markers for evidence of NO biosynthesis within biological samples. Nitrate and nitrite can be detected by the Greiss reaction, which relies on the reduction of nitrate to nitrite after the addition of the enzyme nitrite reductase or a metallic catalyst to the sample, the resultant color changes being then detectable spectroscopically (Green *et al.,* 1982, Stuehr and Marletta, 1987). This technique, however, is quite insensitive requiring the accumulation of micromolar amounts of nitrite. For greater sensitivity a chemiluminescence analyzer is often used to measure authentic NO. A strong reducing agent is used to reduce the nitrite or nitrate present in the sample of interest back to NO. The NO is then reacted with ozone, which results in the generation of light or chemiluminescence, with the amount of light being directly proportional to NO levels (Archer, 1993).

Perhaps one of the better-understood reactions of NO in biological systems is its combination with superoxide anion (O_2^-) to form peroxynitrite anion ($ONOO^-$) (Beckman *et al.,* 1990). Both molecules show a high affinity for each other, the reaction proceeding several-fold more quickly than catalysis of superoxide anion dismutation by superoxide dismutase (SOD). Peroxynitrite is a powerful oxidant and can either augment or abrogate some of the biological actions associated with NO synthesis.

CELLULAR TARGETS OF NO

NO does not require specific receptors to communicate its physiological actions; its small size and lipophilic nature allow it to traverse plasma membranes without the need for a recognized transporter. In biological systems, the principal cellular targets for NO are transition metal ion (containing) proteins. Soluble guanylate cyclase is perhaps the most significant of these metal-ion proteins, with NO demonstrating high affinity for the heme moiety of the enzyme, forming a transient and reversible nitrosyl-heme group. Binding of NO induces a conformational change in the enzyme stimulating the catalysis of cGMP formation. Also well characterized is the binding of NO to hemoglobin, resulting in the formation of met-hemoglobin and nitrate and termination of the activity of NO. It has been proposed that hemoglobin acts as a biological "sink" for NO (Gross and Wolin, 1995), but Jia *et al.* (1996) reported that NO can *s*-nitrosylate hemoglobin to form *s*-nitrosohaemoglobin and this may be important for preserving or potentiating the vascular actions of NO. *s*-Nitrosylation of proteins by NO is also an important intracellular signaling mechanism activating for example the small G-protein $p21^{ras}$ and the ensuing MAP kinase cascade (Lander, 1997).

NO will also bind to and inhibit various iron–sulfur (Fe–S) cluster proteins (Hibbs *et al.,* 1990). Many Fe–S proteins play a significant role in energy metabolism and growth, and NO therefore is able to effect cellular cytotoxicity and cytostasis. In particular, NO inhibits key enzymes involved in mitochondrial respiration, including mitochondrial aconitase, NADH–ubiquone oxidoreductase, and NADH–succinate oxidoreductase (Hibbs *et al.,* 1990; Stuehr and Nathan, 1989), as well as ribonucleotide reductase (Kwon, 1991), which is the rate-limiting enzyme in DNA synthesis. Very recently, a further very important action of NO has been described (Beltrán *et al.,* 2000; Orsi *et al.,* 2000; Fig. 1). Following prolonged exposure to NO, cells evidence a decrease in oxygen utilization as a consequence of two synergistic actions: persistent inhibition of mitochondrial oxygen consumption and production of a hypoxic microenvironment following extraction of oxygen from extracellular medium. It is uncertain whether or not these striking effects occur *in vivo* but should they do so these are likely to be associated with pathological effects.

As mentioned previously, NO and superoxide anion demonstrate a strong affinity, reacting to form peroxynitrite (Beckman *et al.,* 1990). Peroxynitrite is a powerful oxidant with the potential to cause tissue damage; its decomposition products are potent nitrating agents with a particular affinity for protein–tyrosine residues (Beckman *et al.,* 1994; Freeman, 1994) and capable of interfering with tyrosine kinase signaling pathways. Evidence for endogenous peroxynitrite activity has been provided through the immunochemical (Beckman *et al.,* 1994) and biochemical detection of nitrotyrosine species (Kaur and Halliwell, 1994) in tissues and fluids.

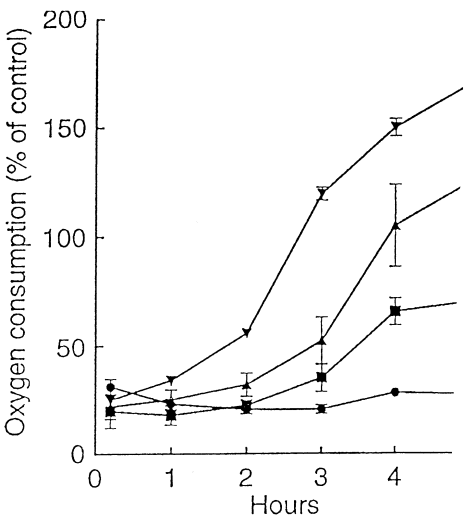

Figure 1 Effects of exposure to the NO donor (DETA-NO) on oxygen consumption by J774 cells. Reproduced from Orsi *et al.* (2000), with permission.

NO or NO species, in particular peroxynitrite, can damage DNA bases, either by oxidation or by base deamination. This damage to DNA can directly stimulate the activation of the enzyme poly-ADP ribose polymerase (PARP), which facilitates DNA repair, by a process that utilises both NADH and ATP (Zhang, 1994). However, prolonged activation of PARP and in particular the continued consumption of NADH and ATP can lead to rapid energy depletion and result in cell death. This may be one mechanism through which NO is able induce cell death by apoptosis. Increased production of NO also correlates with increased expression of the proapoptotic proteins P53 and caspases and downregulation of bcl2.

Nitric Oxide in Bone

Occurrence and Identification of NOS Isoforms

There are now a large number of antibodies and probes available to investigate the expression and localization of NOS enzymes. On the whole, many of the studies performed on bone tissues and cultured cells have resulted in similar descriptions of NOS expression and localization. However, there have been some "controversies" with some groups failing to find expression or localization where others had. In part, such discrepancies can be reconciled by the lack of standardization between studies. Many of the antibodies raised against different NOS enzymes may be species- or even tissue-specific and some may be cross-reactive (Coers *et al.,* 1998). This is also compounded by variations in cell lines studied, differences in culture conditions, or differences in the differentiation status of the cultures. Nonetheless, provided that rigorous controls are implemented, expression and localization studies can yield important information on the role of NO in bone biology.

On the basis of a number of RT-PCR and immunocytochemical investigations performed on whole bone preparations and cultured bone-derived cells from both human and rodents, eNOS and iNOS are the principal NOS isoforms expressed in bone (Helfrich *et al.,* 1997; Fox and Chow, 1998; Macpherson *et al.,* 1999). Although, some investigators have shown expression of nNOS mRNA in bone tissues by RT-PCR (Pitsillides *et al.,* 1995; Helfrich *et al.,* 1997) there is scant evidence for the presence of nNOS protein in bone. That is not to say, however, that nNOS does not have a role in bone. As discussed below, nNOS knockout mice have altered responses to osteogenic hormones like estrogen. It is also likely that nNOS-containing nerves will be present within the bone and may be relevant in regulating bone blood flow.

From the studies performed to date there is consensus that under normal, physiological conditions eNOS is the predominant NOS enzyme expressed by bone and is present in bone marrow stromal cells, osteoblasts, osteocytes, and osteoclasts (Brandi *et al.,* 1995; Helfrich *et al.,* 1997, Fox and Chow, 1998; Macpherson *et al.,* 1999). Studies in our laboratories on rat long bones have shown that expression of eNOS varies according to developmental stage with eNOS mRNA and protein being most abundant in the bones of neonates and subsequently declining in 4-, 8-, and 12-week-old animals (Hukkanen *et al.,* 1999). This age-related regulation of eNOS expression was reflected in the cellular localization. Robust eNOS immunostaining was seen particularly in cuboidal columnar osteoblasts lining trabecular and endosteal bone from neonates and to a lesser extent in osteocytes and multinuclear osteoclasts located in resorption lacunae. In older, 4- to 12-week-old rats the incidence of eNOS positive osteoblasts, osteocytes and osteoclasts became more patchy although stained cells of all three types were still evident and particularly so around remodeling sites. This enzyme was also seen in hypertrophic and degenerating chondrocytes of the epiphyseal growth plate of all ages but particularly in neonatal–4 weeks period. Chondrocytes within the proliferation zone were consistently negative for eNOS expression/staining.

More recent work in our laboratories on NOS expression during fetal development in murine and human fetal long bones (mouse embryonic day 14 and human 8- to 12-week-old abortuses) have shown robust eNOS immunostaining, principally in hypertrophic/degenerating chondrocytes but not in the proliferation zone (Bielby, Buttery, Nohadani, and Polak, unpublished observations).

As discussed above, iNOS is generally absent from untreated cells and tissues and associated with pathophysiology. However, studies by Hukkanen *et al.* (1995), Riancho *et al.* (1995), and Helfrich *et al.* (1997) have detected low levels of iNOS transcripts in unstimulated whole bone and cultured osteoblast-like cells by RT-PCR. Brandi *et al.* (1995) have also described low-level iNOS expression in untreated cultures of a human preosteoclastic cell line. There is also evidence to indicate that in some cells and tissues including bone, iNOS is expressed transiently and has a physiological function. Kasten *et al.* (1994) initially suggested a role for iNOS in regulating osteoclast activity on the basis of *in vivo* administration of NOS inhibitors and this was subsequently supported in studies by Tsukahara *et al.* (1996) and Turner *et al.* (1997). We have shown iNOS expression in whole bones of the developing rat (neonate to 12 weeks old) by RT-PCR being particularly prominent in neonates (Hukkanen *et al.,* 1999). In addition, immunostaining for iNOS protein was seen in sections of neonatal bone, but not older animals, and localized to both osteoblasts and osteoclasts where it was compartmentalized toward ruffled border.

On the whole, it is fair to say that iNOS expression and localization seen in bone preparations or isolated cells is mostly associated with responses mounted to challenge with an inflammatory stimulus. Several groups have demonstrated the expression of iNOS mRNA and protein in cultured rodent and human osteoblast like cells after cytokine stimulation (Ralston *et al.,* 1994; Hukkanen *et al.,* 1995). The level of expression of iNOS by osteoblasts is also quantitative and correlates with the type and combination of cytokine stimuli. In general, combinations of two or more cytokines are more effective than single cytokines. The synergism between IFN-γ, TNF-α, and IL-1β is particularly effective for iNOS induction in osteoblasts.

Moreover, rodent osteoblasts are more responsive to cytokine-stimulated iNOS induction than human osteoblasts.

The evidence for cytokine-stimulated iNOS expression by osteoclasts is less definitive. Brandi *et al.* (1995) have shown marked iNOS expression in rodent and avian osteoclastic cell lines and comparatively "weaker" expression in a human preosteoclastic cell line after cytokine stimulation *in vitro.* Similarly, Sunyer *et al.* (1996) have described marked cytokine-induced iNOS expression in an avian osteoclastic cell line. Conversely, Helfrich *et al.* (1997) failed to detect iNOS by *in situ* hybridization or immunocytochemistry in osteoclast cultures even after cytokine stimulation. The reasons for such differences are unclear but there are corollaries with other cells of leukocyte lineage. Induction of iNOS expression can be readily achieved in rodent monocytes/macrophage after cytokine challenge and the response is often exaggerated, whereas induction of iNOS in human monocytes/macrophages is much more tempered. Human cells are also responsive to combinations of cytokines that are distinct from those described for rodent cells. One possible explanation for these idiosyncracies, other than differences between cell lines or differentiation status, might lie with the "distinctness" of the human iNOS gene sharing only 80% homology with the rodent gene. This has added relevance considering that the constitutive NOS isoforms (eNOS and nNOS) are very highly conserved, with >93% homology between rodent and human.

Other important sites of iNOS expression include the articular joint where iNOS is expressed and localized to chondrocytes and the synovium of arthritic but not normal subjects (Sakurai *et al.,* 1995).

Collectively, these observations demonstrate that NOS isoforms, in particular eNOS and iNOS, are widely expressed in bone tissue and while it is difficult to assign function on expression and localization data alone it can at least be inferred. On this basis these observations are consistent with NO being involved in many aspects of bone growth, modeling, and remodeling under both physiological and pathophysiological conditions.

Osteoclast Effects

As discussed above, osteoclasts express both eNOS and iNOS (Brandi *et al.,* 1995; Sunyer *et al.,* 1996; Helfrich *et al.,* 1997, Fox and Chow, 1998; Macpherson *et al.,* 1999) and accordingly these cells demonstrate sensitivity to both low, basal NO synthesis and higher levels of NO synthesis stimulated by cytokines. The effect of NO on osteoclasts is quite varied and can either suppress or stimulate bone resorption. One of the very first observations on the effects of NO on osteoclasts came from our own laboratories (MacIntyre *et al.,* 1991) showing that exposure of cultured osteoclasts to NO–donor compounds inhibited cell spreading and caused profound inhibition of bone resorption measured by the bone slice assay. Although the concentrations of NO used were supraphysiological, these initial findings have subsequently been confirmed by numerous *in vitro* and *in vivo* studies. Kasten *et al.* (1994), Tsukahara *et al.* (1996), and Turner *et al.* (1997) examined the effects of chronic *in vivo* administration of the NOS inhibitor compounds in rats, in particular aminoguanidine, and demonstrated marked reductions in bone mass. This would seem to indicate that NO is an endogenous inhibitor of osteoclast activity and is consistent with the profound inhibitory effect of NO donors on osteoclastic bone resorption (MacIntrye *et al.,*1991; Kasten *et al.,* 1994). Moreover, on the basis of the reported selectivity of aminoguanidine for iNOS and in the absence of any significant effects following administration of other, "nonselective" NOS inhibitors this has led to the suggestion that iNOS is the principal source of NO in the regulation of osteoclast activity. While there are some concerns relating to NOS inhibitor studies (see below) these observations have important implications for the control of iNOS expression in bone cells and suggest that iNOS might be expressed "consistutively." This would be consistent with studies demonstrating low-level expression of iNOS transcripts in unstimulated whole bone preparations and isolated bone cell cultures (Brandi *et al.,* 1995; Helfrich *et al.,* 1997). Whether or not there is transient localized production of iNOS protein with subsequent activation of the enzyme and, perhaps more importantly, in which cell types this occurs remains to be determined.

It is well established that cytokines including IL-1β, TNF-α, and IFN-γ are powerful regulators of bone resorption (Mundy, 1993). These cytokines are also potent stimulators of iNOS (Ganster and Geller, 2000) and it has been convincingly shown that cytokine-induced iNOS activity exerts marked effects on osteoclastic bone resorption (Löwik *et al.,* 1994; Brandi *et al.,* 1995; Ralston *et al.,* 1995; Ralston and Grabowski *et al.,* 1996). Cytokine-induced NO synthesis can either stimulate or inhibit osteoclastic bone resorption and correlates to the apparent "level of iNOS induction/ activation." The synergetic effects of IL-1β, TNF-α and IFN-γ induce the highest levels of iNOS expression and activity in bone, resulting in marked inhibition of resorption. However, when added singly these cytokines produce very different results. Of the three cytokines IFN-γ is probably the most potent stimulator of iNOS and accordingly IFN-γ stimulated NO production is thought to account for the selective inhibitory effects of this cytokine on bone resorption (Mundy, 1993; Löwik *et al.,* 1994; Ralston *et al.,* 1995). Conversely, IL-1β and TNF-α exert a more modest inductive effect on iNOS expression and activity and this is manifest by inhibition of the proresorptive effects of these cytokines by NOS inhibitors (Löwik *et al.,* 1994; Ralston *et al.,* 1995). These studies also demonstrated synergism between NO and prostaglandin E2, another important regulator of bone resorption (Ralston *et al.,* 1995). This is consistent with recent observations on bone marrow cocultures from iNOS-gene-deficient mice, revealing that iNOS is essential for mediating the bone-resorptive effects of IL-1β (Van't Hof *et al.,* 2000).

In addition to cytokine-induced (iNOS) NO synthesis, osteoclasts are known to express eNOS and the activity of

this constitutive enzyme seems to be important in stimulating bone resorption (Brandi *et al.,* 1995). Indeed, administration of a general NOS inhibitor to untreated neonatal rodent osteoclasts blocks resorption, demonstrating that transient, tonic release of NO or, as discussed above, moderate induction of NO synthesis is an important facet of osteoclast resorptive function.

While it is clear that NO is significant in the regulation of osteoclastic bone resorption, the cellular source(s) that contribute to this process are more controversial. There is evidence to show that preosteoclastic and osteoclast cell lines have a low basal NO synthesis (Brandi *et al.,* 1995), which can be further stimulated by fluid shear-stress (McAllister *et al.,* 2000). In response to cytokine stimulation iNOS expression is induced in avian, rodent, and human osteoclastic cell lines (Brandi *et al.,* 1995; Sunyer *et al.,* 1996) and is accompanied by marked elevation in NO synthesis, as suggested by nitrite accumulation (Sunyer *et al.,* 1996). Such data would be consistent with an autocrine role for NO in osteoclast function. However, other investigators have argued against this after failing to detect appreciable levels of iNOS expression in osteoclasts even after cytokine stimulation (Helfrich *et al.,* 1997). Moreover, on the basis of bone organ culture or osteoblast–bone marrow coculture experiments, this same group of investigators have implicated the osteoblast as being the predominant source of inducible NO affecting osteoclast activity (van't Hof and Ralston, 1997; Van't Hof *et al.,* 2000).

The mechanisms of action of NO on osteoclasts are also quite varied and dependent on the stage of cell development. Exposure to high levels of NO associated with iNOS expression and activation is known to induce damage and death in a number of cell types. Consistent with this, cytokine-stimulated NO synthesis diminishes proliferation of preosteoclasts (Brandi *et al.,* 1995) and may involve induction of apoptotic cell death (van't Hof and Ralston, 1997). What is particularly remarkable about the latter observation is the relative sensitivity of osteoclast progenitors to NO-induced apoptosis with mature osteoclasts and osteoblasts apparently being more resistant (Van't Hof and Ralston, 1997). The upshot of this is a reduction in the formation of mature osteoclasts and suppression of bone resorption.

In mature osteoclasts NO has been shown to both stimulate and inhibit activity and as discussed above this bidirectional effect (Brandi *et al.,* 1995) is related to changes in the local concentration of NO. Exposure of mature osteoclasts to NO stimulates contraction and causes the cells to become detached from the underlying bone surface (MacIntyre *et al.,* 1991; Brandi *et al.,* 1995). This effect is illustrated in isolated rat osteoclasts (Fig. 2). The contraction of isolated osteoclasts is known to be induced by fluxes in calcium ion concentration and appears to be mediated by a calcium-sensitive isoform (eNOS) since NOS inhibitors largely prevent the calcium-induced osteoclastic contraction (Brandi *et al.,* 1995). It is now known that this action of nitric oxide is largely due to cGMP, although this was not apparent in initial studies using slowly permeant cGMP analogs such as 8-bromo- or di-butyryl-cGMP (MacIntyre *et al.,* 1991). However, more recently we demonstrated that rapidly permeant cGMP analogs (8-pCPT-cGMP) produce a dramatic osteoclast contraction. This is also seen after exposure to NO donors and is largely prevented, although not entirely, by guanylate cyclase inhibitors (Mancini *et al.,* 1998). The calcium-stimulated effect of nitric oxide may well be physiological and during osteoclastic bone resorption in which periodic calcium-induced detachment occurs this contracting and detaching effect likely forms an essential part of osteoclastic bone resorption involving osteoclast

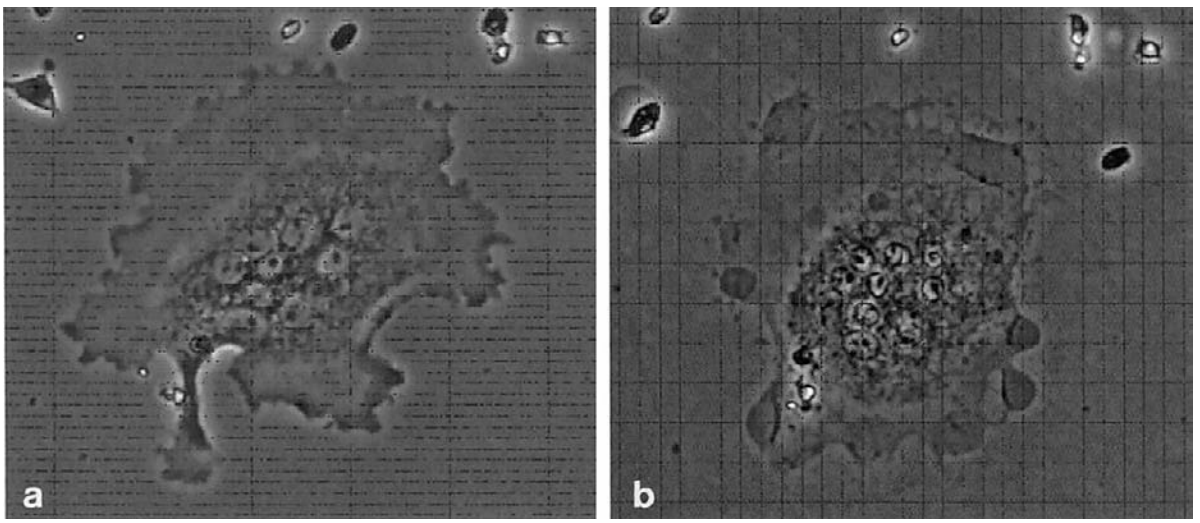

Figure 2 Videomicroscope image of a primary rat osteoclast. (a) A typical rat osteoclast showing large cytoplasmic area and numerous nucleii. (b) The same cell after addition of a nitric oxide donor showing reduced cell area.

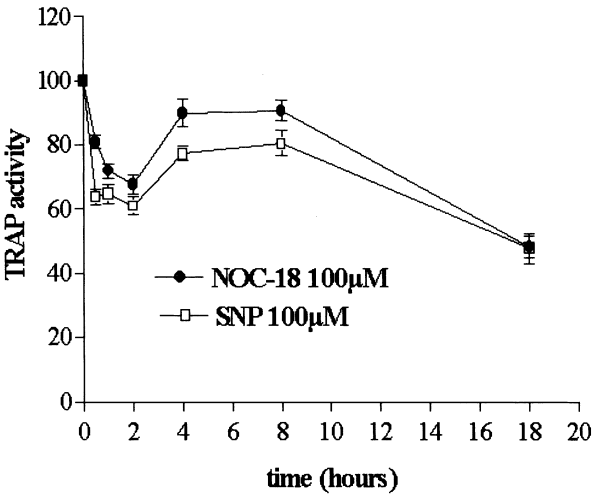

Figure 3 Effect of NO-donors on human type 5 acid phosphatase activity. The two NO donors, SIN-1 and NOC-18, are both able to decrease TRAP activity over time with a maximun reduction observed after 18 hr. Values are the mean of three different experiments and are expressed as percentage of control.

movement. With more prolonged activation this is likely to become inhibitory, increasing the frequency of contraction and detachment and suppressing resorption activity.

Very recently we have shown that NO inhibits the activity of recombinant tartate-resistant acid phosphatase (TRAP) (L. Mancini, T. Cox and I. MacIntyre, unpublished observations; Fig. 3) and this effect might contribute to the inhibitory action of NO on osteoclastic bone resorption. TRAP is mainly localized in resorption vacuoles, suggesting that it is secreted by the osteoclasts at the site of active resorption, although the mechanism by which it promotes bone resorption is still unclear. However, it is clearly established that inhibition of acid phosphatase by chemical and immunological means can abolish osteoclastic bone resorption (Zaidi *et al.,* 1989). Further, acid phosphatase knockout mice have mild osteopetrosis while genetically engineered mice overexpressing acid phosphatase have an increased bone turnover (Hayman *et al.,* 1996, Angel *et al.,* 2000). Thus, acid phosphatase seems to be essential for bone resorption and osteoclast activity and the finding that NO can inhibit TRAP activity, possibly by binding to the iron moiety of the protein, could account for some of the inhibitory actions of NO on osteoclastic bone resorption.

OSTEOBLAST/OSTEOCYTE EFFECTS

The first definitive evidence for synthesis of NO by cells of the osteoblast lineage came from studies on responses of these cells to cytokine stimulation. Several groups independently demonstrated induction of iNOS mRNA and protein expression in cultures of both rodent and human primary osteoblasts and osteoblast cell lines after cytokine challenge (Damoulis and Hauschka, 1994; Löwik *et al.,* 1994; Ralston *et al.,* 1994; Hukkanen *et al.,*1995). Activity of iNOS and synthesis of NO by these cells was confirmed by marked increases in the accumulation of nitrite, one of the oxidation products of NO biosynthesis, in the culture medium. Furthermore, these studies revealed a rank order of potency for induction of iNOS by cytokines. When added to the cultures singly, IFN-γ was found to induce the highest levels of NO synthesis, as assessed by nitrite accumulation, followed by TNF-α and finally IL-1β, which had only mild to inductive effect. Combinations of two or more cytokines and in particular the combination IFN-γ, TNF-α, and IL-1β significantly augmented NO synthesis over levels achieved by single cytokines, suggesting synergistic effects on induction of iNOS.

By including inhibitors of NOS activity in the culture medium during or after cytokine-induced NO production it has been possible to examine the effects of NO on osteoblast function. Under these conditions NO causes profound inhibition of cell proliferation and DNA synthesis (Ralston *et al.,* 1995; Hukkanen *et al.,* 1995) and also induces apoptotic cell death (Damoulis and Hauschka 1997; Jilka *et al.,* 1998). In addition, cytokine induced NO synthesis causes reductions in the expression and activity of markers of osteoblast differentiation including alkaline phosphatase and osteocalcin (Ralston *et al.,* 1995; Hukkanen *et al.,*1995) and formation of mineralized bone nodules (Buttery, Hughes and Hukkanen, unpublished observations; Fig. 4). More recently, Hughes *et al.* (1999) demonstrated that NO generated by iNOS or supplied exogenously by an NO donor was important in stimulating expression of cyclooxygenase 2 and prostaglandin (E2) synthesis and might be relevant to osteoblastic control of bone resorption.

There are also some physiological processes that are stimulated by osteoblast/osteocyte constitutive (eNOS) NO synthesis. Riancho *et al.* (1995) demonstrated basal, constitutive NO synthesis by osteoblasts which promoted cell proliferation and could be augmented by 1,25-dihydroxy vitamin D_3. This basal NO synthesis also stimulated release of IL-6, suggesting a possible role for osteoblast-derived NO stimulating osteoclastic bone resorption. It has been shown in rodent models that the new bone formation induced by mechanical strain is blocked by NOS inhibitors (Fox *et al.,* 1996; Turner *et al.,* 1996). Furthermore, osteocytes and osteoblasts rapidly produce NO when exposed to mechanical strain or pulsatile fluid flow *in vitro* (Pitsillides *et al.,* 1995; Klein-Nulend *et al.,* 1995; Turner *et al.,* 1996) and this is now known to be dependent on the expression and activation of eNOS (Klein-Nulend *et al.,* 1998; Zaman *et al.,* 1999). Such a role for eNOS in sensing and responding to mechanical loading or shear flow is consistent with the molecular regulation of this enzyme (Kleinert *et al.,* 2000). More recently McAllister and Frangos (1999) have examined the kinetics of NO release from osteoblasts exposed to both steady and transient fluid shear stress. The results demonstrated two distinct biochemical pathways with transient flow stimulating a transient "burst" of NO that was dependent on G-protein activation and calcium mobilization, while steady flow produced sustained NO release that was G-protein- and calcium-independent. Such studies are important since they not only confirm

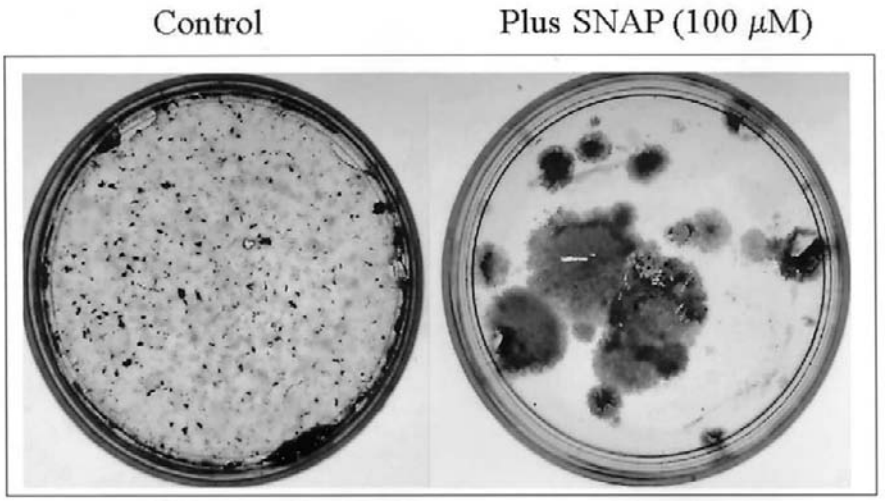

Figure 4 Effects of exogenous NO on rat osteoblast differentiation and formation of mineralized bone nodules. Exposure to SNAP (12 hr) at the time of cell seeding severely inhibited subsequent cell growth and differentiation.

the involvement NO in transducing osteogenic signals but also provide an insight into how perturbations in this signaling pathway might contribute to bone pathology.

In addition to conducting osteogenic effects induced by mechanical loading and fluid flow, NO generated by cells of the osteoblast lineage is important in mediating the anabolic effects of estrogen on bone. While the major effect of estrogen has been thought to be its ability to inhibit osteoclastic bone resorption, estrogen has also been shown to have a direct effect on osteoblast-like cells (Ernst *et al.,* 1989). The presence of functional estrogen receptors in cells of the osteoblast lineage (Eriksen *et al.,* 1988; Komm *et al.,* 1988) suggests estrogen compounds such as 17β-estradiol stimulate bone formation *in vivo* by a direct action on osteoblasts (Chow *et al.* 1992a,b; Tanko-Yamamato and Rodan, 1990; Samuels *et al.,* 1999). Studies *in vitro* have shown 17β-E_2 to enhance both proliferation and differentiation of cultured osteoblasts (Qu *et al.,* 1998; Ernst *et al.,* 1988; Scheven *et al.,* 1992). Although a link between estrogen and stimulation of eNOS had been established in the vascular system (Hayashi *et al.,*1995; Weiner *et al.,*1994) the first studies to demonstrate a link between the osteogenic effects of estrogen and NO in bone were perhaps those of Wimalawansa *et al.* (1996). They demonstrated that the NO donor compound nitroglycerin, long used in the treatment of ischemic heart disease, could prevent or reverse the bone loss and onset of osteopenia induced by ovariectomy in a rat model. Subsequently, Armour and Ralston (1998) demonstrated upregulation of eNOS expression and activity in a human osteoblast cell line after stimulated by 17β-estradiol. Studies in our laboratory (O'Shaughnessy *et al.,* 2000) on primary human and rat osteoblast cultures showed that 17β-estradiol dose-dependently stimulated osteoblast proliferation and differentiation as assessed by alkaline phosphatase activity and bone nodule formation (Fig. 5) and this could be abolished by inhibitors of NOS activity. Additionally, 17β-estradiol increased total eNOS enzyme expression in rat osteoblasts and stimulated increases in NO metabolite levels (Fig. 6), which once again could be abolished NOS inhibitors. A final and important finding from these studies is the lack of response to 17β-estradiol of primary osteoblasts cultures from eNOS gene knockout mice (studies on NOS-gene-deficient mice are discussed in more detail below). Collectively these observations suggest that the stimulatory effect of estrogen on osteoblast proliferation and differentiation rely on local production of NO by bone cells via the eNOS isoform.

Similar results to those described above are also seen after exogenous administration of NO donor compounds to osteoblast cultures. NO donors increase cGMP production, alkaline phosphatase activity, osteocalcin expression, and

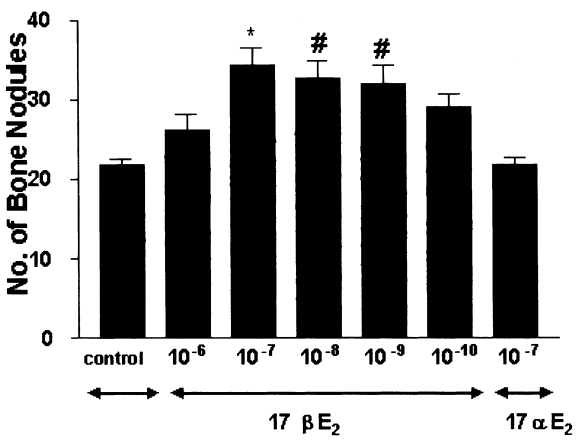

Figure 5 Quantitative assessment of rat osteoblast differentiation by *in vitro* formation of mineralized bone nodules. Estradiol has a dose-dependent effect on rat osteoblast differentiation. in vitro bone nodules formation (Chae *et al.,* 1997; Hikiji *et al.,* 1997; Otsuka *et al.,* 1998). Studies by our group (Mancini *et al.,* 2000) found that while slow release and generation of low concentrations of NO stimulated osteoblast replication and alkaline phosphatase activity, rapid release, and high concentrations of NO inhibited proliferation and induced apoptosis. These observations help to emphasize a fundamental aspect of the biological chemistry of NO, showing that alterations in the kinetics of NO synthesis (loosely equating to eNOS versus iNOS activity) can evoke profoundly different biological responses. Importantly these studies also demonstrated that the biphasic effects of NO on osteoblasts are mediated, in part, by the second messenger cGMP (Mancini *et al.,* 2000).

As such, these results confirm that NO is generated by osteoblasts via eNOS and iNOS and has an important role in osteoblast function. As a general rule of thumb transient low-level production of NO regulated by eNOS is associated with stimulation of osteoblast activity and bone formation. Whereas, more sustained high output NO synthesis associated with iNOS expression and activity inhibits osteoblast function.

NO DONORS

NO donors can be used in the characterization of NO-mediated effects and provide a means of supplying "controlled" levels of NO from an exogenous source to mimic endogenous NO synthesis in biological systems. However, in practice it is often difficult to exert adequate control over NO release and as such studies on NO donors, although useful, should be interpreted with some caution. The kinetics of NO release varies from compound to compound. Some release NO spontaneously in aqueous buffers, whereas others require active metabolic uptake and degradation. Compound-specific susceptibility to changes in pH, oxygen, light, and temperature and formation of different by-products and metabolites during decomposition or metabolism also vary. Studies on NO donors are also complicated by the vast choice of compounds. In terms of bone research the following lists of some of the compounds used and their characteristics:

Nitroglycerin (glyceryl trinitrate, GTN) is an organic nitrate with over a 100 years of therapeutic use particular in cardiovascular disease. It appears to require active metabolic uptake and degradation by cells to be effective and therein lies one the drawbacks of this cell, with cells becoming tolerant after repeated exposure, requiring consistently higher dosage. It does, however, have the advantage that it can readily be used *in vivo* and has been shown to be effective in the prevention or reversal of estrogen-depleted osteoporosis in rodent models and human subjects (Wimalawansa *et al.,* 1996, 2000).

S-Nitroso-*N*-acetyl-penicillamine (SNAP), *S*-nitrosoglutathione (SNOG) 3−morpholinosydnonomine (SIN-1), and sodium nitroprusside (SNP) are NO donor compounds that have been used in a vast number of *in vitro* (and some *in vivo*) experiments including cultured bone cells. All seem to liberate NO or NO adducts more or less spontaneously on contact with aqueous buffers. This can potentially "flood" the culture medium with NO making difficult to quantify cellular responses. However, careful adjustment of donor concentration can be used to create NO gradients that more faithfully mimic both physiological and pathophysiological responses *in vitro* (Damoulis and Hauschka, 1997; Otsuka *et al.,* 1998; Hughes *et al.,* 1999; O'Shaughnessy *et al.,* 2000; Aguirre *et al.,* 2001)

The final class of compounds, the diazeniumdiolates or NONOates, are perhaps the most useful for most closely mimicking endogenous NO synthesis. Although the NONOates release NO spontaneously, their rate of decomposition can be precisely controlled. This enables the kinetics and concentrations of NO liberated into the culture medium to be more accurately predicated and adjusted to correlate more closely with the activity of eNOS or iNOS (Otsuka *et al.,* 1998; Mancini *et al.,* 2000).

INHIBITION OF NO SYNTHESIS

Research directed toward the control of NO synthesis has flourished in the past few years, particularly in view of the roles that NO production may play in various pathophysiological states. Following the initial discovery that N^G-monomethyl-L-arginine (L-NMMA) could inhibit the synthesis of NO, a variety of N^G-substituted L-arginine derivatives and related compounds have been investigated as inhibitors of NO synthesis.

L-NMMA and N^G-N^G-dimethyl-L-arginine (ADMA) are naturally occurring inhibitors of NO synthesis with an equal affinity for the constitutive and inducible isoforms of NO synthase (Vallance *et al.,* 1992). Other commonly used inhibitors of NO synthesis include N^G-nitro-L-arginine (L-NNA), N^G-L-argininemethylester (L-NAME), N^G-iminoethyl-L-ornithine (L-NIO), and L-canavine. Some of these are reported to demonstrate rank-order specificity for particular isoforms

(Knowles and Moncada, 1994). For example, L-NNA, L-NIO, and L-canavine are more selective for iNOS than for either nNOS or eNOS. Aminoguanidine (AG), has been much used as a selective inhibitor of iNOS including studies on bone (Kasten *et al.,*1994; Tsukahara *et al.,*1996) and is reported to be 20- to 30-fold more selective for iNOS than the constitutive isoforms. However, none of these inhibitors is sufficiently effective in their selectivity (and may have effects independent of NOS inhibition) (Peterson *et al.,* 1992) to be able to assign, unequivocally, a specific cellular function to a particular NOS isoform.

NOS GENE-DEFICIENT MICE

Gene knockout mice represent powerful tools for studying possible functions and targets of regulatory factors involved in physiological and pathological processes. Murine gene knockouts have been created for all three isoforms of NOS (Huang *et al.,* 1993, 1995; MacMicking *et al.,* 1995; Wei *et al.,*1995). In all cases the mutant mice were found to be viable, fertile, and identical in general appearance and behavior to their wild-type counterparts.

Mice deficient in nNOS were the first knockouts to be created and revealed that the nNOS gene-deficient mice are largely resistant to brain damage induced by vascular stokes (Huang *et al.,* 1993), confirming the importance of nNOS-derived NO in mediating stroke damage. It is also apparent that nNOS knockout male mice are highly aggressive (Nelson *et al.,* 1995). The observations of iNOS gene-deficient mice were also in keeping with what might have been expected, corroborating the participation of iNOS in mediating inflammatory responses with iNOS gene-deficient mice demonstrating attenuated microbicidal and tumouricidal responses (MacMicking *et al.,*1995; Wei *et al.,* 1995). The findings from mice deficient in eNOS are again in accord with what might have been expected, based on prior observations of its actions. These mice had an elevated blood pressure and isolated aortic rings did not display a relaxant response when challenged with acetylcholine. This demonstrated the important role of eNOS-derived NO in mediating vascular homeostasis (Huang *et al.,* 1995). However, an unexpected finding was the induction of a hypotensive effect following administration of a NOS inhibitor, which could be reversed by infusion of excess L-arginine (Huang *et al.,* 1995). This suggests that blockers of NO synthesis might have independent effects on the vasculature or that other isoforms of NO synthase contribute to the maintenance of blood pressure. The prime candidate for this is nNOS, which is known to be present in the vasomotor centers of the central nervous system and in nerves supplying blood vessels.

In the context of this review NOS gene-deficient mice represent powerful models for studying the role of NO in bone metabolism, circumventing the lack of isoform specificity of the current generation of NOS inhibitors providing a rigorous test of previous proposed actions of NO on bone. Observations by our group (Moradi-Bidhendi, Mancini, Forte, Cafferkey, Benjami, MacIntyre, unpublished observations) show that male nNOS knockout mice have a marked

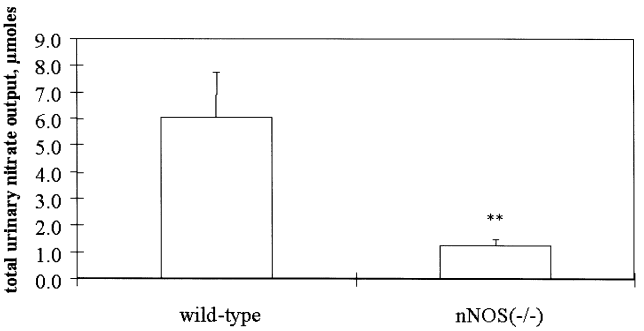

Figure 7 The mean total urinary nitrate output of c57/bl/6 wild-type and nNOS(−/−) knockout mice. nNOS(−/−) knockout mice show a significantly lower nitrate output than wild-type controls. All animals were between 8 and 12 weeks old and maintained on a low nitrate diet throughout experiments. Values mean ± SEM, $n = 6$. ** $P < 0.01$ using Student's *t* test.

reduction in urinary nitrate (Fig. 7). In addition, female nNOS knockout mice fail to respond to the stimulatory effect of estrogen based on urinary nitrate measurements (Fig. 8). Interestingly, male eNOS knockouts have urinary nitrate outputs similar to wild-type controls and females respond normally to estrogen with a cyclic increase in urinary nitrate excretion. These findings imply that nNOS is mainly responsible for urinary nitrate and that nNOS is stimulated by estrogen, thus explaining the normal increase in nitrate after administration of estrogen to eNOS knockouts. Further, it is conceivable that the aggressive behavior of nNOS knockouts resembles the effect of estrogen deficiency on cerebral nNOS.

More detailed investigations by our group and another group on eNOS knockout mice have now demonstrated the considerable role of eNOS in the maintenance of physiological bone mass (Aguirre *et al.,* 2001; Armour *et al.,* 2001). As mentioned earlier, eNOS knockout mice are viable and fertile, and in terms of gross physical appearance (stature, gait, and anatomy) are unremarkable. However, on closer examination of the long bones we found that both the femur and the tibia of eNOS knockouts were significantly shorter (1–2 mm) than the corresponding wild-type. Histomorphometry analysis of the same bones showed a marked reduction in both bone formation rate and bone volume (Fig. 9).

Interestingly, the consequences of eNOS gene deficiency were most pronounced in young (6–9 weeks old) adults and by 12–18 weeks bone phenotype was restored toward wild-type. Regardless of eNOS expression bone turnover was significantly higher in young mice than old mice and similar observations have been made on rats and humans demonstrating that bone modeling/remodeling activity is related to sexual maturity. Moreover, we have shown that eNOS expression correlates with skeletal development and is most abundant in the bones of neonates and young adults, decreasing markedly in older animals (Hukkanen *et al.,* 1999). These data suggest that eNOS expression and activity is important during phases of rapid bone growth or turnover such as in the period from neonate through to

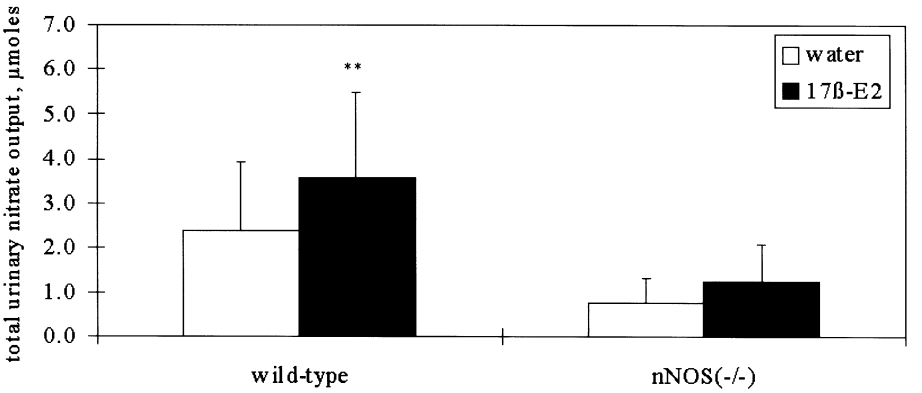

Figure 8 The mean total urinary nitrate output of c57/bl/6 and nNOS(−/−) with estrogen administration. Control c57/bl/6 mice showed a significant increase in urinary nitrate with administration of 10 μg 17β-E_2. There was no significant increase in the urinary nitrate output of nNOS(−/−) mice. All animals were between 8 and 12 weeks old and maintained on a low-nitrate diet throughout experiments. Values mean ± SEM, $n = 6$. $^{**}P < 0.01$ using Student's t test.

sexually mature adult and the attainment of peak bone mass. Clearly, eNOS gene deficiency does not represent a severe or irreversible impediment to skeletal growth as exemplified by our studies, where despite the initial expression of a juvenile osteoporosis-like phenotype these knockouts are still able to attain peak bone mass. The mechanism of recovery is unknown. However, it is possible to suggest that these mice will exhibit altered responses to physiological and, in particular, pathophysiological demands placed upon the skeleton such as the effects of endocrine imbalance (i.e., estrogen deficiency; Armour *et al.,* 2001). Furthermore, upregulation of eNOS activity is important in mechanical load-induced bone growth (Pitsillides *et al.,* 1995; Turner *et al.,* 1996; Klein-Nulend *et al.,* 1998; Zaman *et al.,* 1999) and fracture healing (Corbett *et al.,* 1999a,b; Diwan *et al.,* 2000). Thus, eNOS knockout mice are likely to exhibit defective or protracted bone repair mechanisms following traumatic injury.

In the same study (Aquirre *et al.,* 2001) we found that the reduction in bone formation and volume was not related to increased osteoclast numbers or activity but rather to dysfunctional osteoblasts. Osteoblast number and synthetic and mineralizing activity were all reduced *in vivo. In vitro,* cultures of primary osteoblasts from fetal calvarial explants showed retarded growth and differentiation as assessed by alkaline phosphatase activity and formation of mineralized bone nodules and could be reversed by exposure to low concentrations of the NO donor SNAP. As presented in studies by O'Shaughnessy *et al.* (2000), osteoblasts from eNOS knockouts, unlike wild-type cultures, were unresponsive to the mitogenic effects of estradiol over a range of concentrations, providing further evidence that the eNOS–NO signaling pathway is important in mediating the osteogenic actions of estrogen. Moreover, these cells demonstrated an attenuated chemotaxis response and failed to migrate along a TGF-β gradient (Aquirre *et al.,* 2001), which is known to be a potent cytokine in recruiting osteoblasts to remodeling sites (Pfeilschifter *et al.,* 1990). Taken together these data illustrate that distinct components of the osteoblast phase of the bone remodeling cycle are altered in eNOS knockout mice, strongly implicating NO-dependent signaling via eNOS in the regulation of osteoblast growth, differentiation, recruitment, and extracellular matrix synthesis. Recent studies by Armour *et al.* (2001) show that ovariectomized eNOS knock-

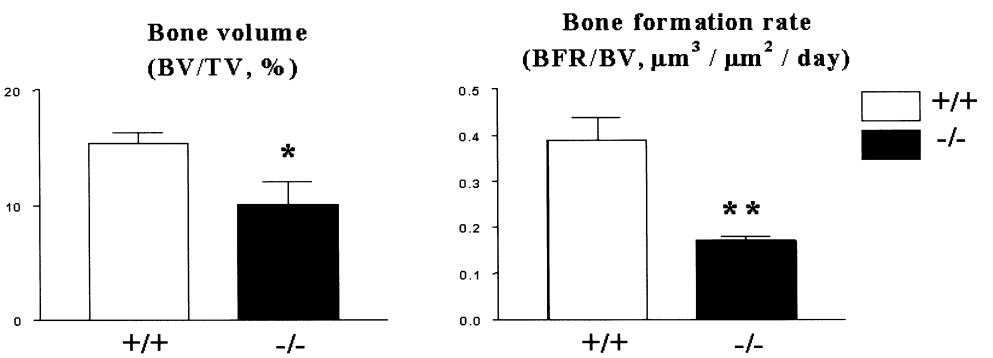

Figure 9 Histomorphemtry analysis of femurs from 6-week-old eNOS gene knockout mice and age-matched wild-types. Both bone formation rate and bone volume are significant reduced in eNOS knockouts. Values mean ± SEM $n = 7$. $^{*}P < 0.05$; $^{**}P < 0.01$.

out mice have a significantly blocked anabolic response to high doses of exogeneous estrogen.

It is important to note that at the time of completing this chapter several issues relating to the effects of eNOS gene deficiency on bone biology remained unresolved. In particular, studies to test the role of eNOS in sensing/transducing signals associated with mechanical loading and shear flow had not be reported, although it is likely that these responses will be blunted. The potential impact of the persistent hypertension associated with eNOS gene deficiency (Huang *et al.,* 1995) on bone turnover needs to be thoroughly evaluated. There is evidence that bone vasculature can modify bone formation through intraosseous pressure (Kelly and Bronk, 1990) and factors released from endothelial cells (including NO) can modulate bone cell function (Collin-Osdoby, 1994). Finally, in addition to the osteoblast we found that osteoclast activity was diminished in eNOS knockouts, based on histomorphometry, with a reduction in eroded surface. This again was prevalent in young (6 weeks old) mice and reversed in older (9–18 weeks) mice. This is consistent with studies by Brandi *et al.* (1995), suggesting that eNOS activity might be required to stimulate osteoclast although more detailed investigation is required to confirm these observations.

With regard to iNOS gene knockouts, studies *in vitro* and *in vivo* by van't Hof *et al.* (2000) demonstrated that IL-1-induced (iNOS) NO production was essential for promoting osteoclast formation and activity. Moreover, osteoblast-bone marrow cocultures revealed that osteoblasts were the principal source of NO regulating osteoclast activity, particularly in osteoclast precursors, and was dependent on NFκB translocation and DNA binding. Importantly, the defects in IL-1-induced bone resorption could be reversed by exogenous supply of the NO donor SNAP (van't Hof *et al.,* 2000). Initial studies on iNOS knockouts by our group (Aguirre, Buttery, Hukkanen, MacIntyre, and Polak, unpublished observations) have revealed marked reductions in bone formation and volume similar to the abnormalities described in eNOS knockouts (Aguirre *et al.,* 2001). However, the underlying mechanism is distinct and appears to relate to increased osteoclast number and activity and would support the NOS inhibitor (iNOS) studies of Kasten *et al.* (1994), Tsukahara *et al.* (1996) and Turner *et al.* (1997). Another interesting observation from iNOS knockouts is a three- to fourfold increase in eNOS mRNA expression in whole bone preparations. The significance of this remains to be determined but could represent a compensatory mechanism to counter the loss of iNOS. Such a phenomenon is not unusual in NOS gene knockouts (Huang and Fishman, 1996).

Potential Molecular Targets for the Action of NO in Bone Cells

As discussed in the section on NO signalling is able to activate various signal transduction pathways in a number of different cell types. Despite this, there is a surprising paucity of information of the detailed signaling mechanisms of NO in bone cells. The guanylyl cyclase-cGMP pathway is a classical target for NO and there is a substantial body of evidence to show that the cGMP-dependent signaling is crucial to normal bone formation. Early studies demonstrated that cGMP was important in transducing the anabolic effects of mechanical loading (Rodan *et al.,* 1975) and more recently those of naturetic peptides on bone formation (Suda *et al.,* 1996; Mericq *et al.,* 2000). cGMP analogs increase the expression of markers of osteoblast differentiation alkaline phosphatase and osteocalcin and augment formation of mineralized bone nodule in rat calvaria cell cultures (Inoue *et al.,* 1995). The marked bone abnormalities and dwarfism seen in mice lacking protein G kinase type II is particularly compelling evidence for the role of cGMP in endochondral ossification (Pfeifer *et al.,* 1996). Evidence for a direct association between NO and cGMP has come from observations on cultured osteoblasts using NO donors. These studies showed that increased alkaline phosphatase activity, osteocalcin expression, and *in vitro* bone nodule formation was accompanied or dependent, at least in part, on cGMP synthesis (Chae *et al.,* 1997; Hikiji *et al.,* 1997; Otsuka *et al.,* 1998; Mancini *et al.,* 2000).

The role of cGMP in mediating osteoclast function is less conclusive. Initial studies suggested cGMP production is not required for the functional modulation of osteoclasts by NO (MacIntyre *et al.,* 1991; Ralson and Grabowski, 1996). However, more recent studies using newer generation cGMP analogs and guanlyly cyclase inhibitors have demonstrated stimulation of cGMP by low concentrations of NO does regulate osteoclast function increasing cell contraction and detachment from bone surfaces (Mancini *et al.,* 1998). In addition, Dong *et al.* (1999) showed that NO-dependent cGMP production reduced transport of HCl osteoclast membranes and inhibited activity.

In addition to the cGMP pathway NO is a potent stimulator of $p21^{ras}$ activity and MAP kinase signaling (Lander, 1997). Although there is no direct evidence for NO-dependent activation of this pathway in bone cells it has been shown that the MAP kinases are involved in stimulating osteoblast proliferation and differentiation (Matsuda *et al.,* 1998) and in regulating expression of the osteoblast transcription factor Cbfa-1 (Xiao *et al.,* 2000). MAP kinase activation is also involved in RANK ligand-induced osteoclast differentiation (Matsumoto *et al.,* 2000).

Expression and activity of VEGF is fundamental to the process of endochondral ossification stimulating chondrocyte cell death, cartilage remodeling, and angiogenesis (Gerber *et al.,* 1999). Again there is no direct evidence to support the involvement of NO in mediating the actions of VEGF in bone but there is certainly evidence to show that NO contibutes to the angiogenic effects of VEGF in other cell types (Papapetropoulos *et al.,* 1997; Frank *et al.,* 1999; Ziche, 2000). As such, NO-VEGF signaling might also be important in the angiogenic response that is crucial to fracture healing.

NO AND BONE PATHOLOGY

Alterations or disruption to NO synthesis within the bone environment has been implicated in the genesis of a number of diseases. Inflammatory diseases such as rheumatoid arthritis, which is characterized by articular cartilage erosion together with juxta articular bone loss is associated with activation of iNOS and production of NO and NO related species including peroxynitrite (Farrell *et al.,* 1992; Stefanovic-Racic *et al.,* 1993; Kaur and Halliwell, 1994; Grabowski *et al.,* 1996). On the basis of studies using NOS inhibitors and iNOS knockouts, activation of iNOS and increased levels of NO production contribute directly to the tissue damage associated with rheumatoid arthritis (McCartney-Francis *et al.,* 1993; Stefanovic-Racic *et al.,* 1994).

There are several other inflammatory conditions associated with activation of iNOS and in which increased production of NO or NO derived oxidants (peroxynitrite) are implicated in pathological bone loss. For example, Hukkanen *et al.* (1997) showed increased staining for iNOS and formation of peroxynitrite in macrophages associated with bone erosions adjacent to prosthetic hip implants, suggesting the involvement of iNOS in the process of loosening of the implant. Such subjects require reoperation to stabilize or replace the loosened prosthesis. Armour *et al.* (1999) presented evidence for iNOS activation and increased NO production as a contributory factor to the extensive bone loss seen in a model of inflammation-induced osteoporosis. Importantly, the deleterious effects of iNOS activation in this model could be largely prevented by administration of a NOS inhibitor. Recent observations by our group (Calder *et al.,* 2000a) have demonstrated robust iNOS expression and staining in osteoblasts, osteoclasts, and in particular osteocytes in bone samples from osteonecrotic subjects. Interestingly, iNOS-positive cells correlated closely with the incidence of apoptotic cells and has lead to the somewhat controversial suggestion that osteocyte apoptosis (induced by NO), might in fact be the underlying mechanism of the extensive bone destruction seen under this condition (Calder *et al.,* 2000a).

The most common bone lesion is fracture and there is evidence to show that NO is involved in various stages of fracture healing. Consistent with the initial inflammatory phase of fracture healing Corbett *et al.* (1999a) demonstrated marked iNOS expression and activity within 24 hr after fracture in rat model where it was localized principally to endosteal osteoblasts. This expression was transient and after 24 hr iNOS was expression/activity was scarcely detectable. During this same period and during the first week after fracture there was a marked increase in expression and activity of (calcium-dependent) eNOS, which was localized, in particular, to cortical blood vessels and osteocytes (Corbett *et al.* 1999a). This is consistent with eNOS being involved in the vascular response and neovascularization that is crucial to successful fracture repair. Indeed, in a further study on the same model Corbett *et al.* (1999b) demonstrated enhanced NO-dependent vasoreactivity about the fracture site supporting a role for NO in the restoration of blood flow to the fractured bone. Subsequently, Diwan *et al.* (2000) have provided similar evidence for the involvement of NO in fracture healing. Of particular interest in that study was the finding that NOS inhibitors significantly impaired fracture healing, which could be reversed by local delivery of a NO donor.

Osteoporosis is an important abnormality because it predisposes to fracture. Although clearly a multifactorial disorder it is becoming increasingly apparent that disrupted NO synthesis is a significant factor in the bone loss associated with osteopenia. Estrogen-deplete osteoporosis induced by ovariectiomy in animal models can be largely reversed by administration of NO donor compounds, notably nitroglycerin (Wimalawansa *et al.,* 1996). This has now been extended to human clinical trial showing that nitroglycerin is equally as effective as hormone replacement therapy (HRT) in preventing or restoring postmenopausal bone loss (Wimalawansa *et al.,* 2000). Additional evidence for NO mediating the osteogenic effects of estrogen is provided by cyclic increases in plasma nitrite and nitrate levels (the oxidation production of NO synthesis) which are highest at the mid-phase of the menstrual cycle, closely following estrogen levels (Cicinelli *et al.,* 1996). Postmenopausal subjects and amenorrheic athletes have reduced serum NO metabolites, which can be elevated by HRT (Rosselli *et al.,* 1995; Cicinelli *et al.,* 1998; Stacey *et al.,* 1998). Finally, *in vitro* studies on rodents, including eNOS knockouts and human osteoblasts demonstrate that eNOS expression and activity is elevated by estrogen and correlates with increased osteoblast proliferation and differentiation (Armour and Ralston, 1998; O'Shaughnessy *et al.,* 2000; Aguirre *et al.,* 2001; Armour *et al.,* 2001).

THERAPEUTIC IMPLICATIONS

It has been clearly shown that NO has an estrogen-like effect and that nitric oxide can in part replace the effect of oestrogen (Wimalawansa *et al.,* 1996; Armour and Ralston, 1998; O'Shaughnessy *et al.,* 2000; Aguirre *et al.,* 2001; Armour *et al.,* 2001). Wimalawansa (2000) has also recently shown that a NO donor in man is as effective as estrogen in inhibiting postmenopausal bone loss. Clearly this has important therapeutic implications in the treatment and perhaps prevention of osteoporosis. Further, it strongly suggests that a NO donor in combination with an osteoclast inhibitor (e.g., calcitonin or bisphosponates) should be useful in the treatment of osteoporosis. Administration of NO donor compounds could also prove to be efficacious in augmenting fracture healing (Corbett *et al.,* 1999a,b; Diwan *et al.,* 2000). There are, however, potential limitations to the use of NO donors. Cellular desensitization following prolonged use of organo-nitrate compounds like nitroglycerin is a particular problem that has been encountered in the treatment of ischaemic heart disease and requires increased dosages to reproduce the beneficial effects.

Alternatives to NO donors include delivering compounds that preserve the signaling actions of messenger molecules downstream of NO synthesis such as cGMP. Indeed, phosphodiesterase (PDE) inhibitors are able to

increase bone mass by accelerating bone formation in mice (Kinoshita *et al.,* 2000). Consequently, PDE inhibitors may have some value in the treatment of osteoporosis. Other approaches for eliciting anabolic effects in the skeleton include the lipid lowering drugs statins, which have recently been found to stimulate new bone formation (Mundy *et al.,* 1999) and reduce the risk of hip fracture in elderly human subjects (Wang *et al.,* 2000). Interestingly, statins upregulate eNOS expression and downregulate iNOS expression (Vaughn and Delany, 1999) at least in brain tissue and may also account for some the osteoprotective effects of these compounds.

Elevated production of NO following iNOS activation is a significant factor in the progression of various inflammatory conditions including rheumatoid arthritis. Consequently, inhibition of iNOS activity appears to be an attractive target in tempering inflammation-induced tissue damage. Although there are several reports to show that when administered prophylactically NOS inhibitors (L-NAME, L-NMMA) were able to suppress the onset of disease in animal models (McCartney-Fancis *et al.,* 1993; Stefanovic-Racic *et al.,* 1994), not all iNOS activity is detrimental. Indeed iNOS does have protective effects such that NOS inhibitors can exacerbate tissue injury. In part this also relates to the fact that in virtually all the studies that have been performed using NOS inhibitors none of the compounds used are sufficiently selective in their action and can often block the beneficial effects of constitutive NO activity. Moreover, there is also evidence to suggest that some iNOS activity is important in normal bone physiology. Thus, while modulation of NOS activity has important therapeutic implication in bone biology and pathology there is still much research required before this becomes commonplace. Continued investigation of NOS gene knockouts, together with developments in the generation of more selective NOS inhibitors and NO donor compounds should provide more definitive information on the cellular targets and mechanisms of action of NO.

Conclusions

The predominant NOS isoforms expressed by bone tissues are eNOS and iNOS and both are present in osteoblasts, osteocytes, and osteoclasts. Synthesis of NO by these cells is stimulated by a variety of signals including hormones, cytokines, and mechanical loading resulting in number of distinct physiological and pathophysiogical responses (Figs. 10 and 11).

PHYSIOLOGY

1. At low concentrations possibly associated with eNOS activity NO stimulates osteoclast contraction and detachment from bone surfaces, and may promote bone resorption by regulating osteoclast movement
2. At higher concentrations, possibly associated with "constututive" iNOS activity, NO inhibits osteoclastic resorption possibly by inducing apoptotic cell death in osteoclast precursors and inhibiting acid phosphatase activity in mature cells.
3. eNOS-dependent NO generation stimulates osteoblast replication and differentiation experimentally. Similar effects are evident *in vivo* where NO facilitates fracture healing and is essential for stress-induced bone formation.
4. Perhaps most importantly NO is significant in mediating the osteogenic effects of estradiol.

PATHOPHYSIOLOGY

1. Disruption of eNOS activity, secondary to estrogen deficiency can contribute to reduction in bone formation and the development of osteoporosis.

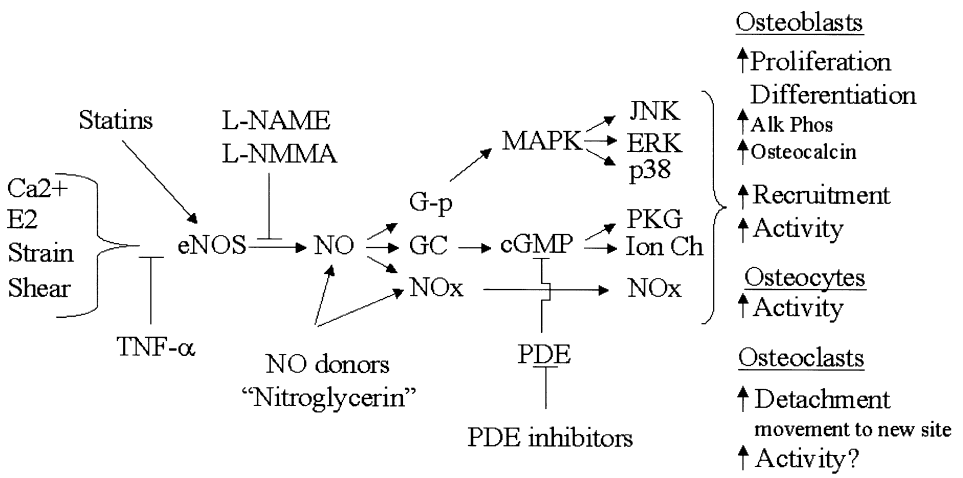

Figure 10 Diagrammatic overview of mechanism of eNOS activation and NO-mediated signaling pathways in bone cells. For detailed discussion refer to main body text. ERK, extracellular signal-regulated kinase; GC, guanylyl cyclase; G-p, G-proteins; Ion Ch, ion channel proteins; JNK, c-Jun N-terminal kinase; MAPK, mitogen-activated protein kinase; NOx, nitric oxide related species; PKG, protein kinase G.

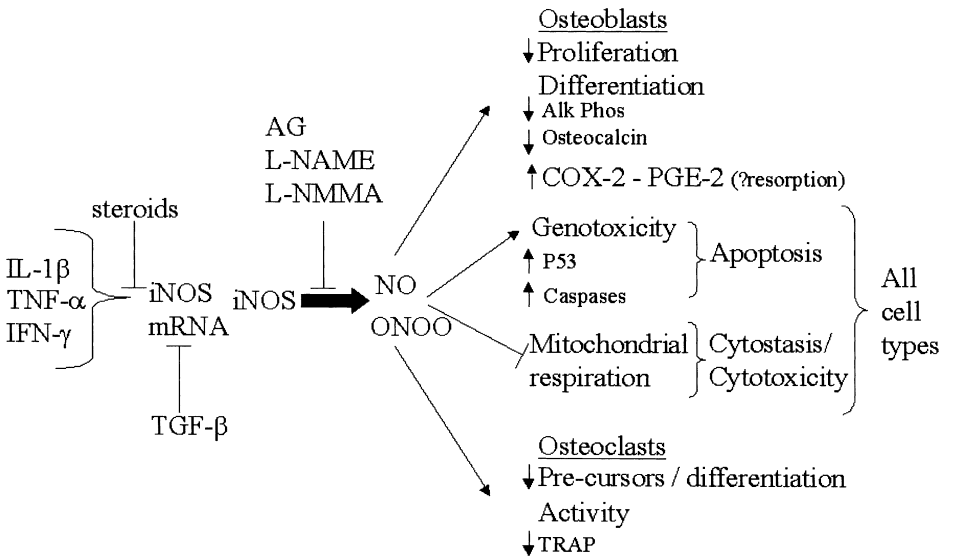

Figure 11 Diagrammatic overview of mechanism of iNOS activation and NO-mediated signaling pathways in bone cells. For detailed discussion refer to main body text. ERK, extracellular signal-regulated kinase; GC, guanylyl cyclase; G-p, G-proteins; Ion Ch, ion channel proteins; JNK, c-Jun N-terminal kinase; MAPK, mitogen-activated protein kinase; PKG, protein kinase G.

2. Inflammation-induced activation of iNOS expression and activity is strongly associated with the development and progression of cartilage and bone lesions that characterize arthritis. *In vitro,* osteoblasts appear to be the predominant source of iNOS-derived NO inducing cell death in osteoblasts themselves, (osteocytes) and osteoclasts.

In summary, NO changes the balance of bone metabolism in favor of formation both by stimulating osteoblast replication differentiation and inhibiting osteoclast action. High concentrations of NO are likely to be damaging in diseases such as rheumatoid arthritis where iNOS is induced. Obviously with this wide range of functions there are possibilities of therapeutic intervention. However, this has so far not been adequately investigated. Thus, although a role for modulation of NO synthesis in the prevention and treatment of diseases like osteoporosis and arthritis or in the process of fracture healing seems feasible this and the other possibilities of therapeutic intervention remain to be exploited.

Other Vasoactive Agents

These include the members of the calcitonin family, the prostaglandins, endothelin, natriuretic peptides and VEGF. The calcitonin family all act as osteoclast inhibitors. Calcitonin is much the most potent while the other members of the group all share vasoactive actions and osteoclast inhibitory effects. Only calcitonin has been thoroughly studied for its action on bone and this is well described elsewhere. Briefly, calcitonin acts directly on the osteoclast to produce a marked inhibition primarily via activation of adenylate cyclase but also involving an increase in intracellular calcium. The prostaglandins have a complex but very important set of actions of bone and these are described elsewhere in this volume. Interestingly, NO is know to activate COX and increase prostaglandin synthesis (Salvemini *et al.,*1993) and may be important in bone cell function (Hughes *et al.,* 1999). Endothelin has not been studied extensively but has been reported to have an osteoclast inhibitory effect. (Alam *et al.,* 1992; Zaidi *et al.,*1993). The effects of endothelins on osteoblast function appear to be contradictory and species-specific. In rodent osteoblast cultures endothelins inhibit osteoblast differentiation (Hiruma *et al.,* 1998; Inoue *et al.,* 2000), whereas in human cultures endothelins promote osteoblast differentiation and mineralization (Kasperk *et al.,* 1996; Nelson *et al.,* 1999).

C-type natriuretic peptide is significant in the physiological control of endochindral ossification and in osteoblast proliferation differentiation (Suda *et al.,* 1996; Yasoda *et al.,* 1998; Mericq *et al.,* 2000; Inoue *et al.,* 2000). In some respects the actions of natriuretic peptide is not unlike those of NO. Finally, VEGF is an important vasoactive factor that plays a fundamental role in endochondral ossification (Gerber *et al.,* 1999).

CHAPTER 56

Molecular Basis of PTH Overexpression

Geoffrey N. Hendy

Andrew Arnold
Center for Molecular Medicine and Division of Endocrinology and Metabolism, University of Connecticut School of Medicine, Farmington, Connecticut 06030

Introduction

Over the past several years application of powerful molecular biology techniques has provided a wealth of new information and insights into the development of tumors. The purpose of this chapter is to review this new information as it relates to our understanding of parathyroid tumorigenesis. Parathyroid hyperfunction is found in several disease states including sporadic primary and secondary hyperparathyroidism and familial disorders such as the multiple endocrine neoplasia (MEN) syndromes.

Primary hyperparathyroidism is a common disorder characterized by hypercalcemia caused by an excessive secretion of parathyroid hormone (PTH). This is due to both an increased parathyroid gland mass and a resetting of the control of PTH secretion from the parathyroid cell by the ambient calcium concentration. Patients with primary hyperparathyroidism have one or more enlarged parathyroid glands with a single, benign adenoma occurring in almost 85% of cases, while multiple hypercellular glands are present in about 15% of patients (Black and Utley, 1968; Castlemen and Roth, 1978). In modern series, parathyroid carcinoma occurs in less than 1% of cases, and the ectopic secretion of PTH from nonparathyroid tumors is extremely rare (Powell *et al.,* 1973; Simpson *et al.,* 1983).

The refractory state of secondary hyperparathyroidism, as seen, for example, in patients with uremia, and tertiary hyperparathyroidism (Galbraith and Quarles, 1994) are characterized by hyperfunctioning parathyroid tissue that no longer responds appropriately to physiological regulators such as ambient calcium and 1,25-dihydroxyvitamin D ($1,25(OH)_2D$).

Hyperparathyroidism may also occur as part of familial syndromes, such as multiple endocrine neoplasia types 1 and 2 (MEN 1 and 2), the hereditary hyperparathyroidism and jaw tumor (HPT-JT) syndrome, and familial hypocalciuric hypercalcemia (FHH) and neonatal severe hyperparathyroidism (NSHPT).

Molecular Oncology

Cancer cells contain genetic damage to key growth-regulating genes that directly contributes to the abnormal neoplastic phenotype. A cardinal feature of cancers is their clonal, or monoclonal, nature. They arise from a single precursor cell which has a selective growth advantage over normal cells and whose progeny outgrow them and ultimately make up the tumor (Fig. 1, see also color plate). Typically, certain identical patterns of DNA damage are seen in each cell of such a tumor, indicating that important underlying genetic events occurred early before major proliferation or clonal expansion took place. The clonality of tumors also implies that these

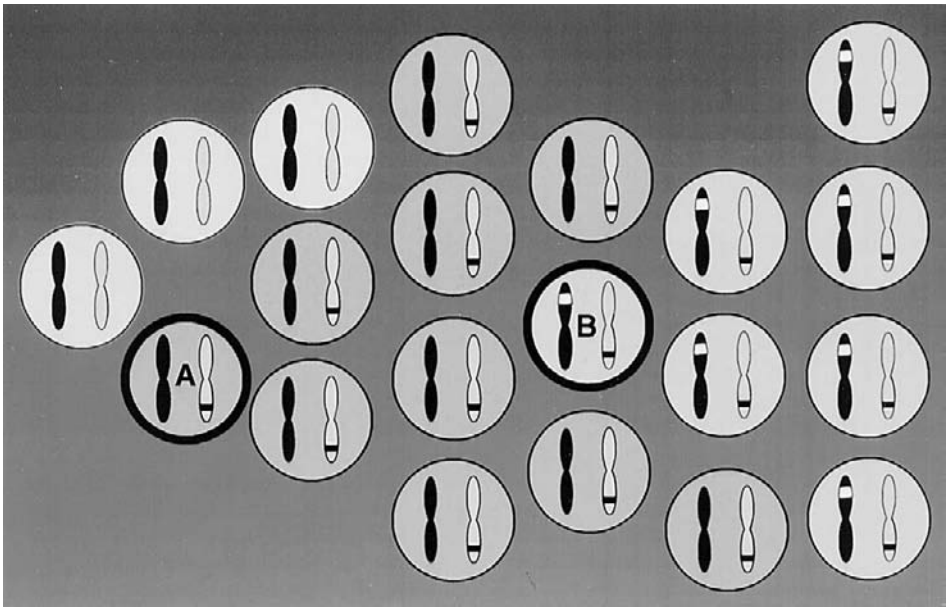

Figure 1 Schematic representation of early genetic events occurring in the development of a clonal tumor. In cell A, DNA damage has occurred to a set of key regulatory genes (one is shown here), which together confer a selective growth advantage to its progeny of identical daughter cells. In clonal precursor cell B, an additional oncogenic "hit" occurs, affecting a different gene, conferring a further growth advantage on its progeny which then overgrow all other cells to form the eventual clonal tumor; this represents the process of clonal evolution. (See also color plate)

events occur only rarely in the large population of cells making up a tissue.

It is important to note the molecular heterogeneity underlying the development of neoplasia (Vogelstein and Kinzler, 1993). Generally, accumulating damage to several distinct genes, within the same cell, is required for the expression of the complete neoplastic phenotype. While certain genes are implicated in tumors of only one or a few cell types, other genes may be involved in many different types of tumor. However, in most cases, no single gene will be both a necessary and a sufficient neoplastic agent. More commonly, the emergence of a particular tumor type may relate to disruption of a specific biochemical pathway, which can be achieved by different combinations of mutated genes resulting in similar cellular and clinical consequences.

Clonal DNA damage in two groups of normal cellular genes contributes to the development of neoplasia. These are protooncogenes and tumor suppressor genes. Protooncogenes are often involved in the physiological control of cellular growth, proliferation, or differentiation. Conversion of a protooncogene to an "oncogene" is caused by a deregulation of the expression of its protein product or by formation of an intrinsically abnormal product. The products of tumor-suppressor genes normally restrain cellular proliferation and their gene inactivation contributes to neoplasia. Protooncogenes can be activated by a variety of mechanisms, including chromosome translocations or inversions, point mutations, proviral insertions, or gene amplification. Inactivation of tumor-suppressor genes can occur by point mutation or deletion, for example.

Clonality of Parathyroid Tumors

Early studies of the clonal status of parathyroid tumors assessed X-chromosome inactivation patterns by measuring isoforms of glucose-6-phosphate dehydrogenase in parathyroid adenomas of women heterozygous for the polymorphism. These studies produced the surprising finding that parathyroid adenomas were polyclonal as opposed to monoclonal growths (Fialkow *et al.,* 1977; Jackson *et al.,* 1982). However, several years later the issue of the clonal status of parathyroid tumors was reexamined using an X-chromosome inactivation method, but this time evaluating DNA polymorphisms, which avoided potential pitfalls in the protein approach, and by the direct demonstration of monoclonal DNA alterations in parathyroid adenomas (Arnold *et al.,* 1988). It was determined that most, if not all parathyroid adenomas are in fact monoclonal (Arnold *et al.,* 1988; Arnold and Kim, 1989; Friedman *et al.,* 1989; Bystrom *et al.,* 1990; Orndal *et al.,* 1990), emphasizing that they are true neoplastic outgrowths of a single abnormal cell. This is consistent with the general experience that surgical removal of such tumors is curative of the disease. As would be expected, parathyroid carcinomas are also monoclonal (Cryns *et al.,* 1994b). In addition, monoclonal parathyroid tumors are seen in familial MEN 1 (Friedman *et al.,* 1989; Thakker *et al.,* 1989; Bystrom *et al.,* 1990), in nonfamilial, sporadic, primary parathyroid hyperplasia (Arnold *et al.,* 1995), and in the refractory secondary or tertiary parathyroid hyperplasia of uremia (Arnold *et al.,* 1995; Falchetti *et al.,* 1993). Therefore, even in parathyroid hyperplasia, which begins with a stimulus for

generalized, polyclonal, parathyroid cell proliferation affecting all of a patient's glands, monoclonal tumors can arise, at least in some of the glands. Such tumors may be more autonomous, and exhibit a more marked dysregulation of PTH secretory control than the hyperplastic, polyclonal glands within the same patient.

An important goal is to identify the specific protooncogenes and tumor suppressor genes that are clonally activated or inactivated, respectively, in parathyroid tumors. Several successes in approaching this aim have already been achieved.

Genetic Derangements in Benign Parathyroid Tumors

DNA rearrangements are some of the best characterized clonal oncogenic abnormalities, and they frequently involve juxtaposition of cellular protooncogenes with regulatory sequences of other genes. This then results in overexpression or deregulated expression of the protooncogene, converting it to an oncogene. To date the only oncogene implicated in parathyroid neoplasia is cyclin D1/*PRAD1*.

Cyclin D1/*PRAD1*

The critical observation in the identification of *PRAD1* was of an abnormally sized band on a Southern blot of DNA from a parathyroid adenoma probed with a PTH genomic fragment (Arnold *et al.,* 1988). A tumor-specific DNA rearrangement separated the 5′ regulatory region and noncoding exon 1 of the *PTH* gene from its protein coding exons with the tumor cells possessing one intact *PTH* gene which accounted for expression of PTH by the tumor. The non-*PTH* gene sequences adjacent to the breakpoint were cloned from a genomic DNA library made from this particular adenoma (Arnold *et al.,* 1989). This sequence was mapped by somatic cell genetics and *in situ* hybridization using normal genomic DNA to chromosome band 11*q*13, the *PTH* gene being located at 11*p*15. Thus, the most likely explanation for the observed tumor-specific DNA rearrangement was a pericentromeric inversion of chromosome 11 (Fig. 2). By Northern blot analysis, the novel DNA hybridized to a distinct 4.5-kb transcript which was present in RNA from a variety of tissues—it was not specific for the parathyroid—however, it was markedly overexpressed in the original parathyroid adenoma from which the DNA had been cloned, relative to other parathyroid tissue (Motokura *et al.,* 1991; Rosenberg *et al.,* 1991). This sequence, which was highly conserved among species, was considered as a putative oncogene, and designated *PRAD1,* for parathyroid adenomatosis 1.

The normal chromosomal *PRAD1* gene contains five exons and four introns spanning approximately 15 kb and is transcribed in a centromeric to telomeric direction (Motokura and Arnold, 1993). In the cases of PTH/*PRAD1* rearrangements characterized to date, the 11*q*13 breakpoints have occurred from 1 to 15 kb upstream of *PRAD1* exon 1 with the *PTH* gene 5′ regulatory region and noncoding exon 1 placed upstream of the breakpoint (Friedman *et al.,* 1990; Rosenberg *et al.,* 1991) (Fig. 3). The overexpression of the *PRAD1* gene is thought to be caused by its aberrant placement in close proximity to the strong tissue-specific enhancer elements of the *PTH* gene (Rosenberg *et al.,* 1993).

At least 5% of parathyroid adenomas contain an activated form of the *PRAD1* oncogene. However, rearrangement breakpoints on 11*q*13 associated with overexpression

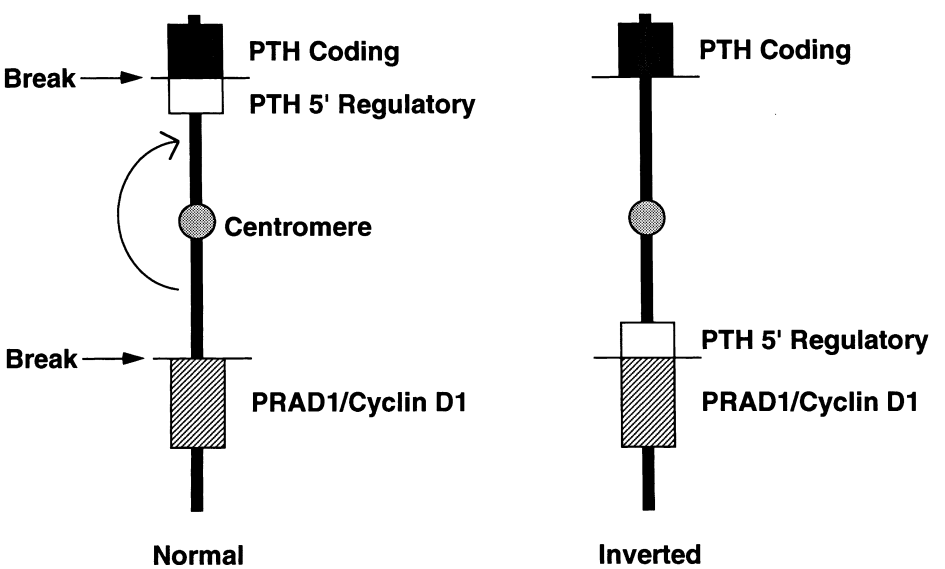

Figure 2 Schematic diagram of rearrangement of chromosome 11 in parathyroid tumors. In a subset of parathyroid adenomas a pericentrometric inversion of chromosome 11 is the most likely cause of the observed rearrangement involving the *PTH* gene and the *PRAD1* gene. Each tumor has another copy of chromosome 11 which bears a normal *PTH* gene. Reproduced with permission from Arnold (1993).

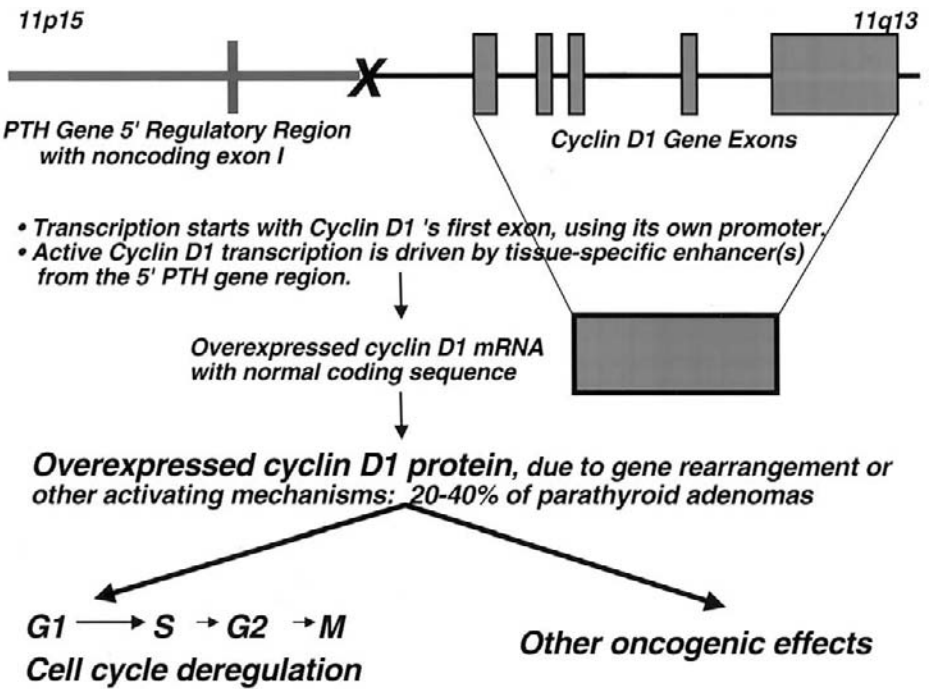

Figure 3 Diagram of directly observed molecular structure of the *PTH/cyclin D1* (*PRAD1*) DNA rearrangement and its functional consequences. Modified with permission from Arnold (1993).

of the *PRAD1* gene in other tumors can occur more than 120 kb upstream of the *PRAD1* gene (Williams *et al.,* 1993; Vaandrager *et al.,* 1996, 1997). These types of rearrangement would have been missed by the Southern blot approach used in initial studies of parathyroid tumors. In addition, PRAD1 expression could be deregulated in some parathyroid tumors by rearrangement with genes other than the *PTH* gene. Therefore, previous studies may not have revealed the full frequency with which *PRAD1* deregulation occurs in parathyroid neoplasia. Recent studies assessing the PRAD1 protein product have indicated that *PRAD1* is in fact overexpressed in 20–40% of parathyroid adenomas (Hsi *et al.,* 1995; Vasef *et al.,* 1999; Tominaga *et al.,* 1999). This may occur more commonly therefore by a *trans*-acting regulatory disturbance like that observed for *PRAD1* overexpression in a variety of human cancer cells (Hosokawa and Arnold, 1998) rather than a clonal mutation in one gene allele.

When the normal cDNA for *PRAD1* was cloned from a human placental cDNA library (Motokura *et al.,* 1991), it was revealed to encode a 295-amino-acid protein which was homologous to various members of the cyclin class of proteins. Cyclins play important roles in regulation of cell cycle progression, and human cyclins have been grouped into several types based upon sequence similarities (Pestell *et al.,* 1999). Each cyclin appears to regulate the cell cycle at a specific time point by binding to and activating cyclin-dependent kinases (CDKs) (Sherr, 1996). Expression of these cyclins is cell cycle phase-dependent and controlled by both transcriptional and posttranscriptional mechanisms.

The *PRAD1* product was designated as cyclin D1, and a large body of evidence is consistent with its role as a G1 cyclin (Sherr, 1996). As such, cyclin D1 can function as a key regulator of the critical G1–S phase transition in the cell cycle. In so doing, its major cdk partners are cdk4 or cdk6, depending upon the tissue type examined. It may also be that cyclin D1 has other cellular functions, mediated through non-cdk-dependent pathways (Bernards, 1999).

An important biochemical pathway in which D-type cyclins participate involves the protein product of the retinoblastoma tumor suppressor gene *RB*. The RB protein (pRB) is a key regulator of the G1–S transition in the cell cycle and is phosphorylated in a cell-cycle-dependent fashion (Weinberg, 1995). In early G1, pRB is hypophosphorylated and in this state is able to bind and inhibit the activity of transcription factors such as E2F. Later in G1, pRB becomes hyperphosphorylated and releases these factors which then drive the cell into S phase. Cyclin D1/cdk4 appears to be an important contributor to the early phosphorylation of pRB. For parathyroid tissue in particular, however, the major cdk (or other) partner and preferred substrates for cyclin D1/cdk activity remain to be determined. In benign tumors such as parathyroid adenomas, overexpression or deregulated expression of a G1 cyclin such as cyclin D1 could accelerate the cell's progress through G1 into S phase or move cells from quiescence (G0) into cycling mode, tilting the balance toward increased cellular proliferation (Fig. 3) without necessarily conferring a full malignant phenotype.

Animal modeling has provided further evidence that cyclin D1 overexpression is capable of driving parathyroid tumorigenesis. A transgenic mouse model for parathyroid

neoplasia has been generated (Imanishi *et al.,* 2001). The mice harbor a transgene in which the cyclin D1 gene is under the control of the regulatory region of the *PTH* gene, mimicking the rearrangement and resultant overexpression observed in the human tumors. These mice develop hyperparathyroidism as evidenced by parathyroid enlargement and increased serum calcium and PTH levels and constitute a potentially useful model of human mild chronic hyperparathyroidism.

Tumor Suppressor Genes: *MEN1*

Inactivation of both alleles of a tumor suppressor gene, often by mutation or deletion, is required to completely deplete the gene's antineoplastic product. A common inactivation mechanism is somatic deletion of a substantial portion of chromosomal DNA that includes the relevant gene. This is revealed by a loss of heterozygosity of DNA markers in tumor DNA relative to normal DNA of the same individual. Identification of regions of chromosomes that are clonally and nonrandomly lost in parathyroid adenomas can indicate the general locations of tumor suppressor genes active in parathyroid cells. Our present state of knowledge in this regard shows that over 70% of parathyroid adenomas (and possibly all) have at least one such clonal defect.

The MEN1 syndrome, which is inherited in an autosomal dominant fashion, is characterized classically by tumors of the parathyroids, pancreatic islets and anterior pituitary. Several years ago, it was established by genetic mapping studies in families affected by MEN1, that the gene responsible is on chromosome 11*q*13 (Larsson *et al.,* 1988; Friedman *et al.,* 1989; Thakker *et al.,* 1989). By analogy with familial retinoblastoma and Li-Fraumeni syndromes, which involve inheritance of mutations in the *RB* and *p53* genes, it was suggested that the *MEN1* gene was a tumor suppressor gene. Early evidence for this was provided by the demonstration of somatic genetic alterations in MEN1 tumors which inactivate one allele of a gene region at 11*q*13 and so reveal the inherited MEN1 mutation on the other allele (Fig. 4). In fact, allelic loss of polymorphic marker DNAs from this region of chromosome 11 has been found in the majority of MEN1-associated tumors including those of the parathyroid (Larsson *et al.,* 1988; Friedman *et al.,* 1989, 1992; Bystrom *et al.,* 1990; Thakker *et al.,* 1989; Radford *et al.,* 1990).

Allelic loss of chromosome 11 markers also occurs in about 25–35% of the large number of sporadic parathyroid adenomas that have been examined (Bystrom *et al.,* 1990; Friedman *et al.,* 1992; Tahara *et al.,* 1996a). This allelic loss, usually but not invariably, involves the region to which the *MEN1* gene has been mapped. By analogy to the *RB* tumor suppressor gene model in which the sporadic, nonfamilial, counterpart of the retinoblastoma tumor results from somatic genetic events, leading to loss or inactivation of both normal *RB* gene alleles (see Fig. 4), these findings suggested that some sporadic parathyroid adenomas may evolve from a clonal precursor cell in which both copies of

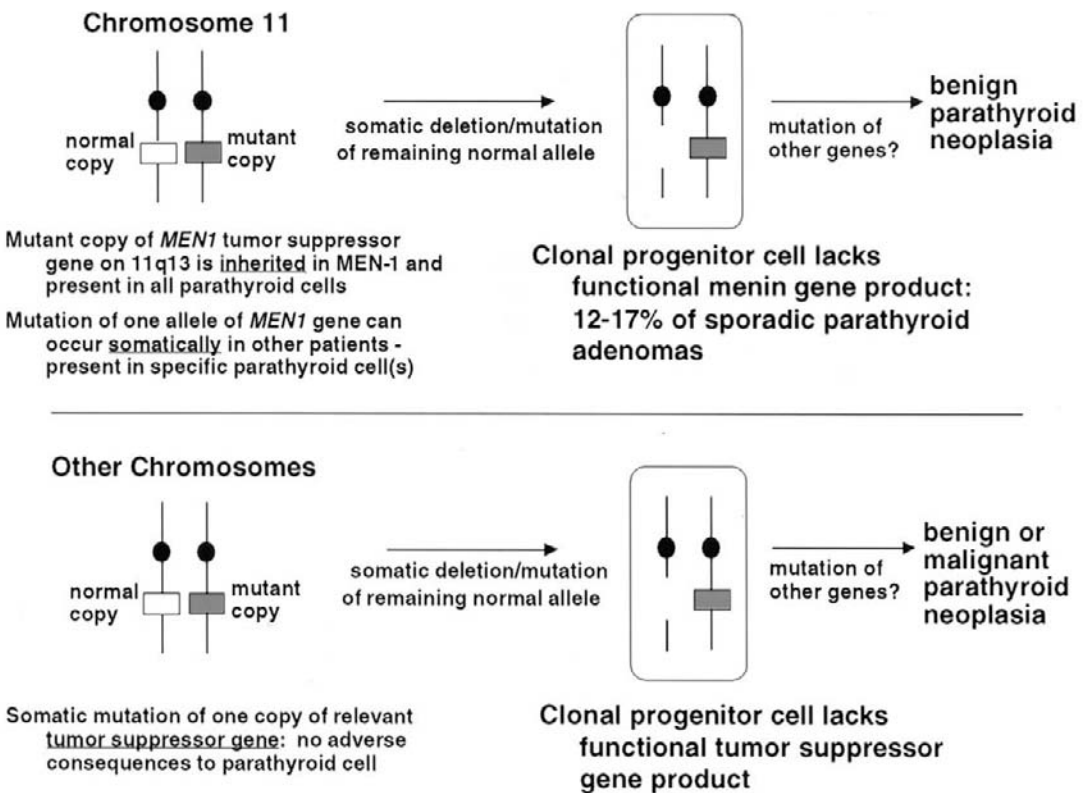

Figure 4 Schematic diagram illustrating the established (for *MEN1*) and hypothesized roles of inactivation of classic tumor suppressor genes as contributory mechanisms in parathyroid neoplasia. Modified with permission from Arnold (1993).

the *MEN1* gene have been inactivated. The recent identification of the *MEN1* gene (see below) has permitted a more direct examination of this hypothesis. Somatic mutation and/or deletion of *MEN1,* resulting in its complete inactivation, has been documented in 12–17% of sporadic parathyroid adenomas (Heppner *et al.,* 1997; Carling *et al.,* 1998; Farnebo *et al.,* 1998a). Interestingly, this 12–17% constitutes only about half of the parathyroid adenomas with allelic losses of 11*q*13. While noncoding mutations in *MEN1,* which would have been missed in these analyses, might be the explanation for some or all of this gap, the magnitude of the discrepancy when compared with other tumor suppressors raises the possibility that a different tumor suppressor gene on chromosome 11 might be the relevant target of mutation in many of the parathyroid adenomas with 11*q* allelic losses.

The *MEN1* gene was identified by positional cloning (Chadrasekharappa *et al.,* 1997; European Consortium on MEN1, 1997). Over 250 independent germ-line and somatic mutations scattered throughout the protein coding region have been identified (see Marx *et al.,* 1999; Pannett and Thakker, 1999, and references therein). There is no correlation between genotype, meaning the specific location of mutation within the gene, and phenotype. Somatic mutations have been found to a variable extent in parathyroid adenoma as well gastrinoma, insulinoma, lung carcinoid, and anterior pituitary tumors. Many of the mutations are clearly inactivating, leading to a truncated product. This would be consistent with *MEN1* acting as a tumor suppressor gene and a lack of the menin protein caused by the loss of both alleles leading to tumor development. The human gene encodes a 610-amino-acid protein with homology to no known protein nor any obvious conserved motifs that would provide clues to its function. Two nuclear localization signal sequences have now been identified at the COOH-terminal portion of the menin protein, which is predominantly located in the nucleus (Guru *et al.,* 1998; Kaji *et al.,* 1999). Menin interacts with the activator protein 1 factor, JunD, and represses JunD-activated transcription (Agarwal *et al.,* 1999). JunD can be considered to be antimitogenic, in contrast to other Jun and Fos family members. Therefore, the repressive effect of menin on JunD-mediated transcriptional activation is paradoxical, and the physiologic or pathophysiologic significance of menin and JunD binding has not been established. The level of menin changes throughout the cell cycle. Pituitary cells synchronized at the G1-S-phase boundary express menin at a lower level than G0–G1-synchronized cells (Kaji *et al.,* 1999). The expression of menin increases as the cell enters S phase, at which time JunD expression also increases. Cells synchronized at the G2–M phase express lower levels of menin. Thus, the emerging knowledge of menin suggests that it functions in transcriptional regulation, DNA replication, or cell cycle control. Stable overexpression of menin in *ras*-transformed NIH3T3 cells inhibits cell growth and tumor formation in nude mice, providing some direct evidence of menin acting as a tumor suppressor (Kim *et al.,* 1999).

A mechanism of tumorigenesis by menin inactivation is suggested by the finding that menin antisense RNA antagonizes TGF-β-mediated cell growth inhibition. Menin interacts with Smad3 and its inactivation suppresses TGF-β- and Smad3-induced transcriptional activity (Kaji *et al.,* 2001).

Putative Oncogenes and Tumor Suppressor Genes

Comparative genomic hybridization—a molecular cytogenetic technique in which the entire tumor genome is screened for chromosomal gains and/or losses—has identified amplified regions on several chromosomes (most consistently 7, 16, and 19) (Fig. 5). These observations suggest the presence of novel parathyroid oncogenes (Palanisamy *et al.,* 1998; Agarwal *et al.,* 1998; Farnebo *et al.,* 1999) in these locations, which remain to be identified.

Besides loci on chromosome 11, several other regions of nonrandom clonal allelic loss have been documented in parathyroid adenomas, pointing to the location of novel tumor suppressor genes. This finding of the involvement of multiple chromosomal regions, which include 1*p* (Cryns *et al.,* 1995a; Williamson *et al.,* 1997), 1*q* (Cryns *et al.,* 1995b), 6*q,* 9*p,* and 15*q* (Tahara *et al.,* 1996a,b), emphasize the molecular heterogeneity of parathyroid adenomatosis.

Comparative genomic hybridization has confirmed the chromosomal losses identified by loss of heterozygosity analysis (allelotyping) (Palanisamy *et al.,* 1998; Agarwal *et al.,* 1998; Farnebo *et al.,* 1999) (Fig. 5, see also color plate). One common defect uncovered to date involves allelic loss on chromosome 1*p* (Cryns *et al.,* 1995a). Interestingly, chromosome 1*p* loss occurs in several other neoplasms including medullary thyroid carcinomas and pheochromocytomas (Mathew *et al.,* 1987; Khosla *et al.,* 1991; Moley *et al.,* 1992; Mulligan *et al.,* 1993a), which occur in association with the MEN2A inherited cancer syndrome, of which parathyroid tumors are also a part. Benign parathyroid tumors are found in 10–20% of MEN2A patients (Schimke, 1984; Gagel, 1998). This pattern of allelic loss is consistent with the existence of a tumor suppressor gene(s) on 1*p,* whose loss or inactivation is pathogenetically important. Numerous candidate genes are present in this region, the involvement of any of them in the development of parathyroid or other types of tumors remains to be established. Some candidates on 1*p,* such as genes for the *p*18 cyclin-dependent kinase inhibitor, and *RAD54* have been excluded as parathyroid tumor suppressors (Tahara *et al.,* 1997; Carling *et al.,* 1999a). Candidate genes within the 9*p* region for the *p*16 and *p*15 cyclin-dependent kinase inhibitors do not appear to be involved in parathyroid tumorigenesis (Tahara *et al.,* 1996b). A major goal for future work is the identification of the entire constellation of oncogenes and tumor suppressor genes that contribute to the development of parathyroid adenomatosis.

It had been assumed that primary parathyroid hyperplasia and uremic refractory secondary hyperparathyroidism involved polyclonal, nonneoplastic cellular proliferation. However, the monoclonal nature of a substantial number of

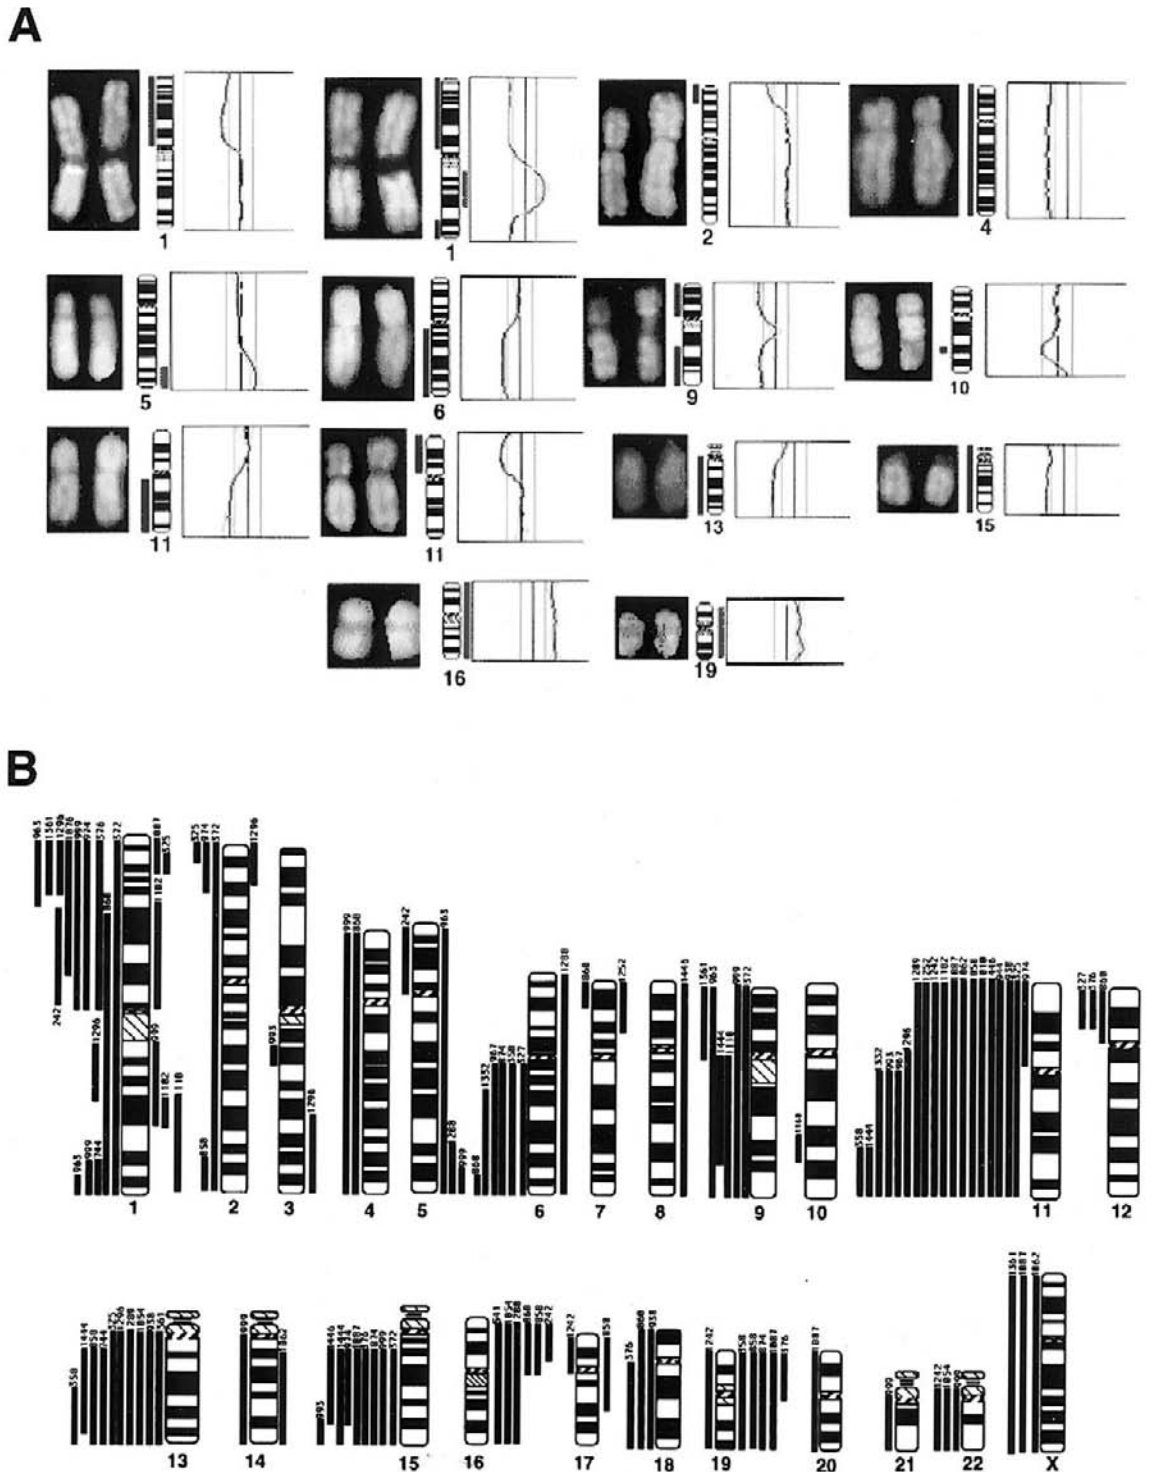

Figure 5 Novel chromosomal abnormalities identified by comparative genomic hybridization (CGH) in parathyroid adenomas. (A) Representative CGH results in parathyroid adenomas. Individual examples of fluorescent ratio profiles (right) and digital images (left) of chromosomes with recurrent gains or losses. The red vertical bar on the left side of a chromosome ideogram (middle) indicates the region of loss and the green vertical bar on the right side of an ideogram indicates the region of gain. (B) DNA copy number changes in 53 parathyroid adenomas. Summary of all gains and losses detected by CGH. The vertical bars on the left side of the chromosome ideograms indicate losses and those on the right side indicate gains of the corresponding chromosomal region for each individual tumor, as numbered. Adapted with permission from Palanisamy *et al.* (1998). (See also color plate.)

the "hyperplastic" tumors from such patients has recently been demonstrated to be monoclonal by X-chromosome inactivation analysis (Arnold *et al.,* 1995). In addition, allelic loss of chromosome 11 markers and/or *MEN1* gene inactivation has been demonstrated in only a few of these types of tumor (Falchetti *et al.,* 1993; Arnold *et al.,* 1995; Farnebo *et al.,* 1997a; Inagaki *et al.,* 1998; Imanishi *et al.,* 1997, 1999a). Furthermore, cyclin D1 overexpression does not appear to be common in these uremia-associated tumors (Vasef *et al.,* 1999; Tominaga *et al.,* 1999), nor is mutation of the vitamin D receptor (VDR) gene, despite the reportedly low expression of this parathyroid cell antiproliferative factor in such tumors (Brown *et al.,* 2000). Neoplastic transformation of preexisting polyclonal hyperplasia involving genes not yet implicated in parathyroid tumorigenesis is thus likely to play an important role in these disorders.

Further Genetic Aspects

Some genes which play an important role in the pathogenesis of other tumor types might have been expected to be involved in the pathogenesis of benign parathyroid adenomas. However, candidate genes such as *ras* (Friedman *et al.,* 1990), *p53* (Yoshimoto *et al.,* 1992; Cryns *et al.,* 1994a; Hakim and Levine, 1994), and *RB* (Cryns *et al.,* 1994b) seem rarely, or not at all, to contribute to the development of benign adenomas. In a single parathyroid adenoma, a cytogenetic translocation between chromosomes 1 and 5 has been reported (Orndal *et al.,* 1990).

The development of primary hyperparathyroidism occurs with increased frequency in individuals exposed to ionizing radiation of the neck. Thus mutations in genes involved in DNA repair and recombination may contribute to parathyroid tumorigenesis irrespective of the actual involvement of irradiation. Such candidates include the *RAD51* and *RAD54* genes on chromosomes 15*q* and 1*p,* respectively, within regions that demonstrate allelic loss in parathyroid adenomas. However, no evidence for a role of somatic inactivation of these particular genes in parathyroid neoplasia has been found (Carling *et al.,* 1999a,b). In some cases, those genes responsible for the rare inherited predisposition to a particular tumor also play a role in the development of the more common sporadic type. The *MEN1* gene, as detailed earlier, has proved to be such an example. Germline gain-of-function mutations in the *RET* protooncogene cause MEN2 (Mulligan *et al.,* 1993b, 1994; Donis-Keller *et al.,* 1993; Carlson *et al.,* 1993; Eng *et al.,* 1996). This made the *RET* gene, which encodes a tyrosine kinase receptor, a candidate for involvement in nonfamilial hyperparathyroidism. However, although MEN2-type *RET* mutations have been implicated in the pathogenesis of some sporadic medullary thyroid carcinomas and pheochromocytomas (Eng *et al.,* 1994, 1995a, 1996; Hofstra *et al.,* 1994), there is no evidence of these *RET* mutations in sporadic parathyroid adenomas (Padberg *et al.,* 1995; Pausova *et al.,* 1996; Williams *et al.,* 1996; Komminoth *et al.,* 1996; Romei *et al.,* 1996; Kimura *et al.,* 1996). It was demonstrated that *RET* is expressed in both MEN2A parathyroid tumors and in sporadic adenomas (Pausova *et al.,* 1995, 1996; Kimura *et al.,* 1996). This suggests that parathyroid disease is an integral part of the MEN2A syndrome, but that MEN2 mutations in *RET* rarely, if ever, play a role in the pathogenesis of sporadic parathyroid tumors. Mutations within the coding region of glial cell-derived neurotrophic factor (GDNF), one of the RET ligands, do not appear to play a role in the genesis of MEN2 neoplasms or in sporadic neuroendocrine tumors such as parathyroid adenomas (Marsh *et al.,* 1997). An interesting candidate parathyroid tumor suppressor, the VDR, is also lacking in evidence for a direct pathogenetic role by specific clonal mutation (Wu *et al.,* 1996; Brown *et al.,* 2000).

Familial hypocalciuric hypercalcemia (FHH), also known as familial benign hypercalcemia, is an autosomal dominant disorder which is characterized by enhanced parathyroid function due to reduced sensitivity to extracellular calcium (Marx *et al.,* 1981; Law *et al.,* 1985). Mutations in the parathyroid calcium-sensing receptor (*CASR*) gene, located on chromosome 3*q*13.3–*q*21 (Janicic *et al.,* 1995a), are a primary cause of this disorder (Pollak *et al.,* 1993; Heath *et al.,* 1996; Janicic *et al.,* 1995b, Pearce *et al.,* 1995; see Hendy *et al.,* 2000 for review). Moreover individuals homozygous for such mutations present with neonatal severe hyperparathyroidism (NSHPT) with marked parathyroid hypercellularity (Pollak *et al.,* 1994) and members of some FHH kindreds atypically manifest hyperparathyroidism and surgical removal of the adenoma or hyperplastic glands is generally curative (Soie *et al.,* 1999; Carling *et al.,* 2000). The apparent link between parathyroid calcium-sensing and proliferative pathways suggested that somatic alterations in the *CASR* gene could be tumorigenic in sporadic parathyroid tumors. However, several studies have failed to document somatic mutation of the *CASR* gene as a significant factor in parathyroid tumorigenesis (Hosokawa *et al.,* 1995; Thompson *et al.,* 1995; Degenhardt *et al.,* 1998; Cetani *et al.,* 1999). It has been reported that more than half of the parathyroid glands of patients with primary and severe uremic secondary hyperparathyroidism show reduced CASR expression (Kifor *et al.,* 1995; Farnebo *et al.,* 1997b, 1998b; Gogusev *et al.,* 1997; Chikatsu *et al.,* 2000). Thus, despite somatic mutation of the *CASR* gene rarely if ever contributing to the pathogenesis of sporadic parathyroid tumors, mutations in growth deregulating genes may secondarily alter the calcium set-point, perhaps in part by decreasing expression of the CASR. A mutation in a gene involved in calcium set-point control might secondarily stimulate proliferation until the serum calcium concentration surpasses the abnormal set-point (Parfitt *et al.,* 1994). Data indicating that the growth rate of parathyroid tumors is generally low, but must have been higher earlier in their development (Parfitt *et al.,* 1994), are consistent with this hypothesis. Interestingly, calcium regulatory abnormalities found in transgenic mice with cyclin D1-driven hyperparathyroidism show that mutations in "set-point" genes need not be the primary instigators in this disease (Imanishi *et al.,* 2001).

The syndrome of hereditary hyperparathyroidism and jaw tumors (HPT-JT) is an uncommon autosomal dominant disorder characterized by recurrent parathyroid tumors and mandibular or maxillary tumors (and occasionally by renal lesions such as Wilms tumor, polycystic kidney disease, and renal hamartomas). Parathyroid carcinoma occurs at increased frequency in this syndrome. The gene responsible for this predisposition has been mapped to chromosome 1*q*21–*q*31 (Szabo *et al.,* 1995) and in more recent linkage studies the interval has been narrowed further (Hobbs *et al.,* 1999). Ultimate identification of this gene may possibly provide insight into the etiology of the more common forms of hyperparathyroidism. Familial hyperparathyroidism also occurs as an isolated endocrinopathy and in some cases could represent a variant of HPT-JT. The distinction between HPT-JT and familial isolated hyperparathyroidism (FIHP) may be difficult (Wassif *et al.,* 1999). In a subset of kindreds with apparent FIHP the disease mapped to the HPT-JT locus (Teh *et al.,* 1998a; Williamson *et al.,* 1999). The parathyroid tumors were single cystic adenomas with allelic loss of chromosome 1*q* markers. These cases were therefore suggested to be variants of HPT-JT with expression of hyperparathyroidism only. Loss of heterozygosity for markers on chromosome 13*q* has also been documented for some parathyroid tumors (adenomas and carcinomas) in FIHP (Yoshimoto *et al.,* 1998; Williamson *et al.,* 1999). Thus a tumor suppressor gene on 13*q* may be involved in the development of these tumors. Comparative genomic hybridization has been applied to a limited number of tumors from familial hyperparathyroid patients (Farnebo *et al.,* 1999). The tumors showed few alterations, but in one HPT-JT case loss of chromosome 13*q* was found and in three other cases not known to be linked to either the HPT-JT or MEN1 loci gain of chromosome 19*p* was noted.

Familial hyperparathyroidism occurring as an isolated endocrinopathy in some cases appears to represent a variant of MEN1. Such families may be considered as MEN1 phenocopies analogous to the subset of MEN2 cases represented as familial medullary thyroid carcinoma (FMTC) which, like other MEN2 cases, have RET mutations (Eng *et al.,* 1996). In those FIHP families linkage to, or tumor allelic loss of, 11*q*13 markers was found (Kassem *et al.,* 1994, 2000; Teh *et al.,* 1998a). The disease was multiglandular with no sex difference in penetrance. In these families novel missense mutations in the *MEN1* gene were later identified. Several families with isolated hyperparathyroidism have now been tested for *MEN1* germline mutations and in some mutations were found and not in others (Agarwal *et al.,* 1997; and reviewed in Marx *et al.,* 1999). The existence of familial hyperparathyroidism distinct from other described inherited disorders remains the subject of debate. However, one kindred has been described with apparent autosomal recessive inheritance of the hyperparathyroidism and large recurrent adenomas (Law *et al.,* 1983). The mode of inheritance in this family would set it apart from the other autosomal dominant disorders, although it may prove with further study, to be autosomal dominant with decreased penetrance.

Molecular Pathogenesis of Parathyroid Carcinoma

The cyclin D1 oncoprotein, overexpressed in 20–40% of adenomas, was found to be overexpressed in 10 of 11 (91%) parathyroid carcinomas in one study (Vasef *et al.,* 1999) and in 2 of 3 in another (Hsi *et al.,* 1996). This observation, which should be confirmed and extended, raises the possibility that cyclin D1 may play a critical and consistent role in parathyroid cancers, and that patients with this disease might be considered for eventual inclusion in clinical trials once novel anti-cyclin D1 therapies have been developed. The tumor suppressor genes *p53* and *RB* have been examined for abnormalities in malignant, as well as benign, parathyroid tumors. Allelic loss of the *p53* gene has been found occasionally in parathyroid carcinomas but direct mutations have not been described, and *p53*′s overall contribution to parathyroid cancer is minimal at best (Cryns *et al.,* 1994a; Hakim and Levine, 1994). In contrast, loss of chromosome region 13*q* which contains *RB, BRCA2,* and other potential parathyroid tumor suppressors, is likely to be a key factor in the pathogenesis of many parathyroid carcinomas (Cryns *et al.,* 1994b; Dotzenrath *et al.,* 1996; Pearce *et al.,* 1996; Imanishi *et al.,* 1999b; Kytola *et al.,* 2000). Similarly, loss of putative tumor suppressor genes in genomic regions including 1*p,* 3*q,* 4*q,* and 21*q* may be involved as significant factors in malignant parathyroid tumors (Cryns *et al.,* 1995; Imanishi *et al.,* 1999b; Kytola *et al.,* 2000; Agarwal *et al.,* 1998). Specific chromosome regional gains, suggesting the involvement of oncogenes, have been found in parathyroid carcinomas by comparative genomic hybridization (Imanishi *et al.,* 1999b; Kytola *et al.,* 2000; Agarwal *et al.,* 1998), but the involved genomic locations show little consistency among the existing reports and the results require confirmation by complementary methods. Interestingly, the patterns of molecular allelic losses and chromosomal losses in carcinomas as compared with adenomas suggests that parathyroid carcinomas tend to arise *de novo* rather than evolve from preexisting adenomas. Furthermore, genetic lesions that are specific for the malignant phenotype may be useful in making a molecular diagnosis, which would aid in overcoming the well known difficulties in distinguishing malignant versus benign parathyroid tumors histopathologically.

Ectopic Secretion of PTH

The ectopic secretion of PTH by nonparathyroid tumors is an extremely rare cause of hyperparathyroidism. The use of modern immunometric assays for PTH which show no cross-reactivity with PTHrP, the major cause of the hypercalcemia of malignancy, combined, in some cases, with molecular analysis using specific human *PTH* gene probes (Hendy *et al.,* 1981; Vasicek *et al.,* 1983), have suggested or confirmed the occurrence of this syndrome in several cases (Schmelzer *et al.,* 1985; Yoshimoto *et al.,* 1989; Nussbaum *et al.,* 1990; Strewler *et al.,* 1993; Rizzoli *et al.,* 1994; Nielsen *et al.,* 1996; Iguchi *et al.,* 1998).

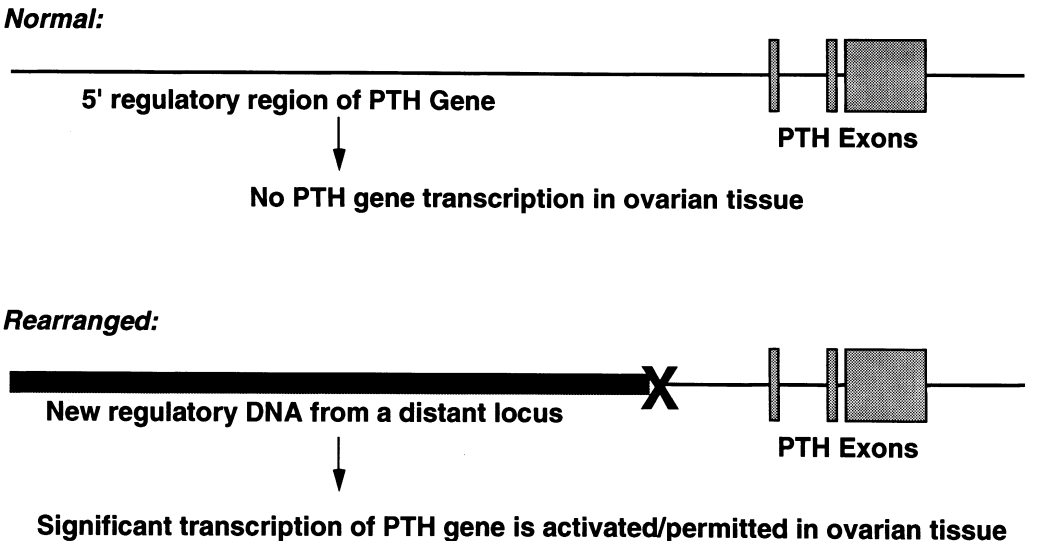

Figure 6 Molecular pathology of the ectopic production of PTH by an ovarian cancer. Schematic diagram of the normal PTH gene region (top) and the rearranged, amplified PTH gene region (bottom) in a PTH-secreting ovarian tumor. The bold "**X**" represents the breakpoint of the DNA rearrangement. Reproduced with permission from Arnold (1993).

In one case of an ovarian carcinoma (Nussbaum *et al.,* 1990), the molecular basis for the aberrant expression of PTH was determined. This involved a rearrangement (Fig. 6) and amplification of the *PTH* gene, such that it was no longer under the control of upstream regulatory elements which may normally act to silence *PTH* gene expression in nonparathyroid tissue. This case is also exceptional in its strong level of documentation that the tumor was in fact the source of the high circulating PTH levels and the patient's hypercalcemia.

Summary

Several advances have been achieved toward the goal of understanding the molecular basis of sporadic parathyroid tumorigenesis. The cyclin D1/*PRAD1* oncogene has been identified as a parathyroid oncogene, is overexpressed in 20–40% of parathyroid adenomas, and is also involved in the development of many additional tumor types. The gene responsible for MEN1 has been identified, and mutations in menin contribute to 12–17% of sporadic parathyroid adenomas. Mutations in the *RET* gene, the causal agent in MEN2, plus CASR and VDR, appear to contribute rarely if ever to the development of sporadic parathyroid tumors. The expected identification of additional major parathyroid tumor suppressor genes will no doubt provide further insights into parathyroid disease including parathyroid carcinoma. Ultimately, a description of parathyroid tumorigenesis will need to account for such features as the rarity of parathyroid carcinoma, the increased incidence of tumors after neck irradiation, and the increased frequency of hyperparathyroidism in postmenopausal women. In addition, the relationship between excessive cellular proliferation and an altered set-point in the mechanism linking extracellular calcium concentration to PTH secretion requires explanation and recently developed animal modeling of primary hyperparathyroidism may assist in this effort.

Discovery and Initial Description

Before the ready availability of inexpensive and accurate measurements of serum calcium concentration, the diagnosis of hypercalcemia was generally considered only when there were overt signs or symptoms to suggest it. Thus, most cases of hypercalcemia that were identified were severe and presented with urolithiasis, nausea and vomiting, weight loss, or renal insufficiency (Albright and Reifenstein, 1948; Trigonis *et al.,* 1983). In the late 1960s, automated multichannel serum chemical analyzers became widely used in the United States and western Europe, leading to "routine" measurement of serum calcium in large numbers of adult medical patients, many having no specific symptoms. This large-scale screening of the population revealed a hitherto-unsuspected group of mildly to moderately hypercalcemic individuals, most of whom turned out to have primary hyperparathyroidism (1° HPT) (Heath *et al.,* 1980). During the past two decades, the literature on mild 1° HPT has expanded enormously, and the syndrome of virtually asymptomatic 1° HPT is now recognized to be the most common form of the disease (Bilezikian *et al.,* 1991; Heath, 1991). Some forms of 1° HPT are inherited, such as in multiple endocrine neoplasia types 1 or 2A (Gagel, 1994; Metz *et al.,* 1994), the hyperparathyroidism–jaw tumor syndrome (Szabo *et al.,* 1995), or isolated familial 1° HPT (Law *et al.,* 1983; Wassif *et al.,* 1993, 1999). However, investigators studying families in which hypercalcemia seemed to be transmitted as an autosomal dominant trait recognized nearly 30 years ago that some kindreds differed in important ways from those having inherited neoplastic parathyroid disease. Jackson and colleagues reported a hypercalcemic family (the WAL kindred) in which the clinical and biochemical characteristics shared certain features with 1° HPT, but in whom surgical exploration of affected individuals neither revealed parathyroid adenomas nor cured the hypercalcemia (Jackson and Boonstra, 1967). These investigators recognized that this family might have a novel hypercalcemic syndrome (Jackson and Boonstra, 1966), but did they not give the disorder a specific name. Only in 1972 did Foley *et al.* offer the first detailed studies, clear description, and distinct name for this syndrome of benign, life-long hypercalcemia that is not associated with clear-cut parathyroid hyperplasia or adenomatosis: familial benign hypercalcemia (Foley *et al.,* 1972). Subsequent studies (D. A. Heath, 1989; H. Heath, 1989;

Table I Comparison of Characteristic Features of Familial Benign Hypocalciuric Hypercalcemia (FBHH), Familial Isolated Primary Hyperparathyroidism (Familial HPT), and Sporadic Primary Hyperparathyroidism (Sporadic HPT)

Variable	FBHH	Familial HPT	Sporadic HPT
Age of onset	At birth	Variable	Usually >40 years
Symptoms	Usually none	Variable	—Asymptomatic in 80% —Cortical bone loss —Urolithiasis in 20%
Serum-plasma level			
Calcium	Elevated	Elevated	Elevated
Magnesium	Normal to elevated	Variable	Variable
Phosphorous	Normal to mild decrease	Normal to very low	Normal to very low
$1,25(OH)_2D$	Normal	Normal to increased	Normal to increased
Intact PTH	Normal (80–85%) Elevated (15–20%)	Elevated in >80%	Elevated in >80%
Urinary excretion			
Cyclic AMP	Normal to mildly increased	High normal to increased	High normal to increased
Calcium	Normal to low	Low to elevated	Low to elevated
Ca:Cr clearance ratio	Generally < 0.01	Generally >0.03	Generally >0.02
Magnesium	Low	Normal to high	Normal to high
Other findings	Possibly increased risk of chondrocalcinosis, gallstones	Typical findings of HPT	Typical findings of HPT

Heath, 1994; Law and Heath, 1985; Marx *et al.,* 1981a; Menko *et al.,* 1983) reinforced and extended Foley's original description, establishing the disorder as having the characteristics shown in Table I.

A related familial disorder occurring in neonates, characterized by severe hypercalcemia, bone demineralization, respiratory distress, and failure to thrive, had been described several decades earlier (Hillman *et al.,* 1964; Landon, 1932; Philips, 1948). Spiegel *et al.* were the first to recognize the relationship of this syndrome, now known as neonatal severe hyperparathyroidism (NSHPT), to familial benign hypercalcemia (Cooper *et al.,* 1986; Lillquist *et al.,* 1983; Marx *et al.,* 1982, 1985; Matsuo *et al.,* 1982; Page and Haddow, 1987; Spiegel *et al.,* 1977; Steinmann *et al.,* 1984). Almost a decade before the molecular basis for these two related syndromes was identified, Marx *et al.* suggested that they represented the expression of homozygous and heterozygous abnormalities in calcium-sensing, respectively (Fujimoto *et al.,* 1990; Marx *et al.,* 1982, 1985).

Familial Benign Hypocalciuric Hypercalcemia

As just noted, Foley and colleagues provided the first full clinical description of this syndrome (Foley *et al.,* 1972) as well as the name familial benign hypercalcemia (FBH)—a simple but very descriptive and reassuring name. Later, investigators at the National Institutes of Health reported the same condition as familial hypocalciuric hypercalcemia (FHH) (Marx *et al.,* 1977), in recognition of the unexpectedly low urinary excretion of calcium in affected persons. The literature is about evenly divided between the use of these two names, i.e., FBH or FHH, to describe this clinical entity (D. A. Heath, 1989; H. Heath, 1989; Heath, 1994; Law and Heath, 1985; Marx *et al.,* 1981a, 1977; Menko *et al.,* 1983). A unifying term describing the key features of the syndrome, familial benign hypocalciuric hypercalcemia (FBHH), was proposed by Heath (1989) and later adopted by Strewler (1994). This unifying term will be used in this chapter.

Clinical and Basic Laboratory Characteristics of FBHH

The earliest kindreds reported to have FBHH usually had one family member who had been misdiagnosed as having 1° HPT and, therefore, had undergone surgical exploration, only to have either no histologic abnormality (the commonest finding) or subtle "hyperplasia" of the parathyroids identified (Davies *et al.,* 1981; D. A. Heath, 1989; Heath, 1994; Law and Heath, 1985; Marx *et al.,* 1981a, 1977; Menko *et al.,* 1983; Paterson and Gunn, 1981; Sereni *et al.,* 1982). In any event, even subtotal parathyroidectomy failed to normalize serum calcium levels. Subsequent family investigations often revealed someone else with failed neck exploration and/or a large number of hypercalcemic, but asymptomatic, individuals of widely varying ages within a given kindred. Approximately 9% of patients referred to the National Institutes of Health in the 1970s with failed parathyroid surgery turned out to have FBHH (Marx *et al.,* 1980). As the syndrome of FBHH became more widely recognized in the 1980s, the

syndrome began to be diagnosed before any family members were subject to unnecessary parathyroid surgery.

The FBHH Syndrome Is Clinically Benign

This rare hypercalcemic syndrome is inherited in an autosomal dominant fashion and is usually characterized by lifelong asymptomatic hypercalcemia, relative hypocalciuria and the lack of the classical complications of hypercalcemia, including bone disease and renal stone disease. General morbidity and mortality appeared to be essentially normal in series from the Mayo Clinic, and National Institutes of Health, as well as in studies by other investigators (D. A. Heath, 1989; H. Heath, 1989; Heath, 1994; Law and Heath, 1985; Marx *et al.,* 1977, 1981a; Menko *et al.,* 1983). Furthermore, almost all affected persons probably lack symptoms of hypercalcemia (Foley *et al.,* 1972; D. A. Heath, 1989; Law and Heath, 1985; Marx *et al.,* 1977; Menko *et al.,* 1983), although symptoms consistent with hypercalcemia have been described in some probands (Marx *et al.,* 1981a). The studies of Law and Heath (1985) suggest that selection, referral, and "coaching" biases account for the presence of symptoms among probands; that is, the probands see physicians for various reasons that lead to biochemical screening and the incidental discovery of hypercalcemia. Probands may undergo repeated questioning about possible symptoms of hypercalcemia and be prompted inadvertently to answer in the affirmative. Thus, probands in FBHH kindreds often have a variety of symptoms, but affected family members detected by screening generally have no more symptoms than unaffected persons (see Associated Clinical Findings, below).

Associated Clinical Findings

Some observers have suggested that FBHH increases the risk of acute pancreatitis (Damoiseaux *et al.,* 1985; Davies *et al.,* 1981; Falko *et al.,* 1984; Robinson and Corall, 1990; Toss *et al.,* 1989), but others have questioned the validity of this claim (Stuckey *et al.,* 1990). Indeed, Stuckey *et al.* evaluated 10 cases with FBHH and pancreatitis: in 8/10 cases there were potential confounders for pancreatitis such as alcohol abuse ($n = 5$) and biliary pathology ($n = 3$) (Stuckey *et al.,* 1990). Clearly, there is a potential for ascertainment bias; that is, patients presenting with acute pancreatitis commonly are examined for hypercalcemia. Thus, hypercalcemia would be found incidentally in any patient with FBHH who developed pancreatitis for any reason. *Post hoc ergo propter hoc* reasoning would then lead the physician to conclude that FBHH caused the pancreatitis. This remains an unresolved issue. It is possible, nonetheless, that under certain conditions the hypercalcemia of FBHH predisposes to or aggravates acute pancreatitis. There is one report of increased prevalence of chondrocalcinosis in FBHH families (Marx *et al.,* 1981a); and cholithiasis appeared to occur at increased frequency in FBHH kindreds (Law and Heath, 1985). The association of symptoms associated with FBHH was systematically studied by Law and Heath who administered an interview to 15 well documented families with FBHH: 82 individuals were hypercalcemic and 52 were normocalcemic first-degree relatives. Whereas nocturia, arthritis, gallstones, and arterial hypertension were significantly more common in the index cases than in normocalcemic individuals, only gallstones were found to occur with increased frequency in cases found solely by family screening (Law and Heath, 1985). These associations require systematic reevaluation in a greater number of FBHH kindreds.

The skeleton in patients with FBHH generally appears to be normal histologically, radiographically, and by mineral densitometry (Abugassa *et al.,* 1992; Gilbert *et al.,* 1985; D. A. Heath, 1989; H. Heath, 1989; Heath, 1994; Law and Heath, 1985; Law *et al.,* 1984c; Marx *et al.,* 1977, 1981a; Menko *et al.,* 1983; Monfort-Gourand, 1993). Some case reports have described increased bone turnover on biopsy of FBHH patients (Alexandre *et al.,* 1982; Kristiansen *et al.,* 1987; Sereni *et al.,* 1982), but the data are very limited. As previously stated, serum alkaline phosphatase levels are normal in most patients with FBHH (D. A. Heath, 1989; Marx *et al.,* 1977, 1981a; Menko *et al.,* 1983). It is not clear if the bone in patients with FBHH is altered in a manner similar to that described by others in patients with 1° HPT, who exhibit increased or preserved iliac crest trabecular bone connectivity accompanied by cortical thinning (Christiansen *et al.,* 1992; Parisien *et al.,* 1990). While FBHH does not appear to threaten skeletal integrity, it does not confer immunity to osteoporosis; certainly, we have observed elderly members of some FBHH kindreds to have had osteoporosis that was clinically indistinguishable from that expected for their ages (Heath, H., III, unpublished observations).

Probably because of the relative hypocalciuria in patients with FBHH, nephrolithiasis is extremely uncommon, but has, however, been described in a few cases (see Renal Function and Ion Excretion, below).

Biochemical Findings in FBHH

The biochemical picture in FBHH is also benign, but can be indistinguishable from that of mild-to-moderate 1° HPT (H. Heath, 1989). The only absolute finding is hypercalcemia, which represents a true elevation of serum and total and ionized calcium; serum protein concentrations are normal, and calcium binding is normal (D. A. Heath, 1989; H. Heath, 1989; Heath, 1994; Law and Heath, 1985; Marx *et al.,* 1977, 1981a; Menko *et al.,* 1983). There is a variable degree of hypophosphatemia, and while this finding can occasionally be marked, absolutely low values for serum phosphorous are uncommon. Serum total magnesium levels are increased on average to about the upper limit of normal, being absolutely elevated in no more than half of affected individuals (Marx *et al.,* 1981a). Serum alkaline phosphatase activity has been reported as elevated in some cases (Marx *et al.,* 1981a), but is usually normal (D. A Heath, 1989; H. Heath,

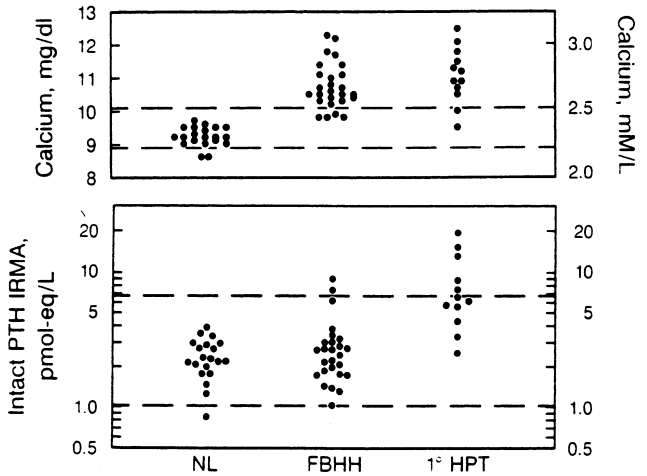

Figure 1 Serum calcium (top) and parathyroid hormone (PTH, bottom panel) concentrations in healthy adults (NL), patients with familial benign hypocalciuric hypercalcemia (FBHH), and patients with primary hyperparathyroidism (1 HPT) that was surgically verified. PTH was measured by a two-site immunoradiometric assay (Intact PTH, IRMA). Note the logarithmic scale for PTH. Normal ranges are indicated by horizontal dashed lines. Reprinted with permission from Rajala *et al.* (1991) *J. Bone Miner. Res.* **6,** 117–124.

1989; Heath, 1994; Law and Heath, 1985; Menko *et al.,* 1983). Other markers of bone turnover (e.g., osteocalcin or pyridinium cross-links) have not been reported in FBHH.

PTH levels have been measured in the serum of FBHH patients (Fig. 1) by first-generation radioimmunoassay (Kent *et al.,* 1987; Marx *et al.,* 1978b), cytochemical bioassay (Allgrove *et al.,* 1984), extraction-cell-based bioassay (Rajala *et al.,* 1991), and two-site immunoradiometric (Rajala *et al.,* 1991) and immunochemiluminometric assays (Firek *et al.,* 1991). The findings from all these methods are in general agreement: most persons affected with FBHH have paradoxically normal serum PTH values, and many are in the lower half of the normal range. However, 10–20% of FBHH patients have absolutely elevated serum PTH values (Fig. 1) (Firek *et al.,* 1991; Rajala *et al.,* 1991). In addition, one kindred coded as $FBHH_{Ok}$ had elevated serum PTH levels in affected individuals, specially the elderly (McMurtry *et al.,* 1992). In contrast, serum PTH values are supranormal in >85% of patients having 1° HPT (Firek *et al.,* 1991; Rajala *et al.,* 1991). One can imagine the ease with which mild to moderate hypercalcemia (say, 11.0 mg/dl), hypophosphatemia (perhaps 2.0–2.5 mg/dl), and slight elevation of serum intact PTH (70 pg/ml, as an example) could be mistakenly ascribed to 1° HPT in a patient who actually had FBHH.

Renal Function and Ion Excretion

The characteristic urinary mineral profile in FBHH led to the moniker "familial hypocalciuric hypocalcemia" (Marx *et al.,* 1978a); however, most affected persons are not truly "hypocalciuric" (below the normal range), but rather excrete less calcium than expected for their degree of hypercalcemia (a finding that has been termed "relative hypocalciuria"). About 75% of affected persons excrete less than 100 mg of calcium daily (Law and Heath, 1985), and some excrete strikingly low amounts of calcium in the face of hypercalcemia; values as low as 5 mg/day have been noted. However, the physician must be aware that a few individuals with FBHH may excrete as much as 250 mg of calcium daily (Law and Heath, 1985; Marx *et al.,* 1981a). The relatively low urinary excretion of calcium in FBHH results from avid renal tubular reabsorption of calcium, as detailed in the following section. Similarly, urinary excretion of magnesium is unexpectedly low given that the serum level is in the upper part of the normal range or, in some cases, mildly elevated (Kristiansen *et al.,* 1985, 1986; Marx *et al.,* 1978a).

The excretion of calcium in suspected FBHH cases may be expressed either as an absolute figure (mg/day) or as a unitless calcium:creatinine clearance ratio (fractional excretion of calcium), as advocated by Marx and colleagues (1980): [UCa.SCr]/[SCa.UCr], where UCa is the urinary calcium concentration, SCr the serum creatinine concentration, SCa the serum calcium concentration, and UCr the urinary creatinine concentration, all in milligrams per deciliter. Most patients having FBHH have urinary Ca:Cr clearance ratios below 0.01 (Law and Heath, 1985; Marx *et al.,* 1980, 1981a). There is considerable overlap between the absolute values for total urinary calcium excretion and Ca:Cr clearance ratios among persons having FBHH, their unaffected family members and unrelated patients having 1° HPT, as shown in Fig. 2. The ratio is most helpful in supporting a diagnosis of FBHH in a kindred, rather than in an individual patient, because the mean Ca:Cr clearance ratio generally will be less than 0.01 when averaged across affected members of the kindred.

Calcium infusions have been used to compare renal calcium handling in FBHH and hyperparathyroidism (Attie *et al.,* 1983; Davies *et al.,* 1984; Kristiansen *et al.,* 1986; Stuckey *et al.,* 1987). In response to a rising filtered calcium load, subjects with hyperparathyroidism increase their urinary calcium excretion more than FBHH patients do. This avid tubular calcium reabsorption persists even in FBHH patients who have been rendered surgically aparathyroid, pointing to a primary renal tubular abnormality in calcium reabsorption (Attie *et al.,* 1983; Davies *et al.,* 1984; Kristiansen *et al.,* 1986; Watanabe and Sutton, 1983). Renal function is well preserved in FBHH (D. A Heath, 1989, H. Heath, 1989; Heath, 1994; Law and Heath, 1985; Marx *et al.,* 1977, 1981a; Menko *et al.,* 1983), and there appears to be no more than the usual age-related loss of glomerular filtration rate. Moreover, the hypercalcemia of FBHH does not appear to alter renal sensitivity to vasopressin as it does in 1° HPT. Marx and colleagues demonstrated convincingly that reduced maximal urinary concentrating ability occurs in 1° HPT but not in FBHH (Marx *et al.,* 1981b). As stated above, urolithiasis is rare in patients having FBHH, but has been reported (Marx *et al.,* 1981a; Menko *et al.,* 1983; Toss

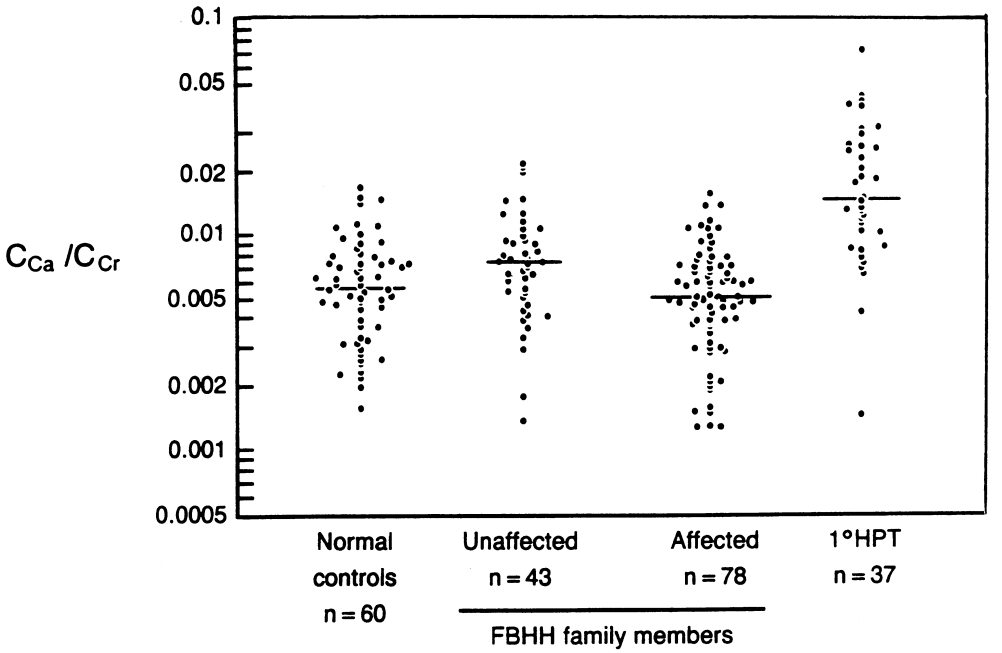

Figure 2 Ratios of calcium clearance to creatinine clearance in patients with familial benign hypocalciuric hypercalcemia (FBHH), unaffected family members, unrelated normal controls, and patients with surgically confirmed primary hyperparathyroidism (1° HPT). Note the logarithmic scale for C_{Ca}:C_{Cr} ratios. There is substantial overlap between FBHH and 1° HPT; however, a ratio of >0.02 is helpful in excluding FBHH. Reprinted with permission from Heath, H., III.

et al., 1989). A Swedish family with a syndrome that presented as a hybrid between 1° HPT and FBHH, with hypercalciuria that subsided after parathyroidectomy (Carling *et al.,* 2000).

In summary, the clinical and laboratory picture of FBHH is generally that of incidentally discovered hypercalcemia that bears no clear relationship to any of the patient's symptoms. The biochemical picture can be very similar to that of patients with asymptomatic 1° HPT, although elevation of serum PTH levels is much less common in FBHH than in 1° HPT (Allgrove *et al.,* 1984; Firek *et al.,* 1991; Kent *et al.,* 1987; Marx *et al.,* 1978b; Rajala *et al.,* 1991). While chondrocalcinosis, gallstones, and acute pancreatitis have been reported in FBHH, the relationship of these events to the FBHH is uncertain. Hyperparathyroid bone disease, hyposthenuria, and urolithiasis are conspicuously absent. The greatest importance of the FBHH syndrome to clinicians is that it is so easily misdiagnosed as mild to moderate 1° HPT, leading to excessive testing and to inappropriate, unnecessary, and potentially harmful cervical exploratory surgery.

Pathophysiologic Studies in FBHH

Extensive clinical research studies have clarified the organ-level pathogenesis of FBHH. Because the molecular basis of the predominant form of FBHH is now known (see the following), these studies now are mainly of value for providing a clear definition of the syndrome, but they also suggested basic research leads that ultimately resulted in determination of the molecular pathogenesis of one form of the syndrome.

Parameters of Systemic Plasma Calcium Regulation

PTH DYNAMICS

As previously stated, the hypercalcemia of FBHH is a "true" hypercalcemia, not an artifact of calcium-binding. It is stable across time and usually is reduced little or not at all by subtotal parathyroidectomy (Law and Heath, 1985; Marx *et al.,* 1981a). However, total parathyroidectomy results in permanent hypocalcemia that responds to the usual measures for treating hypoparathyroidism. The hypercalcemia of FBHH is therefore clearly PTH-dependent in a qualitative sense, but recent data show that this is also true in a quantitative sense (Firek *et al.,* 1991). Since the first application of PTH RIAs to the study of 1° HPT, a clear, direct relationship between the degree of hypercalcemia and the elevation of serum immunoreactive PTH has been evident (Arnaud *et al.,* 1971). Studies at the Mayo Clinic (Firek *et al.,* 1991) demonstrated a similar positive correlation between serum calcium and intact PTH levels in FBHH—but with a much shallower slope than the one described for hyperparathyroidism—and an inverse relationship was present between PTH and serum inorganic phosphorous levels. Clearly, hypercalcemia and hypophosphatemia are maintained in FBHH at

lower levels of ambient PTH than in 1° HPT, suggesting that inappropriately high PTH levels result from abnormal calcium-sensing at the level of the parathyroid gland. The reduced responsiveness of the parathyroid glands to changes in serum calcium has been documented carefully in FBHH. Induction of relative hypocalcemia by infusion of ethylenediaminetetraacetic acid (EDTA) or of relative hypercalcemia by calcium infusion causes appropriate increases and decreases of serum PTH concentrations (Auwerx *et al.,* 1984; Heath and Purnell, 1980; Khosla *et al.,* 1993). The decreases of PTH are greater in FBHH than in 1° HPT—in fact, indistinguishable from normal, although they occur at a higher level of serum calcium than do the corresponding reductions in PTH in normal persons—and increases are less than in 1° HPT. Systematic evaluation of PTH dynamics in FBHH patients compared to normal control is under way using consecutive citrate and calcium infusions. Preliminary results indicate a shift in the calcium–PTH relationship to the right, again consistent results with altered calcium-sensing (Fig. 3). PTH secretion responds in the usual inverse manner to changes in serum calcium concentration, but is reset so as to maintain a higher-than-normal level of plasma calcium. Interestingly, Foley *et al.* presciently interpreted their 1972 findings on FBHH as being consistent with a genetic abnormality of parathyroid calcium sensing (Foley *et al.,* 1972).

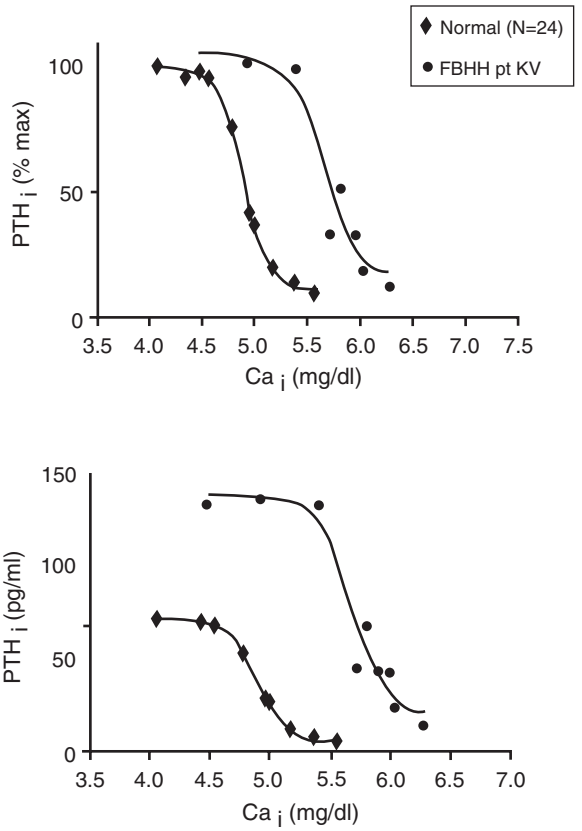

Figure 3 Inverse sigmoid curve between serum intact PTH and ionized calcium (Ca_i/PTH_i) in response to consecutive citrate and calcium infusions in patient KV with FBHH S. T. Haden, E. M. Brown, and G. El-Hajj Fuleihan, unpublished observation) in comparison to the Ca/PTH curve derived from 24 healthy subjects (adapted from Haden *et al.* (2000) *Clin. Endocrinol.* **52,** 329–338). There is a clear abnormality of PTH dynamics in the patient with FBHH compared to normal controls: a shift in the Ca/PTH curve to the right, increased PTH levels in response to hypocalcemia, and decreased suppression in response to hypercalcemia. The set-point, the calcium concentration at which there was 50% suppression in PTH levels, was 4.89 mg/dl in the curve derived from 24 healthy controls and 5.65 mg/dl in the patient with FBHH.

PARATHYROID GLANDS

The histologic findings in parathyroid glands of patients having FBHH are controversial. Most case and single-family reports have described unremarkable parathyroid tissue (Davies *et al.,* 1981; Paterson and Gunn, 1981; Sereni *et al.,* 1982, and reviewed in Law *et al.,* 1984b). These findings were corroborated by studies of large kindreds (Law and Heath, 1985; Menko *et al.,* 1983; Toss *et al.,* 1989). However, the two large histologic studies published to date focusing on parathyroid pathology yielded conflicting results. Thorgeirsson *et al.* reported that a highly variable parathyroid hyperplasia was typical in their examination of 55 parathyroid glands from 18 patients thought to have FBHH (Thorgeisson *et al.,* 1981). Conversely, Law *et al.* examined 28 parathyroid glands from 23 patients in 16 FBHH kindreds, quantifying fat to parathyroid parenchymal ratios in comparison with 82 normal glands from 47 control patients, and found no evidence to support the presence of parathyroid hyperplasia in FBHH (Law *et al.,* 1981). The discrepancy in the findings between these two large studies would be explained by referral bias or differences in the study populations (see Phenotype–Genotype Associations below).

OTHER CALCIOTROPIC HORMONES

Hypercalcemia in FBHH might be explained by increased formation of 25-hydroxyvitamin D or 1,25-dihydroxyvitamin D; however, plasma concentrations of these vitamin D metabolites are normal in FBHH patients (Davies *et al.,* 1983; Gilbert *et al.,* 1985; Kristiansen *et al.,* 1985; Law *et al.,* 1984a; Law and Heath., 1985; Lyons *et al.,* 1986), as is intestinal calcium absorption (Kristiansen *et al.,* 1985; Law and Heath 1985; Menko *et al.,* 1983). Thyroid C-cells increase calcitonin excretion in response to calcium; while calcitonin levels are inappropriately normal in FBHH for the degree of calcium elevation (Kristiansen *et al.,* 1985; Law and Heath, 1985; Menko *et al.,* 1983), they exhibit a normal response to other secretagogues (Rajala *et al.,* 1991).

THE KIDNEY

Two careful studies of very small numbers of patients have provided evidence for an intrinsic defect of renal tubular reabsorption of calcium in FBHH (Attie *et al.,* 1983; Davies *et al.,* 1984). These patients, who were later recognized to have FBHH, had inadvertently been rendered totally aparathyroid during surgical explorations for parathyroid tumors. Comparisons with individuals who became

hypoparathyroid after removal of typical sporadic parathyroid adenomas demonstrated greater PTH-independent, renal tubular reabsorption of calcium and magnesium in the FBHH patients than the sporadic hypoparathyroid controls (Attie *et al.,* 1983).

In summary, studies of the FBHH syndrome have almost uniformly suggested a genetic disorder of calcium sensing by the parathyroid gland paired with enhanced renal tubular reabsorption of calcium. PTH secretion persists at normal or slightly elevated values in the face of hypercalcemia, but without obvious disturbances of other calcium-regulating hormone concentrations. These pathophysiologic abnormalities would be most parsimoniously explained by dominant mutations of a single calcium-sensing receptor expressed both in parathyroid glands and in kidneys.

Genetic Studies in FBHH

No formal segregation analyses have been reported for FBHH kindreds, but inspection of numerous published and unpublished pedigrees shows beyond any doubt that the FBHH trait is inherited in an autosomal dominant pattern (Foley *et al.,* 1972; D. A. Heath, 1989; H. Heath, 1989; Heath 1994; Law and Heath, 1985; Marx *et al.,* 1977; 1981a; Menko *et al.,* 1983; Jackson and Boonstra, 1966; Toss *et al.,* 1989). Across numerous families, the sex distribution is essentially 1:1, and about half of all persons at risk manifest hypercalcemia. There is a considerable variation in clinical manifestation, that is, in the extent of hypercalcemia (there being almost no other clinical marker). Several groups have observed that the "hypercalcemia breeds true"; that is, there are FBHH families with relatively high and those with relatively low serum calcium concentrations (Marx *et al.,* 1981a; Rajala and Heath, 1987). There is, however, considerable variability of serum calcium values even within kindreds (Fig. 4). We have had the opportunity to follow affected women whose husbands were normocalcemic through three pregnancies and deliveries. Hypercalcemia was present in all three infants at birth, with serum calcium levels of up to 18 mg/dl observed in cord blood and during the first few days of life; subsequently, serum calcium declined by age 3–4 years to values similar to the affected mother's (unpublished results).

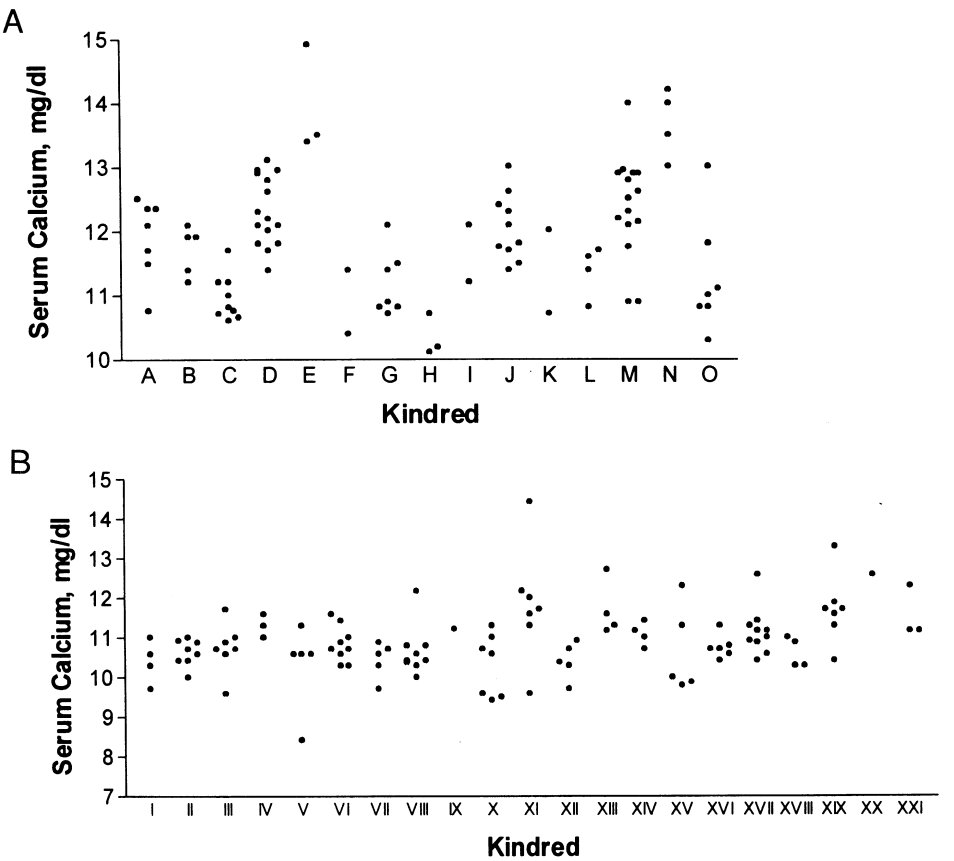

Figure 4 Scatter of serum calcium levels in FBHH kindreds. (A) Data from 15 kindreds reported by the National Institutes of Health group (adapted from Marx *et al.* (1981) *Medicine* **60,** 397, with permission). (B) Data from 21 kindreds reported by the Mayo Clinic group (adapted from Rajala and Heath (1987) *J. Clin. Endocrinol. Metab.* **65,** 1039, with permission). The mean ± SD calcium level in A is 12.1 ± 1.6 mg/dl and in B 10.9 ± 0.8, the mean serum calcium level from both studies is 11.4 ± 1.4 mg/dl.

Early genetic linkage studies excluded a number of candidate genes and loci as causes of FBHH, including the MEN 1 and MEN 2A loci, the PTH gene, and others (Heath and Leppert, 1992; Menko *et al.,* 1984; Paterson *et al.,* 1985). As it turns out, the FBHH syndrome is genetically heterogeneous: in the majority (over 85%) the FBHH phenotype links to a region of chromosome 3 that contains the calcium-sensing receptor sensor gene (CaSR), a disease subtype called $FBHH_{3q}$ (Heath *et al.,* 1993; Pearce *et al.,* 1995b). In two-thirds of $FBHH_{3q}$ families specific inactivating mutations of the CaSR were found to account for the hypercalcemia (Fig. 5). The remainder may have CaSR mutations outside of the coding region. In a smaller number of families the linkage of the trait was to markers on the short arm of chromosome 19 (Heath *et al.,* 1993), thus termed $FBHH_{19p}$ (Heath, 1994; Heath *et al.,* 1996; Strewler, 1994). Trump and colleagues carried out genetic linkage studies in the FBHH kindred described by Whyte *et al.* (Trump *et al.,* 1995), and found linkage neither to chromosome 3*q* nor chromosome 19*p* markers, establishing that there are three genetically distinct forms of the FBHH syndrome: $FBHH_{3q}$, $FBHH_{19p}$, and $FBHH_{OK}$ or $FBHH_{19q}$ ["OK" for Oklahoma, the family's state of residence (Trump *et al.,* 1995, Lloyd *et al.,* 1999)].

The Molecular Basis of $FBHH_{3q}$: Mutations in the CaSR

Chou *et al.* achieved the first linkage of the FBHH trait to markers on chromosome 3 (Chou *et al.,* 1992), specifically, $3q21-q24$. This linkage coincided with the cloning of the bovine parathyroid calcium-sensing receptor by Brown *et al.,* (1993), and the same group quickly demonstrated three distinct missense mutations in the calcium receptor genes in three separate families with $FBHH_{3q}$ (Pollack *et al.,* 1993). Several groups have since found point mutations of this gene that cosegregate with the $FBHH_{3q}$ trait (Aida *et al.,* 1995; Chou *et al.,* 1995; Heath *et al.,* 1996; Janicic *et al.,* 1995; Pearce *et al.,* 1995b).

The CaSR exhibits a modest degree of homology with the metabotropic glutamate receptors and has three domains: a large extracellular domain (612 aa), a seven-transmembrane-spanning segment that characterizes the G-protein-coupled receptor superfamily (250 aa), and an intracytoplasmic tail (222

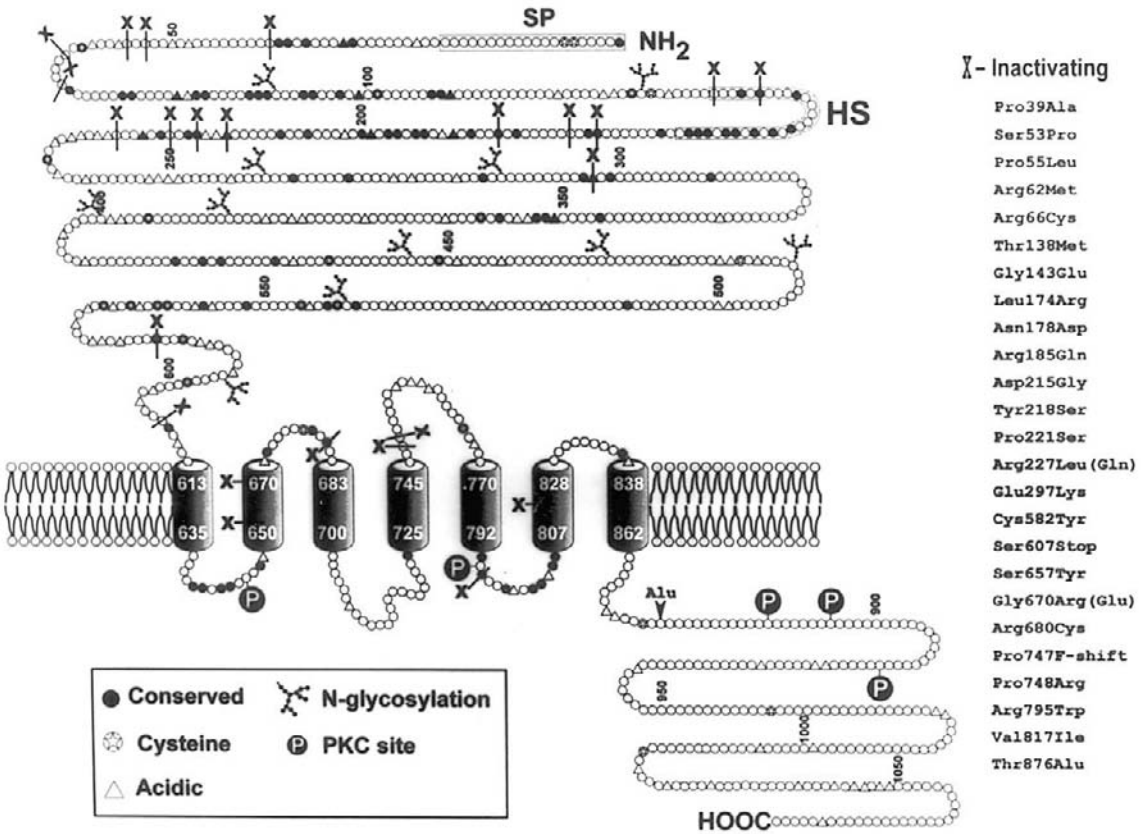

Figure 5 Schematic representation of the proposed structure of the extracellular Ca^{2+} calcium receptor cloned from human parathyroid gland. SP, signal peptide; HS hydrophobic substance. Also shown are 25 inactivating (missense and nonsense) mutations causing familial benign hypocalciuric hypercalcemia (FBHH). Mutations are indicated using the three-letter amino acid code, with the normal amino-acid indicated before and the FBHH mutation shown after the number of the relevant codon. Adapted from Bai *et al.* (1996), with permission.

aa). This receptor is expressed in many tissues but is found at the highest levels in the parathyroid gland, the thyroid C-cells and various regions of the kidney, especially the cortical thick ascending limb, a segment that plays a critical role in calcium handling (Brown *et al.,* 1995b). Activation of the normal calcium receptor suppresses parathyroid hormone secretion and enhances renal calcium excretion. Therefore, reduction or loss of the normal function of one allele of the calcium receptor, in FBHH, impairs calcium-sensing, with a resultant shift in the calcium–PTH curve to the right and reduced excretion of renal calcium at any given level of serum calcium concentration. Most of the inactivating mutations of the human CaSR gene found so far represent single amino-acid substitutions, but truncation (Pearce *et al.,* 1995b) and Alu insertion mutations (Janicic *et al.,* 1995) have also been described. In addition, "benign" polymorphisms have been described in up to one-third of unaffected subjects (Heath *et al.,* 1996). However, Cole *et al.* subsequently reported subtle abnormalities in serum calcium albeit within the normal range for the serum calcium concentration, in subjects with these "benign" polymorphisms (Cole *et al.,* 1999). To date, more than 25 different FBHH mutations of the CaSR gene are known. These $FBHH_{3q}$ mutations have been mostly in the extracellular or transmembrane part of the receptor (Fig. 5). Recently, however, a Swedish group described a kindred with a mutation in the cytoplasmic tail of the receptor, who presented with symptoms that combine those of FBHH and hyperparathyroidism (Carling *et al.,* 2000).

Several mechanisms have been suggested to account for the reduced activity of the CaSR and decreased calcium-sensing (Bai *et al.,* 1996):

1. Decreased affinity of the receptor for its physiological agonists, specifically calcium (the receptor also likely senses magnesium in a physiologically relevant manner).
2. Inability to form a fully active calcium receptor.
3. Failure of the receptor to couple normally to its respective signal-transduction pathway(s), e.g., activation of appropriate G-proteins.
4. A dominant-negative effect where in the mutated receptor interferes with the function of the normal receptor.

The role of the CaSR gene in controlling parathyroid function and the role of CaSR inactivation in causing FBHH have been elegantly supported by the mouse gene inactivation studies of Ho *et al.* (1995). Mice heterozygous for a disrupted CaSR gene had mild hypercalcemia [10.4 ± 0.55 mg/dl (mean ± SD)], non suppressed PTH levels, and reduced urinary calcium excretion compared to normal mice. The affected mice had normal radiographic skeletal morphology and parathyroid gland histology.

The Molecular Bases of $FBHH_{19p}$ and $FBHH_{OK}$

Two hypercalcemic syndromes that are similar to $FBHH_{3q}$ have been linked to loci on chromosomes 19*p* (Heath *et al.,* 1993) and 19*q*, the latter originally known as $FBHH_{OK}$ (Trump *et al.,* 1995; Lloyd *et al.,* 1999). At this writing, the molecular bases of the non-3*q* forms of FBHH are still unknown. However, the region mapped for $FBHH_{19p}$ (chromosome 19*p*ter) contains an interesting candidate gene, GNA11, which encodes a Gsa protein that is expressed in human parathyroid tissue (Varrault *et al.,* 1995). It is possible that GNA11 is the $FBHH_{19p}$ gene. The GNA11 gene product may be the Gsa protein acting in concert with the CaSR protein to control PTH secretion (Brown *et al.,* 1995b; Nemeth and Heath, 1995). Thus, inactivation either of one copy of the CaSR gene or of the GNA11 gene might confer the FBHH syndrome.

Autoimmune FBHH

Recently, two cases were described with autoimmune FBHH with biochemical features undistinguishable from usual FBHH (Kifor *et al.,* 2000). The two subjects had autoimmune disorders, thyroiditis and sprue, respectively. In those two subjects, FBHH was due to the presence of anti-CaSR antibodies that interfered with calcium-mediated suppression of PTH and calcium-sensing at the kidney.

POSSIBLE PHENOTYPE-GENOTYPE ASSOCIATIONS

When various missense or nonsense mutations identified in patients with FBHH are introduced into the normal CaSR by site-directed mutagenesis, a spectrum of CaSR activity emerges (Pearce *et al.,* 1995b), reflecting the spectrum in the syndrome's phenotypic expression. Hypercalcemia was noted to be the mildest in the $FBHH_{19p}$ kindred (Heath *et al.,* 1993); this observation is based on the evaluation of a single small family. In contrast, a putative "dominant negative" mutation is associated with more severe elevation of serum calcium levels through interference by the mutated receptor with the function of the wild-type allele (Bai *et al.,* 1996). This interference most likely occurs because the normal CaSR functions as a dimer, and functional interactions are known to occur between the two CaSR monomers within the dimer. However, as mentioned previously, within any given family there can a considerable variation in the degree of the hypercalcemia independent of the specific mutation (Fig. 4).

Some FBHH kindreds may be at increased risk for pancreatitis, and in three such kindreds Pearce found three heterozygous missense mutations in the extracellular domain of the calcium receptor (1996). This observation, in conjunction with that of an expression of the calcium receptor in the pancreatic duct (Bruce *et al.,* 1999), suggests the intriguing possibility that specific mutations may indeed carry a higher risk of pancreatitis.

The recent description by Carling *et al.,* of a novel mutation in the cytoplasmic carboxy-terminal tail of the calcium receptor, with a clinical and biochemical phenotype that is similar to primary hyperparathyroidism, with hypercalciuria and parathyroid hyperplasia, also raises the possibility that specific mutations may be associated with the unusual complications of stone disease and hyperplasia of the parathyroid glands that have been occasionally reported in FBHH

kindreds (Menko *et al.,* 1983; Toss *et al.,* 1989; Marx *et al.,* 1981a). Perhaps this mutant receptor couples differentially to its downstream effectors in parathyroid and kidney, conferring more resistance to extracellular calcium on parathyroid than on kidney cells. Similarly the presence of a receptor truncated in its carboxy-terminal tail owing to the insertion of an Alu element that produces a premature stop codon has also been associated with parathyroid hyperplasia (Cole *et al.,* 1997; Janicic *et al.,* 1995).

Finally, the $FBHH_{OK}$ syndrome has been associated with osteomalacia in one family for reasons that are yet to be unraveled since the genetic basis of that syndrome is still unknown (Trump *et al.,* 1995).

A Clinical Strategy for FBHH

The differential diagnosis of hypercalcemia is not the dilemma it once was; in patients with established hypercalcemia, a single measurement of serum PTH by an immunometric assay will allow a correct diagnosis of 1° HPT at least 80% of the time. However, many patients with 1° HPT are asymptomatic or oligosymptomatic, many have serum intact PTH concentrations within population normal ranges, and some have surprisingly low urinary calcium excretion (Marx *et al.,* 1977). A given patient, then, may present with asymptomatic, mild to moderate hypercalcemia, minimal or no hypophosphatemia, urinary calcium excretion below 100 mg/day (Law and Heath, 1985), and mild elevation of serum intact PTH, with no family history of hypercalcemia. The physician will have no simple or reliable way of determining if this patient has a parathyroid tumor or one of the variants of FBHH. What is the clinician to do? Genetic linkage studies are not practical, because of family sampling problems, cost, the large number of possible mutations, and the genetic heterogeneity of the syndrome, including the existence of FBHH variants whose molecular etiologies are not yet understood. Direct DNA screening studies of the CaSR gene could be informative, if abnormal, but even $FBHH_{3q}$ families do not have known mutations of the CaSR gene coding region in a substantial minority (about a third) of cases. The strategy to be followed must be based, for now, on clinical judgement.

For hypercalcemic patients over the age of 40, with no familial history of hypercalcemia, a clinical and biochemical picture consistent with 1° HPT is overwhelmingly likely to represent just that. The data of Marx *et al.* suggest odds of >1000:1 in favor of 1° HPT in this situation (Marx *et al.,* 1980). Obtaining a measurement of 24-hr urinary calcium could be helpful, hypercalciuria virtually excludes the diagnosis of FBHH, but normocalciuria or even low urinary calcium levels do not exclude 1° HPT, particularly in elderly women. Furthermore, families with FBHH and hypercalciuria have been described. A conservative approach, if the urinary calcium were very low, the serum PTH normal, and the patient clinically well, would be to sample available first-degree relatives for occult hypercalcemia. If surgical exploration were indicated for symptoms or complications [e.g., osteopenia (Nemeth and Heath, 1995), it could be done without great concern. In either case, long-term observation of untreated, uncomplicated 1° HPT and FBHH is a safe course of action. One's suspicion for FBHH would be heightened if the patient were young (under age 40, especially if under 30), if there were a family history of hypercalcemia, if anyone in the family had undergone unsuccessful neck exploration for hypercalcemia, if neonatal hyperparathyroidism had occurred in the family, and if the urinary excretion of calcium were particularly low (say, less than 50 mg/day) in the patient and other hypercalcemic relatives. In such case, one should defer surgical therapy and observe. The key point is that FBHH does not require treatment in the vast majority of cases. The goal in the clinic must be to identify FBHH before any family member has surgery, but this is regrettably not always going to be possible with our current state of knowledge.

Neonatal Primary Hyperparathyroidism

Clinical Characteristics

Neonatal primary hyperparathyroidism can be a mild syndrome representing the neonatal expression of FBHH, or it can present as a much more dramatic disease with high morbidity and even mortality if untreated, a syndrome known as neonatal severe primary hyperparathyroidism (NSHPT). Due to the severity of its symptoms, signs, and biochemical abnormalities, NSHPT was described several decades before FBHH. It manifests at birth, with severe hypercalcemia, hypotonia, osteitis fibrosa cystica, respiratory difficulty, failure to thrive, parathyroid hyperplasia, and, in general, markedly elevated serum levels of PTH (Fujita *et al.,* 1983; Marx *et al.,* 1982; Page and Haddow, 1987; Sereni *et al.,* 1982; Steinmann *et al.,* 1984). Additional clinical features include chest wall deformities with a flail chest syndrome secondary to multiple rib fractures, dysmorphic facies, and anovaginal and rectovaginal fistulas (Marx *et al.,* 1982; Spiegel *et al.,* 1977; Steinmann *et al.,* 1984). The hypercalcemia is usually severe, ranging from 14 to 20 mg/dl, one patient had a serum calcium of 30.8 mg/dl (Corbeel *et al.,* 1968), PTH levels are elevated by 5- to 10-fold (Fujimoto *et al.,* 1990) and examination of the parathyroid glands reveals four gland hyperplasia (Cooper *et al.,* 1986; Fujimoto *et al.,* 1990; Lutz *et al.,* 1986; Marx *et al.,* 1982; Matsuo *et al.,* 1982). Some affected infants have died from NSHPT, others have survived after total or subtotal parathyroidectomy, and, in more recent series, a substantial percentage of cases survived without parathyroid surgery. Indeed, some neonates with neonatal hyperparathyroidism who originally presented with respiratory compromise and demineralization have been reported to improve (Harris and D'Ercole, 1989; Orwoll *et al.,* 1982; Page and Haddow, 1987; Wilkinson and James, 1993). In

neonatal hyperparathyroidism, the serum calcium level is usually less elevated than in NSHPT and patients have no evidence of bone disease, the latter being a prominent feature of NSHPT. This probably reflects the fact that these neonates carry only one abnormal copy of the FBHH gene, whereas the severity of hypercalcemia and bone disease in NSHPT results from the inheritance of a double dose of the abnormal gene.

Genetic Basis of NSHPT

This syndrome may occur as a sporadic disorder, but has also been described in kindreds having FBHH (Fujita *et al.,* 1983; Marx *et al.,* 1982; Page and Haddow, 1987; Sereni *et al.,* 1982; Steinmann *et al.,* 1984). When NSHPT has occurred in FBHH families, in some cases, both parents have been hypercalcemic, suggesting the possibility that NSHPT is the clinical manifestation of homozygosity for an FBHH mutation (Chou *et al.,* 1995; Janicic *et al.,* 1995; Pollak *et al.,* 1993).

NSHPT can result from any of the following genetic alterations in the CaSR:

1. Homozygous form of FBHH: the neonate from a consanguineous marriage inherits a double dose of FBHH mutation, one from each heterozygous parent (Marx *et al.,* 1981, 1982, 1985; Pollak *et al.,* 1994).
2. Compound heterozygous form of FBHH: the neonate results from the marriage of two individuals with two different mutations in the CaSR (Kobayashi *et al.,* 1997).
3. Heterozygous form of NHPT: when the neonate occurs sporadically or comes from an FBHH family with only one parent affected (Harris and D'Ercole, 1989; Orwoll *et al.,* 1982; Page and Haddow, 1987; Powel *et al.,* 1993; Spiegel *et al.,* 1977; Wilkinson and James, 1993). Several potential explanations may be offered for that observation. The parents are both carriers of a CaSR mutation but only one is recognized, the offspring may experience a negative dominant effect of the abnormal gene on the normal one (Bai *et al.,* 1997) or the offspring carries *de novo* heterozygous mutations (Bai *et al.,* 1997; Pearce *et al.,* 1995b).

MICE MODELS OF NSHPT

Mice homozygous for a disrupted CaSR gene have more substantial hypercalcemia (14.8 $\pm$ 1.0 mg/dl) and increased parathyroid size compared to mice heterozygous for the mutated gene (Ho *et al.,* 1995) than did the heterozygous animals. The homozygotes grow poorly, have multiple bony abnormalities and usually die within 4 weeks (Ho *et al.,* 1995). Homozygous null mutation mice also have reduced skeletal radiodensity, kyphoscoliosis, and bowing of long bones, reminiscent of the skeletal anomalies in human NSHPT (Fujita *et al.,* 1983; Marx *et al.,* 1982; Page and Haddow, 1987; Sereni *et al.,* 1982; Steinmann *et al.,* 1984). These important data fulfill "Koch's postulates" for $FBHH_{3q}$ and make it almost certain that inactivating mutation of the human CaSR gene is the cause of FBHH and NSHPT in many if not most kindreds.

Management of Neonatal Hyperparathyroidism

In older reports, cases that were managed medically had a much worse prognosis than did those who underwent total parathyroidectomy (Cooper *et al.,* 1986; Fujimoto *et al.,* 1990; Hillman *et al.,* 1964; Marx *et al.,* 1982; Matsuo *et al.,* 1982; Spiegel *et al.,* 1977). Since 1980, milder forms of neonatal hyperparathyroidism have been noted that may improve with medical therapy alone. At this point it would be wise to aggressively support any neonate presenting with NSHPT or neonatal hyperparathyroidism with hydration, mechanical ventilation, and rely on surgery only in those who fail to improve with supportive measures. The surgical intervention of choice would be total parathyroidectomy with immediate or delayed auto-transplantation. Bony remineralization generally occurs within a matter of months(s) after successful parathyroid surgery (Cooper *et al.,* 1986; Fujimoto *et al.,* 1990; Lutz *et al.,* 1986). Any person known to have FBHH should ask his/her spouse to have a measurement of serum calcium performed; if the other spouse is hypercalcemic and both appear to have FBHH, then a pediatrician knowledgeable about NSHPT should be in attendance at the birth of any child. Consanguinity of the couple obviously would heighten concern about NSHPT, because there would be a 25% chance of their child having the disorder.

CaSR-based therapeutics are well into clinical trials (Silverberg *et al.,* 1997; Wada *et al.,* 1999). They may be useful tools not only in our understanding of the role of the CaSR in several organs, but also in the medical management of disorders of abnormal calcium-sensing. In NSHPT, as long as there is some residual function of the CaSR, calcium receptor agonists would presumably be helpful. They could also be used in the more severe variants of FBHH in the neonatal period as well as in adulthood—for instance in the most recent FBHH syndrome described (Carling *et al.,* 2000), as well as in autoimmune FBHH.

Conclusions

As predicted some years ago (Law and Heath, 1985), study of the FBHH syndrome has led to fascinating, important advances in our understanding of the regulation of systemic calcium metabolism (Brown *et al.,* 1995a; Pearce *et al.,* 1995a). What appeared just a few years ago to be a single, homogeneous hypercalcemic syndrome is now known to represent at least three genetically distinct disorders, $FBHH_{3q}$ (probably always a disorder of the parathyroid CaSR), $FBHH_{19p}$ (which may result from mutation of a gene encoding another component of the calcium receptor activation pathway, a $G_{s\alpha}$ protein gene), and $FBHH_{OK}$. $FBHH_{3q}$ accounts for the overwhelming majority of cases to date. It is possible that FBHH may also

map to as-yet-unidentified genes that encode for additional CaSR or for proteins that alter the function of these sensors. $FBHH_{3q}$ appears to be the clinical manifestation of heterozygous reduction or loss of CaSR function in the parathyroid glands and renal tubules, whereas NSHPT is the phenotype of homozygous loss or reduction of CaSR function. On the other end of the spectrum, activating mutation in the CaSR causes under expression of PTH, otherwise known as autosomal dominant hypocalcemia (see Chapter 62). Further insights into the structure–function relationship of the CaSR will undoubtedly enhance our understanding of the wide spectrum of the phenotypic expressions of FBHH and NSHPT. Furthermore, as-yet-unexplained phenotypic features of NSHPT may be providing subtle hints in this "experiment of nature" of currently unknown roles for the CaSR in nonclassical calcium-targeted organs. When the physician suspects FBHH in an individual patient, current knowledge permits only presumptive nongenetic diagnosis of the syndrome, but continuing research may soon lead to DNA-based screening studies not only for diagnosis of the FBHH syndrome, but also for determining the specific molecular basis, in individual patients. The goal of avoiding needless surgery in FBHH would then be achievable.

CHAPTER 58

Multiple Endocrine Neoplasia Type 1

Maria Luisa Brandi,[*] Cesare Bordi,[†] Francesco Tonelli,[‡] Alberto Falchetti,[*] and Stephen J. Marx[§]

[*]Department of Internal Medicine and [‡]Surgery Unit, Department of Clinical Physiopathology, University of Florence, 6-50139 Florence, Italy; and [†]Department of Pathology and Laboratory Medicine, Section of Anatomic Pathology, University of Parma, 1-43100 Parma, Italy; [§]Metabolic Diseases Branch, National Institute of Diabetes and Digestive and Kidney Diseases, National Institutes of Health, Bethesda, Maryland 20892

Introduction

Multiple endocrine neoplasia type 1 (MEN1) syndrome is a rare disorder presenting with varying combinations of parathyroid adenoma, gastrinoma, and prolactinoma. MEN1 can be operationally defined as a case with two of these three principal MEN1-related endocrine tumors. Other endocrine and nonendocrine neoplasms such as foregut carcinoid, lipoma, and skin tumor are also common. Furthermore, other endocrine and nonendocrine tissues can be affected but with a lower frequency (Table I). Many tumors in MEN1 are benign, even if some entero-pancreatic neuroendocrine tumors (mainly gastrinomas) and foregut carcinoids are often malignant. Though often regarded as a treatable endocrinopathy, MEN1 can also be regarded as a cancer syndrome lacking effective prevention or cure for associated malignancies. MEN1 exhibits an autosomal dominant pattern of inheritance. There is growing evidence of sporadic cases, some associated with mutation of the *MEN1* gene. Familial MEN1 is defined as a family with one MEN1 case plus a first-degree relative, showing one of the three principal tumors. The tumor develops after loss of function via inactivation of both gene copies at chromosome $11q12-q13$, a process that led to initial localization of the *MEN1* gene and also that assisted later in *MEN1* gene discovery (Larsson *et al.,* 1988; Chandrasekarappa *et al.,* 1997).

The syndrome was originally described as an autopsy finding in a patient with acromegaly and four enlarged parathyroid glands (Erdheim, 1903). More than 20 years later, two groups reported a patient with the triad of parathyroid, pancreatic, and pituitary adenomas (Cushing and Davidoff, 1927). In 1953, Underdahl *et al.,* published an early review of related syndromes with a total of 14 cases (Underdahl *et al.,* 1953). However, it remained for Wermer to suggest that the trait was caused by an autosomal dominant gene with high penetrance (Wermer, 1954). This insight is commemorated by referring to MEN1 also as Wermer's syndrome.

The clinical features of the disorder were then clarified greatly after 1960, when radioimmunoassays for the various products of the affected endocrine tissues were developed (Yalow, 1978; Malarkey, 1979; Nussbaum and Potts, 1991). Progress in the management of MEN1 paralleled knowledge of the pathogenesis of common-variety endocrine tumors and included improving surgical and pharmacological interventions (Albright and Ellsworth, 1990; Bevan *et al.,* 1992; Schmid *et al.,* 1961).

Clinical Aspects

MEN1 Variants

Due to the constantly growing clinical and genetic knowledge about this syndrome, the MEN1-associated endocrinopathies, and their sporadic counterparts, it has been possible to recognize peculiar MEN1 variants and

Table I MEN1-Associated Tumors

Typical tumors (or more frequent)	Less prominent tumors	Rare tumors
	Endocrine	
Parathyroid adenoma (≈90%)	Foregut-derived carcinoid* (5%)	Pheochromocytoma
Anterior Pitutitary (≈25%)	Adrenal cortical (≈25%)	Ependymoma
(prevalently PRLoma) (20%)	(mainly nonfunctioning)	Leiomyoma
Neuroendocrine cells of g-I tract (gastrinoma, insulinoma, VIP-oma, glucagonoma, PP-oma) (≈50%)		Ductal adenocarcinoma of the pancreas
	Nonendocrine	
	Lipoma (visceral and cutaneous) (≈30%)	
	Skin tumor [facial angiofibroma (85%), collagenoma (70%)]	

phenocopies (phenocopy, similar phenotype but not from the same gene) (Marx, 2001).

Since primary hyperparathyroidism (PHPT) is the earliest and most frequent expression of MEN1, familial isolated hyperparathyroidism (FIHP) (Kassem *et al.,* 1994) in one-fifth of families with isolated hyperparathyroidism can be a prelude to typical MEN1 or an atypical expression of MEN1 (Marx *et al.,* 1982). However, in a much larger and more "elderly" family, isolated hyperparathyroidism could be a distinctive variant from *MEN1* mutation (Kassem *et al.,* 2000).

A variant (or phenotype or subtype), caused by *MEN1* mutation, termed the prolactinoma or "Burin" MEN1 variant shows high penetrance of hyperparathyroidism and of prolactinoma and low penetrance of gastrinoma (Olufemi *et al.,* 1998). The prolactinoma MEN1 variant has been associated with *MEN1* mutation or 11*q*13 linkage in each of three tested families (Agarwal *et al.,* 1997). The *MEN1* mutations in FIHP and "Burin" MEN1 phenotypes have not shown any informative pattern; thus, the causes of these phenotypes are not known. A family with an MEN1-variant and proven or likely *MEN1* mutation should remain under surveillance for other expressions of MEN1.

MEN1 Phenocopies

An MEN1 phenocopy is a trait that strongly resembles MEN1 in a patient or a family. It could be a case of FIHP in which *MEN1* mutation analysis failed to detect mutation; thus, other genes such as the calcium-sensing receptor gene (*CaSR*), accounting for familial hypocalciuric hypercalcemia (FHH) syndrome (Pollak *et al.,* 1993), and the putative gene responsible for the hyperparathyroidism–jaw tumor syndrome (HPT-JT) (Szabo *et al.,* 1994; Teh *et al.,* 1998a) might be involved.

Familial isolated pituitary tumor, generally somatotrophinoma, has so far yielded no *MEN1* mutation with a collective experience of more than 15 tested families (Tanaka *et al.,* 1998; Teh *et al.,* 1998b). Linkage analysis has been possible in only one large family, pointing to 11*q*13, and thereby suggesting undiscovered mutation of *MEN1* or a nearby gene (Gadelha *et al.,* 2000).

Primary Hyperparathyroidism in MEN1

Primary hyperparathyroidism is the most common endocrinopathy in MEN1, reaching nearly 100% by age 50 (Skarulis, 1998), and it is usually the first clinical manifestation, recognized by age 8 in several cases (Trump *et al.,* 1996).

The clinical features of the parathyroid hyperfunction in MEN1 show similarities to those of sporadic or common-variety primary hyperparathyroidism (Bilezikian *et al.,* 1995; Kleerekoper, 1995) with a long period of asymptomatic hypercalcemia and a low morbidity. The complications of the disorder are prevented by early intervention from an experienced surgeon.

In contrast to sporadic hyperparathyroidism, hyperparathyroidism (often asymptomatic) in patients with MEN1 develops at a younger age (Betts *et al.,* 1980; Skogseid *et al.,* 1991). Its average onset age is 20–25 years (Trump *et al.,* 1996; Skarulis *et al.,* 1998), three decades earlier than typical for sporadic parathyroid adenoma. Moreover, different from sporadic primary hyperparathyroidism (Heath *et al.,* 1980), primary hyperparathyroidism in MEN1 has a similar prevalence in females and males. Finally, unlike single adenoma of sporadic primary hyperparathyroidism, primary hyperparathyroidism in MEN1 is associated with multiple and asymmetric parathyroid gland enlargement (Hellman *et al.,* 1992; Marx *et al.,* 1991). MEN1-associated

hyperparathyroidism increases gastrin secretion from gastrinoma(s) and consequently a successful parathyroidectomy could decrease the severity of the Zollinger–Ellison (ZES) in MEN1 (Jensen, 1997). Still, because of excellent pharmacotherapy for ZES, ZES does not represent a sufficient indication for parathyroidectomy in MEN1.

After successful subtotal parathyroidectomy, hyperparathyroidism in MENI recurs progressively, reaching 50% by 8–12 years after surgery (Rizzoli *et al.,* 1985; Burgess *et al.,* 1998). It can be due to the growth of a neoplastic remnant of parathyroid tissue or to a new somatic mutation at 11*q*13 in the parathyroid remnant.

Burgess *et al.,* (1999) reported a reduction of bone mass in MEN1-affected women with hyperparathyroidism by 35 years of age (44%), with an increased likelihood of skeletal fractures. Parathyroidectomy and maintenance of a normocalcemic state resulted in improvement of both lumbar and femoral BMD.

Enteropancreatic and Foregut Carcinoid Manifestations of MEN1

The prevalence of enteropancreatic involvement in MEN1-affected individuals varies in different clinical series at 30–75% (Marx, 2001; Skogseid *et al.,* 1991; Vasen *et al.,* 1989) and approaches 80% in surgery or autopsy series. An enteropancreatic tumor is often recognized due to clinically overt features during the fifth decade but may be biochemically detected much earlier (third decade) in asymptomatic *MEN1* carriers.

Unlike nonfamilial variety endocrine tumor of the upper gastrointestinal tract, tumors in patients with MEN1 are usually multiple and develop at a younger age; MEN1-associated gastrinoma and insulinoma exhibit an average onset age 1 decade earlier than their sporadic counterparts (Skarulis, 1998). Moreover, the gastrointestinal manifestations are influenced by other endocrinopathies (mainly primary hyperparathyroidism) (Bone, 1990; Norton *et al.,* 1993).

Initial presentation of MEN1 as occurs only in a small proportion of patients (Benya *et al.,* 1993). The early presentation of these tumors is frequently associated with the lack of detection of the tumor by routine abdominal imaging techniques (Galiber *et al.,* 1988; Norton *et al.,* 1993). The majority of tumors with MEN1 ZES are in the duodenum, and are usually small (Ø <0.5 cm). The most frequent entero-pancreatic functional endocrine tumors in MEN1 are gastrinomas (54%) and benign insulinomas (21%) (Eberle and Grun, 1981; Jensen and Gardner, 1993; Metz and Jensen, 1993; Norton *et al.,* 1993). About 40% of MEN1 cases exhibit gastrinoma, and about one-fourth of all gastrinoma cases have MEN1. Most MEN1 gastrinomas are malignant; half have metastasized before diagnosis (Townsend *et al.,* 1990). One-third of sporadic and MEN1-associated ZES cases eventually die from the malignant aspects of their tumor(s). Poor prognosis is associated with pancreatic (not duodenal) primary, metastases (lymph node, liver, or bone), ectopic Cushing syndrome, or very high gastrin level (Yu *et al.,* 1999).

The diagnosis of gastrinoma is made by elevated serum gastrin and high gastric acid output, with or without symptoms. Confirmatory tests can include pentagastrin-stimulated acid output and secretin-stimulated gastrin levels (Wiedenmann *et al.,* 1998). A 72-hr fast protocol may be helpful in the diagnosis of insulinoma.

Glucagonomas, VIP-omas, GRF-omas, and somatostatinomas have also been described in MEN1 (Eberle and Grun, 1981; Norton *et al.,* 1993). However, nonfunctional[1] endocrine tumors are the most prevalent enteropancreatic endocrine neoplasms in MEN1, more than half being PP-omas (Eberle and Grun, 1981; Metz and Jensen, 1993; Norton *et al.,* 1993). Type II tumors of gastric histamine-secreting enterochromaffin-like cells (ECL-omas or gastric carcinoids) frequently accompany with Zollinger–Ellison-associated hypergastrinemia (Jensen and Gardner, 1991; Maton and Dayal, 1991). It is generally believed that prolonged hypergastrinemia causes ECL-omas (Frucht *et al.,* 1991; Maton and Dayal, 1991; Bordi *et al.,* 1998). This is particularly true for patients with MEN1 (Frucht *et al.,* 1991; Jensen and Gardner, 1991; Maton and Dayal, 1991).

Though sporadic carcinoid tumors are mainly in the midgut or hindgut, MEN1 carcinoids are all in the foregut (Duh, 1987; Godwin, 1975). Foregut carcinoids in MEN1 rarely oversecrete amine or peptide hormones. MENl bronchial carcinoid is mainly in females. MEN1 thymic carcinoid exhibits a male predominance. Cigarette smoking appears to be associated with a higher risk for thymic carcinoid (Teh *et al.,* 1997). Carcinoid tumors can be asymptomatic until a late stage, and their course appears more aggressive with than without MEN1.

Tumors of the Anterior Pituitary or the Adrenal in MEN1

An anterior pituitary tumor is the first clinical manifestation of MEN1 in less than 20% of cases (Carty *et al.,* 1998). The prevalence of pituitary tumor in MEN1 patients ranges from 10 to 50% (Metz *et al.,* 1994) of affected members, depending on the patients and methods utilized in the various studies. Microadenomas (Ø <1 cm) represent about 65% of the MEN1-associated pituitary tumors. Every type of anterior pituitary adenoma, except "true" gonadotropinoma, has been reported in MEN1 (Teh *et al.,* 1998b; Corbetta *et al.,* 1997). The frequency of plurihormonal tumors is greater in MEN1 tumors, with fewer null-cell tumors when compared to sporadic isolated pituitary tumors (Scheithauer *et al.,* 1987).

The mean age at the time of diagnosis of MEN1 pituitary tumors is about 40 years (Oberg *et al.,* 1989; Vasen *et al.,*

[1]Nonfunctional tumors are those that do not make a known hormone, make a hormone but do not secrete enough to cause a syndrome, or make and secrete a hormone (such as pancreatic polypeptide or calcitonin) that does not cause a syndrome.

1989; Skarulis, 1998), similar to that for sporadic isolated pituitary tumors (Scheithauer *et al.,* 1987). Prolactinoma (with or without simultaneous GH oversecretion) is the most frequent pituitary tumor in MEN1, followed by GH-oma (Scheithauer *et al.,* 1987).

Primary adrenocortical neoplasms are common in MEN1 (20–40%) and they are usually bilateral, hyperplastic, and nonfunctional (Skarulis, 1998; Skogseid *et al.,* 1992, 1995; Burgess *et al.,* 1996). Glucocorticoid excess, albeit rare, more often results from pituitary oversecretion of adrenocorticotropic hormone (ACTH) (Maton *et al.,* 1986). Hyperaldosteronism has been reported (Beckers *et al.,* 1992). Most of the adrenal enlargements exhibit an indolent clinical course (Metz *et al.,* 1994; Burgess *et al.,* 1996).

Unilateral pheochromocytoma is rare in MEN1. However, since 11*q*13 LOH is associated, pheochromocytoma should be considered a direct result of *MEN1* gene inactivation (Cote *et al.,* 1998).

Nonendocrine Tumors

Lipomas are frequently associated with MEN1 (20–30%) (Marx *et al.,* 1982; Metz *et al.,* 1994; Darling *et al.,* 1997). They are often multiple and can also occur viscerally. Lesions, often multicentric, may be small or large and cosmetically disturbing. They typically do not recur after removal. Multiple facial angiofibromas were observed in 40–80% of MEN1 patients, with half of the cases having five or more; Hoang-Xuan and Steger, 1999; Sakurai *et al.,* 2000); trunkal collagenomas were almost as common (Darling *et al.,* 1997). Angiofibromas are clinically and histologically similar in MEN1 or in tuberous sclerosis. Leiomyoma of the esophagus, uterus, or rectum has occurred; the frequency of leiomyoma in MEN1 has not been analyzed (Vortmeyer *et al.,* 1999; Dackiw *et al.,* 1999).

Treatments

Primary Hyperparathyroidism

Surgery for hyperparathyroidism in MEN1, more so than for the sporadic form, is the preferred treatment. The decision about timing for parathyroid surgery usually take into account the following criteria: (1) severity of symptoms or signs of HPT; (2) concentration of circulating PTH and calcium; (3) presence of MEN1-associated endocrinopathies, especially ZES; (4) patient age. Successful treatment of HPT is often followed by a decrease of the elevated circulating levels of gastrin. Persistence, late recurrence, and hypoparathyroidism are all more frequent after surgery for MEN1 than sporadic adenoma. Several approaches address these problems. First, surgery is delayed for stronger indications in MEN1 than sporadic cases. Second, several approaches to subtotal parathyroidectomy are aimed at limiting the frequency of hypoparathyroidism.

The development of a rapid intraoperative PTH assay makes it possible to monitor the correction of hyperparathyroidism, to assure when the important tumors have been removed, and to perform, when necessary, an immediate parathyroid autograft (Tonelli *et al.,* 2000).

Recently, calcium-sensing receptor agonists, a new and novel class of drugs, have been demonstrated to act directly on the parathyroid gland, decreasing PTH release (Silverberg *et al.,* 1997), and perhaps even decreasing parathyroid tumor growth. They might acquire an important role in treatment of hyperparathyroidism, including that from MEN1.

Subtotal Parathyroidectomy

Subtotal parathyroidectomy is the surgical ablation of three parathyroid glands and part of the fourth gland, leaving no more than 50 mg of tissue of the least compromised gland. Some authors suggest that the whole fourth parathyroid gland be saved when it appears to be of normal size. This kind of procedure has been proposed in order to avoid permanent hypoparathyroidism and to reduce the period of temporary postsurgical hypocalcemia. Rates of chronic hypocalcemia with this surgical approach range from 0 to 30% (Goretzki *et al.,* 1991; Grant and Weaver, 1994; Kraimps *et al.,* 1992; O'Riordain *et al.,* 1993; Thompson and Sandelin, 1994). A considerable rate of recurrence of hyperparathyroidism has been described after successful subtotal parathyroidectomy in MEN1. The incidence of recurrence increases proportionately with time after surgery (Hellman *et al.,* 1992; Kraimps *et al.,* 1992; Prinz *et al.,* 1981; Rizzoli *et al.,* 1985; Burgess *et al.,* 1998a). It is uncertain if the recurrence of hyperparathyroidism is due to the increased function of the tumor remnant or rather to new development of a tumor in a normal remaining ectopic or supernumerary parathyroid gland.

Total parathyroidectomy with autologous parathyroid graft (Wells *et al.,* 1980) is a more radical approach for MEN1-associated hyperparathyroidism. The whole parathyroid and thymic tissues are removed for the purpose of both avoiding subsequent cervical exploration and thymic carcinoid onset. The parathyroid graft is performed according to two main procedures. The first is the use of fresh autologous tissue stored in refrigerated saline solution and grafted immediately at the end of surgery. The advantage of this approach is that the graft is more likely to succeed. The disadvantage is not being able to verify the absence of functioning tissue remnant, normal remaining ectopic gland, or supernumerary gland. In the second procedure, implantation is performed some days or months after surgery using cryopreserved tissue. With this approach the lack of circulating PTH can be evaluated after parathyroidectomy. However, the viability of parathyroid tissue may be lower after cryopreservation. In both techniques, the parathyroid gland to be transplanted is the one that macroscopically exhibits the features closest to a normal gland possibly lacking nodular histopathology. The tissue to be transplanted varies from 5 to 20 1-mm^3-sized fragments. The graft is generally placed within the brachioradialis muscle so that it is possible to verify its function by simple blood sampling from the ipsilatered antecubital vein.

Because normal parathyroid glands can also be found in MEN1 patients, some authors believe that four-glands surgery is not always necessary. In this way the risk of permanent hypocalcemia is avoided. If partial parathyroidectomy is performed, an acceptable approach includes removal of the pathological and the normal homolateral gland, including thymectomy, and biopsy of the contralateral apparently normal parathyroids (Dralle and Scheumann, 1994). Consequently, the risk of persistent hyperparathyroidism is reduced and the lack or presence of multiglandular parathyroid involvement is determined. Whatever the approach to parathyroidectomy, an initial neck operation in MEN1 should include transcervical thymectomy. Most of the thymus can thereby be removed along with possibly included parathyroid tissue and carcinoid tissue.

Neuroendocrine Tumors

GASTRINOMA

Gastric acid hypersecretion in virtually all patients with hypergastrinemia can be effectively controlled using histamine H_2-receptor antagonists or H^+, K^+-ATPase inhibitors (Brunner *et al.,* 1989a,b; Jensen, 1997).

The surgical approach, if any, to be taken for gastrinoma(s) in MEN1 is controversial (Norton *et al.,* 1999). Some authors recommend surgery only in case of precise localization of gastrinoma, or in presence of particularly aggressive familial gastrinomas (Melvin *et al.,* 1993; Sheppard *et al.,* 1989), while other authors would perform surgery in all cases (Thompson *et al.,* 1993). Surgery has to follow the necessary procedures of tumor localization, such SRS and selective infusion of secretin or calcium in selective pancreatic arteries followed by hepatic vein sampling for gastrin measurement (Imamura and Takahashi, 1993). Even though none of these procedures is completely reliable for identifying sites of hypersecretion, *trans*-arterial challenge can indicate if excessive hormonal release is in the head or in the corpo-caudal segment. Small duodenal gastrinomas are not easily appreciated by external palpation, by intraoperative ultrasound, or by duodenal transillumination. The best approach appears to be intraluminal digital examination of tumors after large longitudinal exposure of the duodenum. The possibility that removal of duodenal gastrinomas and peripancreatic periduodenal lymph nodes might cure hypergastrinemia has been proposed. However, the experience is still insufficient to be certain. A more aggressive surgical approach is represented by the duodenum–cephalous pancreatectomy. This procedure should be used in those cases where gastrin production is clearly localized in the duodenum or head of pancreas. The procedure results in removal of duodenum, a frequent site of one or more gastrinomas, and removal of metastatic peripancreatic lymph nodes and of tumoral nodules from the pancreatic head. The great difficulty of this approach is principally represented by the high operative mortality and by postsurgical complications. In other functioning neuroendocrine tumors (glucagonoma, VIP-oma, PP-oma, and somatostatinoma) and nonfunctioning tumors, the therapeutic choice is easier, because the latter are generally represented by large neoplasms which are easily localized. The long-acting somatostatin analog octreotide is now considered to be the drug of choice for controling hormone secretion under conditions like glucagonoma and VIP-oma (Lamberts *et al.,* 1998; Maton *et al.,* 1989). Cases with systemic metastasis are usually excluded from surgery. Total pancreatectomy is generally not justified because of associated complications.

INSULINOMA

Although one-third of MEN1 microadenomas exhibit insulin immunoreactivity, only selected lesions larger than 5 mm are symptomatic (Kloppel *et al.,* 1986). Only rarely does insulinoma in MEN1 exhibit malignant degeneration, characterized by extrapancreatic infiltration and/or metastasis. Insulinoma surgery is mandatory for the following reasons: (a) generally hypoglycemia is not easily controlled by drugs; (b) during pancreatic surgery one or more incidental macroscopic lesions are found; (c) hypoglycemic syndrome is cured by radical resection of pancreatic macroscopical lesions (O'Riordain *et al.,* 1994) and; (d) malignant degeneration is prevented. Surgery has to be performed often with preoperative localization of a pancreatic nodule. The treatment of choice is removal of the main insulinoma with removal of residual tumors in the head of the pancreas. Splenic preservation is recommended when possible. Removal of nodules in the pancreatic head is needed in about 50% of patients. This surgical procedure can cause both pancreatic fistulas and pancreatitis. Intraoperative monitoring of glucose and insulin is helpful to verify removal of the tumor.

CARCINOIDS

Surgery remains the first choice of treatment of bronchial and thymic carcinoid tumors. In contrast to the surgical approach suggested for the tumors previously mentioned, the approach to ECL-omas in the setting of MEN1 is controversial, because of the multiplicity of gastric primary lesions and because of the uncertainties regarding the prospects of long-term cure as a result of partial or total gastrectomy. The treatment protocol for MEN1 ECL-omas should, therefore, be lowering of gastrin levels, intensified endoscopic surveillance therapy, and gastrectomy on appearance of macrolesions.

Somatostatin analogs have been successfully employed in the treatment of type II gastric carcinoids in three patients with MEN1 syndrome (Tomassetti *et al.,* 2000). During the treatment serum gastrin levels dramatically decreased and tumors regressed in all patients; one of the patients exhibited more than 30 foci widespread throughout the corpus and the fundus of the stomach that disappeared after 1 year of treatment. The regression of tumors was attributed to the decreasing of serum gastrin levels known to be an important factor in the pathogenesis of gastric carcinoid tumors in patients with MEN1 and ZES (Rindi *et al.,* 1996; Bordi *et al.,* 1998)

Pituitary Tumors

The therapy (medical, radiation, surgical) of pituitary tumors is the same as for sporadic pituitary tumors. Medical treatments with dopamine-agonists is the therapy of choice in patients with microprolactinoma.

Pathophysiology

MEN1 is an autosomal dominant disorder with penetrance that approaches 100% with increasing age and with a variable expression (different clinical phenotypes in affected members within a MEN1 kindred, in terms of tumor localization, onset age, and clinical aggressiveness) (Marx, in press). Pathogenic and pathophysiological issues include recent identification of the *MEN1*-encoded protein, named menin, and its largely unknown metabolic pathways at its target tissues.

Pathology/General Considerations

Pathological changes in the target organs of the MEN1 syndrome are more extended than suggested by clinical and biochemical features of the patients. Several lesions, including most pancreatic or gastric endocrine proliferations, can be clinically silent, and others may present overt symptomatology only at advanced stages. A review of 32 autopsy case reports (Majewski and Wilson, 1979) revealed that, by the age of 30, pathological lesions are consistently found in each of the three main involved glands (parathyroids, endocrine pancreas, pituitary), initiating the concept that the MEN1 syndrome is an "all-or-none" phenomenon. Whether this concept may apply to other organs whose involvement has become apparent since that review has not been clarified. These include the carcinoid tissues of the embryonic foregut (duodenum, stomach, lung, thymus), whose involvement may have serious clinical implications, as well as tissues that only rarely exhibit clinical morbidity in MEN1, such as adrenal cortex, adipose tissue, and skin (Friedman *et al.,* 1994; Padberg *et al.,* 1995; Darling *et al.,* 1997).

The sequence of events leading to neoplasia appears to be a subtle, diffuse, follows a similar pattern in all MEN1 target organs. On histopathological basis the initial lesion appears to be a diffuse proliferation of the affected endocrine tissue with bilateral involvement of paired organs and multifocal growth. Whether this change reflects polyclonal hyperplasia or *de novo,* arising multiple clonal lesions, however, has not been clarified yet.

The next step is development of multiple micro- and, eventually, macronodular lesions (Fig. 1). The transition between these lesions and true neoplasms is virtually unrecognizable on histopathological grounds. In fact, evidence from clonality studies in MEN1 parathyroids and pancreatic lesions revealed monoclonality of tissues classifiable as hyperplastic according to the established histopathological

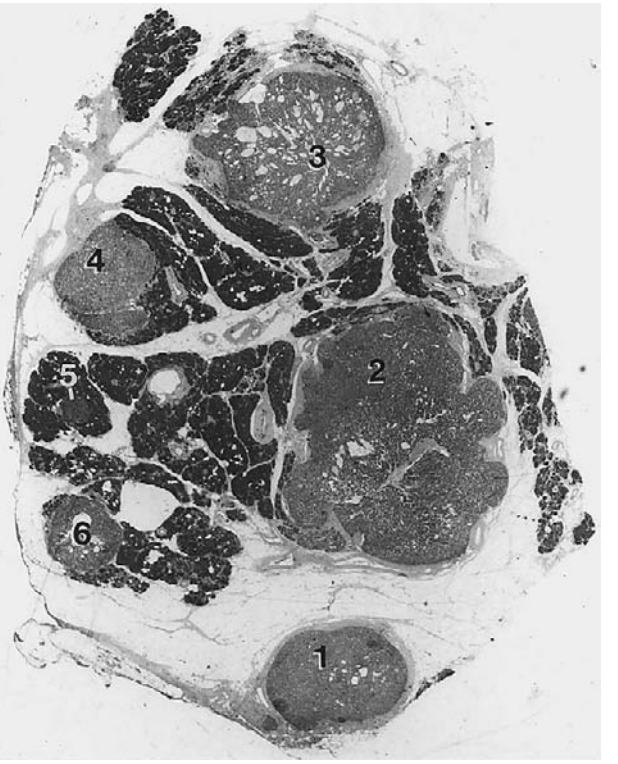

Figure 1 Numerous, scattered islet cell adenomas (numbered 1–6) of various size and architecture in a transverse section of the pancreas of a patient with MEN1 syndrome and ZES (H&E, 4). Reprinted with permission from Pilato *et al.* (1988).

criteria (Larsson *et al.,* 1988; Friedman *et al.,* 1989). LOH analysis of multiple tumors of the same organ, including parathyroids, pancreas, duodenum, and stomach (Morelli *et al.,* 1996; Lubensky *et al.,* 1996; Debelenko *et al.,* 1997a; Debelenko *et al.,* 1997b), consistently showed different patterns and sizes of chromosomal or subchromosomal deletions, indicating that each of multiple tumors is the result of an independent multinational event.

Malignancy in MEN1 syndrome is mostly confined to pancreatic, duodenal, thymic, and bronchial neoplasms. Notably, malignancy in the parathyroid is very rare in MEN1 (Sato *et al.,* 2000). Gastric carcinoid tumors may also pursue a very aggressive course (Bordi *et al.,* 1997; R. T. Jensen, pers. commun.). In a study of a large Tasmanian kindred enteropancreatic malignancies were found in 14 of 69 patients (20%) (Burgess *et al.,* 1998b). All but one of these patients also presented hypergastrinemia. Liver metastases are common in these cases but their origin may be difficult to ascertain. They may derive from either pancreatic (more commonly) or duodenal gastrinoma(s). However, ECL cell carcinoids of the stomach, which are dependent on the trophic stimulus of hypergastrinemia, may also contribute (Bordi *et al.,* 1998). Immunostaining for gastrin or for the isoform 2 of the vesicular monoamino transporter (VMAT-2), the latter of which is specific for ECL cells (Rindi *et al.,* 2000), may help to establish the primary tumor. As typical of endocrine tumors, histopathological

definition of malignancy based on traditional criteria is often flawed. The use of immunohistochemical markers of cell proliferation, however, is useful in this regard (Bordi and Viale, 1995).

Immunohistochemistry using markers of neuroendocrine cells, such as chromogranin A, synaptophysin, and neuron-specific enolase, as well as specific hormonal products of the individual endocrine glands is useful in tumor characterization and in the assessment of preneoplastic lesions. Due to the identification in serum of an MEN1 mitogenic factor (Brandi *et al.,* 1986), structurally similar to basic fibroblast growth factor (FGF) (Zimering *et al.,* 1993), immunohistochemistry, alone or in combination with molecular biology, has also been used to localize basic FGF in MEN1-related endocrine tissues. Ezzat *et al.* (1995) found high levels of basic FGF mRNA in adenomatous but not in normal pituitary glands, a finding consistent with the evidence of a pituitary origin of circulating basic FGF in MEN1 and sporadic pituitary tumor (Zimering *et al.,* 1993). Basic FGF mRNA levels correlated with *in vivo* and *in vitro* release of basic FGF but were consistently associated with lack of basic FGF immunoreactivity in tumor cells, suggesting a constitutive secretion of this peptide. However, basic FGF is elevated in many patients with MEN1 and may play a pathogenetic role (Hoang-Xuan and Steger, 1999). In contrast, immunohistochemical expression of basic FGF was well documented in the gastric proliferating ECL cells (Fig. 2) (Bordi *et al.,* 1994) and in pancreatic endocrine tumors (Chaudhry *et al.,* 1993) in both MEN1 and sporadic patients.

The expression of glycoprotein hormone α-subunit has been revealed by immunohistochemistry in all types of endocrine tumors involved in the MEN1 syndrome, including those of pituitary, pancreas, foregut, and parathyroids (Carlinfante *et al.,* 1998) (Fig. 3). Such expression has been regarded as a marker of malignancy in pancreatic (Heitz *et al.,* 1983) but not in gastric (Bordi *et al.,* 1995a) or pulmonary (Bonato *et al.,* 1992) endocrine tumors. Burgess *et al.* (1998b) reported that serum levels of this protein were elevated in 71% of MEN1 patients with metastatic tumors but only in 7% of those without metastatic neoplasms ($P < 0.05$).

Pathology of the Parathyroids

It is generally assumed that in MEN1 syndrome all parathyroid glands are pathologically involved. Size heterogeneity of parathyroid glands is, however, a consistent finding in MEN1 (Friedman *et al.,* 1994; Padberg *et al.,* 1995) with an average ratio of 9.5 between volumes of the largest and the smallest glands (Marx *et al.,* 1991). Small glands may show no detectable differences from normal glands, also when observed at the microscopic level (Harach and Jasani, 1992). When associated with asymmetric growth of one gland these findings rarely simulate adenoma (DeLellis, 1995). Parathyroid tumor within the thymus, in the thyroid gland, at the carotid bifurcation, or in the mediastinum may be responsible for surgical failures (Mallette, 1994).

By histology, the parathyroid changes are very similar to those of non-MEN1 hyperplasia or of secondary hyperparathyroidism although size variability is a more striking feature in MEN1 (Harach and Jasani, 1992). Both nodular and diffuse patterns of hyperplasia occur, the former being more frequently seen (DeLellis, 1995). In either pattern chief cells are the predominant cell type and are variously associated with oxyphil or transitional oxyphil cells. Neighboring nodules may strongly differ in their cytological and architectural features (Friedman *et al.,* 1994).

Morphological distinction between these hyperplastic nodules and true adenomas is difficult if not impossible (Friedman *et al.,* 1994; Padberg *et al.,* 1995). To date, the

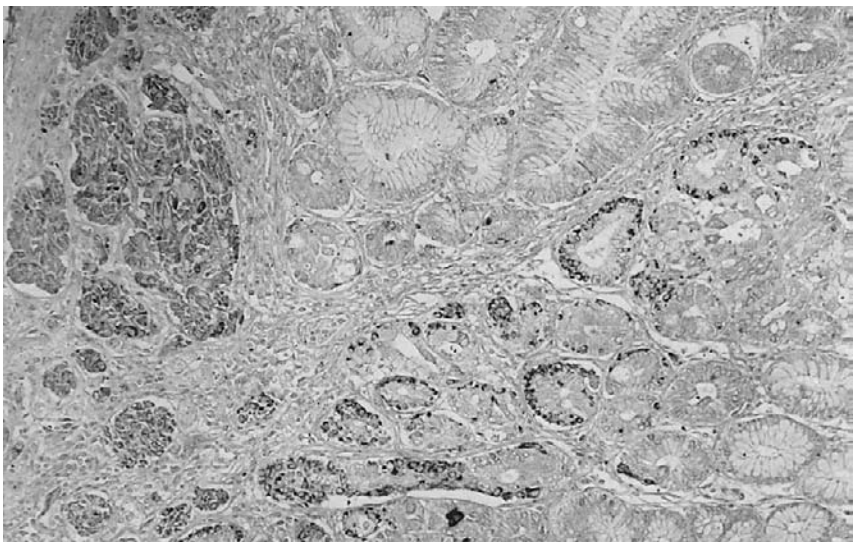

Figure 2 Immunostaining for basic FGF in the gastric endocrine cells of a patient with MEN1 syndrome and ZES. The peptide is expressed by both intraglandular cells showing hyperplastic pretumoral lesions (on the right) and carcinoid tumor (on the left) (immunoperoxidase, 100).

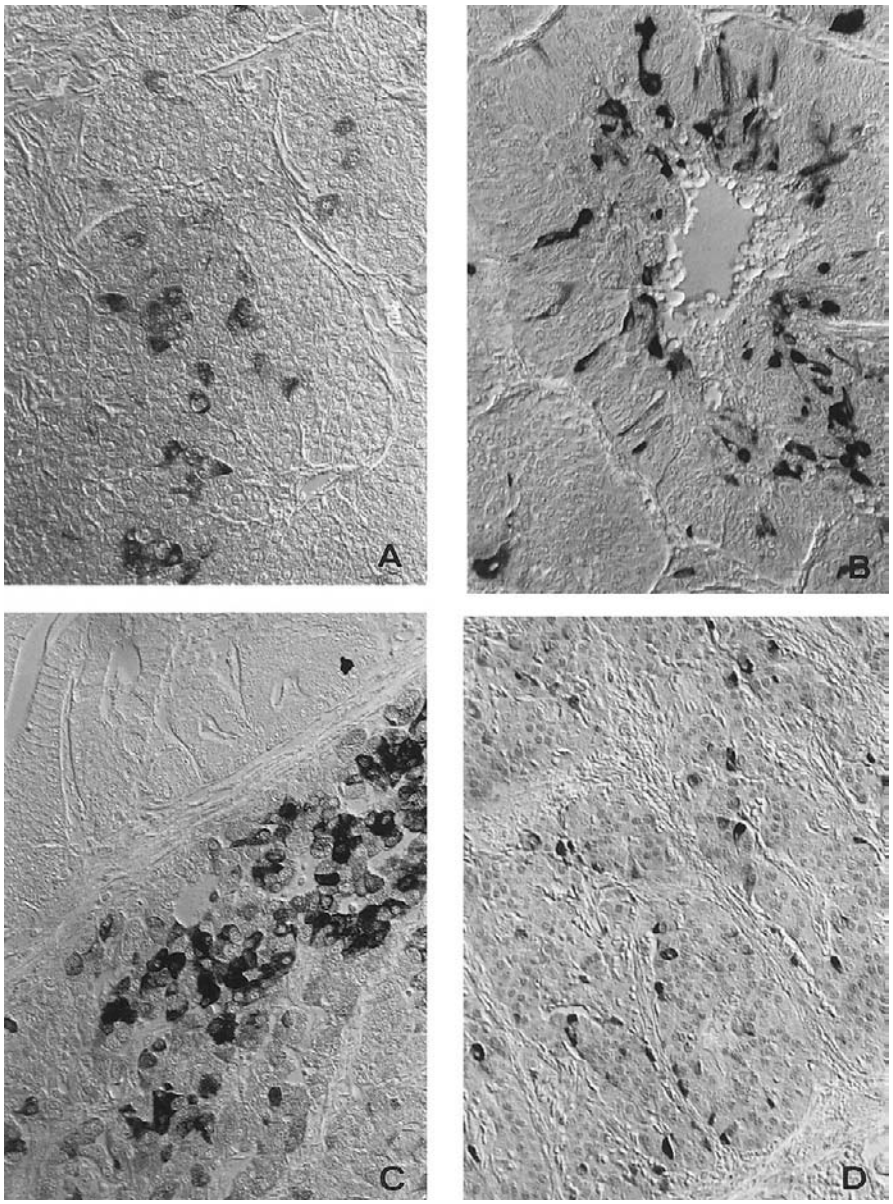

Figure 3 Immunohistochemical expression of γ-subunit of glycoprotein hormones in different types of tumors in MEN1 patients: parathyroid (A), lung carcinoid (B), gastric carcinoid (C), duodenal gastrinoma (D), (immunoperoxidase, 170).

issue has not been clarified even by clonality studies. As a rule the size of monoclonal lesions is significantly larger than that of polyclonal lesions (Friedman *et al.,* 1989; Falchetti *et al.,* 1993). Arnold *et al.,* (1995), using X-chromosome inactivation analysis in patients with either primary MEN1 and non-MEN1 parathyroid hyperplasia or uremic hyperparathyroidism demonstrated definite monoclonal status in 67% of glands with nodular hyperplasia and in 62% of glands with diffuse hyperplasia. These results cast doubts on the long-standing assumption that multiglandular parathyroid disease is a morphologic feature specific for polyclonal parathyroid hyperplasia.

The intensity and topographic distribution of parathyroid hormone immunoreactivity show pronounced variations in MEN1 parathyroid glands (Friedman *et al.,* 1994; Harach and Jasani, 1992). As a rule, hyperplastic areas reveal less immunoreactive hormone content than contiguous normal areas (Harach and Jasani, 1992), a finding consistent with defective mechanism(s) for hormone storage.

The endothelial cells of parathyroid glands, a target of the mitogenic activity of MEN1 growth factor (Brandi, 1991; Friedman *et al.,* 1994), have been investigated by ultrastructural morphometry in a series of MEN1 patients (D'Adda *et al.,* 1993). The parathyroid endothelial component was found to be significantly more expanded in MEN1 than in uremic hyperparathyroidism, indicating its potential role in the proliferation of parathyroid tissues in MEN1.

Pathology of Enteropancreatic Endocrine Tissues

Pathological changes of the pancreas in MEN1 patients have been often inconsistently defined, making evaluation of the actual incidence of specific lesions and of their relationships difficult and unreliable. Two basic changes showing specific functional and clinical characteristics, multiple islet cell microadenomas (microadenomatosis) and grossly single endocrine tumors, may be found (Friedman *et al.,* 1994; Klöppel *et al.,* 1986; Padberg *et al.,* 1995; Thompson *et al.,* 1984). Terms such as nesidioblastosis or islet cell hyperplasia should be avoided owing to their difficult histological identification and uncertain clinical significance.

Microadenomatosis is the most common pancreatic lesion in MEN1 cases. The multiple adenomas, scattered throughout the whole pancreatic gland (Fig. 1), may be very numerous (up to 100 in some cases) and range in size from microadenomas slightly larger than unaffected islets to occasional macroadenomas with a diameter larger that 0.5 cm. Like multiple nodules of parathyroid hyperplasia, even contiguous pancreatic lesions may exhibit striking variations in their histological arrangement, stromal content, and cytological characteristics. The adenomas are functionally silent and are consistently benign both histologically and clinically. They are composed exclusively of cell types normally present in the pancreas, often coexisting in single tumors but lacking the typical topographic distribution seen in normal islets. The immunoreactive cell composition of these adenomas is not random (Pilato *et al.,* 1988), a definite predominance of glucagon-, insulin-, and PP-producing cells being most often observed (Klöppel *et al.,* 1986; Pilato *et al.,* 1988; Padberg *et al.,* 1995; Le Bodic *et al.,* 1996). In small lesions such a predominance may be the only distinctive feature with respect to unaffected islets. In spite of their most frequent association with ZES, gastrin immunoreactivity is uncommonly found in these multiple adenomas, duodenal microgastrinomas, and/or their metastases being responsible for hypergastrinemia in these patients.

Large, macroscopically single endocrine tumors, indistinguishable from those found in those found without MEN1, are less frequently found in MEN1 syndrome. Usually they develop on the background of islet cell microadenomatosis. Like their sporadic counterparts, these neoplasms are frequently malignant and may metastatize to the liver. A large tumor size ($\geq$3 cm) is predictive of this metastatic evolution (Cadiot *et al.,* 1999). Macroscopically single pancreatic tumors are composed of cells producing either endogenous (insulin, glucagon, PP) or ectopic (gastrin, VIP, GHRF, calcitonin, PTH-related peptide) hormones and often show functional activity covering the wide spectrum of clinical syndromes associated with pancreatic endocrine tumors. It has been assumed that functioning insulinomas in MEN1 are more frequently single tumors curable with surgical resection (Klöppel *et al.,* 1986; Thompson *et al.,* 1984). However, others reported a frequent multicentricity of MEN1 insulinomas (DeLellis, 1995). When the one dominant insulinoma in MEN1 is removed with confirmation of its overproduction of insulin (preoperative insulin localization, intraoperative fine needle aspiration for insulin assay, intraoperative serum glucose and insulin), the nonfunctional feature of coexistent pancreatic nodules is evident (Libutti, S., unpublished).

Pathology of the Pituitary

At the pathological levels pituitary lesions are found in more than 60% of MEN1 patients (Scheithauer *et al.,* 1987; Capella *et al.,* 1995) and are often appreciated only when the gland is examined microscopically (Majewski and Wilson, 1979). They are usually represented by macroadenomas associated with diffuse or nodular hyperplasia of extratumoral pituitary cells (Capella *et al.,* 1995). The MEN1 tumors, like sporadic tumors, are grossly invasive in 10–15% of cases. By immunohistochemistry, they are most often found to produce GH or PRL, to be endocrinologically functioning, and to be plurihormonal more often than their sporadic counterparts.

Pathology of Diffuse Neuroendocrine System of Embryonic Foregut Origin

Duodenal gastrinomas are common MEN1 tumors, being the cause of the ZES in more than 90% of MEN1 cases (Padberg *et al.,* 1995). They are multiple tumors, often so small that they escape detection even at intraoperative inspection and so diffusely distributed that they might require removal of the whole duodenum for adequate correction of hypergastrinemia. Immunostaining for gastrin is usually strong. Metastases are frequent but mostly restricted to regional lymph nodes (Pipeleers-Marichal *et al.,* 1990).

Gastric, ECL cell carcinoids may develop in MEN1 patients affected by ZES through a sequence hyperplasia–dysplasia–neoplasia (Solcia *et al.,* 1988; Bordi *et al.,* 1998). In these cases hypergastrinemia acts as a potent promoter for ECL cell proliferation (Bordi *et al.,* 1995a). However, the lack of ECL cell carcinoids in cases of sporadic ZES indicates that biallelic inactivation of the *MEN1* gene (Cadiot *et al.,* 1993; Debelenko *et al.,* 1997a) is essential for the evolution of ECL cell hyperplasia into neoplasia (Solcia *et al.,* 1990; Bordi *et al.,* 1998). Malignant behavior is rare in these carcinoids (Rindi *et al.,* 1996). However, several recent cases of gastric endocrine tumors having aggressive behavior and very poor outcome have been observed (Bordi *et al.,* 1997; R. T. Jensen, pers. commun.). In one of these cases multiple benign gastric carcinoids coexisted with malignant poorly differentiated endocrine carcinomas causing the patient's death (Bordi *et al.,* 1997). 11*q*13 LOH was documented in these undifferentiated neoplasms.

Thymic and bronchial carcinoid tumors can also be regarded as an integral part of the MEN1 syndrome (Padberg *et al.,* 1995). The former are low-grade malignant neoplasms in more than 80% of cases, whereas 3/4 of the latter are benign (Duh *et al.,* 1987; Teh *et al.,* 1997).

Pathology of Other Organs
