Various tumors of thyroid follicular cells, adrenal cortex, cutaneous, and visceral adipose tissue, and skin have been described in MEN1 patients (Brandi *et al.,* 1987; Friedman *et al.,* 1994; Padberg *et al.,* 1995). These tumors are mostly benign lesions. Multiple facial angiofibromas similar to those in tuberous sclerosis, and discrete papular collagenomas are commonly found in MEN1 patients (Darling *et al.,* 1997). Enlargement of adrenal glands *is* found in about 40% of MEN1 patients (Burgess *et al.,* 1996; Komminoth, 1997). The underlying pathologic lesions affect the adrenal cortex and are usually represented by diffuse or (macro)nodular hyperplasia or by adenoma although exceptional cases of carcinomas have been reported (Komminoth, 1997). Due to their common occurrence and lack of *MEN1* inactivation in the general population, thyroid lesions do not seem to be casually related to the MEN1 syndrome. In contrast, allelic loss at the *MEN1* locus has been reported in dermal angiofibroma, truncal collagenoma, esophageal leiomyoma and lipoma (Morelli *et al.,* 1995; Pack *et al.,* 1998; Vortmeyer *et al.,* 1999). Moreover, 11*q*13 LOH was found in rare adrenal medullary tumors (Skogseid *et al.,* 1992; Cote *et al.,* 1998b) but not found in the common adrenocortical hyperplasia of MEN1 patients (Skogseid *et al.,* 1992).

Miscellaneous Malignancies in Patients with MEN1 Syndrome

A number of malignant tumors of various, nonendocrine origin, including exocrine pancreas, kidney, bladder, endometrium, and skin have been reported in MEN1 patients (Bordi *et al.,* 1995b; Thompson *et al.,* 1984: Doherty *et al.,* 1998; Nord *et al.,* 2000). At least five cases of ductal pancreatic adenocarcinoma have been reported, suggesting an increased risk for this tumor in MEN1 (Bordi and Brandi, 1998). 11*q*13 LOH was not found in the single tumor investigated (Bordi *et al.,* 1995b). Malignant melanomas have been reported in seven typical patients from seven MEN-1 kindreds (Nord *et al.,* 2000). However, no role of the *MEN1* gene in the development of sporadic or familial melanomas is proven (Boni *et al.,* 1999; Nord *et al.,* 2000).

Biochemical and Radiological Tests for Tumors in Likely *MEN1* Mutation Carriers

Affected individuals may present with any of the MEN1-associated lesions in early teenage years or escape clinical symptoms for several decades (Skogseid *et al.,* 1991). A periodic investigation should be performed to look for the frequent endocrine and nonendocrine tumors associated with this syndrome in potentially affected individuals. MEN1-associated lesions may develop slowly in unaffected mutation carriers, despite earlier extensive biochemical testing. Early screening for MEN1 tumors in asymptomatic *MEN1* mutation carriers may help to reduce morbidity, but this is not proven. The overall age-related penetrance of tumors is near zero below age 5 years (Stratakis *et al.,* 2000), rising quickly to >50% by 20 years, and >95% by 40 years (Metz *et al.,* 1994; Trump *et al.,* 1996; Bassett *et al.,* 1998; Skarulis, 1998). Individuals at highest risk of developing MEN1 tumors (i.e., mutant *MEN1* carriers have near 100% lifetime risk) should be screened yearly for tumors. Screening should commence in early childhood, and it should continue for life (Trump *et al.,* 1996). However, screening for MEN1 tumors can be difficult and expensive because of large numbers of available and of recommended tests.

Primary hyperparathyroidism is often the first clinical manifestation and the most common pathology associated with the MEN1 syndrome (Lamers and Froeling, 1979; Marx *et al.,* 1986; Oberg *et al.,* 1982), being asymptomatic in 50% of hyperparathyroid cases. Accurate clinical and laboratory screening for parathyroid function (Table II) makes possible an early biochemical diagnosis. A bone mineral density evaluation by DEXA, QCT, or US, both at cortical and trabecular sites can define the fracture risk in cases with hyperparathyroidism. Preoperative parathyroid tumor imaging has little role in the unoperated case. Tc-99m Sesta-MIBI scan is the most useful among many methods prior to parathyroid reoperation. However, a well experienced neck surgeon remains the most important "clinical device" for successful surgery of hyperparathyroidism. Intraoperative measurement of PTH "on-line" is promising to test if deleterious amounts of parathyroid tumor remain during initial or repeat surgery (Tonelli *et al.,* 2000).

Gastrinoma constitutes the second commonest manifestation but the most morbid feature of MEN1 (Croisier *et al.,* 1971; Eberle and Grun, 1981). As for hyperparathyroidism, accurate clinical and biochemical screening could help the physician to detect enteropancreatic disease early, such as basal and maximal acid output, basal evaluation of gastrin, insulin, C-peptide, blood glucose, proinsulin, glucagon, PP, HCG, chromogranin A for an early detection of neoplasms (Skogseid *et al.,* 1987). Challenge tests (secretin or calcium stimulation for gastrin, standard meal for PP, supervised fasting for insulin) have been developed to increase sensitivity; they may be used selectively. Tests with abnormal levels should be repeated. False-positives include high proinsulin/-insulin levels in patients developing insulin resistance or

Table II Biochemical Screening of Primary Hyperparathyroidism in MEN1 Patients

Blood	Urine

hypergastrinemia in patients with hypochlorhydria. Somatostatin receptor scintigraphy ([^{111}In]DTPA-otreotide scan) and endoscopic ultrasound are proven pancreatic imaging methods; CAT or MRI are interchangeable here. Unfortunately, because of the small size and multiplicity of duodenal gastrinomas, these methods most sensitive for the pancreas have low sensitivity for MEN1 gastrinomas (Bansal *et al.,* 1999; Cadiot *et al.,* 1996).

Insulinoma negative to the preoperative imaging is usually readily identified by intraoperative ultrasonography (Bansal *et al.,* 1999). However, since radiology of the enteropancreatic lesion is neither sensitive nor specific, surgery should be done if the biochemical diagnosis is unequivocal, even without symptoms (Skogseid *et al.,* 1996; Granberg *et al.,* 1999).

Symptoms of pituitary neoplasms associated with the MEN1 syndrome depend on both the tumor volume and the hormonal secretion from the gland. Prolactin is the most frequent product of hypersecretion from the anterior pituitary (Croisier *et al.,* 1971; Eberle and Grun, 1981; Majewski and Wilson, 1979). Circulating prolactin measurement should be performed under basal conditions at 0 and 60 min in order to avoid an influence of stress on hormonal secretion. MRI is the preferred pituitary imaging method. Finally, even in cured patients, pituitary tumor screening should continue as *MEN1* somatic mutations ("second hits") in the remaining pituitary cells may predispose to recurrence or the development of new adenoma.

Computed tomography or magnetic resonance imaging of the chest are recommended for early diagnosis of thymic or bronchial carcinoids. Type Il gastric enterochromaffin-like (ECL) cell carcinoids are recognized mainly at gastric endoscopy incidental to evaluation for ZES.

Germline DNA-Based Tests

Human genetic diseases can be derived from different and complex molecular lesions. The simplest to explain are disorders from germline mutation of a single gene. Genetic diagnosis of monogenic disorders is made possible only if either cloned material from a specific gene is sequenced to allow mutation testing or the chromosomal localization of the specific gene is known, and tightly linked genetic markers have been characterized. Testing the *MEN1* mutation carrier state is possible by either approach.

The application of the techniques of molecular genetics has enabled the identification of the gene causing MEN1 syndrome and the detection of its mutations in patients. These recent advances led to experience with an *MEN1* mutation test for the identification of mutant *MEN1* gene carriers who are at a high risk of developing this disorder.

Most laboratories find an *MEN1* mutation in 70–100% of index cases in typical MEN1 families (Agarwal *et al.,* 1997; Teh *et al.,* 1998b; Marx, 2001). The positive rate is lower (20–80%) in index cases with sporadic MEN1. The positive rate is even lower (20%) in familial isolated hyperparathyroidism (Kassem *et al.,* 2000), and the rate is zero in familial somatotrophinoma (Tanaka *et al.,* 1998; Gadelha *et al.,* 2000). There has been no genotype–phenotype relationship, including unrevealing *MEN1* mutations in index cases for families with the prolactinoma variant of MEN1 (Agarwal *et al.,* 1997).

ADVANTAGES OF DNA-BASED ANALYSIS

The advantages of *MEN1* mutation analysis are first that it does not need to be repeated serially, unlike the biochemical screening test for ascertainment of MEN1 through tumor discovery. Second, most results of an *MEN1* mutation test influence long-range planning. Thus, a test identifying an *MEN1* mutant gene carrier may lead to earlier and more frequent biochemical screening for tumors. Screening for MEN1 tumors in asymptomatic mutation carriers may help to reduce morbidity. Moreover, finding family members at no risk for tumors because of no mutation may lead to a decision for no further screening.

LIMITATIONS OF DNA-BASED ANALYSIS

Unfortunately, the obtained information does not influence an immediate intervention or longevity. This reflects the lack of a therapy or prevention of proven value for MEN1-associated malignancy. Second, mutation analysis may provide false negatives since *MEN1* mutations are not detectable in 5–30% of MEN1 families. If large enough, virtually any MEN1 family is likely to be positive for an 11*q*13 haplotype (Larsson *et al.,* 1995; Courseaux *et al.,* 1996).

DNA-BASED ANALYSIS OF TUMORS

Tumor DNA has been evaluated extensively for 11*q*13 LOH and for *MEN1* mutation. These analyses have contributed importantly to research. In particular, analysis of 11*q*13 LOH contributed to narrowing the *MEN1* gene candidate interval for gene discovery (Emmert-Buck *et al.,* 1997; Chandrasekharappa *et al.,* 1997) and to understanding the clonality of certain lesions, such as parathyroid tumors and skin lesions in MEN1 (Friedman *et al.,* 1989; Pack *et al.,* 1998). *MEN1* mutation analysis confirmed a role of *MEN1* inactivation in oncogenesis of many sporadic tumors (Heppner *et al.,* 1997; Boni *et al.,* 1998). On the other hand, analysis of tumor DNA for *MEN1* involvement has little application in current clinical settings. It does not give a useful predictor of tumor aggressiveness, and it does not substitute for mutation analyses of germline DNA.

Early DNA-Based Studies of the *MEN1* Gene

CHROMOSOMAL LOCATION OF THE *MEN1* GENE

Combined studies of both linkage in MEN1 kindreds (Larsson *et al.,* 1988), and microdeletion analysis in tumors (Larsson *et al.,* 1988; Friedman *et al.,* 1989, Emmert-Buck *et al.,* 1997) demonstrated that the MEN1 trait was in close linkage to *PYGM*, the gene for muscle phosphorylase, at chromosome 11*q*13. The proposed model for tumorigenesis in familial MEN1 was according to Knudson's "two hit" hypothesis (Knudson, 1993). In fact, an affected *MEN1* copy is inherited in the germline from the affected parent

(first hit) while the wild copy, from the healthy parent, is eliminated at the somatic level (second hit). The second hit was indirectly suggested by loss of heterozygosity or allelic loss when tumoral DNA is compared to germline DNA. These findings strongly suggested gene inactivation as the mechanism of tumorigenesis from *MEN1*.

THE NORMAL *MEN1* GENE

In 1997 the *MEN1* gene was identified by positional cloning (Chandrasekharappa *et al.,* 1997; Lemmens *et al.,* 1997).

The gene spans 9 kb and consists of 10 exons with a 1830-bp coding region (Fig. 4) that encodes a novel 610-amino-acid protein, referred to as menin. The first exon and last part of exon 10 are not translated. A major transcript of 2.8 kb has been described in a large variety of human tissues (pancreas, thymus, adrenal glands, thyroid, testis, leukocytes, heart, brain, lung, muscle, small intestine, liver, and kidney, Lemmens *et al.* (1997)). Moreover, an additional transcript of approximately 4 kb has been detected in pancreas and thymus, suggesting a tissue-specific alternative splicing (Lemmens *et al.,* 1997).

MENIN: THE *MEN1* GENE-ENCODED PRODUCT

Initial analysis of the predicted amino acid sequence encoded by the *MEN1* transcript did not reveal homologies to any other proteins, sequence motifs, signal peptides, or consensus nuclear localization signals and thus the putative function of the protein menin could not be predicted (Guru *et al.,* 1998).

Intracellular Localization The first studies, based on immunofluorescence, revealed that menin was located primarily in the nucleus. Furthermore, at least two independent nuclear localisation signals (NLS) were identified and located in the C-terminal quarter of the protein (Guru *et al.,* 1998). All of the truncated *MEN1* proteins that would result from the nonsense and frameshift mutations, if expressed, would lack at least one of these NLS.

Menin Molecular Partner The nuclear localization of menin suggested that it may act either in the regulation of transcription, DNA replication, or in the cell cycle. Further studies performed in order to identify proteins that may interact with menin revealed that it directly interacts with the N-terminus of the AP-1 transcriptional factor (Karin *et al.,* 1997) JunD and that it can repress JunD-activated transcription (Agarwal *et al.,* 1999). Analysis of several *MEN1* missense and deletional mutations indicated that a central domain of menin and an amino-terminal domain of junD have a critical role in menin–JunD interaction (Agarwal *et al.,* 1999; Guru *et al.,* 1999). Menin might inhibit junD-activated transcription by recruiting histone deacetylase, a common mediator for many inhibitors of transcription, the so-called corepressors (Gobl *et al.,* 1999). Any role of the menin–JunD interaction remains to be proved. Separate studies have suggested that junD has growth suppressive activity (Agarwal *et al.,* 1999) and that homozygous knockout of the junD gene in the mouse does not cause tumors or tissue effects resembling those in MEN1 (Thepot *et al.,* 2000). Furthermore, the drosophila homolog of menin does not interact with the drosophila jun molecule or even with the human or mouse junD (Guru *et al.,* in press).

Lymphocytes from patient with heterozygous *MEN1* mutation exhibit a premature centromere division, suggesting a possible role of menin in controlling DNA integrity (Sakurai *et al.,* 1999). Hypersensitivity to alkylating agents occurs in lymphocytes from patients with MEN1 (Itakara *et al.,* 2000) with a possible role of menin as a negative regulator of cell proliferation after one type of DNA damage (Ikeo *et al.,* 2000).

MUTATION TYPES IN THE *MEN1* GENE

About 300 different mutations, both somatic and germline, of the *MEN1* gene have been identified. The mutation are varied and scattered throughout the coding region with no clear evidence for clustering (Fig. 4). Approximately half of mutations are unique. The other half are repeating mutations; the repeats reflect either a common founder or a mutational hotspot (Agarwal *et al.,* 1998). These potential mutational hot spots could be due to the presence in the vicinity of repeated long tracts of either single nucleotides or shorter elements. These repeated sequences may undergo misalignment during replication; a slipped strand mispairing model is the most likely mechanism to be associated with this sort of mutational hot spot (Agarwal *et al.,* 1999; Calender, 1999). All or most *MEN1* mutations are likely inactivating, as expected for a tumor suppressor gene: 60% of mutations are frameshift and 25% are nonsense. Truncating mutations predict an inactive or absent protein product. None of them could be associated to specific clinical manifestations of the disorder. Thus genotype/phenotype correlations appear to be absent in MEN1 (Teh *et al.,* 1998b; Agarwal *et al.,* 1997; Bassett *et al.,* 1998) (Fig. 4).

Mutational analysis of the *MEN1* gene in many centers failed to detect mutations in 5–30% of MEN1 patients. This failure could be explained if the mutation was a large deletion, causing the loss of the whole gene or a whole exon (Teh *et al.,* 1998b; Agarwal *et al.,* 1997; Bassett *et al.,* 1998). Consequently, the PCR amplification and mutational analysis shows only the normal allele. Alternatively, mutations may be within the untested parts of the gene, such as introns or the regulatory region. Thus, even though no *MEN1* gene mutation is found in some MEN1 index cases, this does not exclude its involvement. In fact, when MEN1 families have been large enough for linkage analysis, the trait has been linked to 11*q*13 in each (Larsson *et al.,* 1992; Corseaux *et al.,* 1996), suggesting cause by the same gene.

MEN1 GENE AND ENDOCRINE TUMORS

Endocrine tumors may occur either as part of MEN1 or, more commonly, as sporadic, nonfamilial, tumors.

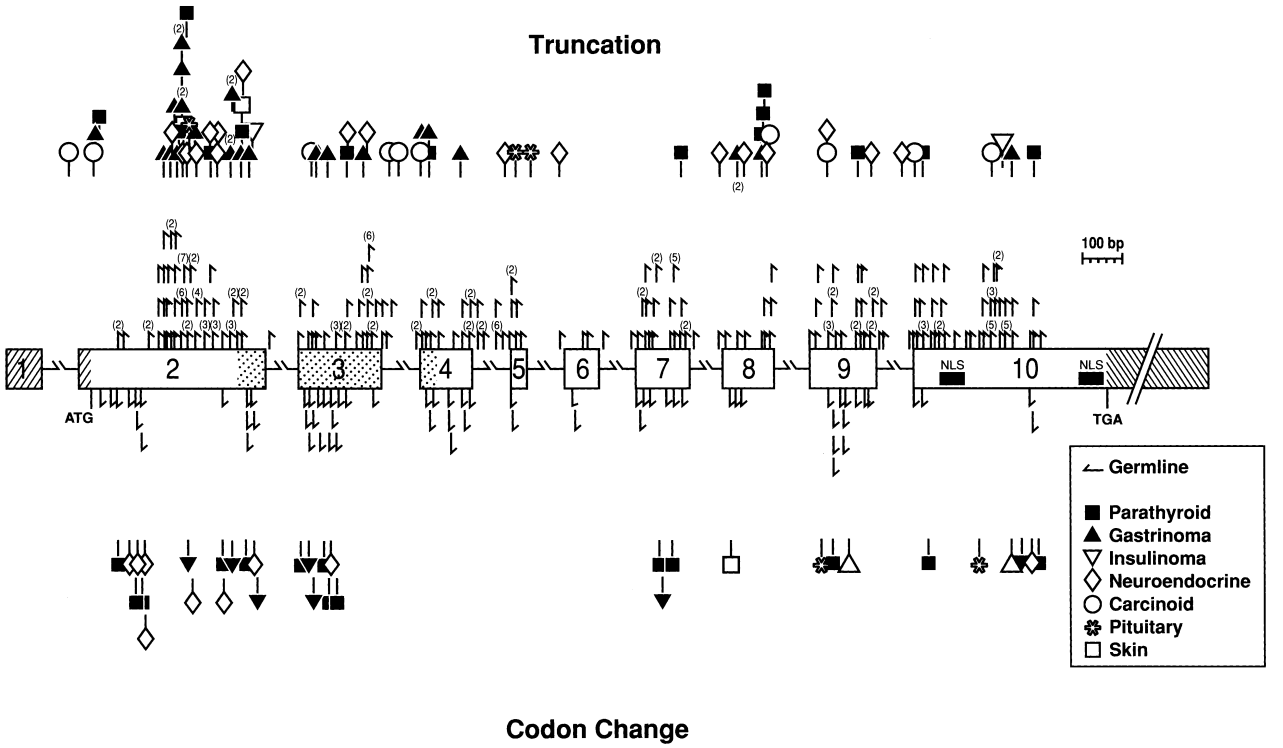

Figure 4 Genomic organization of the *MEN1* gene and of *MEN1* germline and somatic mutations, published as of June 2000. The gene contains 10 exons (with the first exon untranslated) and extends across 9 kb. Mutations shown above the exons cause menin truncation, and those shown below the exons cause a codon change. All unique mutations are represented; numbers in parenthesis designate multiple reports of the same mutation in presumed unrelated persons. The hatched areas indicate the untranslated regions. The location of the two nuclear localization signals (NLS), at codons 479–497 and 588–608, are indicated. Missense mutations in a region of menin (aa 139–242) (identified by stippling) prevented interaction with the AP1 transcription factor JunD.

Mutational analysis of MEN1-associated and sporadic endocrine tumors revealed that most tumors from MEN1 patients harbor the germline mutation together with a somatic LOH involving chromosome 11q13 (Marx *et al.,* 1998), as expected from Knudson's model and the proposed role of the *MEN1* gene as a tumor suppressor. However, LOH involving chromosome 11*q*13, which is the location of the *MEN1* gene, has also been observed in 5 to 50% of sporadic endocrine tumors, suggesting inactivation of the *MEN1* gene in the etiology of these tumors. Of those with 11*q*13 LOH, about half have shown somatic *MEN1* mutation; this includes sporadic parathyroid adenomas, sporadic gastrinomas, sporadic insulinomas, sporadic bronchial carcinoids, and sporadic anterior pituitary adenomas (Heppner *et al.,* 1997; Debelenko *et al.,* 1997; Zhuang *et al.,* 1997). Altogether, these observations establish that *MEN1* is the known gene most frequently mutated in nonfamilial variety endocrine tumors.

Nonendocrine Tumors

At least four different mesenchymal tumors can be caused by inactivation of the *MEN1* gene. These include skin/dermal lipoma, angiofibroma (Fig. 5), and collagenoma. In each case loss of the normal allele has been proven with material from MEN1 patients (Pack *et al.,* 1998). Furthermore sporadic lipoma and sporadic angiofibroma is occasionally associated with somatic *MEN1* mutation (Vortmeyer *et al.,* 1998; Boni *et al.,* 1998). Esophageal leiomyoma also was associated

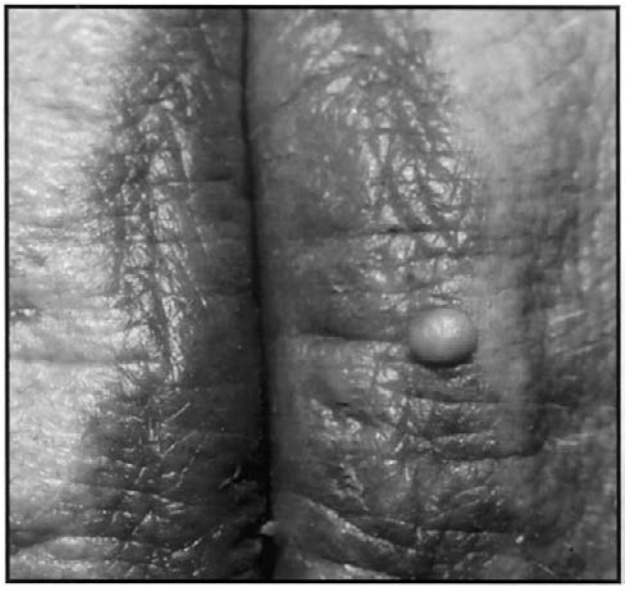

Figure 5 MEN1-associated angiofibroma.

with 11*q*13 LOH in one case (Vortmeyer *et al.,* 1999). This establishes that, like other multiple neoplasia syndromes, the tissue pattern of tumors in MEN1 does not follow a developmental distribution or any other recognizable distribution

Animal Models

Inactivation of certain other tumor suppressor genes alone or in combination can cause specific endocrine tumors in mice. In particular, mice with simultaneous homozygous knockout of two genes, $p18^{INK4c}$ and $p27^{KIP1}$, develop tumors of parathyroid, pituitary, pancreas islet, and duodenum (like MEN1). They also develop C-cell cancers and pheochromocytoma (like MEN2) (Franklin *et al.,* 2000). The knocked out genes encode members of the two cyclin-dependent kinase inhibitor families that participate in the G1 phase of the cell cycle, a phase that also includes retinoblastoma and cyclin D1. This syndromic resemblance raises the possibility that the pathways of MEN1 and/or MEN2 interact with the cell cycling pathway and perhaps with each other.

The mouse *Men1* gene is highly homologous to *MEN1*. Heterozygous knockout of *Men1* in the mouse results in a promising model of MEN1 (Crabtree *et al.,* 2000). Those mice develop tumors of the parathyroids, pancreatic islets, and pituitary. Unlike the pituitary intermediate lobe tumors with G1 phase tumor suppressor gene knockouts, these pituitary tumors are prolactinomas. The mouse tumors are associated with LOH at the mouse *Men1* locus.

Conclusion

The discovery of the *MEN1* gene has led to changes in clinical management and to new insights about normal and abnormal functions. New tools are in place to answer many questions shortly. Similarly there are prospects for novel treatments based upon DNA, RNA, or even other small molecules.

CHAPTER 59

The Role of the *RET* Protooncogene in Multiple Endocrine Neoplasia Type 2

Robert F. Gagel* **and Gilbert J. Cote†**

Division of Internal Medicine, and †Department of Endocrine Neoplasia and Hormonal Disorders, University of Texas M. D. Anderson Cancer Center, Houston, Texas 77030

Introduction

The *RET* proto-oncogene is a tyrosine kinase receptor that regulates neuronal differentiation and kidney development. It is expressed in the neural crest during early embryonic life. Migration of *RET*-positive cells from the neural crest leads to development of the gastrointestinal neuronal system and the dorsal sympathetic system. In an unexpected twist, mutations of the *RET* proto-oncogene were identified in multiple endocrine neoplasia type 2A (MEN 2A), a syndrome composed of medullary thyroid carcinoma (MTC), pheochromocytoma, and hyperparathyroidism (Sipple, 1961). The identification of these activating mutations and a parallel series of fundamental observations seeking to clarify the role of glial cell-derived neurotrophic factor (GDNF) has defined a new receptor system that is important for development and differentiation of neural crest-derived cells. This chapter will outline the substantial progress over the past 5 years toward an understanding of the *RET* receptor system.

Multiple Endocrine Neoplasia Type 2 (MEN 2)

Sipple was the first to describe an association between thyroid carcinoma and pheochromocytoma (Sipple, 1961), leading to a decade in which the clinical and heritable features of this syndrome were defined (Steiner *et al.,* 1968; Melvin *et al.,* 1972). Williams and his coworkers (Williams and Pollock, 1966) are generally credited with the reidentification of the mucosal neuroma syndrome (MEN 2B) first described earlier (Froboese, 1923) and the recognition that this clinical syndrome is associated with MTC and pheochromocytoma. Additional variants of MEN 2 include familial medullary thyroid carcinoma (FMTC) with no other manifestations of MEN 2 (Farndon *et al.,* 1986), MEN 2A in association with cutaneous lichen amyloidosis (Gagel *et al.,* 1989; Nunziata *et al.,* 1989), and MEN 2A in association with Hirschsprung disease (Table I) (Verdy *et al.,* 1982).

Multiple Endocrine Neoplasia Type 2A

The term Sipple syndrome is most correctly applied to the association of MTC, pheochromocytoma, and parathyroid neoplasia (Table I), now known as MEN 2A. Our thinking about this syndrome has evolved over the past several decades. During the first decade after Sipple's report, the three major components of the syndrome were characterized (Schimke *et al.,* 1965, 1968). The convergence of several observations led to the use of provocative tests for diagnosis of early MTC. These included the identification of the peptide hormone calcitonin (Copp *et al.,* 1961; Hirsch *et al.,* 1964), the identification of the C cell (thyroid parafollicular cell) as the transformed cell type in MTC (Williams, 1966), the recognition it produces calcitonin (CT) (Foster *et al.,* 1964), and the development of radioimmunoassays for calcitonin

Table I Multiple Endocrine Neoplasia Type 2 (MEN 2) Classification

Marfanoid features
Absence of parathyroid neoplasia

(Deftos *et al.,* 1968; Melvin *et al.,* 1972). The observation that either intravenous calcium or pentagastrin could be used to stimulate calcitonin release provided early investigators with a tool for identifying early C cell abnormalities (Cooper *et al.,* 1971; Melvin *et al.,* 1971; Hennessey *et al.,* 1973, 1974). These provocative tests were subsequently used by others to screen MEN 2 kindreds for early C cell abnormalities (Wells *et al.,* 1975; Leape *et al.,* 1976; Graze *et al.,* 1978; Gagel *et al.,* 1988). In parallel studies, hyperplasia of the adrenal medulla was identified as a precursor lesion (Carney *et al.,* 1976; DeLellis *et al.,* 1976). Implementation of prospective screening studies over the next two decades resulted in the routine identification of MTC and pheochromocyoma at early developmental stages. It is now reasonable to believe that death related to either of these manifestations can be prevented in most patients by surgical intervention at an appropriate point during the natural history of this clinical syndrome (Cance and Wells, 1985; Gagel *et al.,* 1988).

The Three Components of MEN 2

Neoplastic Transformation of the C Cell

The parafollicular cells are neural crest-derived neuroendocrine cells located adjacent to the thyroid follicle (Fig. 1). These cells produce CT, a small peptide that binds to specific receptors on osteoclasts and inhibit bone resorption. The C cells are distributed within the thyroid gland in a characteristic pattern. The greatest concentration is found in the upper one-third of each lobe along a hypothetical cephalad–caudal axis. It is therefore not surprising that hereditary MTC, in which each cell has an activating mutation, occurs most frequently at this anatomic location. There is a progression of histologic events in the development of MTC: C cells progress through several stages including hyperplasia, nodular hyperplasia (a single focus of C cells that displace a thyroid follicle, giving the appearance of a nodule of cells within the follicle), and microscopic MTC (Wolfe *et al.,* 1973; Carney *et al.,* 1979; Wolfe *et al.,* 1981). At some point along this pathway of progression metastasis may occur (Graham *et al.,* 1987; Niccoli-Sire *et al.,* 1999). Separate foci at different stages of neoplastic development are found commonly within the thyroid gland of a gene carrier. Metastasis to central lymph nodes of the neck is found most commonly

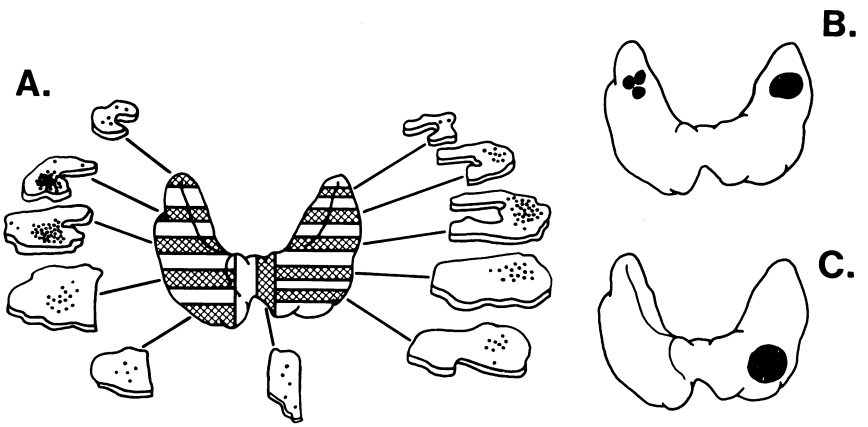

Figure 1 Distribution of C cells in the thyroid gland. (A) Reconstruction of the distribution of C cells in the thyroid gland. The greatest concentration of C cells occurs at the junction of the upper one-half and lower-two thirds of the gland. This distribution explains the characteristic location of hereditary medullary thyroid carcinoma. (Modified from Wolfe H. J., Voelkel, E. F., Tashjian, A. H., Jr: Distribution of calcitonin containing cells in the normal adult human thyroid gland: a correlation of morphology with peptide content. *J. Clin. Endocrinol. Metab.* **38,** 688–694, 1974.) (B) Hereditary medullary thyroid carcinoma is almost always bilateral, although the extent of involvement may not be equal. (C) Sporadic medullary thyroid carcinoma is most commonly a unilateral process that may develop at any location within the thyroid gland.

in patients with a visible focus of MTC, although it has been reported with microscopic MTC (Niccoli-Sire *et al.,* 1999). It is thought that local lymph node metastasis precedes distant metastasis in most cases, because surgical resection of lymph nodes metastasis in patients with early MTC will cure about 25% of patients (Miller *et al.,* 1972; Gagel *et al.,* 1988).

Hereditary MTC is characteristically multifocal. Each tumor appears as a whitish-yellow circumscribed lesion on a background of thyroid tissue. The characteristic histologic features of the tumor include a nested endocrine-type appearance or sheets of cells interspersed with amyloid which is derived at least in part from calcitonin gene products (Livolsi, 1990).

Tumor markers that are useful for management of hereditary or sporadic MTC include CT and carcinoembryonic antigen (Baylin *et al.,* 1972). A variety of other peptides are produced by MTC including somatostatin (Gagel *et al.,* 1986), chromogrannin A (Deftos *et al.,* 1988), histaminase (Baylin *et al.,* 1970), and DOPA decarboxylase (Baylin *et al.,* 1979).

Adrenal Medullary Abnormalities

There are several features that differentiate pheochromocytomas associated with the MEN 2 from sporadic pheochromocytomas. These include the development of pheochromocytoma on a background of medullary hyperplasia, production of a greater proportion of epinephrine than is seen in sporadic pheochromocytomas, and bilaterality. Analogous to the thyroid, pheochromocytomas in MEN 2 evolve out of medullary hyperplasia and it is not uncommon to identify multiple discrete pheochromocytomas set on a background of hyperplasia. MEN 2-related pheochromocytomas, unlike sporadic pheochromocytomas or those associated with von Hippel Lindau syndrome, express the enzyme phenylethanolamine-*N*-methyltransferase at higher levels and therefore produce disproportionate amounts of epinephrine. The first abnormality in a MEN 2A-related pheochromocytoma is an absolute increase of epinephrine production (Gagel *et al.,* 1975; Hamilton *et al.,* 1978; Miyauchi *et al.,* 1982; Telenius-Berg *et al.,* 1987) or an increase in plasma normetanephrine or metanephrine values (Eisenhofer *et al.,* 1999). These biochemical findings lead to symptoms of epinephrine excess including palpitations, nervousness, jitteriness, and the absence of hypertension. There may be subsequent development of hypertenision as norepinephrine production increases. Most MEN 2 pheochromocytomas are intraadrenal lesions. Extraadrenal pheochromocytomas in this syndrome are thought to have arisen from adrenal rest tissue or represent recurrence of a pheochromocytoma in the anatomic region of the adrenal gland (Lips *et al.,* 1981; Modigliani *et al.,* 1995). Pheochromocytomas occur in approximately 50% of gene carriers and are bilateral in approximately one-half (Steiner *et al.,* 1968; Lips *et al.,* 1981; Gagel *et al.,* 1988; Howe *et al.,* 1993; Modigliani *et al.,* 1995).

Parathyroid Abnormalities

There is a low incidence of hyperparathyroidism in MEN 2A (5–20%). There are several unique features. Hyperparathyroidism occurs in some kindreds with greater frequency than others (Wells *et al.,* 1975). In addition, early prophylactic thyroidectomy for MTC appears to have resulted in a lower incidence of hyperparathyroidism despite follow-up periods that now exceed 25 years in some kindreds (Gagel *et al.,* 1988; Bone *et al.,* 1992). Development of hyperparathyroidism following total thyroidectomy in a single member of a kindred in which there is a high incidence of this disorder suggests this is not always the case (author's experience). Is it unclear whether the observed lower incidence of hyperparathyroidism in some kindreds treated by prophylactic thyroidectomy is related to a growth stimulatory factor produced by the thyroid gland or has resulted from the inevitable loss of parathyroid tissue during total thyroidectomy. Pheochromocytoma may rarely cause hypercalcemia, possibly related to production of parathyroid hormone-related protein, and should be excluded prior to surgical exploration (Gagel *et al.,* 1988).

Hyperplasia of multiple parathyroid glands is the most common abnormality found in hyperparathyroidism associated with MEN 2, although many reports emphasize the occurrence of multiple parathyroid adenomas in individuals who present with the fully developed MEN 2 syndrome, generally after the age of 35 years. Most surgeons treat hyperparathyroidism by multiple gland resection, although in kindreds where hyperparathyroidism is a significant problem, total parathyroidectomy with transplantation of a normal amount of tissue to the nondominant forearm may be appropriate.

Familial Medullary Thyroid Carcinoma

Familial MTC is defined as the occurrence of hereditary MTC without other manifestations of MEN 2A and represents 10–15% of all hereditary cases. The MTC tends to develop later and is less likely to behave aggressively (Farndon *et al.,* 1986). Categorization as FMTC should be made only after observing several generations; pheochromocytoma and hyperparathyroidism are much less penetrant in classic MEN 2A (50 and 15%, respectively) and it is possible to incorrectly asssign the term FMTC to small families in which these manifestations have not developed. This distinction is important to ensure appropriate screening for pheochromocytoma.

The MEN 2A/Hirschsprung's Phenotype

Classic Hirschsprung disease has been observed in association with MEN2A in 20–40 kindreds (Wohllk *et al.,* 1996; Decker *et al.,* 1998). The Hirschsprung disease associated with MEN 2A does not differ from other forms of

childhood Hirschsprung disease and is usually correctable surgically. In contrast MEN 2B, described below, is characterized by neuromas in the oral cavity and throughout the gastrointestinal tract.

MEN 2A with Cutaneous Lichen Amyloidosis

In fewer than 20 kindreds with MEN 2A a unilateral or bilateral pruritic skin lesion located over the upper back (dermatomes C6-T5) has been identified (Gagel *et al.,* 1989; Nunziata *et al.,* 1989). Clinical features in these kindreds are identical to classic MEN 2A, although there may be a lower incidence of parathyroid disease (Ferrer *et al.,* 1991; Chabre *et al.,* 1992b; Robinson *et al.,* 1992). The characteristic feature of this variant is intense intermittent periods of prurritus that may develop in childhood and be a premonitory indication of gene carrier status (Chabre *et al.,* 1992a). Biopsy of advanced forms of this lesion has demonstrated typical findings of cutaneous lichen amyloidosis (Gagel *et al.,* 1989), whereas amyloid is infrequent in early skin lesions (Gagel *et al.,* 1989; Ferrer *et al.,* 1991; Chabre *et al.,* 1992b). Several explanations have been considered to explain the presence of amyloid. Friction amyloidosis, caused by the incessant scratching, appears to be the most logical mechanism for amyloid accumulation (Chabre *et al.,* 1992a). This is supported by the finding of positive immunohistochemical staining for keratin in the amyloid and the absence of CT gene products (Donovan *et al.,* 1989). The dermatome-like distribution of the skin lesion, which matches the normal expression pattern of *RET* (Durbec *et al.,* 1996), suggests an effect of *RET* on neuronal firing, leading to the prurritic symptomatology. Abnormal cutaneous innervation in *RET* knockout mice provides independent support for this hypothesis (Fundin *et al.,* 1999).

Multiple Endocrine Neoplasia Type 2B

The clinical findings of MTC, pheochromcytoma, mucosal neuromatosis, skeletal abnormalities suggestive of Marfan's syndrome, and the absence of hyperparathyroidism define the clinical features of multiple endocrine neoplasia type 2B (MEN 2B). Although there is wide variability in clinical presentation, most patients with MEN 2B have mucosal neuromas on the tip of the tongue, on the conjunctival surface of the eye lids and throughout the gastrointestinal tract. Children most commonly present with abdominal pain or pseudoobstruction (Carney *et al.,* 1976). The Marafanoid-like features of longer arms and legs, pectus abnormalities, long, thin fingers, hyperextensibility of joints, and epiphyseal abnormalities combined with mucosal neuromas are pathognomonic for this clinical syndrome (Carney *et al.,* 1978, 1981; Williams and Pollock, 1966). Lens ectopia, cataracts and dissecting aortic aneurysm, frequent findings in Marfan syndrome, have never been reported in MEN 2B, although the author has seen a patient who inherited the genes for MEN 2A and Marfan syndrome from separate parents.

Penetrance of MTC in MEN 2B is high; metastasis has been described during the first year of life. Medullary thyroid carcinoma in the context of MEN 2B commonly pursues an aggressive course, although this is not uniformly the case. A number of multigenerational kindreds with this disorder have been described, suggesting a more benign course in some (Sizemore *et al.,* 1992; Vasen *et al.,* 1992). Hyperparathyroidism is a rare finding in MEN 2B (Carney *et al.,* 1980).

Genetic Linkage Analysis and the RET Receptor System

The gene for MEN 2 was localized to centromeric chromosome 10 in 1987 (Mathew *et al.,* 1987; Simpson *et al.,* 1987) and the mutations of the *RET* proto-oncogene were identified in 1993 (Donis-Keller *et al.,* 1993; Mulligan *et al.,* 1993). In the period since 1993 the individual components of the *RET* receptor system have been identified (Fig. 2). The first is the RET tyrosine kinase receptor, identified in 1985 (Takahashi *et al.,* 1985, 1987). Two other components of this receptor system, a ligand (glial cell-derived neurotrophic factor or GDNF) and a second extracellular component of the receptor system (glial cell-derived neurotrophic factor receptor alpha-1 or GFRα-1) have been identified (Fig. 2) (Hoff *et al.,* 2000). Individual disruption of each of the three components of the receptor system in mice leads to nearly identical phenotypes that include failure of normal kidney development, a Hirschsprung-like neuronal phenotype in the gastrointestinal tract (disordered neuronal development), and abnormal dorsal sympathetic development (Schuchardt *et al.,* 1995; Durbec *et al.,* 1996b; Jing *et al.,* 1996; Moore *et al.,* 1996; Pichel *et al.,* 1996; Sanchez *et al.,* 1996; Treanor *et al.,* 1996). Subsequent studies showed that GDNF is a ligand for RET (Durbec *et al.,* 1996a; Treanor *et al.,* 1996) and identified GFRα-1, a protein that is tethered to the extracellular membrane, binds GDNF, but contains no transmembrane or intracellular domain. Together, RET and GFRα-1 form a receptor system for GDNF.

Mutations of *RET* Cause Multiple Endocrine Neoplasia Type 2

Two broad categories of mutations cause hereditary MTC or MEN 2. The most common are extracellular mutations of the cysteine-rich dimerization domain; less common are mutations that change single amino acids in the intracellular tyrosine kinase domain (Table I). The extracellular domain mutations associated with MEN 2 or familial MTC affect codons 609, 611, 618, 620, 630, and 634 and change a highly conserved cysteine to another amino acid (Table I). Mutations at codon 634 mutations are most common, accounting for approximately 80% of all mutations in MEN 2; a single

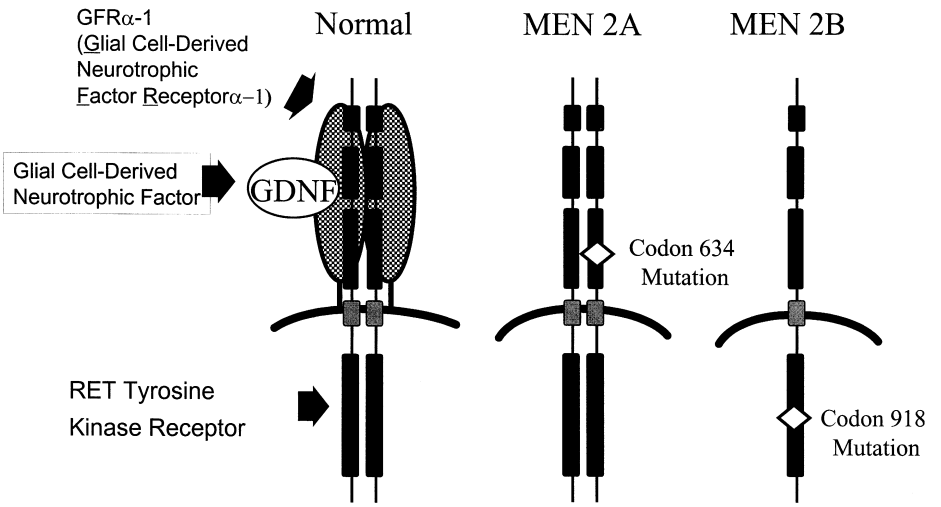

Figure 2 The RET receptor complex and mechanism of RET activation. Normal: Glial cell-derived neurotrophic factor (GDNF) is a small peptide that promotes neuronal survival. It interacts with a receptor complex formed by the RET tyrosine kinase receptor (RET) and the glial cell-derived neurotrophic factor receptor (GFRα-1). GDNF and RET/GFRα-1 interactions promote development of the collecting system of the kidney, normal migration of neurons from the neural crest into the gastrointestinal tract, and normal sympathetic nervous development in those neurons derived from the first six somites. MEN 2A: Mutations of highly conserved cysteines in a region immediately outside the extracellular membrane promote RET dimerization and activation of downstream signaling pathways. MEN 2B: Mutation of codon 918 (methonine to threonine) results in activation of the tyrosine kinase domain in the absence of either ligand or dimerization of the receptor.

change (TGC to CGC; cysteine to arginine) accounts for approximately 50% of all *RET* mutations found in hereditary MTC. The extracellular domain mutations cause dimerization of the RET receptor complex, autophosphorylation, and activation of downstream tyrosine kinase pathways in the absence of GDNF. Intracellular mutations change codons 768, 790, 791, 804, 891, 883, and 918. The intracellular changes activate the intracellular kinase domain directly without the necessity for receptor dimerization (Asai *et al.,* 1995; Santoro *et al.,* 1995).

There are mutation-specific correlations between codon substitutions and the clinical phenotype (Table I). A codon 634 mutation is most commonly associated with classic MEN 2A (Eng *et al.,* 1996). MEN 2A has also been found in patients with mutations of codons 609, 611, 618, 620 (Donis-Keller *et al.,* 1993; Mulligan *et al.,* 1994), 791 (Berndt *et al.,* 1998), and V804L (Nilsson *et al.,* 1999). Kindreds with the MEN 2A/cutaneous lichen amyloidosis variant invariably have a mutation at codon 634 (Eng *et al.,* 1996), whereas individuals with the MEN 2A/Hirschsprung variant have codon 609, 618, or 620 mutations (Lacroix *et al.,* 1994; Mulligan *et al.,* 1994; Decker *et al.,* 1998).

Kindreds in which there is multigeneration FMTC may also have codon 609, 611, 618, or 620 *RET* mutations 620 (Donis-Keller *et al.,* 1993; Mulligan *et al.,* 1994), although mutations at these same codons may also be associated with MEN 2A (Table I). FMTC is uniquely associated with mutations at codons 768 (Boccia *et al.,* 1997), 790 (Berndt *et al.,* 1998), V804M (Bolino *et al.,* 1995; Miyauchi *et al.,* 1999), and 891 (Hofstra *et al.,* 1997; Dang *et al.,* 1999).

MEN 2B is most commonly associated with a codon met918thr substitution (Carlson *et al.,* 1994; Hofstra *et al.,* 1994). There have been a handful of MEN 2B patients described with codon 883 substitutions (Gimm *et al.,* 1997; Smith *et al.,* 1997). The majority of MEN 2B mutations occur *de novo* (neither parent carries a germline mutation), although a small number of multigeneration MEN 2B kindreds exist. Most of the *de novo* mutations occur in the paternal allele (Carlson *et al.,* 1994).

There are still a handful of kindreds with MEN 2 or FMTC ($<$2% of the total) in which no *RET* mutation has been identified. This suggests that there are other as yet unidentified mutations of *RET* or that mutations of a second gene may be involved in this hereditary syndrome. It is important to keep this point in mind when evaluating a kindred with hereditary MTC; although there may be no identifiable mutation at present, consideration should be given to retesting at periodic intervals as new mutations are identified.

The Mechanism of Transformation

Missense mutations of *RET* cause transformation by one of two different mechanisms. Mutations of the extracellular domain (609, 611, 618, 620, 630, and 634) cause dimerization and activation of the receptor (Fig. 2), presumably in the absence of GDNF (Asai *et al.,* 1995; Santoro *et al.,* 1995). In contrast, dimerization of the receptor is not required for transformation caused by a codon 918 mutation

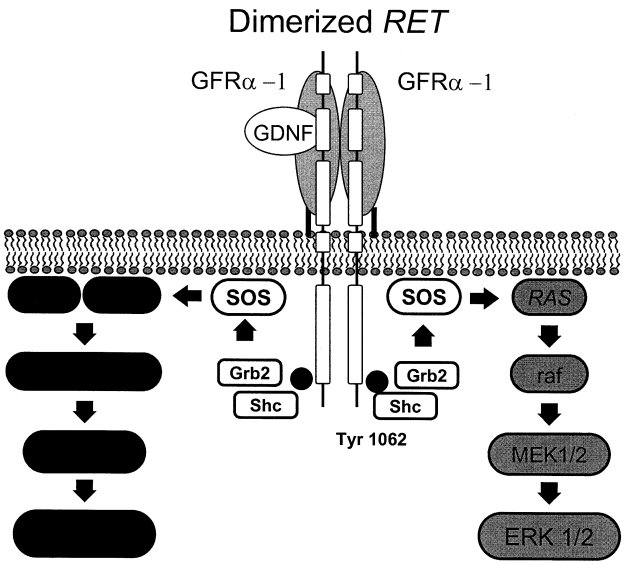

Figure 3 Intracellular signaling pathways activated by the GDNF–GFRa-1/Ret signaling system. Two different intracellular signaling pathways (JNK/SAPK and ERK 1/2) are activated by this the the GDNF-GFRa-1/Ret receptor complex.

(Fig. 2), the most common intracellular domain mutation (Asai *et al.,* 1995; Santoro *et al.,* 1995). Both intracellular and extracellular mutations cause receptor autophosphorylation and phosphorylation of different sets of downstream proteins in the signaling cascade. The tyrosine at codon 1062 (a *Shc* binding site) is autophosphorylated, interacts with c-*src,* and appears to mediate most of the transforming activity caused by either codon 634 or codon 918 mutations (Asai *et al.,* 1996; Ohiwa *et al.,* 1997; Santoro *et al.,* 1999; De Vita *et al.,* 2000). Activation of a JNK and ERK 1 pathways mediates the transforming effects of both types of mutations (Fig. 3) (Chiariello *et al.,* 1998).

Other Genetic Mechanisms in MEN 2

Recent studies suggest that either loss of the normal copy of *RET* (loss of the normal chromosome) or reduplication of the mutant chromosome 10 (Fig. 4; trisomy 10) are found in a high percentage of MEN 2-related tumors (Huang *et al.,* 2000). These findings suggest that the ratio of mutant to normal RET expression may be an independent factor (a second hit) in the transformation process. These findings imply that a homodimer containing two mutant copies of RET have a greater transforming effect than a receptor complex consisting of a heterodimerized receptor.

In addition, genetic abnormalities at other loci are found in MEN 2-related tumors. These include a loss of heterozygosity (LOH) on chromosome 1*p* in MTC (Mathew *et al.,* 1987; Moley *et al.,* 1992), 3*p* [Cooley *et al.,* 1995; (Khosla *et al.,* 1991), and chromosome 22 (Takai *et al.,* 1987; Cooley *et al.,* 1995). Specific genes at these loci have not been identified.

The Role of *RET* in Normal Development

The GDNF/RET/GFRα-1 receptor system is a major determinant of neuronal migration from neural crest tissue. RET-positive cells presage the development of the facial, glossopharyngeal, trigeminal, vagus cranial, and sympathetic ganglia, and spinal motor neurons (Tsuzuki *et al.,* 1995). RET-positive cells also migrate from the neural crest into the developing gastrointestinal tract and are found in the developing ureteric bud. Targeted deletion of the GDNF (Moore *et al.,* 1996; Pichel *et al.,* 1996; Sanchez *et al.,* 1996), *RET* (Schuchardt *et al.,* 1995; Durbec *et al.,* 1996a), or GFRα-1 (Cacalano *et al.,* 1998) genes in mice cause major abnormalities of the sympathetic nervous system and cause a Hirschsprung-like phenotype in the gastrointestinal tract. Indeed, this finding predicted the presence of inactivating RET mutations in one-half of patients with familial Hirschsprung disease, although more recent studies suggest a role for rare polymorphisms of *RET* in nonfamilial Hirschsprung disease (Borrego *et al.,* 1999). Other phenotypic abnormalities in knockout animals include diminished ganglionic development and a failure of normal kidney development, a defect caused by a failure of interaction between RET (expressed in the ureteric bud) and GDNF (expressed in the renal mesoderm).

Use of Genetic Information in the Clinical Management of MEN 2

Genetic testing in MEN 2 has quickly become one of the more successful examples of use of this technology for management of cancer. This differs from the experience with other malignancies such as breast or colon cancer where use of genetic testing is utilized to focus screening efforts or exclude individuals with negative tests from the risk pool.

Rapid acceptance of genetic testing for management of this disorder occurred for several reasons. The most important was a 25-year experience utilizing provocative CT testing for early diagnosis of MTC in MEN 2 (Cance and Wells, 1985; Gagel *et al.,* 1988). These studies demonstrated the long-term effectiveness of early thyroidectomy in the management of this malignancy. Approximately one-half of children identified by this approach had C cell hyperplasia, a premalignant lesion and the remainder were found to have microscopic MTC (Gagel *et al.,* 1988). A second component in the rapid acceptance of this approach is how well tolerated thyroidectomy is in children. Although there is concern that failure to take thyroid hormone as directed could lead to altered intellectual development, there is little evidence that this is a real concern. Hypoparathyroidism, although rare following thyroidectomy in this age group, remains a greater concern.

It is important to recognize, however, that not all children who received early thyroidectomy (mean age of 13 years) were cured of their disease. Recurrent disease has been reported in 15–25% of individuals treated by thyroidectomy before the age of 20 years. The finding of metastatic MTC

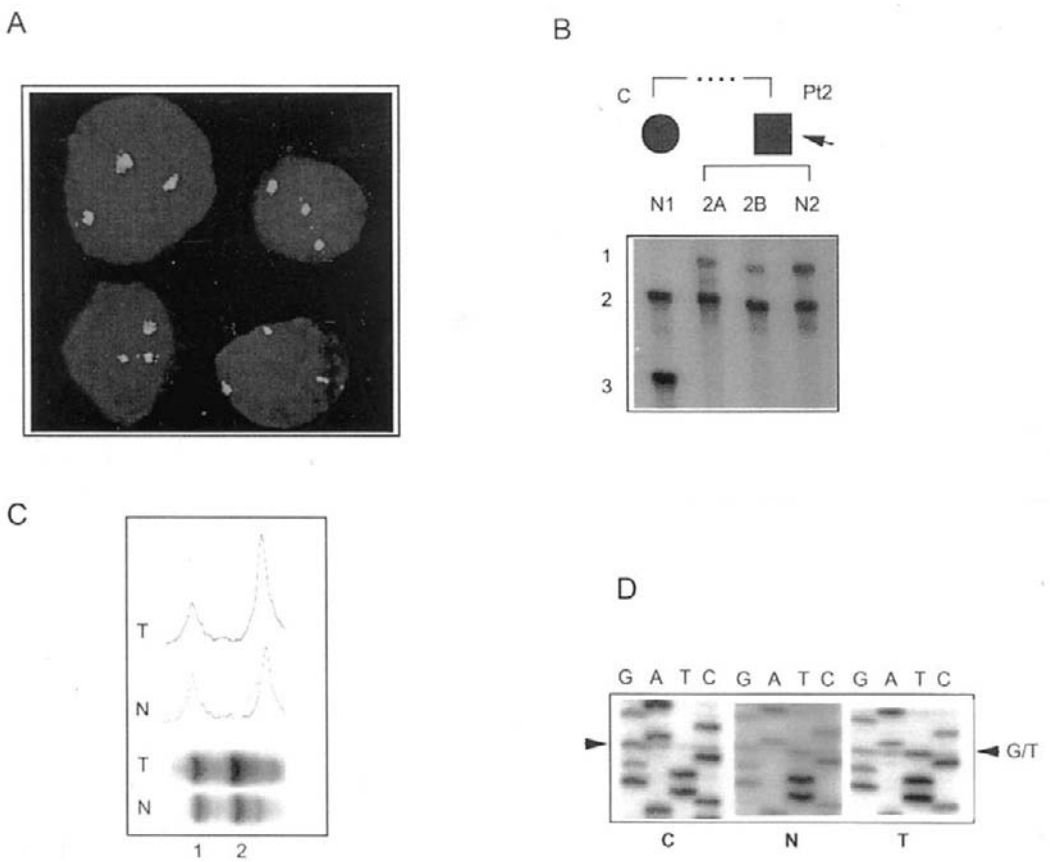

Figure 4 Trisomy 10 with nonrandom duplication of the mutant *RET* allele in MEN 2-associated pheochromocytoma. (A) Representative interphase FISH analysis on tumor touch. Three copies of chromosome 10 are shown using a centromeric α-satel-ite probe (FITC, green signal) specific for chromosome 10. (B) Combined pedigree and tumor allelic analysis. Arrow, affected patient. Filled symbols, individuals with microsatellite marker *D10S1239* linked to the *RET* locus. Allele 2 of *D10S1239* is coinherited with the disease in this patient's family. In the affected patient, allele 2 shows a greater intensity in lanes 2A and 2B (tumors) than allele 1, representing the wild-type allele, as compared with lane N2 (blood DNA). Lane N1 (blood DNA) shows equal intensities of mutant and wild-type allele in the patient's affected cousin (C). (C) Representative results of microsatellite and phosphorimage analyses. After PCR amplification using marker *D10S1239,* quantitative measurement of allelic intensity was performed using phosphorimage analysis. In tumor tissue (D), allele 2 is more intense than allele 1. Phosphorimage densitometry shows a 2:1 imbalance between the two alleles in tumor (*T*) as compared with the normal tissue (N). D, representative results of sequencing analysis of *RET* in tumor 3A. Blood DNA from an unaffected/healthy individual (C, left) shows the wild-type *RET* seqeunce (codon 631 GAC). Blood DNA from patient 3 (N, middle) shows the germ-line mutation (G/T). Tumor DNA (T, right) shows a higher intensity of the mutant nucleotide (T) compared with the wild-type nucleotide (G). Reprinted with permission from Huang *et al.* (2000).

in children as young as 3 years of age or younger has led clinicians who care for these children to advocate earlier thyroidectomy based on genetic testing (Niccoli-Sire *et al.,* 1999). Experience with families with specific mutations over the past 8 years suggests that there is a correlation between mutations at specific codons and MTC aggressiveness although the experience is incomplete and certainly imperfect. In addition, there is a growing *in vitro* body of information describing the relative ability of specific mutations to cause *in vitro* transformation. For example, there is evidence that a codon 634 mutation has greater transforming capacity than codon 609, 611, 618 or 620 mutations (Carlomagno *et al.,* 1997; Takahashi *et al.,* 1998). Based on the combined clinical and *in vitro* eperience there has been a stratification into three broad groups of aggressiveness.

MTC caused by a codon 918 mutation (MEN 2B) is generally considered to be the most aggressive form of this disease. Children with this mutation should have a total thyroidectomy and central node dissection performed during the first month of life or at the earliest time of detection. Cure is difficult because these children frequently come to attention between the ages of 5 and 10 years. In children with gross MTC an extensive lymph node dissection will improve the chances of a surgical cure (Moley *et al.,* 1997, 1998; Evans *et al.,* 1999).

Children with codon 611, 618, 620, and codon 634 mutations are considered to have a high risk of developing aggressive MTC. In these children there is a general recommendation for thyroidectomy at the age of 5–6 years of age, although recent reports of metastatic MTC in children

ages 2–4 suggests that earlier thyroidectomy may be required to cure most children. A total thyroidectomy with central lymph node dissection is generally considered to be appropriate therapy for these children (Lips *et al.,* 1994; Gagel *et al.,* 1995; Dralle *et al.,* 1998). A minority of surgeons perform a total thyroidectomy, central neck dissection, and concomitant transplantation of parathyroid tissue to the nondominant arm to lower the risk of hypoparathyroidism (Wells *et al.,* 1994; Dralle *et al.,* 1998).

Finally, children with 609, 768, 790, 791, 804, or 891 mutations are considered to have an intermediate risk of aggressive disease. Although deaths from MTC have been reported in kindreds with all of these mutations except for codon 790 or 791 mutations and there are kindreds where metastasis has occurred in family members before the age of 30 years (Feldman *et al.,* 2000), it is also clear there are some kindreds with one of these mutations in which death from MTC has never been reported. It is difficult to convince a parent with one of these mutations and a clearly defined family history of benignity to have younger child with a mutant *RET* gene undergo early thyroidectomy. As a result, clinicians caring for kindreds with these mutations have continued provocative testing for calcitonin abnormalities, delaying a thyroidectomy until the development of an abnormal test result. This type of approach may delay thyroidectomy until the mid-teenage years or later. A total thyroidectomy with central lymph node dissection is generally appropriate therapy for these cases.

There is at present no evidence that earlier intervention will further improve outcomes in children with germline mutations. Initial reports suggest that early intervention is associated with a high rate of success (Lips *et al.,* 1994; Wells *et al.,* 1994; Dralle *et al.,* 1998; Niccoli-Sire *et al.,* 1999) However, this enthusiasm must be tempered by the reality that the genetic abnormality in MEN 2 affects all cells. Any remaining C cell has the potential for subsequent transformation. This underscores the importance of completeness of the thyroidectomy and the need for long-term follow-up. Most of these children are under the age of 5 years at the time of thyroidectomy and will be under the age of 30 years at the time of 25-year follow-up.

The Future

Effective therapeutic options for treatment of the neoplastic components of MEN 2 have been limited to surgical removal of neoplastic components. The recent demonstration that an inhibitor of tyrosine phosphorylation was used successfully to treat two malignancies caused by activating mutations of a tyrosine kinase provides clear direction for investigators in this field (Druker *et al.,* 2001a,b; Joensuu *et al.,* 2001). The findings that the first and second genetic "hit" in MEN 2 activates a tyrosine kinase receptor, that tumor development proceeds over years, and that transformation can be prevented by inactivation of the tyrosine kinase receptor suggest that this disorder could be prevented or treated by a similar approach.

CHAPTER 60

Systemic Factors in Skeletal Manifestations of Malignancy

Janet E. Henderson,[*] Richard Kremer,[†] and David Goltzman[†]

[*]Department of Medicine, Lady Davis Institute, Montreal, Quebec, Canada H3T 1E2; and [†]Calcium Research Laboratory, Royal Victoria Hospital, Montreal, Quebec, Canada H3A 1A1

Malignancy-Associated Hypercalcemia

History

ALBRIGHT'S HYPOTHESIS

The association between elevated blood calcium and neoplastic disease was first noted in the 1920s by a group of German physicians (Zondek *et al.,* 1923), who believed that release of calcium from bone by the direct osteolytic action of malignant cells was responsible for hypercalcemia associated with malignancy. However, hypercalcemia was often accompanied by hypophosphatemia, the hallmark of hyperparathyroidism (HPT), and also occurred in the absence of skeletal metastases. This constellation of abnormalities was frequently seen in association with certain histological types of tumors, notably renal cell carcinomas and squamous cell cancers originating in a variety of primary sites. It was Fuller Albright in 1941 who hypothesized that a malignant tumor might release a systemically active factor resulting in hypercalcemia (Albright, 1941). The hypothesis was raised when a patient with a renal carcinoma, metastatic to bone, presented with hypercalcemia and hypophosphatemia in the absence of any obvious parathyroid dysfunction. The patient's biochemical abnormalities were temporarily normalized following tumor reduction but became apparent again as the tumor resumed its growth. Dr. Albright reasoned that since hyperphosphatemia did not accompany hypercalcemia, despite evidence of osteolysis, perhaps the tumor was secreting a phosphaturic substance like parathyroid hormone (PTH). Although no bioassayable hormone was detected in the tumor, the important and insightful observation had been made that hypercalcemia associated with malignancy could have a humoral basis and that the factor might be related to PTH. The term humoral hypercalcemia of malignancy (HHM) or malignancy-associated hypercalcemia (MAH) was later coined to distinguish this syndrome, commonly seen in patients with renal cell and squamous carcinoma, from hypercalcemia caused by the direct lytic action of tumor cells in bone, which was commonly associated with hematologic malignancies and with metastatic breast disease. Nevertheless, it is now clear that the "direct" lytic action of tumor cells is also mediated by humoral factors and that these locally acting factors may include those which also act on a systemic basis.

CHARACTERISITICS OF HYPERCALCEMIA OF MALIGNANCY

Despite the striking similarities between the biochemical manifestations of HPT and MAH that precipitated Albright's hypothesis, it subsequently became apparent that there were also a number of important differences between these syndromes. Early attempts at the differential diagnosis of these hypercalcemic disorders identified not only normal to subnormal concentrations of immunoreactive PTH but also a mild hypokalemic alkalosis in patients with MAH compared with the elevated PTH and mild metabolic acidosis associated with HPT (Lafferty, 1966). In addition, circulating $1,25(OH)_2D_3$ levels were often low in patients with malignancy and elevated in patients with HPT (Stewart *et al.,* 1980). Histomorphometric evaluation of bone biopsies also revealed discrepancies in bone formation, which appeared to be decreased in hypercalcemic cancer patients but increased in those

with parathyroid disease (Stewart *et al.,* 1982), whereas catabolic activity was significantly increased in both disorders. These apparent discrepancies were not resolved by early animal models of MAH in which circulating $1,25(OH)_2D_3$ levels were high and bone turnover appeared to be coupled (Sica *et al.,* 1983; Strewler *et al.,* 1986). Neither was the problem solved by *in vivo* and *in vitro* studies performed with synthetic amino terminal fragments of PTHrP, which suggested that the peptides had identical bioactivity (Chorev and Rosenblatt, 1994; Fraher *et al.,* 1992; Rabbani *et al.,* 1988). These issues were later revisited in a longitudinal study using nude rats implanted with a human PTHrP-producing tumor (Yamamoto *et al.,* 1995). Unlike the dramatic uncoupling of bone formation and resorption observed in the terminal stages of human disease, a substantial increase in both indices was observed at an earlier time point, prior to a detectable elevation in circulating PTHrP or hypercalcemia. Taken together with evidence that serum $1,25(OH)_2D_3$was also elevated in the tumor-bearing rats during the early stage of disease, these observations suggested that PTHrP and PTH do indeed elicit the same biological activity in bone. Furthermore, the discovery that PTH/PTHrP receptors were present on osteoblasts and their precursors (Rouleau *et al.,* 1988), but not on osteoclasts, suggested that cells of the osteoblast lineage ultimately regulated the catabolic activity of PTHrP in bone.

With the advent of sensitive and specific immunochemical and molecular biochemical assays for PTHrP it became apparent that a wide variety of tumors, including those of breast, hematologic and endocrine origin expressed the protein. (Asa *et al.,* 1990; Henderson *et al.,* 1990). Moreover, 60% of primary breast tumors and 90% of metastatic foci in bone were shown to be PTHrP positive (Powell *et al.,* 1991), which caused a reassessment of the relative contributions of "humoral" and "local" factors to MAH.

Purification and Cloning of PTHrP

Until the 1980s investigators continued with their attempts to identify PTH as the causative agent in MAH. However, immunoreactive PTH could not be detected in the circulation (Powell *et al.,* 1973) or PTH mRNA in the tumors (Simpson *et al.,* 1983) of hypercalcemic cancer patients. The search for a novel protein with PTH-like bioactivity intensified using several bioassays that had been developed for PTH (Goltzman *et al.,* 1981; Nissenson *et al.,* 1981; Rodan *et al.,* 1983). Using both *in vivo* and *in vitro* approaches, PTH-like bioactivity was identified in the blood and in tumor extracts from patients with MAH. These same bioassays were used in various combinations during the purification of a novel protein, named parathyroid-hormone-like peptide (PLP), from tumor tissue (Burtis *et al.,* 1987; Moseley *et al.,* 1987; Strewler *et al.,* 1987). When the gene was cloned and demonstrated to be structurally homologous to *PTH,* the protein was renamed parathyroid-hormone-related protein, or PTHrP (Mangin *et al.,* 1989; Suva *et al.,* 1987).

Molecular and Cellular Biology of PTHrP

Characterisitics of the PTHrP Gene and Its Protein Products

Localization of the genes encoding PTH and PTHrP to the short arms of human chromosomes 11 and 12, respectively, placed them among syntenic groups of functionally related genes and suggested a common ancestral origin (Goltzman *et al.,* 1989). Similarities in their structural organization and in the functional properties of their amino termini provide further support for the hypothesis that *PTH* and *PTHrP* are members of a single gene family. The human *PTHrP* gene is a complex unit that spans more than 15 kb of DNA. Its mRNA is transcribed from at least three promoters and undergoes differential splicing, giving rise to heterogenous mRNA species. The cDNA encodes a prototypical secretory protein with predicted mature isoforms of 139, 141, and 173 amino acids. The rat *PTHrP* gene is driven by a single promoter, and encodes a protein of 141 amino acids with marked sequence homology to human PTHrP up to residue 111, which suggests conserved functionality (Yasuda *et al.,* 1989). These proteins appear to undergo endoproteolytic cleavage in the secretory pathway, resulting in the release of fragments 1–36, 1–86, 38–94 and 38–101 (Rabbani *et al.,* 1993; Wu *et al.,* 1996).

PTHrP Overproduction in Malignancy

In view of its broad distribution pattern in embryonic and adult tissues, overproduction of PTHrP by malignant cells most likely results from deregulated expression of an endogenous protein during the process of malignant transformation, that is "eutopic" rather than "ectopic" production. Whereas tumor-bearing animal models have contributed enormously to our knowledge of the pathogenesis and treatment of MAH, *in vitro* cell models of carcinogenesis and solution biochemistry have provided valuable information regarding the molecular control of PTHrP expression and metabolism.

Transcriptional Regulation At the level of transcription a number of potential mechanisms have been invoked to explain overexpression of PTHrP in malignant cells, including gene amplification (Sidler *et al.,* 1996) and alterations in the methylation status of critical regulatory regions of the gene during neoplastic transformation (Broadus and Stewart, 1994; Ganderton and Briggs, 1997). Furthermore, the complex organization of the human *PTHrP* gene suggests that changes in tissue-specific promoter usage or splice variants might also contribute to overproduction of PTHrP during the process of malignant transformation. An extensive clinical study examined a variety of tumors, including 13 breast malignancies, with exon-specific probes to identify transcripts arising from all three promoters and from the different 3′ splice variants (Southby *et al.,* 1995). Although the authors failed to identify tissue-specific or tumor-specific transcripts, they did show that PTHrP was transcribed from multiple promoters in tumor samples, compared with a single promoter in normal tissue harvested from the same individual. The resulting overall increase in transcription could

then lead to cumulative overexpression of the protein in neoplastic tissue.

Adult T-cell leukemia-lymphoma (ATL) is an aggressive malignancy that is endemic to parts of Japan, Africa, the Carribean, and the United States. The disease develops after 20–30 years of latency in about 5% of individuals infected with human T-cell leukemia virus type I (HTLV-I) (Ejima *et al.,* 1995). PTHrP mRNA has been identified in samples harvested from asymptomatic HTLV-I carriers as well as from leukemic cells of ATL patients (Motokura *et al.,* 1989), and elevated circulating levels of PTHrP were detected in most hypercalcemic individuals in the acute phase of the disease (Ikeda *et al.,* 1994). In view of the documented role of HTLV-I infection in the pathogenesis of this disorder, and the high incidence of PTHrP overexpression in these patients, it was proposed that the viral protein TAX may stimulate PTHrP gene transcription. TAX is a 40-kDa nuclear phosphoprotein that transactivates its own promoter as well as those of a number of cellular genes. It interacts with a variety of transcription complexes that bind to DNA consensus elements in the *PTHrP* promoter including the cAMP response element, Ets-1, serum response element and the AP-1 binding site (Dittmer *et al.,* 1993; Ejima *et al.,* 1993). The MT-2 cell line, in which TAX is overexpressed, was used to determine that maximal stimulation of *PTHrP* involved activation of PKA and PKC (Ikeda *et al.,* 1995).

Regulation by Hormones and Growth Factors The apparent association between PTHrP overproduction and a malignant phenotype prompted investigators to use cell culture models of malignant progression to examine the regulation of PTHrP by hormones and growth factors. A variety of growth factors were found to be potent stimulators of *PTHrP* gene transcription (Kremer *et al.,* 1991; Sebag *et al.,* 1994), whereas $1,25(OH)_2(D)_3$ was found to be a potent inhibitor (Kremer *et al.,* 1991; Sebag *et al.,* 1992).

With the knowledge that keratinocytes were the first nontransformed cells in which PTHrP bioactivity was identified (Merendino *et al.,* 1986), a model of human epithelial cell carcinogenesis was chosen to examine the regulation of PTHrP production by hormones and growth factors (Henderson *et al.,* 1991; Kremer *et al.,* 1991; Sebag *et al.,* 1992). Basal levels of mRNA and unstimulated release of PTHrP into conditioned medium were both significantly higher in Ras-transformed keratinocytes compared with their nontransformed counterpart. In addition, the response to both positive (serum, EGF) and negative ($1,25(OH)_2D_3$) regulators of PTHrP production was significantly blunted in the malignant keratinocytes compared with either established or normal cells. The deregulated response to $1,25(OH)_2D_3$ was not a function of altered receptor status but was associated with a decrease in the ability of the steroid to inhibit mitogen-induced c-*myc* expression and progression through the cell cycle. Similar experiments performed on normal, human mammary epithelial cells indicated that the induction of PTHrP expression by serum and growth factors, and its repression by $1,25(OH)_2D_3$, were partially regulated at the level of gene transcription (Sebag *et al.,* 1994).

A $1,25(OH)_2D_3$ responsive repressor sequence (Fig. 1) was later identified between bases –1121 to –1075 upstream of the single promoter in the rat *PTHrP* gene (Kremer *et al.,* 1996). Using nuclear extracts prepared from normal human keratinocytes in mobility shift analyses, it was determined that the PTHrP repressor site bound a vitamin D receptor (VDR)–retinoid X receptor (RXR) heterodimer. The VDR–RXR complex was also identified in extracts of nuclei from immortalized keratinocytes but not from the Ras transformed cells that had previously shown resistance to $1,25(OH)_2D_3$ induced inhibition of PTHrP expression (Solomon *et al.,* 1998). Expression of wild-type RXRα in the transformed cells resulted in reconstitution of the VDR–RXR heterodimer. Subsequent work by the same group determined that disruption of the VDR–RXR complex in Ras transformed keratinocytes resulted from mitogen-activated protein kinase (MAPK)-stimulated phosphorylation of RXRα by the activated Ras/Raf/MAPK pathway (Solomon *et al.,* 1999). Taken together, these studies indicated that increased PTHrP production can result from alterations in the interaction between stimulatory and inhibitory signaling pathways in malignant cells.

In view of the evidence that signaling by growth factors through receptor tyrosine kinases (RTKs) was an important mechanism for regulating PTHrP gene expression, and that oncogenic transformation by the Ras component of the RTK signal transduction pathway was associated with overproduction of PTHrP by many malignant cells, studies were undertaken to examine the molecular mechanisms that linked PTHrP overexpression with RTK signaling. Transfection of a constitutively active derivative of the hepatocyte growth factor receptor known as Tpr-Met into PTHrP-producing cells resulted in a substantial increase in the expression and release of PTHrP (Aklilu *et al.,* 1996). Introduction of a point mutation into Tpr-Met, which prevented its association with the Ras signaling pathway, led to a significant reduction in PTHrP expression and release. Similar reductions were observed in cells treated with agents that inhibit Ras function by preventing it from anchoring to the cell membrane and transducing a signal (Aklilu *et al.,* 1997, 2000). These studies demonstrated the central role of Ras in enhancing PTHrP production in transformed cells and suggested a potential therapeutic role for Ras inhibitors in the treatment of MAH.

Processing and Degradation of PTHrP The Fischer rat implanted with the Rice-H500 Leydig cell tumor is a well characterized model of the human syndrome of MAH. The central role played by amino-terminal PTHrP in the pathogenesis of MAH in this model was demonstrated by passive immunization of tumor-bearing rats with antiserum raised against synthetic PTHrP-(1–34) (Henderson *et al.,* 1990). Hypercalcemic rats treated with PTHrP antiserum

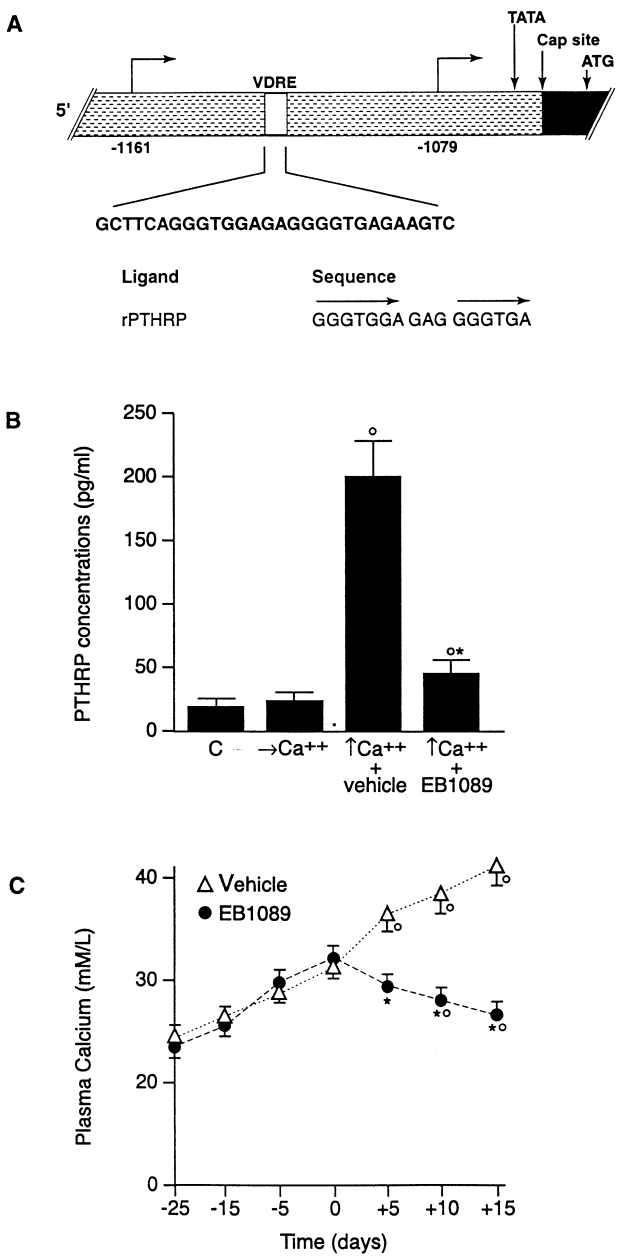

Figure 1 Repression of PTHrP and hypercalcemia by the vitamin D analog EB1089. $1,25(OH)_2D_3$ is a potent inhibitor of PTHrP production *in vitro* and *in vivo* and EB1089 is a low-calcemic analog of this active metabolite of vitamin D. (A) A consensus vitamin D response element (VDRE) in the *PTHrP* promoter was shown to bind a VDR–RXR heterodimer, which mediated repression of gene transcription *in vitro.* Infusion of EB1089 into hypercalcemic mice carrying a PTHrP-producing human squamous carcinoma resulted in a decline in systemic levels of immunoreactive PTHrP and in plasma calcium. (B) Plasma PTHrP was significantly reduced in EB1089-treated mice compared with vehicle treated control mice (*), although it was still elevated compared with control mice that did not carry tumors (O). (C) Plasma calcium levels continued to rise in the mice treated with vehicle whereas they approached near normal levels 15 days after commencing treatment with EB1089. Adapted in part from Kremer *et al.* (1996) and Abdaimi *et al.* (1999).

demonstrated a rapid and prolonged reversal of biochemical abnormalities, while those treated with preimmune serum or anti-PTH-(1–34) antiserum soon died of complications resulting from hypercalcemia. The Rice H-500 Leydig tumor cells were subsequently used to investigate the regulation of PTHrP production (Liu *et al.,* 1993) and metabolism (Rabbani *et al.,* 1993). Biosynthetic labeling of nascent PTHrP revealed rapid processing into three distinct amino-terminal species of 1–36, 1–86, and 1–141 amino acids, which were constitutively released into the extracellular environment. These observations were in agreement with similar studies that had been performed in malignant human cells (Soifer *et al.,* 1992).

Like PTH, PTHrP is synthesized as a prohormone with an amino-terminal extension. The biological potency of pro-PTHrP is considerably less than that of PTHrP-(1–34) (Liu *et al.,* 1995). The presence of a furin recognition sequence between the propeptide and the mature protein, and the knowledge that mature PTHrP was released from the cell through a constitutive pathway, predicted that pro-PTHrP was a substrate for the prohormone convertase furin. Transfection of COS-7 cells with a pro-PTHrP expression vector resulted in high levels of immunoreactive and bioactive PTHrP being released into the culture medium (Liu *et al.,* 1995). Coexpression of pro-PTHrP and anti-sense furin resulted in marked inhibition of furin expression and secretion of a PTHrP species that comigrated with synthetic pro-PTHrP and exhibited a marked reduction in its capacity to stimulate adenylate cyclase. This work supported the hypothesis that PTHrP is a furin substrate and raised the possibility that reducing furin activity inhibited production of bioactive PTHrP by malignant tissues.

From the preceding passages it is apparent that PTHrP shares certain properties with oncofetal proteins, transcription factors and cell cycle regulatory proteins, all of which are induced in a rapid and transient manner in response to mitogenic stimuli and are overexpressed in transformed cells. Taken together with evidence that PTHrP localizes to the nuclear compartment in a cell-cycle dependent manner, these observations suggest that the intracellular degradation of PTHrP might represent an important means by which cell proliferation and cell death are kept in check. Credence to this hypothesis was provided by studies that identified prepro-PTHrP as a target for multiubiquitination and ubiquitin-dependent proteolysis by the 26S protease complex (Meerovitch *et al.,* 1997). The ubiquitin pathway is most commonly associated with the rapid degradation of defective proteins and of short-lived cytosolic and nuclear proteins. However, ubiquitin and its activating enzymes have also been localized to a post ER compartment of the secretory pathway, and to the 26S proteasome at the cytosolic face of ER membranes. Recent studies have suggested that PTHrP might exit the secretory pathway between the ER and the Golgi to undergo ubiquitin-mediated degradation in the cytosol (Meerovitch *et al.,* 1998). This degradative pathway might also target PTHrP that reenters the cell following release into the extracellular environment (Aarts *et al.,* 1999) and suggests a potential mechanism that could regulate the balance between intracellular and secreted forms of PTHrP.

Mechanisms of Action of PTHrP

INTERACTION OF NH_2 TERMINAL PTHRP WITH CELL SURFACE RECEPTORS.

PTHrP was originally identified by virtue of its capacity to activate the classic G-protein-coupled PTH receptor (PTH1R) in kidney and bone. Thus, an elevation in the circulating level of PTHrP in patients with MAH initially results in calcium retention and phosphate wasting by the kidney, in association with an increase in the nephrogenous component of excreted cAMP. The increase in circulating PTHrP also stimulates bone resorption, which results in release of calcium and phosphate into the circulation. The excess phosphate is cleared through the action of PTHrP in the kidney, while calcium is retained, and the patient develops hypercalcemia and hypophosphatemia. Hypercalciuria ensues when the filtered load of calcium exceeds the reabsorptive capacity of the kidney. While PTH and PTHrP appear to influence the renal handling of calcium and phosphate in a similar manner, PTHrP may have a distinct mechanism of action in regulating the renal 1α hydroxylase enzyme. It has been pointed out that circulating levels of $1,25(OH)_2D_3$ are often low in advanced stages of MAH. Hypotheses that have been forwarded to explain this anomalous decrease include cosecretion of a specific 1α hydroxylase inhibitory factor from the tumor along with PTHrP, direct inhibition of the 1α hydroxylase enzyme by severe hypercalcemia or direct inhibition of the enzyme by non-amino terminal species of PTHrP (Kremer *et al.,* 1996)

Sequence homology between PTH and PTHrP is restricted to 8 of the first 13 residues, which include those required for activation of signal transduction cascades through adenylate cyclase and phospholipase C (Chorev and Rosenblatt, 1994). Additional conformational similarities in the 14–34 region permit amino-terminal fragments of the proteins to act as equivalent agonists for their common receptor, PTH1R. Whereas PTH1R is expressed in a wide variety of embryonic and adult tissues, including cartilage and bone, the recently identified PTH2R (see Chapter 24) appears to be preferentially expressed in the brain, where its principal ligand appears to be a hypothalamic peptide called tuberoinfundibular protein (TIP) (Usdin, 1997). In addition to these receptors for amino terminal species of PTHrP, several reports suggest the presence of cell surface binding proteins for carboxyl terminal fragments of PTHrP on skeletal cells (Orloff and Stewart, 1995) where they are believed to mediate anti-resorptive functions.

MECHANISM OF ACTION OF COOH-TERMINAL PTHRP

In the past, several investigators have reported a variety of functions for fragments of PTHrP that share no homology with PTH. These include the pentapeptide PTHrP-(107–111), which was named osteostatin for its potential to inhibit osteoclastic bone resorption in culture (Fenton *et al.,* 1991). Other studies using carboxy-terminal fragments of PTHrP have shown that they inhibit production of the early osteoblast marker osteopontin (Seitz *et al.,* 1995) in isolated osteoblasts and to be almost as effective as PTHrP-(1–34) in stimulating functional osteoclast formation from progenitor cells, both in the presence and absence of osteoblastic cells (Kaji *et al.,* 1995). These studies support *in vivo* observations demonstrating decreased osteoblastic and increased osteoclastic activity in association with elevated circulating levels of carboxy-terminal fragments of PTHrP in patients with MAH (Burtis *et al.,* 1994). In light of the considerable advances that have recently been made in the mechanisms that regulate bone turnover (see Chapter 58), further examination of the effects of carboxy-terminal fragments of PTHrP on bone cells may well be warranted at this time.

INTRACELLULAR MECHANISM OF PTHRP ACTION

Most of the cellular actions of PTHrP have been attributed to the interaction of its amino-terminus with the common PTH1R receptor and activation of signal transduction cascades through cAMP, inositol phosphates and DAG. However, similar to other growth regulatory proteins (Henderson, 1997), increasing evidence now points to a direct, intracellular mechanism of PTHrP action mediated through residues 87–107 in the mid-region of the protein. This region shares sequence homology with a lysine-rich bipartite nuclear targeting sequence (NTS) in nucleolin (Schmidt-Zachmann and Nigg, 1993), and with an arginine-rich NTS in the retroviral regulatory protein TAT (Dang and Lee, 1989). The PTHrP NTS is both necessary and sufficient to direct the passage of transfected PTHrP, as well as the cytoplasmic protein β-galctosidase, to the nuclear compartment of transfected cells and to localize endogenously expressed PTHrP to nucleoli in chondrocytes and osteoblasts *in vitro* and *in vivo* (Henderson *et al.,* 1995). Endogenous PTHrP has been identified in the coarse fibrillar component of nucleoli by immunoelectron microscopy. This area is occupied by complexes of newly transcribed 45s ribosomal RNA and protein that are destined for assembly into ribosomes. The biological relevance of nucleolar PTHrP was demonstrated when chondrocytes expressing wild-type PTHrP were protected from apoptosis induced by serum deprivation, whereas cells expressing the protein without the NTS were not.

These initial studies were corroborated by subsequent work that has implicated nuclear PTHrP in events that regulate cell cycle progression in vascular smooth muscle cells (Massfelder *et al.,* 1997) and keratinocytes and in differentiation in chondrocytes (Henderson *et al.,* 1996). Taken together, the observations have changed the way in which PTHrP is viewed and have paved the way for studies that have examined the molecular mechanisms that mediate its intracellular localization and action. The work is of physiological importance to cartilage and bone development as well as of pathophysiological importance in defining the role of PTHrP in MAH. One of the questions currently being addressed relates to the translocation of a prototypical secretory protein into the cytoplasic compartment of target cells. Three potential routes of entry are being evaluated. One involves retrograde transport of nascent PTHrP from the endoplasmic reticulum (Meerovitch *et al.,* 1998), a second involves internalization of secreted PTHrP (Aarts *et al.,* 1999), and a third involves

the alternative initiation of translation to exclude the "pre" sequence, which is necessary for entry into the endoplasmic reticulum.

In the original work using transfected COS-1 cells, the protein was detected in the secretory pathway of 100% of PTHrP-expressing cells, but only 15% of cells had nucleolar PTHrP. This suggested that PTHrP might be secreted and then reenter a subpopulation of randomly cycling cells. Using immunofluorescence microscopy and immunoblot analysis, full-length wild-type PTHrP was found on the cell surface, in the cytoplasm, and in the nuclear compartment of target cells *in vitro.* Furthermore, nuclear localization occurred in the presence and in the absence of PTH1R, which supports the previous studies suggesting the presence of an alternative cell surface binding protein for PTHrP (Aarts *et al.,* 1999).

Some insight into the regulated entry of cytoplasmic PTHrP into the nucleus was recently provided by studies performed on immortalized keratinocytes, which showed that PTHrP was a substrate for cell cycle associated kinases (Lam *et al.,* 1999). Phosphorylation of PTHrP at Thr^{85} by CDC2–CDK2 was proposed to anchor the protein in the cytoplasm during G2/M, whereas dephosphorylated PTHrP localized to nucleoli during other stages of the cell cycle. A similar mechanism of cytoplasmic anchoring has been proposed for SV40T antigen, which contains a bipartite NTS similar to that seen in PTHrP.

A third series of experiments has addressed the functional role of PTHrP in the nuclear compartment. The work was based on the original observation that PTHrP localized to a region of the nucleus that is rich in RNA–protein complexes. This led to the hypothesis that nucleolar PTHrP could interact with RNA and that it might play a role in ribosome biogenesis. Wild-type PTHrP was subsequently shown to bind to GC-rich homopolymeric RNA and to total cellular RNA with specificity and with high affinity (Aarts *et al.,* 1999). The PTHrP NTS peptide was effective in competing for this binding, whereas the equally basic nucleolin NTS was not. Furthermore, exogenous PTHrP NTS peptide translocated to the nucleolus of chondrocytes in culture, whereas a similar basic peptide corresponding to the nucleolin NTS was not internalized itself and could not prevent internalization of the PTHrP NTS peptide by competitive inhibition. These data suggested that the PTHrP NTS was recognized specifically by a cell surface binding protein. Site-directed mutagenesis identified a conserved GxKKxxK motif within the PTHrP NTS that was critical for both cell surface attachment and for RNA binding. These properties of the PTHrP NTS, namely to mediate internalization, nuclear translocation and RNA binding, are reminiscent of those bestowed on the RNA binding protein TAT by its NTS. Ultimately, however, *in vivo* studies will be required to determine the role of nuclear PTHrP in the physiology and pathophysiology of the skeleton.

PTHrP Action in Bone

Indirect Action of PTHrP on Osteoclasts Under physiological circumstances, PTH and PTHrP bind to receptors on preosteoblastic stromal cells and to mature osteoblasts (Rouleau *et al.,* 1990, 1988). Activation of PTH1R then promotes proliferation of committed osteoprogenitor cells and mediates coupled bone turnover. One of the most striking features of patients with MAH is the apparent dissociation of this coupled activity in favor of catabolic activity, which ultimately results in massive bone destruction and osteopenia.

Although it was recognized early on that stimulation of PTH1R on osteoblastic cells provided a signal to osteoclasts to resorb bone, it was not apparent that the two cells needed to be in physical contact for the signal to be generated. In retrospect, it was not surprising that early attempts to examine catabolic activity by isolated osteoclasts consistently failed, whereas coculture of cells derived from fetal mouse calvaria (source of osteoblasts) and mouse spleen (source of osteoclasts) resulted in the formation of multinucleated, bone resorbing cells (Takahashi *et al.,* 1988). These cells expressed tartrate-resistant acid phosphatase (TRAP), which is a recognized marker for osteoclasts *in vivo,* and were seen only in cultures treated with $1,25(OH)_2D_3$ in which osteoblastic and spleen cells were not physically separated by a porous membrane. These studies, therefore, indicated that osteolytic factors, after binding to preosteoblastic cells, could mediate the differentiation of hematopoietic mononuclear precursor cells into mature, multinucleated, functional osteoclasts and that the process required contact between the two cell lineages. The KS-4 cell line was cloned from fetal mouse calvaria and characterized as preosteoblastic on the basis of type I collagen expression and alkaline phosphatase activity. It was subsequently used to examine osteoclast formation and bone resorption *in vitro* in response to osteolytic factors like PTH, vitamin D and calcitonin (Yamashita *et al.,* 1990).

The RANKL/RANK/OPG System Some of the most significant advances in bone cell biology over the past few years have emerged as a consequence of studies that examined the basic signaling molecules that couple anabolic to catabolic activity in bone. In 1997 a novel, secreted member of the tumor necrosis factor receptor superfamily was identified in rat intestine (Simonet *et al.,* 1997). This soluble binding protein was named osteoprotegerin (OPG) when it was subsequently discovered that the most pronounced phenotypic trait of transgenic mice with high circulating levels of OPG was osteopetrosis caused by a dramatic decrease in bone resorbing osteoclasts. Administration of the recombinant protein to normal mice elicited a similar phenotype and inhibited the formation of osteoclasts *in vitro.* The same protein was independently purified from human embryonic lung fibroblasts and called osteoclastogenesis inhibitory factor (OIF), which was shown to inhibit PTH and $1,25(OH_2)D_3$-induced osteoclast formation (Tsuda *et al.,* 1997). The endogenous ligand for OPG/OIF was subsequently cloned by the same two groups who named it OPG ligand (OPGL) (Lacey *et al.,* 1998) and osteoclast differentiation factor (ODF) (Yasuda *et al.,* 1998), respectively. This novel TNF family member, now named RANKL is attached to the surface of cells of

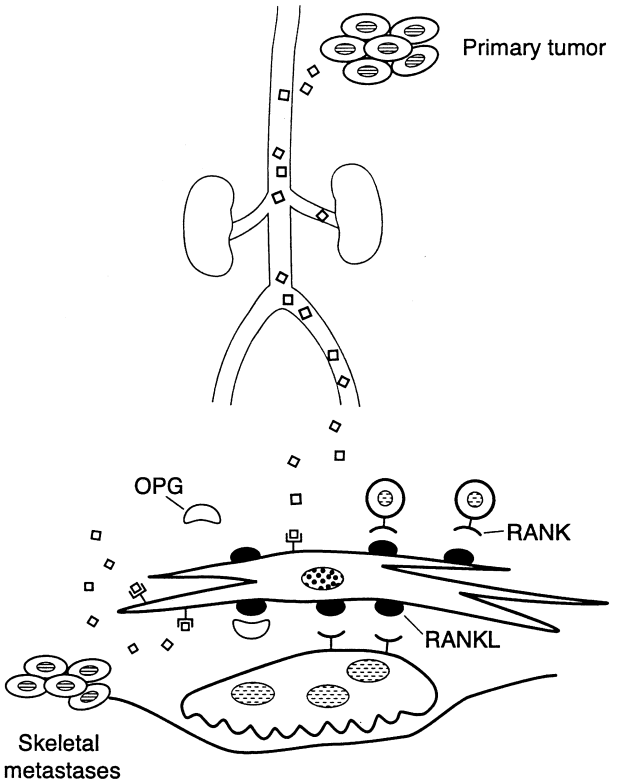

Figure 2 Systemic and local actions of tumor-derived PTHrP. Many primary tumors of diverse histological origin have been shown to release PTHrP into the systemic circulation, which carries the hormone to its primary target tissues of kidney and bone. Hypercalcemia ensues when PTHrP stimulates the renal reabsorption of calcium and promotes osteoclastic bone resorption, in part via its influence on the RANKL/RANK/OPG system. PTHrP is also released within the bone microenvironment from metastatic tumor cells. Binding of PTHrP to PTH1R on preosteoblastic stromal cells upregulates RANKL and downregulates the soluble RANKL receptor OPG. The interaction between RANKL and its receptor RANK on preosteoclasts and osteoclasts leads to an increase in the number of mature osteoclasts as well as an increase in their activity.

the osteoblast lineage and induces osteoclast differentiation and activation by binding to a receptor on the surface of osteoclast precursors and mature osteoclasts. Systemic administration of RANKL to normal mice resulted in bone destruction and hypercalcemia as a consequence of increased bone resorption with no associated increase in bone formation. The cell surface receptor for RANKL was later identified as receptor activator of NF-κB or RANK (Hsu *et al.,* 1999). Binding of RANKL to RANK results in the differentiation of pre-osteoclasts into mature osteoclasts and stimulates the activity of mature, bone-resorbing cells (Lacey *et al.,* 1998). The necessity of a functional RANKL/RANK/OPG system for osteoblast-mediated activation of bone was clearly demonstrated in mice with a targeted disruption of the gene encoding RANKL (Kong *et al.,* 1999). Mice lacking a functional *RANKL* gene exhibited severe osteopetrosis and defective tooth eruption, which were attributed to the complete absence of osteoclasts.

The physical association of osteoblast and osteoclast precusors in the bone microenvironment was, therefore, necessary for osteoclast differentiation and induction of bone resorption. Thus RANKL, while bound to the surface of osteoblastic cells, interacts with its cognate receptor RANK on the surface of preosteoclastic and osteoclastic cells to intiate bone resorption. On the other hand, the soluble receptor OPG can nonproductively bind to RANKL and prevent its interaction with the cell surface receptor RANK.

Regulation of the RANKL/RANK/OPG System by Calciotropic Hormones A local increase in calciotropic factors such as PTH, PTHrP, or $1,25(OH)_2D_3$ results in suppression of OPG and an increase in RANKL, which then binds its cognate receptor RANK to promote bone resorption (Lee and Lorenzo, 1999). Fragments of PTH with an intact amino-terminus were recently shown to inhibit OPG expression in osteoblastic cells in culture by a cAMP-dependent pathway (Kanzawa *et al.,* 2000). Experiments using bone marrow stromal cells have demonstrated an inverse relationship between the stage of differentiation and stimulation of RANKL expression by $1,25(OH)_2D_3$ (Menaa *et al.,* 2000).

MAH and the RANKL/RANK/OPG System It is readily apparent that the implications of the RANKL/RANK/OPG system for the pathogenesis of MAH are far-reaching (Fig 2). The vast majority of cases of MAH are thought to be caused by release of PTHrP from tumor cells, whether they are in the form of a solid tumor, a metastatic lesion in bone, or a hematologic malignancy. Tumor-bearing animal models, which were initially used to characterize the biochemical and histologic abnormalities associated with PTHrP-producing tumors in the 1980s and 1990s, are now in use to examine the relationships between PTHrP, the RANKL/RANK/OPG system and bone resorption. One such study used tumor-bearing mice to investigate the capacity of recombinant OPG to prevent, or inhibit, PTHrP-induced hypercalcemia (Capparelli *et al.,* 2000). Daily subcutaneous administration of 2.5 mg of recombinant protein prevented the onset of hypercalcemia in tumor-bearing mice and rapidly reduced blood calcium in mice with established hypercalcemia. These changes were associated with a reduction in osteoclast numbers, as assessed by histomorphometry, to well below the level seen in control mice. However, this treatment protocol did not affect the tumor burden, plasma PTHrP or cachexia in tumor-bearing mice. Although administration of 0.5 mg/day OPG was sufficient to reduce osteoclast numbers to below normal it did not prevent hypercalcemia in the tumor-bearing mice, which suggests the presence of a significant renal component to hypercalcemia associated with PTHrP overproduction by tumors. This later observation is in keeping with previous work using rats carrying the Rice-500 Leydig cell tumor as a model of MAH. Hypercalcemic, tumor-bearing rats treated with a bolus dose of anti-PTHrP-(1–34) antiserum sustained a rapid decrease in plasma calcium, associated with an increase in urinary calcium, followed by a sustained period of normocalcemia (Henderson *et al.,* 1990). The biphasic

response was attributed to an initial neutralizing effect of PTHrP bioactivity on calcium reabsorption in the kidney followed by sustained suppression of its catabolic activity in bone. In the mouse model, treatment with OPG would adequately suppress osteoclastic bone resorption but could not antagonize the renal component, which would result in residual hypercalcemia. These studies therefore reemphasize the importance of developing therapeutic strategies that take into account the dual role of PTHrP in the kidney and in bone, and which are aimed primarily at removing PTHrP as the principal pathogenetic agent in MAH.

Hypercalcemia associated with hematologic malignancies has traditionally been viewed as a consequence of the local lytic activity of tumor cells in bone. However, elevated circulating levels of PTHrP have been reported in hypercalcemic patients with a variety of hematologic malignancies (Burtis *et al.,* 1990; Henderson *et al.,* 1990). Further analysis of patients with lymphoma revealed similar results to those found in patients with breast cancer, in that high plasma PTHrP was associated with severe bone destruction and was most often associated with late-stage disease and high-grade pathology (Kremer *et al.,* 1996). In retrospect, these observations are not surprising. In both cases, bone destruction is mediated by the direct action of systemic and locally derived PTHrP on osteoblastic cells, to inhibit OPG and to stimulate RANKL, with a subsequent increase in bone resorption. Malignant cells also adhere to the marrow stroma, causing release of cytokines such as interleukins and tumor necrosis factor (TNF), which also stimulate RANKL production. In the case of multiple myeloma, residual OPG is inactivated by binding to syndecan-1, which is overproduced by the malignant B cells (Tricot, 2000).

Recently a soluble form of RANKL was discovered (sODF) in SCC-4 cells, which also secrete high levels of PTHrP and were derived from a tumor removed from a patient with MAH (Nagai *et al.,* 2000). The reading frame of the novel protein lacks a transmembrane domain and is homologous with the 74–318 region of the membrane-bound form of RANKL. Hence, solid tumors expressing both PTHrP and soluble RANKL pose a double "long-distance" threat to skeletal metabolism by releasing both of these catabolic agents into the systemic circulation. Indeed, the "uncoupling" of bone formation and resorption in some patients with MAH could conceivably be due to the predominant production of such a soluble RANKL, which would selectively activate the resorptive pathway in bone.

Experimental Approaches to Controlling Overproduction of PTHrP in MAH

Inhibition of Signaling through Receptor Tyrosine Kinases

Growth factors acting via receptor tyrosine kinases (RTKs) have been shown to be potent stimuli of *PTHrP* gene transcription. One of the best characterized signal transduction pathways downstream of RTKs is the Ras/Raf/Mek pathway. Activation of this pathway by growth factors or activated Ras was shown to increase PTHrP expression and release from a variety of cells in culture. Conversely, inhibition of the pathway through pharmacologic intervention successfully reduced PTHrP production *in vitro.* This suggested that specific inhibitors of components of the Ras signaling pathway could be used for therapeutic intervention to prevent the hypercalcemic syndrome associated with PTHrP overproduction *in vivo.* The direct role of Ras signaling in overproduction of PTHrP was investigated in rat 3T3 fibroblasts stably transfected with oncogenic Ras (Aklilu *et al.,* 1997). Release of PTHrP was increased up to 10-fold in the Ras-transformed cells, which rapidly formed tumors and induced MAH when implanted into nude mice. B-1086 is a small molecule that acts as a competitive inhibitor of Ras farnesylation, which is one of the metabolic conversions that is required for Ras to be anchored to the inner aspect of the cell membrane and transmit a signal downstream. Treatment of the Ras-3T3 fibroblasts *in vitro,* or of the Ras-3T3 tumor-bearing rats *in vivo,* with B-1086 led to a significant reduction in PTHrP secretion. In hypercalcemic mice this was reflected in a decrease in tumor growth and reversal of the biochemical abnormalities associated with MAH. Constitutive expression and release of PTHrP from the rat H-500 Leydig cell tumor could also be diminished using dominant negative forms of Ras and Raf (Aklilu *et al.,* 2000).

Vitamin D-Mediated Repression of PTHrP

$1,25(OH)_2D_3$ is a potent inhibitor of PTHrP in a variety of culture systems including keratinocytes, Leydig cells, prostate cells, and mammary and cervical epithelial cells. This inhibitory activity is mediated through the classic VDR, which also mediates the effects of $1,25(OH)_2D_3$ on calcium homeostasis. For this reason, administation of $1,25(OH)_2D_3$ in cases of MAH is counterproductive due to its intrinsic hypercalcemic effects. A concentrated effort has, therefore, been focused on the development of low-calcemic analogs of $1,25(OH)_2D_3$ that will effectively suppress PTHrP production but will not stimulate calcium absorption by the gut, calcium reabsorption by the kidney and, most importantly, bone resorption.

EB1089 and MC903 are two $1,25(OH)_2D_3$ analogs with conservative side-chain modifications that have been used to inhibit PTHrP production *in vitro,* and with variable degrees of success to prevent the hypercalcemic syndrome in animal models of MAH. Both EB1089 and MC903 were equipotent with $1,25(OH)_2D_3$ in their capacity to inhibit the release of PTHrP from immortalized and malignant keratinocytes in a previously characterized model of tumor progression (Yu *et al.,* 1995). Using the H-500 Leydig tumor model, constant infusion of either $1,25(OH)_2D_3$ or EB1089 inhibited the early increase in PTHrP expression and release from the tumors following implantation into syngeneic rats (Haq *et al.,* 1993). EB1089 was also effective in reversing hypercalcemia in nude mice carrying human squamous (Abdaimi *et al.,* 1999) and breast (El Abdaimi *et al.,* 2000) tumors (Fig. 1). Ras-transformed keratinocytes expressing high

levels of PTHrP rapidly developed into palpable tumors that continued to grow throughout the 100-day duration of the experiment. However, plasma calcium did not rise above the upper limit of normal until the final 20 days before sacrifice. Initiation of treatment by constant infusion of EB1089 at this stage resulted in a decline in serum calcium and PTHrP to near normal levels over the following weeks. However, the primary tumor continued to grow, suggesting that factors other than PTHrP were involved in tumor growth or that EB1089 had a greater effect on PTHrP release than it did on PTHrP expression in this case. Nude mice injected with MD-MB-231 human breast cancer cells and treated from the outset with EB 1089 exhibited a significant reduction in skeletal tumor burden over the 5-week experimental time course. These studies suggested that low calcemic vitamin D analogs may prove useful in the management of MAH and in inhibiting skeletal metastases associated with breast cancer.

ANTISENSE INHIBITION OF PTHRP PRODUCTION

An alternative approach for diminishing PTHrP overproduction in malignancy employed antisense technology to inhibit endogenous PTHrP expression. Transduction of H-500 rat Leydig tumor cells with antisense PTHrP followed by implantation of the transduced tumor cells into Fischer rats led to diminished hypercalcemia, decreased tumor cell proliferation, and prolonged survival of the host animal (Rabbani *et al.,* 1995). In view of evidence demonstrating that antisense furin could also reduce the production of bioactive PTHrP *in vitro,* presumably by inhibiting processing of mature PTHrP from its relatively inert precursor, it was decided to examine the effect of this maneuver *in vivo.* When Leydig tumor cells transduced with antisense furin were implanted *in vivo,* the host animals remained normocalcemic and tumor growth was reduced. Furthermore, survival of the animals was markedly prolonged (Liu *et al.,* 1995).

Overall these studies suggest that knowledge of the regulation of PTHrP production and processing can identify targets that may be useful for the development of agents to reduce circulating concentrations of bioactive PTHrP *in vivo* and to diminish hypercalcemia. Given the reduced size of tumors expressing antisense PTHrP, such agents may also reduce PTHrP levels indirectly by inhibiting tumor growth.

Role of 1,25-Dihydroxyvitamin D in MAH

Until quite recently the site of conversion of 25(OH)D to its active metabolite, $1,25(OH)_2D_3$, by the 25(OH)D 1 α-hydroxylase enzyme was thought to be restricted to the kidney. Although the kidney is still recognized as the primary site of $1,25(OH)_2D_3$ production *in vivo,* several extrarenal sites of 1 α-hydroxylase activity have been identified. These include cells of the hematopoietic and immune systems, the skin, the placenta and the developing skeleton . In contrast to the systemic role played by kidney-derived $1,25(OH)_2D_3$ in calcium homeostasis, locally produced hormone is thought to regulate cell proliferation and differentiation (Holick, 1999).

In contrast to the low circulating levels seen in the majority of hypercalcemic cancer patients, elevated serum concentrations of $1,25(OH)_2D_3$ have been reported in some cases of non-Hodgkin's (Breslau *et al.,* 1984) and Hodgkin's lymphoma (Jacobson *et al.,* 1988). This increase in circulating $1,25(OH)_2D_3$ was often seen in the presence of renal impairment, suggesting an extrarenal source of the hormone. More recently a human small cell lung cancer cell line, NCI H82, was shown to synthesize a vitamin D metabolite with similar biochemical properties and bioactivity to authentic $1,25(OH)_2D_3$ (Mawer *et al.,* 1994). Whether or not the systemic increase in $1,25(OH)_2D_3$ makes a significant contribution to hypercalcemia in these isolated cases remains a question of debate as the same malignancies also release cytokines and PTHrP, which are known mediators of MAH. On the contrary, in view of the recognized inhibitory activity of $1,25(OH)_2D_3$ on tumor growth and PTHrP production, coproduction of these factors by a tumor might be considered a good prognostic indicator, although this hypothesis has not yet been tested.

Cytokines as Systemic Mediators of MAH

Circulating proinflammatory cytokines most probably contribute to a number of the systemic manifestations of malignancy such as anorexia, dehydration, and cachexia (Ogata, 2000). Mounting evidence also suggests that cytokines released into the systemic circulation by a variety of solid tumors, which often coexpress PTHrP, contribute to the bone destruction associated with MAH. In this respect it is interesting to note that circulating concentrations of IL-6 correlate in a positive manner with tumor burden in patients with squamous and renal cell carcinoma, which represent the 2 prototypical malignancies associated with hypercalcemia and elevated circulating levels of PTHrP (Costes *et al.,* 1997; Nagai *et al.,* 1998).

Cytokines such as interleukin (IL)-1, IL-6, and TNF have been identified as physiological regulators of skeletal metabolism. They are produced by cells in the bone microenvironment, where they regulate their own and each other's expression and activity, as well as that of their cell surface receptors and soluble binding proteins (see Chapter 53 for details). The overall effect of this complex, interdependent activity is to stimulate bone resorption and to inhibit bone formation. Thus, the apparent uncoupling of resorption and formation in malignancies like myeloma that localize to bone has been attributed in large part to increased production of these cytokines in the bone microenvironment by the malignant cells (see Chapter 61 for details).

The relative contributions of systemically active PTHrP and cytokines to MAH has been examined in immune-compromised rodents carrying human tumors that overexpress both factors (Nagai *et al.,* 1998). Nude rats transplanted with a human squamous carcinoma of the oral cavity (OCC), which was shown to overproduce both PTHrP and

IL-6, rapidly developed severe hypercalcemia in association with high circulating levels of both PTHrP and IL-6. Hypercalcemic animals immunized with anti-IL-6 monoclonal antibody demonstrated a complete reversal in the biochemical abnormalities associated with elevated circulating IL-6, but only a small reduction in serum calcium. As measured by quantitative histomorphometry, there was a significant decrease in indices of bone resorption, as well as an increase in the mineral apposition rate in rats that received the neutralizing antibody. These results suggest that although IL-6 contributed to the skeletal abnormalities seen in OCC tumor-bearing rats, its contribution to the hypercalcemic syndrome was minor compared with that of PTHrP.

Using an alternate model, others demonstrated that mice carrying a human esophageal tumor (EC-GI), which coexpresses PTHrP and IL-1, develop a modest elevation in blood calcium (Sato *et al.,* 1989). A comparable level of hypercalcemia was observed in normal mice receiving a continuous infusion of IL-1. However, a significant increase in blood calcium was noted in mice that received a minimal daily dose of PTHrP in addition to the IL-1 infusion, suggesting a synergistic effect of PTHrP and IL-1 on bone resorption in this model. This hypothesis was supported by experiments in which addition of a small amount of synthetic PTHrP to the culture medium greatly enhanced ^{45}Ca release from prelabeled mouse bones, in response to recombinant IL-1.

This work using animal models of human disease predicts that PTHrP is the principal mediator of MAH. The hypothesis is further supported by clinical studies in which elevated circulating levels of PTHrP correlate strongly with hypercalcemia in patients with tumors of widely diverse histological origin (Ogata, 2000). No such correlation has been demonstrated for hypercalcemia and elevated circulating levels of cytokines such as IL-6 or IL-1. However, it has been proposed that a systemic increase in PTHrP not only promotes hypercalcemia but also stimulates normal cells to produce factors such as TNF-α, IL-1, IL-5, IL-6, and IL-8 in patients presenting with end-stage malignancy. The observation that infusion of anti-PTHrP antibody into mice with high circulating levels of PTHrP and IL-6 resulted in a prolonged decrease in the concentration of both factors in the bloodstream lends some support to this hypothesis.

Focal Osteolysis

Although PTHrP is more commonly recognized as a mediator of MAH while acting as an endocrine factor, increasing evidence suggests that it may also be a mediator of focal osteolysis induced by skeletal metastases while acting in a paracrine mode. Evidence for this has been presented in models of MDA-MB-231 breast cancer (El Abdaimi *et al.,* 2000; Guise *et al.,* 1996) and prostate cancer (Rabbani *et al.,* 1999). Indeed, it has been postulated that growth factors released from bone, notably transforming growth factor (TGF)-β, may increase PTHrP production and release from breast tumor metastases, further enhancing bone resorption (Yin *et al.,* 1999). In view of the fact that MDA-MB-231 breast cancer cells inoculated into nude mice by intracardiac injection will rapidly metastasize to bone and produce PTHrP, mice inoculated with tumor were treated with EB1089. Continuous infusion with EB1089 from the time of implantation caused a reduction of the tumor burden in bone, which resulted from a decrease in both the number and the size of metastatic lesions, compared with control mice that were infused with vehicle alone (El Abdaimi *et al.,* 2000). It appears, therefore, that the low-calcemic analog of $1,25(OH)_2D_3$ might also prove to be an effective therapeutic modality to reduce the skeletal tumor burden of patients with late-stage breast cancer.

The presence of PTHrP in breast cancer patients has been associated with rapid progression of disease and with a poor outcome (Pecherstorfer *et al.,* 1994). Early work showed elevated circulating levels of amino-terminal PTHrP in a large percentage of hypercalcemic breast cancer patients (Henderson *et al.,* 1990) and that the vast majority of breast cancer metastases in bone expressed high levels of PTHrP (Powell *et al.,* 1991; Southby *et al.,* 1990; Vargas *et al.,* 1992). Another recent study used MCF-7 breast cancer cells transfected with PTHrP as a model system to explore the potential role of PTHrP in breast cancer metastases to bone (Thomas *et al.,* 1999). PTHrP-producing MCF-7 cells not only supported osteoclast formation and activity via the RANKL/RANK/OPG system *in vitro* but also enhanced the potential of these tumor cells to metastasize to bone *in vivo.* Taken together these observations predict that tumor-derived PTHrP acts at both the systemic (primary tumor) and local (skeletal matastases) levels to stimulate osteoclastic bone resorption, at least in part, through the RANKL/RANK/OPG system.

Inhibition of Osteolysis by Bisphosphonates

The bisphosphonates, which are nonhydrolyzable analogs of pyrophosphate, are highly effective inhibitors of osteoclastic bone resorption (see Chapter 78). They are now considered to be the modality of choice in the treatment of MAH and have been advocated as well in the treatment of focal osteolysis caused by breast cancer (Hortobagyi *et al.,* 1996) and multiple myeloma (Berenson *et al.,* 1996). Their efficacy as antiresorptive agents is a function of their metabolic stability, their capacity to bind avidly to hydroxyapatite and to stabilize crystal structure, and their ability to directly inhibit osteoclast activity and apparently to promote osteoclast apoptosis. This is accomplished by inhibition of prenylation of small GTP binding proteins or incorporation of the compounds into toxic forms of ATP (Rodan, 1998). Unlike calcitonin, which elicits a mild and short-lived hypocalcemic response, a single dose of a bisphosphonate such as pamidronate can result in a steady decline in serum calcium over several days.

Using metastatic breast cancer as an example of PTHrP-driven MAH, evidence from long-term clinical trials suggest that bisphosphonate therapy may not, unfortunately, be effective in the long-term management of MAH. Despite the marked reduction in skeletal tumor burden seen in women treated with pamidronate during late stage disease, the prophylactic use of these agents at earlier time points has met with variable success (Lipton, 2000). This has been attributed variously to low tolerance for the drugs, to resistance to their action in bone, and, most importantly, to their failure to attack the source of the problem, which in large part appears to be overproduction of PTHrP. In one study serum calcium was normalized in 90% of patients with MAH after an initial treatment with pamidronate, whereas hypercalcemia was corrected in only 15% of those patients by the third consecutive treatment (Body *et al.,* 1998). Furthermore, circulating PTHrP continued to rise in association with enhaced renal calcium reabsorption. Resistance to ibandronate, another bisphosphonate therapy for recurrent hypercalcemia, was observed in a large cohort of patients with a variety of PTHrP-producing tumors (Rizzoli *et al.,* 1999). Taken together, the results suggest that although bisphosphonates are invaluable members of our armamentarium for inhibiting osteolysis, additional therapeutic modalities may need to be developed, to inhibit the action of PTHrP in both kidney and bone. This may require inhibitors of production, processing, and/or action of this systemic factor (Ogata, 2000).

CHAPTER 61

Local Factors in Skeletal Malignancy

Gregory R. Mundy, Toshiyuki Yoneda, Theresa A. Guise, and Babatunde Oyajobi
Department of Medicine, University of Texas Health Science Center, San Antonio, Texas 78284

Tumors have multiple effects on the skeleton, all of which are mediated by tumor cells altering the behavior of bone cells and causing disruptions or enhancement of the normal bone remodeling process. These effects on bone cells are caused by increased production of peptides in tumor-bearing patients, some of which act at short range and some at a distance as systemic or hormonal factors, which then modulate bone cell activity. This is certainly the major and possibly the only mechanism by which tumors affect bone, and in this chapter a number of the peptides that have been implicated will be discussed. It is possible that tumor cells also interact directly with bone cells by cell–cell contact, or directly with the mineralized bone matrix without the intervention of bone cells, but the biological or clinical significance of these effects is unclear.

The common skeletal syndromes that tumors cause are:

1. The humoral hypercalcemia of malignancy (HHM), due to circulating hormonal mediators of osteoclastic bone resorption and renal tubular calcium reabsorption, which are secreted by tumor cells from a primary (or secondary) site distant from bone.
2. Osteolytic bone metastasis (with or without hypercalcemia), due to solid tumors metastatic to the bone marrow cavity and causing localized bone destruction at those sites.
3. Osteoblastic bone metastases, caused by solid tumor metastasis to the bone marrow cavity and causing new bone formation by producing local growth regulatory factors which activate osteoblasts.
4. Myeloma bone disease, the characteristic and distinctive form of osteolysis caused frequently by myeloma cells.
5. Oncogenic osteomalacia, the syndrome of phosphate depletion caused by urinary phosphate loss and characterized by rickets or osteomalacia.

When tumor cells affect the skeleton, the results are often catastrophic for the patient. However, the skeletal effects are only part of the overall clinical picture. The patient may also suffer from other paraneoplastic syndromes which greatly affect quality of life. Some of these syndromes occur with increased frequency in patients with hypercalcemia, and will be described in more detail.

Each of these paraneoplastic endocrine syndromes has been associated with soluble mediators produced either by tumor cells or by other cells in response to the tumor. In none, however, can all of the features of the associated clinical syndrome be accounted for entirely by a single mediator so far discovered or described. In some of these syndromes, most notably humoral hypercalcemia of malignancy, parathyroid hormone-related peptide (PTH-rP) is a major mediator. It is the purpose of this chapter to review evidence for the role of some of the other factors produced in excess in malignancy and the potential role that these may have on bone.

Humoral Hypercalcemia of Malignancy Syndrome

Parathyroid Hormone-Related Peptide

The possibility that a factor with PTH-like effects may cause humoral hypercalcemia was first suggested by Albright (1941). This hypothesis was confirmed almost 50 years later when a parathyroid hormone-like peptide was purified from a number of cell lines as well as tumor

extracts and then eventually cloned (Moseley *et al.,* 1987; Stewart *et al.,* 1987; Strewler *et al.,* 1987). With a similar amino acid sequence to PTH at the N-terminal end of the molecule, this peptide mimics the biological effects of PTH on both bone resorption and renal tubular function. It does this by binding to and activating the PTH receptor. It causes increased nephrogenous cyclic adenosine monophosphate (cyclic AMP) generation, inhibition of renal tubular phosphate reabsorption, and enhanced reabsorption of calcium from the renal tubules (Yates *et al.,* 1988). These features are characteristic of patients with humoral hypercalcemia of malignancy, and in that syndrome PTH-rP is the presumed mediator. However, there are differences between the syndrome of humoral hypercalcemia of malignancy and primary hyperparathyroidism that are unaccounted for. Primary hyperparathyroidism is caused by excess parathyroid hormone produced by a parathyroid adenoma or parathyroid gland hyperplasia. If HHM was due entirely to a factor that binds to and interacts with the PTH receptor in an identical manner to PTH, then the two syndromes should be the same. Differences in the two syndromes however, are quite clear. In most patients with the humoral hypercalcemia of malignancy, there is a decrease in intestinal calcium absorption and 1,25-dihydroxyvitamin D synthesis (Stewart *et al.,* 1980), in contrast to that seen in patients with primary hyperparathyroidism. In patients with humoral hypercalcemia of malignancy bone formation is decreased (Stewart *et al.,* 1982), again in contrast to patients with primary hyperparathyroidism. In patients with humoral hypercalcemia of malignancy, there is no evidence of renal tubular bicarbonate wasting, which is characteristic of primary hyperparathyroidism. In view of the differences between these syndromes, it appears likely that other factors are responsible for the differences. Another alternative is that there are differences in the biological effects of PTH and PTH-rP that have not been described as yet, despite intense investigation. PTH-rP has been described in detail in other chapters and will not be discussed further here.

Parathyroid Hormone

Since the earliest observations of Albright, PTH has been sought for in tumors associated with hypercalcemia. There were early reports that PTH was produced frequently in patients with breast cancer and other malignancies associated with extensive osteolysis (Benson *et al.,* 1974), but in retrospect it now appears likely that these were due to insensitivity in the immunoassays that were used to detect PTH-like activity. Nevertheless, PTH is a rare cause of hypercalcemia associated with cancer (Simpson *et al.,* 1983). Due to ectopic PTH production by nonparathyroid tumors (Yoshimoto *et al.,* 1989; Nussbaum *et al.,* 1990; Strewler *et al.,* 1990). In the case described by Nussbaum *et al.,* there was a potential molecular explanation for the aberrant production of PTH by the tumor cells. In this tumor, there was a DNA rearrangement in the region of the promoter which may have been responsible for the overexpression of PTH by the tumor.

Cytokines Which Have Been Associated with Malignancy

A number of cytokines have been associated with the humoral hypercalcemia of malignancy syndrome. These include interleukin-1, tumor necrosis factor and interleukin-6. We think it is likely that they may be involved in some other clinical manifestations in addition to hypercalcemia. As an example, interleukin-6 is frequently produced by either tumor cells or host cells in patients with malignancy, and it may be responsible for some of the other endocrine syndromes associated with malignancy such as cachexia, anemia, thrombocytosis, and acute phase reactions. Interleukin-6 markedly enhances the effects of PTH and PTH-rP on bone resorption and hypercalcemia (De la Mata *et al.,* 1995). It presumably does this because of its effects to increase pools of cells at earlier stages in the osteoclast lineage (De la Mata *et al.,* 1995). Interleukin-6 causes a marked increase in generation of CFU-GM and committed marrow precursors. It is in itself a weak bone resorbing factor (Black *et al.,* 1991), but may act permissively for the effects of other factors which act later on the osteoclast lineage such as PTH-rP (De la Mata *et al.,* 1995). This has been demonstrated using Chinese hamster ovarian cells that have been transfected with the interleukin-6 and PTH-rP genes (De la Mata *et al.,* 1995). On its own, however, interleukin-6 has been associated with the hypercalcemia–leukocytosis syndrome. In the MH-85 human squamous cell carcinoma of the maxila, there is marked production of interleukin-6 by the tumor cells, and Yoneda *et al.* (1991) have shown that hypercalcemia in this syndrome is abrogated by the use of neutralizing antibodies to human interleukin-6. These antibodies do not react with murine interleukin-6, and thus the interleukin-6 which is presumably responsible for the syndrome is produced by the human tumor.

Other cytokines have also been associated with the humoral hypercalcemia of malignancy syndrome. Interleukin-1α is frequently produced by tumors in association with PTH-rP (Sato *et al.,* 1989; Fried *et al.,* 1989; Nowak *et al.,* 1990). In fact, in the human tumor studied by Sato *et al.* (1989), PTH-rP was produced together with interleukin-1α and it was shown by these authors that the two factors together caused synergistic effects on hypercalcemia.

There have also been a number of other examples where solid tumors have been shown to stimulate normal host immune cells to produce osteotropic cytokines such as tumor necrosis factor (Sabatini *et al.,* 1990 a,b; Yoneda *et al.,* 1991). Examples are the human melanoma cells A375, the rat Leydig cell tumor and the MH-85 human squamous cell carcinoma of the maxilla. In each of these tumors, it has been shown that the tumor cells secrete soluble factors which can stimulate normal host immune cells and particularly cells in the monocyte-macrophage family, to produce cytokines such as tumor necrosis factor. Sabatini *et al.* (1990b) showed that the mediator responsible for tumor necrosis factor (TNF) production in the A375 tumor was granulocyte macrophage colony-stimulating

factor (GM-CSF). In the case of the MH-85 tumor, Yoneda *et al.* (1991) showed that another mediator was involved that was distinct from GM-CSF. In this latter case, the hypercalcemia could be reversed by treating tumor-bearing mice with antibodies to tumor necrosis factor. There was a fourfold increase in circulating tumor necrosis factor in tumor-bearing animals. Removal of the spleens also caused a reduction in the hypercalcemia, presumably because the spleen is the major source of host immune cells producing TNF. There was no production of TNF by the tumor cells themselves.

The production of these cytokines by host immune cells may be part of the normal humoral defense mechanism designed to protect the host from the presence of a tumor. However, at the same time these cytokines are having a beneficial effect, they also may be causing some of the paraneoplastic endocrine syndromes associated with malignancy. In the examples described here, they were likely to be responsible for cachexia, leukocytosis, anemia, and hypertriglyceridemia, which occurred in the tumor-bearing host. Reduction of the cytokine levels with the use of neutralizing antibodies relieved some of these syndromes in the above models, and particularly in the rat Leydig tumor and in the MH-85 tumor (Yoneda *et al.,* 1991; Sabatini *et al.,* 1990a,b).

Prostaglandins of the E Series

It has been known for 25 years that prostaglandins of the E series stimulate osteoclastic bone resorption in organ cultures of fetal rat long bones and neonatal mouse calvariae (Klein and Raisz 1970). Following these seminal observations, it was for some time thought that prostaglandins may be important mediators in the bone destruction associated with metastatic breast cancer and also possibly in the humoral hypercalcemia of malignancy (Powles *et al.,* 1976; Bennett *et al.,* 1975; Seyberth *et al.,* 1975). The coculture of breast cancer cells together with bone results in osteoclastic bone resorption which could be reversed by inhibitors of prostaglandin synthesis such as aspirin and indomethacin (Powles *et al.,* 1973, 1976; Bennett *et al.,* 1975; Greaves *et al.,* 1980). However, this may have been an artifact of the culture conditions, and studies using prostaglandin synthesis inhibitors in patients with breast cancer metastatic to bone have been uniformly disappointing (Powles *et al.,* 1982). It now appears more likely that prostaglandins of the E series are minor pathogenetic factors in the humoral hypercalcemia of malignancy. They are occasionally found in patients in which it is clear that the increase in bone resorption can be reversed by drugs such as indomethacin, but these patients are unusual (Mundy *et al.,* 1983). Moreover, it is also possible that in the animal models which are associated with increased prostaglandin production (Tashjian *et al.,* 1972), other mediators as well may be involved. Prostaglandins are probably rarely if ever sole causes of the humoral hypercalcemia of malignancy syndrome.

Myeloma Bone Disease

The malignant disorder, myeloma, is characterized by extensive bone destruction. It is the major clinical hallmark of the disease. Bone destruction is manifested by a number of important clinical features including intractable bone pain, fractures that occur either spontaneously or following trivial injury, and hypercalcemia, which can be life-threatening. The majority of patients, probably more than 80%, have bone pain as a presenting symptom (Snapper and Kahn 1971). The bone lesions which occur in myeloma occur in several patterns (Mundy and Bertolini 1986), the most common of which are multiple, discrete lytic lesions which occur at the site of deposits or nests of myeloma cells. These are apparent in the axial skeleton, skull, vertebrae, ribs, and proximal ends of long bones. The characteristic lesions show discrete lysis without evidence of new bone formation. Some patients develop diffuse osteopenia, which can be readily confused with osteoporosis. However, this osteopenia is extremely severe, aggressive, of rapid onset, and associated with vertebral body compression and collapse. In some patients, there may be pressure on the spinal cord with associated symptoms of spinal cord compression. Some patients with myeloma have solitary plasmacytomas with single discrete osteolytic lesions associated. Even more rarely, patients with myeloma have no lytic lesions or bone loss, but rather demonstrate an increase in new bone formation around collections of myeloma cells. These patients with osteosclerotic myeloma often have the so-called POEM's syndrome (severe progressive sensory and mode of polyneuropathy, organomegaly, endocrine dysfunction, and papilloedema associated with their myeloma) (Bardwick *et al.,* 1980).

The bone destruction which is associated with myeloma is mediated by osteoclasts. Osteoclasts in myeloma always occur adjacent to collections of myeloma cells, so it is likely that the mechanism for the bone destruction in myeloma is locally mediated, presumably by cytokines released by the myeloma cells in the microenvironment of the osteoclast (Mundy *et al.,* 1974a,b). The major area of dispute in myeloma is the identity of the responsible cytokine or cytokines.

About one-third of patients with myeloma develop hypercalcemia at some time during the course of the disease (Mundy and Bertolini, 1986). Hypercalcemia is almost always accompanied by an impairment in glomerular filtration. This impairment in glomerular filtration may be due to multiple causes in patients with myeloma, including the production of free light chains (or Bence Jones proteins) by the myeloma cells, by uric acid nephropathy, by chronic infections, or by the hypercalcemia itself.

Bone formation is usually markedly impaired in patients with myeloma for reasons that are totally unclear. This can be manifested clinically by measurement of serum alkaline phosphatase which is not increased, unlike most other patients with osteolytic bone lesions, and radionuclide bone scans which show no evidence of increased skeletal uptake

of the isotope, which indicates impaired osteoblastic responses to the increase in bone resorption.

Although the observation that local cellular mechanisms were largely responsible for the bone destruction in myeloma was first made 25 years ago (Mundy *et al.,* 1974a), there are still unresolved questions as to the nature of the local mediator(s) responsible for the increased osteoclast recruitment and activation. Numerous cytokines have been implicated including interleukin-1, interleukin-6, and tumor necrosis factor β (lymphotoxin) and hepatocyte growth factor, all of which can stimulate osteoclast formation and activity. Independently or together, each of these cytokines has been associated with the bone destruction of myeloma (Cozzolino *et al.,* 1989; Garrett *et al.,* 1987; Kawano *et al.,* 1989; Hjertner *et al.,* 1999). The evidence for a role of these cytokines comes from the different modes of studying the mechanisms of bone resorption. Part of the problem is the lack until recently of reliable animal models of the disease. As a consequence, it has not been possible in myeloma to confirm that production of any single cytokine *in vitro* is also relevant *in vivo,* as it has been in patients with the humoral hypercalcemia of malignancy due to solid tumors. The evidence for lymphotoxin as a possible mediator comes from cultures of established human and animal myeloma cell lines (Garrett *et al.,* 1987). In these cultures, it has been shown that the bone resorbing activity produced by the myeloma cells can be mostly accounted for by lymphotoxin, and that this bone resorbing activity can be largely neutralized by antibodies to lymphotoxin. However, freshly isolated cells from patients with myeloma give a different picture. In this situation, the cultured cells, which are not homogeneous, produce interleukin-1β (Cozzolino *et al.,* 1989; Kawano *et al.,* 1989). Whether this is artifact or whether this is due to the conditions of the culture remains unknown. For example, for a number of years the field was misled by the production of prostaglandins *in vitro* from cultured freshly isolated cells which turned out to be most likely a culture artifact.

Interleukin-6 plays an important role in myeloma, independent of its effects on bone (Klein *et al.,* 1989; Bataille *et al.,* 1989). Interleukin-6 is the major growth factor which is produced by myeloma cells and is responsible for the neoplastic phenotype in myeloma cells. Myeloma cells produce small amounts of interleukin-6, as do the stromal cells in the myeloma cell microenvironment. It is a point of controversy over whether myeloma cell growth *in vitro* is due to autocrine production of interleukin-6 by myeloma cells or paracrine production by the host cells. Nevertheless, interleukin-6 is likely to be an important factor in bone resorption. Although interleukin-6 shows weak bone resorbing factor activity (Black *et al.,* 1991), it is more likely to be acting in a permissive role rather than as the major bone resorbing factor (De la Mata *et al.,* 1995).

HGF has also been reported to be involved in myeloma bone disease. It is secreted by freshly isolated myeloma cells and myeloma cell lines. Moreover, high-serum HGF has been reported to be associated with poor prognosis in myeloma patients (Seidel *et al.,* 1998). Although there is presently no direct evidence that HGF mediates myeloma-associated bone disease in patients *in vivo,* HGF has been shown to be chemotactic for osteoclasts *in vitro* and to stimulate osteoclastogenesis and bone resorption *in vitro* (Sato *et al.,* 1995; Fuller *et al.,* 1995). This effect of HGF is via a paracrine effect on marrow stromal/osteoblastic cells (Sato *et al.,* 1995; Grano *et al.,* 1996). It is interesting to note that serum HGF levels have also been shown to be elevated in breast cancer patients (Taniguchi *et al.,* 1995).

As mentioned above, neither human nor murine myeloma cells, which cause extensive bone resorption *in vivo,* produce significant amounts of bone resorbing cytokines *in vitro.* Data now emerging suggest that the dichotomy between *in vitro* and *in vivo* observations may be related to the fact that *in vivo,* myeloma cells exist tightly bound to various elements of the marrow stroma. It is now apparent that myeloma cells behave differently in the marrow microenvironment and that cell–cell and/or cell–extracellular matrix (ECM) interactions between tumor cells and marrow stroma are critical, not only for the growth and survival of the tumor cells, but also for initiating and maintaining the aggressive bone destruction.

Cell–cell and cell–ECM adhesion events are increasingly being implicated in the etiology and pathogenesis of many diseases including cancer. Human and murine myeloma cells express very late antigen 4 (VLA4) (Michigami *et al.,* 2000; Teoh and Anderson, 1997; Vanderkerken *et al.,* 1997), a heterodimeric complex of α4 and β1 integrin subunits. All the three known VLA4 ligands, VCAM-1, fibronectin, and osteopontin, are present in the marrow, and of particular significance for myeloma, VCAM-1 is expressed by bone marrow stromal cells constitutively. There is evidence that indicates that myeloma cells use VLA4 not only to home to bone, but also to preferentially adhere to bone marrow stromal cells through VCAM-1 as well as the ECM (Faid *et al.,* 1996; Teoh and Anderson 1997; Michigami *et al.,* 2000). Data from other studies including ours provide compelling evidence implicating these cellular interactions, not only in the growth of myeloma in bone, but also in initiating the sequence of events that lead to bone destruction. For example, data from our studies indicate a link between VCAM/1/VLA4 and osteoclast formation via induction of RANKL following direct cell–cell contact between bone marrow stromal cells and myeloma cells. RANKL is a member of the TNF ligand superfamily whose expression by marrow stromal osteoblastic cells has been shown to be obligatory for osteoclast formation and activity. 5TGM1 myeloma cells exhibit tight adherence to the mouse marrow stromal cell line ST2 *in vitro,* and contact between the two cell types increased RANKL mRNA expression in comparison to either cell type alone. This interaction also causes production of a soluble factor(s) by the myeloma cells capable of enhancing RANKL expression in ST2 cells and inducing resorption in fetal rat long bones (Michigami *et al.,* 2000; Oyajobi *et al.,* 1998). The effect of these cell–cell interactions was mimicked by treating the myeloma cells with recombinant soluble VCAM-1 (Oyajobi *et al.,* 1998) and, conversely, the production of the

soluble activity was blocked by neutralizing antibodies to either α4 or to VCAM-1 (Michigami *et al.,* 2000).

Recent evidence suggests a role for MIP-1α in myeloma bone disease. MIP-1α belongs to a family of small (8–12 kDa) proteins that are chemoattractive for leukocytes (Opdenakker and Van Damme, 1999; Rollins, 1997; Zlotnik *et al.,* 1999). These proteins called chemokines are classified into two major groups, cysteine–cysteine (CC) or cysteine–X–cysteine (CXC), depending on the positions of the first two invariant cysteine residues. Using competitive PCR, mRNA for MIP-1α, a CC chemokine, was shown to be elevated in bone marrow plasma of myeloma patients compared to normal controls (Choi *et al.,* 2000). Furthermore, elevated levels of MIP-1α were detected in marrow supernatants from a majority of myeloma patients with active disease (8/12) by ELISA but not in normal controls (0/9). An anti-MIP-1α neutralizing antibody blocked the stimulatory effect of bone marrow supernatants from myeloma patients on osteoclast formation in human bone marrow cultures, but had no effect on control levels of osteoclast formation (Choi *et al.,* 2000). Other workers have also recently reported elevated MIP-1α levels in four of eight aspirates from myeloma patients (Abe *et al.,* 1999). MIP-1α-producing myeloma cell lines markedly enhanced formation of $TRAP^+$ multinucleated cells when cocultured with rabbit bone marrow cells, and this was abrogated by an anti-VLA4 antibody (Abe *et al.,* 1999). We have found also that MIP-1α is expressed by human and murine myeloma cell lines including 5TGM1 cells. Importantly, MIP-1α level is increased in a 5TGM1/ST2 coculture system, implying a role for VLA4–VCAM-1 interaction in regulating MIP-1α expression. Since MIP-1α is known to promote cellular adhesion by upregulating expression of integrins such as α4 (Rollins, 1997; Zlotnik *et al.,* 1999), MIP-1α could potentially increase adherence of myeloma cells to marrow stromal cells by upregulating α4 and consequently activating VLA4. This increased cellular adhesion would, in turn, augment MIP-1α production as previously described (Steinhauser *et al.,* 1998), resulting in recruitment of monocytes/macrophages, which are precursors of osteoclasts.

Thus, there is a growing body of evidence linking the growth of myeloma cells in the bone marrow microenvironment, their capacity to stimulate bone resorption, and the cytokines that they produce. Myeloma seems to have a special predilection for bone, unlike other hematologic malignancies. We believe that this special predilection may be related to the capacity of bone, and in particular of osteoclasts, to produce the major growth factor for myeloma cells, namely interleukin-6. Osteoclasts are the most prodigious cell source of interleukin-6 that is known (Bonewald, unpublished observation). Other cells in the bone marrow microenvironment also produce interleukin-6 and in particular cells from the osteoblast lineage in response to cytokines such as interleukin-1 and tumor necrosis factor. This production of interleukin-6 in this microenvironment may be responsible for enhancing the growth of myeloma cells and for promoting their aggressive behavior (Garrett *et al.,* 1995). Thus, we propose that there may be a vicious cycle in the bone marrow microenvironment between the myeloma cell and osteoclastic bone destruction—the more aggressive the behavior of the myeloma cells, the greater the bone destruction, which in turn causes excess production of interleukin-6 which makes the myeloma cell growth even more aggressive.

The implications of these findings may be very important. For example, if bone destruction can be reduced in patients with myeloma, this may have beneficial effects not just on the bone disease and the capacity to reduce skeletal complications, but also on the growth of the myeloma cells in that microenvironment. The results of extensive studies with the use of drugs such as the bisphosphonates in myeloma is eagerly awaited, particularly if their use is accompanied by a beneficial effect on tumor burden.

Osteoblastic Bone Metastases

Some tumors affect the skeleton by causing osteoblastic metastases. This situation is much less common than that of the osteolytic metastasis, probably representing no more than 5–10% of all metastatic bone lesions. However, it is very common in some tumors, and particularly solid tumors of the male urogenital tract. Prostate cancer is the most notable example of a human tumor that is associated with increased bone formation. In prostate cancer, almost all patients will eventually develop osteoblastic bone metastases if they live long enough (Galasko, 1986; Mundy and Martin 1993). The osteoblastic metastasis is due to the production by the tumor cells of growth regulatory factors which enhance the activity of osteoblasts to proliferate and differentiate to form bone nodules (Charhon *et al.,* 1983).

The mechanism of formation of the osteoblastic metastasis of course has been of great interest to everyone in the field of bone biology. The early histomorphometric studies suggested that osteoblastic metastases were due to soluble factors which were produced by the tumor cells which had metastasized to the marrow cavity (Charhon *et al.,* 1983). This new bone formation occurred without prior bone resorption and therefore does not represent an example of enhancement of the coupling process (Charhon *et al.,* 1983). Extensive studies have been carried out to identify some of the mediators that may be produced by prostate cancer cells which could be responsible for this effect. Jacobs and Lawson (1980) identified mitogenic factors for fibroblasts which were produced by prostate cancer cells that were partially characterized. Following that, workers such as Simpson *et al.* (1985) and Koutsilieris *et al.* (1987) found that there was activity that stimulated osteoblasts also produced by prostatic cancer tissue.

We have studied several human and animal tumors which are associated with extensive new bone formation *in vivo.* These include the PA-III rat adenocarcinoma of the male urogenital tract and the WISH human amniotic tumor. The WISH tumor has been noted for almost 25 years to

stimulate bone formation (Wlodarski *et al.,* 1970). We examined extracts and conditioned media from the WISH tumor and identified a mitogenic activity for osteoblasts (Izbicka *et al.,* 1993). This was purified to homogeneity and we identified an extended form of basic fibroblast growth factor. The PA-III rat prostate adenocarcinoma produces a number of bone growth stimulatory factors *in vitro.* These factors belong to the bone morphogenic protein (BMP)-like family. One of these factors in preliminary studies has been neutralized by using antisense to BMP-3 (Harris, unpublished observation). Identification of the precise nature of these factors is awaited with considerable interest.

The factors which have been associated as potential mediators of osteoblastic metastases associated with prostate cancer are transforming growth factor β, fibroblast growth factors, plasminogen activator sequences, and the bone morphogenetic proteins.

Transforming Growth Factor β

Transforming growth factor β is abundant in PC3 human prostate cancer cells (Marquardt *et al.,* 1987; Wilding, 1991), one of the common human models of prostate cancer. Because transforming growth factor (TGF) βI and -II have profound effects on bone cells, including enhancement of bone formation *in vivo* and stimulation and proliferation of osteoblast precursors as well as chemotaxis of osteoblast precursors, this TGFβ production could in fact be part of the osteoblastic response to prostate cancer. However, much work would need to be done in determining the precise role and its relationship to binding proteins which mask its biological activity.

Fibroblast Growth Factors

Prostate cancer cells frequently produce large amounts of acidic and basic fibroblast growth factors. Fibroblast growth factors are powerful stimulators of new bone formation (Dunstan *et al.,* 1999). Recently, we have found that the human WISH tumor causes bone formation by an increase in the extended form of basic fibroblast growth factor (Izbicka *et al.,* 1993). There is now an extensive range of factors in the fibroblast growth factor family that could be responsible for increased bone formation.

Fibroblast growth factors are powerful stimulators of bone formation *in vivo.* They cause bone formation without any evidence of previous bone resorption (Dunstan *et al.,* 1999). They are also critical in normal skeletal development and limb bud formation (Cohn *et al.,* 1995). Point mutations in receptors for the fibroblast growth factor family cause skeletal defects such as achondroplasia (Rousseau *et al.,* 1994).

Bone Morphogenetic Proteins

The bone morphogenetic proteins are polypeptide members of the extended transforming growth factor β family. They are powerful stimulators of bone formation *in vivo.* They have different effects on bone cells from TGFβ, since their primary effect is to promote differentiation and new bone formation *in vitro.* Their effects on bone cell proliferation are probably indirect. These peptides are frequently produced by prostate cancer cells (Harris *et al.,* 1994) and are likely mediators of at least part of the osteoblastic response associated with prostate cancer (Harris *et al.,* 1992).

Plasminogen Activator Sequences

Recently, purification of mitogenic activity from the human prostate cancer cell line PC3 has identified amino acid sequences of plasminogen activator (Rabbani *et al.,* 1990 a,b). Plasminogen activator sequences do have growth regulatory effects. These peptides are similar or identical to the urokinase-type plasminogen activator. It is possible that they have mitogenic effects in their own right, and they also may be responsible for activation of other growth factors which could cause stimulation of the bone formation process.

Endothelin-1

Endothelin-1 has been implicated as a potential mediator of the osteoblastic metastases that are associated with prostate cancer and possibly with other solid tumors that cause osteoblastic metastasis. Endothelin-1 has been found in increased amounts in the serum of patients with prostate cancer (Nelson *et al.,* 1995) and has been shown to increase bone cell proliferation. We have also found that it increases osteoblast accumulation, maturation, and bone formation in organ cultures of neonatal calvaria (Yin *et al.,* 1999). We have found that endothelin-1 expression is enhanced in cultured breast cancer cells that are associated with osteoblastic metastasis when these cells are inoculated into the left cardiac ventricle of nude mice (Yin *et al.,* 1999). Moreover, we have found that the effects to form osteoblastic metastasis are alleviated *in vivo* by a specific receptor antagonist to the endothelin-A receptor, and the bone forming activity which is produced by the cultured tumor cells *in vitro* is also inhibited by this receptor antagonist (Yin *et al.,* 2000).

Platelet-Derived Growth Factor

Recently we have found evidence that platelet-derived growth factor (PDGF) is also a potential mediator of osteoblastic metastasis. It has been known for many years that PDGF is a powerful stimulator of osteoblast proliferation (Canalis *et al.,* 1980, 1989). We have identified PDGF in the conditioned media of a human breast cancer associated with osteoblastic metastasis, namely the MCF-7 tumor (Yi *et al.,* 1999). The conditioned media from cultured tumor cells stimulated bone formation in murine calvarial bones, and was blocked by neutralizing antibodies to PDGF (Yi *et al.,* 1999).

Osteolytic Bone Metastases

Our understanding of the mechanisms involved in tumor cell metastasis to distant organ sites has improved considerably during the past 15 years. Most studies have examined tumor cell metastasis to common sites such as liver and lung. However, until recently, there have been few studies on the mechanisms of tumor cell metastasis to bone. Tumor cell metastasis to bone initially involves the same steps involved in tumor cell metastasis to any organ, but in addition there are special extra features of the bone microenvironment which render some tumors more likely to grow in this site. Our understanding has increased recently with the development of animal models for studying human tumor cell spread to bone (Nakai *et al.,* 1992; Mundy and Yoneda, 1995), techniques with the features that the tumor cells can be manipulated as well as the bone microenvironment to study important interactions which take place at the metastatic bone site.

Some tumor cells have a particular predilection to spread to bone. The commonest examples among human tumors are carcinomas of the lung, breast, and prostate (Mundy and Martin, 1993). For these tumor cells to spread to bone, they clearly have functional properties which enable them to travel from the tissue of origin to the site of metastasis (Fig. 1), occupy a niche at that site, and then grow avidly. Clarifying the special properties which are important in metastasis of tumor cells to the bone site will hopefully lead to potential therapeutic targets for either prevention or reversal of this process.

Several cellular mechanisms have been suggested for the destruction of bone which occurs at osteolytic sites. First, it is possible that tumor cells themselves can cause bone destruction. They certainly have the capability of doing this *in vitro.* We have previously shown that human breast cancer cells, when cultured on devitalized bone matrices, can cause resorption of bone (Eilon and Mundy 1978). However, *in vivo,* it seems likely that the major mechanism for bone destruction is osteoclast-mediated. Meticulous scanning electron microscopy studies of bone surfaces always reveal evidence of resorption pits made by osteoclasts, but no evidence of resorption pits made by tumor cells (Boyde *et al.,* 1986). Although scanning electron microscopy cannot exclude the possibility that tumor cells cause some bone destruction, it is obvious that osteoclastic bone resorption is probably the major mechanism whereby osteolysis occurs in patients with tumors.

The mechanisms that tumor cells utilize to stimulate osteoclast activity are probably similar to those used in the humoral hypercalcemia of malignancy. The tumor cells or host cells that are activated by the presence of the tumor release osteoclast stimulating factors which cause new osteoclast formation and subsequent bone resorption, in the absence of a normal osteoblastic response to prior resorption. The factors which are responsible for osteoclast activation

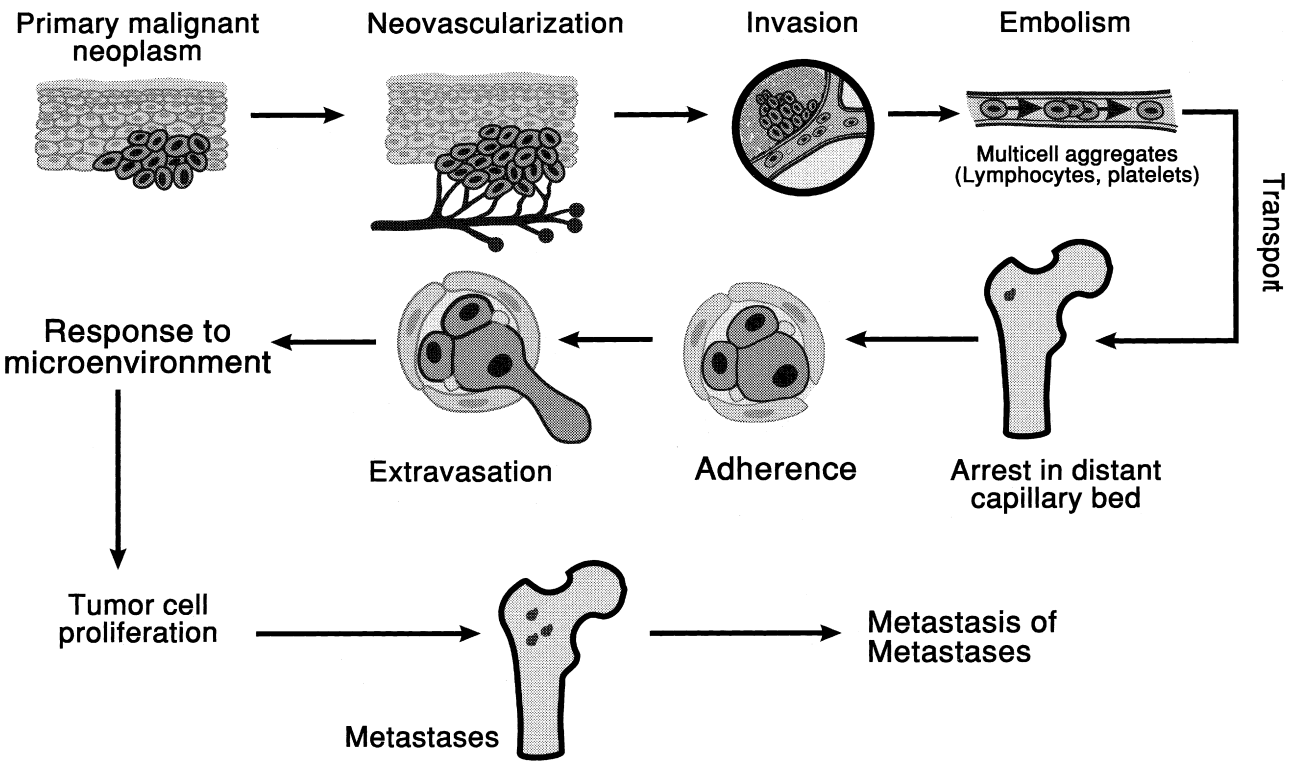

Figure 1 Multiple steps that are utilized by tumor cells that metastasize to bone. Note that each step represents a potential therapeutic target for development of pharmacologic agents to prevent or inhibit the bone metastatic process.

include PTH-rP. This may occur even in the absence of significant PTH-rP production at the primary site. For example, clinical studies have shown that although only about 50% of primary human breast cancers express PTH-rP and that PTH-rP production is not common in nonbone metastatic sites, when breast cancer cells are grown in bone PTH-rP expression is enhanced in over 90% of cases (Powell *et al.,* 1991). We have examined the potential pathophysiologic mechanisms which are responsible for enhanced PTH-rP production by breast cancer cells in metastatic bone sites. We have utilized the human breast cancer cell line MDA-231 which in culture produce low concentrations of PTH-rP (3–5 pmol). When these tumor cells are inoculated into the left ventricle of nude mice, they cause characteristic osteolytic metastases associated with increased osteoclastic bone resorption. In tumor-bearing nude mice, plasma PTH-rP is not detectable, and the mice do not develop hypercalcemia. However, bone marrow plasma at the sites of osteolytic lesions reveal markedly increased PTH-rP, paralleling what is seen in the clinical studies in patients, and suggesting that MDA-231 cells in the bone microenvironment produce increased amounts of PTH-rP. We have treated these tumor-bearing mice with a murine monoclonal antibody direct against PTH-rP 1–34, and found that the antibodies prevent the development of bone metastases, decrease the area of osteolytic metastases which are already established, and moreover decrease tumor bulk in bone (Guise *et al.,* 1996). The antibodies also cause a significant increase in survival of the tumor-bearing nude mice. These data suggest not only that PTH-rP is playing an important pathophysiological role in the bone metastasis, but that enhanced local PTH-rP expression can occur without hypercalcemia or increased plasma PTH-rP and indicates that PTH-rP can mediate the effects of tumors on the skeleton without causing hypercalcemia.

We have been interested in the pathophysiologic mechanisms that may be responsible for PTH-rP production by breast cancer cells at the bone site. From the studies of Paget of over a century ago, it was recognized that tumor cells have a special predilection to grow at some sites. Paget described the environment of favorable metastatic sites as "congenial soil." The bone matrix may well be such a congenial soil. Bone matrix is the most abundant source of growth regulatory factors in the body and these are released when bone is resorbed. Presumably they could alter the behavior of tumor cells in the bone microenvironment. This notion suggests that rates of bone remodeling may be related to tumor cell growth for certain susceptible tumors. To investigate this hypothesis, we have treated nude mice which were inoculated with human breast cancer cells with the bisphosphonate risedronate, which impairs bone remodeling (Sasaki *et al.,* 1995). Under these circumstances, we found complete inhibition of the capacity of tumor cells not only to cause osteolytic bone lesions but also to grow in the bone microenvironment (Sasaki *et al.,* 1995). One of the possible mechanisms by which this occurs is through excess production of factors such as PTH-rP. We found that TGFβ, which is one of the most abundant and biologically important growth factors in the bone matrix, enhances PTH-rP production by metastatic breast cancer cells (Guise *et al.,* 1994). Similar results have previously been described by others, as well as us (Firek *et al.,* 1994; Guise *et al.,* 1994). When neutralizing antibodies of PTH-rP administered to mice inoculated with the breast cancer cells, PTH-rP production is suppressed and bone metastasis is inhibited.

To further test this hypothesis, we have enhanced bone resorption at sites where bone metastasis rarely occurs. This was done over the calvaria of mice by local injections of interleukin-1. Following interleukin-1 injections, and then inoculation into the left ventricle of the heart with human MDA-231 cells, we found marked enhancement of tumor cell metastasis to calvarial sites (Yoneda *et al.,* 1995). This also indicates that tumor cell metastasis is dependent on local rates of bone remodeling and that rapidly remodeling bone provides a very fertile soil for tumor cell growth.

Further studies have emphasized the importance of the bone microenvironment in the behavior of human breast cancer cells once they have metastasized to bone. We have found that tumor cells which are made unresponsive to TGFβ by stably transfecting them with mutant truncated receptors to TGFβ caused decreased PTH-rP production and less osteolysis when inoculated into the left cardiac ventricle (Yin *et al.,* 1999). In contrast, when these same tumor cells are stably transfected with constitutively active TGFβ receptors, this effect is reversed. Under these circumstances, the tumor cells produce excess PTH-rP and more osteolysis. This effect of these tumor cells to cause osteolysis is blocked by neutralizing antibodies to PTH-rP. These data confirm that there is an important vicious cycle in the bone microenvironment which is mediated on one hand by TGF produced in bone as a consequence of bone remodeling and on the other by PTH-rP, which is expressed by the tumor cells in the bone microenvironment and enhances bone turnover, bone remodeling, and TGFβ production. It is important to note that TGFβ may not be the only factor produced by bone in the bone microenvironment as a consequence of remodeling that affects breast cancer cells. For example, IGF-1 is also present in bone in abundant amounts and is released in active form when bone is resorbed and can enhance breast cancer cell proliferation.

The implications of these findings for the treatment of patients with cancer may be very important. For example, it is certainly possible to manipulate rates of bone remodeling *in vivo* by the use of resorption inhibitors such as the bisphosphonates. The use of these compounds may be very important not only in preventing the skeletal complications of cancer such as intractable bone pain, fractures, and hypercalcemia, but also in preventing tumor cell growth in the metastatic site. In other words, inhibitors of bone resorption may turn out to be useful adjuvant therapy in association with cytotoxic drugs for the treatment of metastatic cancer. In particular, for those tumors which have a special predilection to grow in bone such as breast cancer, it may be advisable to use relatively

nontoxic drugs early in the disease if the patient has a high risk of developing bone metastases.

Associated Syndromes

The hypercalcemia of malignancy, whether occurring in association with osteolytic bone disease or as a consequence of the production of humoral mediators of bone resorption by tumor cells, is caused by soluble factors acting as humoral agents. These mediators are also responsible for other paraneoplastic syndromes which frequently accompany hypercalcemia. These include cachexia, hypertriglyceridemia, and anemia.

One paraneoplastic syndrome that is particularly common in hypercalcemia is leukocytosis. Yoneda *et al.* (1991a,b) examined a series of patients with squamous cell carcinomas of the head and neck. They found that the hypercalcemia–leukocytosis syndrome was extremely common. We believe that this syndrome is frequently overlooked or the leukocytosis is ascribed to other factors such as infection. It is most likely that the leukocytosis is due to cytokines produced either by the tumor cells or by host immune cells which are activated by the presence of the tumor (Fig. 2). Tumor cells frequently produce colony-stimulating factors in association with PTH-rP. Colony-stimulating factors which have been shown to be produced by tumors and which could be responsible for leukocytosis include GM-CSF, G-CSF, and CSF-1. However, other cytokines are frequently overproduced in patients with cancer and could be responsible for leukocytosis. These include tumor necrosis factor, interleukin-6, and interleukin-1α. Yoneda and colleagues have shown that in several human tumors inoculated in nude mice, the hypercalcemia-leukocytosis syndrome occurs, and that the features of this syndrome can be reversed by neutralizing antibodies to cytokines such as tumor necrosis factor and interleukin-6. Not only can these paraneoplastic syndromes be reversed, but these antibodies also reverse other paraneoplastic syndromes which frequently occur such as cachexia, hypertriglyceridemia and anemia.

Some of the well-described animal models of humoral hypercalcemia of malignancy in which PTH-rP is implicated also produce excess amounts of these cytokines and are associated with the hypercalcemia–leukocytosis syndrome. Examples include the rat Leydig tumor and Walker tumor in the rat. A model which was studied extensively by Yoneda *et al.* (1991a), the MH-85 human squamous cell carcinoma, is also associated with hypercalcemia and leukocytosis in tumor-bearing nude mice. In this model, the hypercalcemia–leukocytosis can be reversed by neutralizing antibodies to interleukin-6 and tumor necrosis factor (Yoneda *et al.,* 1991a; 1993). A similar model is the murine breast cancer model studied by Lee and colleagues (Lee and Baylink, 1983). In this model, hypercalcemia and leukocytosis also occur and this model has also been associated with increased production of colony-stimulating factors.

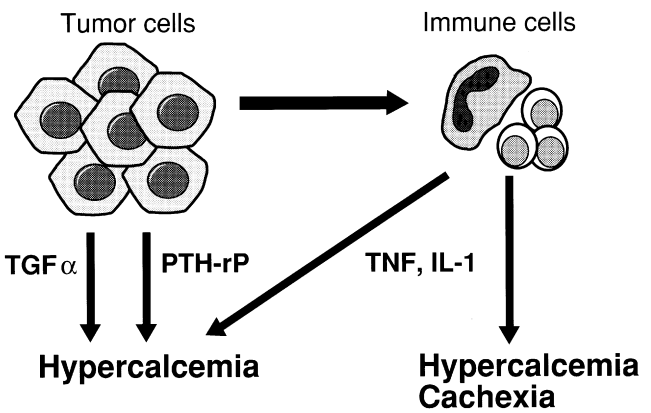

Figure 2 Hypothesis for production of bone-resorbing cytokines by normal host immune cells in hypercalcemia of malignancy, confirmed now in several cases (see text for details).

Conclusions

Tumors frequently, possibly always, produce aberrant amounts of multiple growth factors and cytokines which work in conjunction to cause paraneoplastic syndromes associated with malignancy, of which hypercalcemia is one. Moreover, the effects of these factors, which may originate not only from the tumor cells but also from normal host cells, may be synergistic rather than additive. Under these circumstances, inhibition of the effects of one factor by neutralizing antibodies, peptide antagonists, or inhibitors may abrogate the syndrome. Studies on the multiple mechanisms which tumors utilize to alter the behavior of normal cells such as bone cells has increased our understanding not only of the pathophysiology of the effects of tumors on the skeleton, but also of normal bone development and bone remodeling.

Acknowledgments

We are grateful to Nancy Garrett for her help in the preparation of this review. Some of the work described here was supported in part by Grants P01-CA-40035, RR-01346, CA-69158, CA-63628, and DK-45229 from the National Institutes of Health and a grant from the Multiple Myeloma Research Foundation.

Hypoparathyroidism is an endocrine disorder in which hypocalcemia and hyperphosphatemia are the result of a deficiency in parathyroid hormone (PTH) secretion or action (Thakker, 1993; Bilezikian and Thakker, 1998). There are a variety of causes of hypoparathyroidism (Table I) and the disorder may occur as part of a pluriglandular autoimmune disorder or as a complex congenital defect, as for example in the DiGeorge syndrome or in association with other developmental anomalies involving dysmorphic features, nephropathy, sensorineural deafness, lymphoedema, and cortical thickening of tubular bones. In addition, hypoparathyroidism may develop as a solitary endocrinopathy and this form has been called *isolated* or *idiopathic* hypoparathyroidism. Familial occurrences of *isolated* hypoparathyroidism have been reported and autosomal dominant (Barr *et al.,* 1971; Ahn *et al.,* 1986), autosomal-recessive (Bronsky *et al.,* 1968; Parkinson and Thakker, 1992), and X-linked recessive (Peden, 1960; Whyte and Weldon, 1981; Thakker *et al.,* 1990) inheritances have been established (McKusick, 1988). The molecular genetic basis for each of these forms of hypoparathyroidism has been investigated and this has helped to elucidate further the mechanisms involved in the control of extracellular calcium homeostasis (Fig. 1).

Extracellular calcium ion concentration is tightly regulated through the actions of PTH on kidney and bone. The intact peptide is secreted by the parathyroid glands at a rate that is appropriate to, and dependent upon the prevailing extracellular calcium ion concentration. Hypocalcemic disorders can be classified according to whether they arise from a deficiency of PTH, a defect in the PTH-receptor (i.e., the PTH/PTHrP receptor), or an insensitivity to PTH caused by defects downstream of the PTH/PTHrP receptor (Fig. 1). The application of the recent developments in molecular biology to the study of the hypoparathyroid disorders has enabled the characterization of some of the mechanisms involved in the regulation of parathyroid gland development, of PTH secretion, and of PTH-mediated actions in target tissues (Thakker, 1993; Bilezikian and Thakker, 1998). Thus, mutations in the calcium-sensing receptor (CaSR) gene have been reported in patients with autosomal dominant hypocalcaemia with hypercalciuria. In addition, mutations in the PTH gene, the transcriptional factor GATA3, and the mitochondrial genome have been demonstrated to be associated with some forms of hypoparathyroidism; defects in the PTH/PTHrP receptor gene have been identified in patients with Blomstrand's chondrodysplasia; and mutations in the stimuatory G protein ($G_s\alpha$) have been found in individuals with pseudohypoparathyroidism type Ia and pseudo-pseudohypoparathyroidism. Furthermore, the gene causing the polyglandular autoimmune syndrome (APECED) has been characterized and candidate genes have been identified for the DiGeorge syndrome and for pseudohypoparathyroidism type Ib. These molecular genetic studies have provided unique opportunities for elucidating the pathogenesis of the hypoparathyroid disorders and these advances together with the structure and function of the PTH gene, will be reviewed in this chapter.

Isolated Hypoparathyroidism

Isolated hypoparathyroidism may be inherited either as an autosomal-dominant, autosomal-recessive, or X-linked recessive disorder. Some autosomal forms of hypoparathyroidism have been shown to be due to abnormalities of the PTH, CaSR, and Gcm2 genes.

Table I Inherited Forms of Hypoparathyroidism and Their Chromosomal Locations

Disease	Inheritance	Gene product	Chromosomal location
Isolated hypoparathyroidism	Autosomal dominant	PTH[a]	11*p*15
	Autosomal recessive	PTH[a]	11*p*15
	X-Linked recessive	Unknown	X*q*26–*q*27
Hypocalcaemic hypercalciuria	Autosomal dominant	CaSR	3*q*13–*q*21
Hypoparathyroidism associated with complex congenital syndromes			
DiGeorge type 1 (DGS1)	Autosomal dominant	*rnex40*[b] *nex2.2–nex3*[b] UDF1L[b]	22*q*11
DiGeorge type 2 (DGS2)	Autosomal dominant		10*p*13–*p*14
HDR	Autosomal dominant	GATA3	10*p*15
Hypoparathyroidism associated with KSS, MELAS, and MTPDS	Maternal	Mitochondrial genome	
Blomstrand lethal chondrodysplasia	Autosomal recessive	PTH/PTHrPR	3*p*21.1–*p*22
Kenney–Caffey	Autosomal dominant[c]	Unknown	?
Barakat	Autosomal recessive[c]	Unknown	?
Lymphoedema	Autosomal recessive	Unknown	?
Nephropathy, nerve deafness	Autosomal dominant[c]	Unknown	?
Nerve deafness without renal dysplasia	Autosomal dominant	Unknown	?
Dysmorphology, growth failure	Autosomal recessive	Unknown	1*q*42–*q*43
Hypoparathyroidism associated with polyglandular autoimmune syndrome (APECED)	Autosomal recessive	AIRE	21*q*22.3
Pseudohypoparathyroidism (type Ia)	Autosomal dominant parentally imprinted	GNAS1	20*q*13.2–*q*13.3
Pseudohypoparathyroidism (type Ib)	Autosomal dominant parentally imprinted	GNAS1	20*q*13.3–*q*13.3

Note HDR, hypoparathyroidism, deafness and renal anomalies; MELAS, mitochondrial encephalopathy, stroke like episodes and lactic acidosis. KSS, Kearns–Sayre syndrome; MTPDS, mitochondrial trifunctional protein deficiency syndrome.?, Location not known.

[a] Mutations of PTH gene identified only in some families.

[b] Most likely candidate genes.

[c] Most likely inheritance shown.

PTH Gene Abnormalities

PTH Gene Structure and Function

The PTH gene is located on chromosome 11*p*15 and consists of three exons, which are separated by two introns (Naylor *et al.,* 1983). Exon 1 of the PTH gene is 85 bp in length and is untranslated (Fig. 2), whereas exons 2 and 3 encode the 115-amino-acid pre-proPTH peptide. Exon 2 is 90 bp in length and encodes the initiation (ATG) codon, the prehormone sequence, and part of the prohormone sequence. Exon 3 is 612 bp in size and encodes the remainder of the prohormone sequence, the mature PTH peptide, and the 3′ untranslated region (Vasicek *et al.,* 1983). The 5′ regulatory sequence of the human PTH gene contains a vitamin D response element 125 bp upstream of the transcription start site, which downregulates PTH mRNA transcription in response to vitamin D receptor binding (Okazaki *et al.,* 1988; Demay *et al.,* 1992). PTH gene transcription (as well as PTH peptide secretion) is also dependent upon the extracellular calcium and phosphate (Naveh-Many *et al.,* 1995; Slatopolsky *et al.,* 1996, Almoden *et al.,* 1996) concentrations, although the presence of specific upstream "calcium or phosphate response element(s)" have not yet been demonstrated (Russell *et al.,* 1983, Naveh-Many *et al.,* 1989). The mature PTH peptide is secreted from the parathyroid chief cell as an 84-amino-acid peptide and this is regulated through a G protein-coupled CaSR which is also expressed in renal tubules. However, when the PTH mRNA is first translated it is as a pre-proPTH peptide. The "pre" sequence consists of a 25-amino-acid signal peptide (leader sequence) which is responsible for directing the nascent peptide into the endoplasmic reticulum to be packaged for secretion from the cell (Kemper *et al.,* 1974). The "pro" sequence is 6 amino acids in length and, although its function is less well defined than that of the "pre" sequence, it is also essential for correct PTH processing and secretion (Kemper *et al.,* 1974). After the 84-amino-acid mature PTH peptide is secreted from the parathyroid cell, it is cleared from the circulation with a short half-life of about 2 min, via nonsaturable hepatic uptake and renal excretion. PTH shares a receptor with PTH-related peptide (PTHrP also known as PTHrH, PTH-related hormone) (Jüppner *et al.,* 1991), and

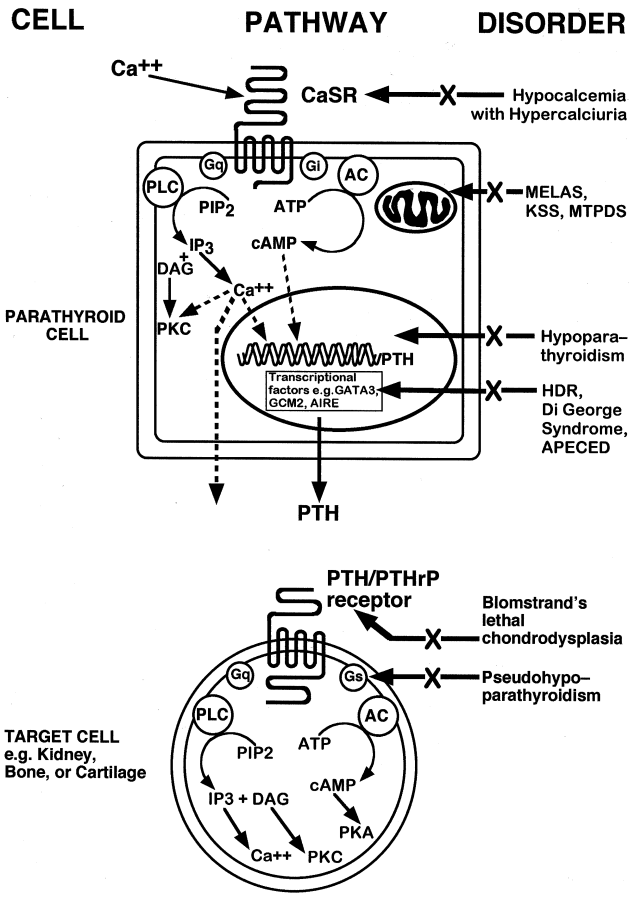

Figure 1 Schematic representation of some of the components involved in calcium homeostasis. Alterations in extracellular calcium are detected by the calcium-sensing receptor (CaSR), which is a 1078-amino-acid G-protein coupled receptor. The PTH/PTHrP-receptor is also a G-protein coupled receptor. Thus, Ca^{2+}, PTH, and PTHrP involve G protein-coupled signaling pathways, and interaction with their specific receptors can lead to activation of Gs, Gi, and Gq. Gs stimulates adenylyl cyclase (AC) which catalyzes the formation of cAMP from ATP. Gi inhibits AC activity. cAMP stimulates PKA which phosphorylates cell-specific substrates. Activation of Gq stimulates PLC, which catalyzes the hydrolysis of phosphoinositide (PIP_2) to inositol triphosphate (IP_3), which increases intracellular calcium, and diacylglycerol (DAG), which activates PKC. These proximal signals modulate downstream pathways, which result in specific physiological effects. Abnormalities in several genes and encoded proteins in these pathways, have been identified in patients with hypoparathyroid disorders (Table I). Adapted from Thakker (1999).

this receptor (Fig. 1) is a member of a subgroup of G protein-coupled receptors. The PTH/PTHrP receptor gene is located on chromosome 3*p*21–*p*24 (Gelbert *et al.,* 1994) and is highly expressed in kidney and bone, where PTH is its predominant agonist (Abou-Samra *et al.,* 1992). However, the most abundant expression of the PTH/PTHrH receptor occurs in chondrocytes of the metaphyseal growth plate where it mediates predominantly the autocrine/paracrine actions of PTHrP (Segré, 1996; Potts and Jüppner, 1997). Five polymorphisms of the PTH gene have been reported and two of these are associated with restriction fragment length polymorphisms (RFLPs) (Schmidtke *et al.,* 1984), another two are the result of single base changes that are not associated with RFLPs (Miric and Levine, 1992), and one is due to a variation in the length of a microsatellite repetitive sequence in intron 1 (Parkinson *et al.,* 1993). These polymorphisms are inherited in a Mendelian manner and are thus useful as genetic markers in family studies. Mutations involving the PTH gene affect the regulation of calcium homeostasis (Fig. 1) and are associated with hypoparathyroidism (Table I).

AUTOSOMAL DOMINANT HYPOPARATHYROIDISM

DNA sequence analysis of the PTH gene (Fig. 2) from one patient with autosomal dominant isolated hypoparathyroidism has revealed a single base substitution (T→C) in codon 18 of exon 2 (Arnold *et al.,* 1990), which resulted in the substitution of arginine (**C**GT) for the normal cysteine (**T**GT) in the signal peptide. The presence of this charged amino acid in the midst of the hydrophobic core of the signal peptide impeded the processing of the mutant preproPTH, as demonstrated by *in vitro* studies. These revealed that the mutation impaired the interaction with the nascent protein and the translocation machinery, and that cleavage of the mutant signal sequence by solubilized signal peptidase was ineffective (Arnold *et al.,* 1990; Karaplis *et al.,* 1995). Ineffective cleavage of the prepro PTH sequence results in a molecule that does not proceed successfully through the subsequent intracellular steps required for ultimate delivery of PTH to secretary granules. The parathyroid cell, therefore, cannot respond to hypocalcaemia with the secretion of native, biologically active PTH.

AUTOSOMAL RECESSIVE HYPOPARATHYROIDISM

Autosomal recessive hypoparathyroidism has usually arisen in families with consanguineous marriages (Parkinson and Thakker, 1992; Parkinson *et al.,* 1993). Abnormalities in the PTH gene have been sought (Parkinson *et al.,* 1993) and mutations identified in two unrelated families (Parkinson and Thakker, 1992; Sunthorneprarakul *et al.,* 1999). In one such family a donor splice site at the exon 2-intron 2 boundary has been identified (Parkinson and Thakker, 1992). This mutation involved a single base transition (**g→c**) at position 1 of intron 2 and an assessment of the effects of this alteration in the invariant **gt** dinucleotide of the 5′ donor splice site consensus on mRNA processing were assessed by an analysis of the non-tissue-specific transcription of the normal and mutant PTH genes. This non-tissue-specific expression of genes has been estimated to be at the rate of one molecule of correctly spliced mRNA per 1000 cells (van Heijne, 1983; Chelly *et al.,* 1989). Although the physiological relevance of this low level of non-tissue-specific, or illegitimate transcription is not known, it is of clinical importance. Easily accessible peripheral blood lymphocytes can be used to detect abnormalities in mRNA processing, thereby avoiding the requirement for tissue that may only be obtainable by biopsy. Use of these methods revealed that the donor splice site mutation resulted in exon skipping, in which exon 2 of the PTH gene was lost and exon 1 was spliced to exon 3.

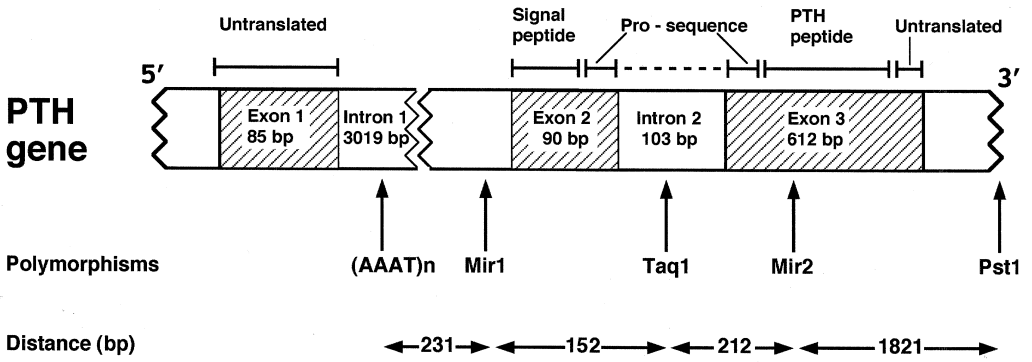

Figure 2 Schematic representation of the PTH gene. The PTH gene consists of three exons and two introns; the peptide is encoded by exons 2 and 3. The PTH peptide is synthesized as a precursor which contains a pre- and a pro-sequence. The mature PTH peptide, which contains 84 amino acids, and larger carboxy-terminal PTH fragments are secreted from the parathyroid cell. The polymorphic sites associated with the PTH gene are indicated. Two restriction fragment length polymorphisms (RFLPs) are associated with the PTH gene, and the *Taq*I polymorphic site is within intron 2 and the *Pst*I polymorphic site is 1.7 kbp downstream in the 3' direction of the gene (Schmidtke *et al.,* 1984). Two other polymorphisms (Miric and Levine, 1992) of the PTH gene designated Mir1 and Mir2 are located in intron 1 and exon 3, respectively, and the tetranucleotide $(AAAT)_n$ polymorphism is in intron 1 (Parkinson *et al.,* 1993). The distance between the tetranucleotide $(AAAT)_n$ polymorphism and the Mir1 polymorphism is 231 base pairs (bp), that between the Mir1 polymorphism and the *Taq*1 RFLP is 152 bp, that between the *Taq*I RFLP site and the Mir2 polymorphism is 212 bp, and that between the Mir2 polymorphism and the *Pst*I RFLP is 1821 bp. Linkage disquilibrium between the $(AAAT)_n$, *Taq*I, and *Pst*I polymorphic sites has been established (Parkinson *et al.,* 1993). Adapted from Parkinson and Thakker (1992).

The lack of exon 2 would lead to a loss of the initiation codon (ATG) and the signal peptide sequence (Fig. 2) which are required respectively for the commencement of PTH mRNA translation and for the translocation of the PTH peptide. Thus, the patients' parathyroid cells would not contain any translated PTH products. In the other family a single base substitution (**T→C**) involving codon 23 of exon 2 was detected. This resulted in the substitution of proline (**C**CG) for the normal serine (**T**CG) in the signal peptide (Sunthornepvarakul *et al.,* 1999). This mutation alters the −3 position of the pre-pro-PTH protein cleavage site (van Heijne, 1983). Indeed, amino acid residues at the −3 and −1 positions of the signal peptidase recognition site have to conform to certain criteria for correct processing through the rough endoplasmic reticulum (RER), and one of these is an absence of proline in the region −3 and +1 of the site (van Heijne, 1983). Thus, the presence of a proline, which is a strong helix-breaking residue, at the −3 position is likely to disrupt cleavage of the mutant pre-pro-PTH that would be subsequently degraded in the RER, and PTH would not be available (Sunthornepvarakul *et al.,* 1999).

Calcium-Sensing Receptor Gene Abnormalities

Mutations of the PTH gene have been detected in only a minority of autosomal forms of isolated hypoparathyroidism and this indicates that other genes are likely to be involved (Table I). One of these is the CaSR gene, and another is the Gcm2 (Glial Cells Missing 2) gene (see below).

The CaSR, which is located in the plasma membrane of the cell (Fig. 1), is at a critical site to enable the cell to recognize changes in extracellular calcium concentration. Thus, an increase in extracellular calcium leads to CaSR activation of the G-protein signaling pathway, which in turn increases the free intracellular calcium concentration and leads to a reduction in transcription of the PTH gene. CaSR mutations that result in a loss of function are associated with familial benign (hypocalciuric) hypercalcemia (FHH) (Pollak *et al.,* 1993; Chou *et al.,* 1995; Pearce *et al.,* 1995; Lanicic *et al.,* 1995; Aida *et al.,* 1995; Heath *et al.,* 1996). However, CaSR missense mutations that result in a gain of function (or added sensitivity to extracellular calcium) lead to hypocalcemia with hypercalciuria (Pollak *et al.,* 1994; Finegold *et al.,* 1994; Perry *et al.,* 1994; Pearce *et al.,* 1996; Baron *et al.,* 1996). These hypocalcemic individuals are generally assymptomatic and have serum PTH concentrations that are in the low-normal range, and because of the insensitivities of previous PTH assays in this range, such patients have often been diagnosed to be hypoparathyroid. In addition, such patients may have hypomagnesemia. Treatment with vitamin D or its active metabolites to correct the hypocalcemia in these patients results in marked hypercalciuria, nephrocalcinosis, nephrolithiasis, and renal impairment. Thus, these patients need to be distinguished from those with other forms of hypoparathyroidism, and in order to further emphasize this, it is probably best to refer to this disorder due to CaSR mutations as autosomal dominant hypocalcemic hypercalciuria (ADHH).

Gcm2 Gene Abnormalities

Gcm2, which is the mouse homolog of the Drosphilia gene Gcm, is expressed exclusively in the parathyroid glands, suggesting that it may be a specific regulator of parathyroid gland development (Günther *et al.,* 2000; Kim *et al.,* 1998). In order to investigate this, mice deleted for Gcm2

were generated by the method of homologous recombination using embryonic stem cells. Mice that were heterozygous (+/−) for the deletion were normal, whereas mice that were homozygous (−/−) for the deletion lacked parathyroid glands and developed the hypocalcemia and hyperphosphatemia observed in hypoparathyroidism (Günther *et al.,* 2000). However, despite their lack of parathyroid glands, Gcm2-deficient (−/−) mice did not have undetectable serum PTH levels, but instead had PTH levels identical to those of normal (+/+, wild-type) mice. This endogenous level of PTH in the Gcm2-deficient (−/−) mice was too low to correct the hypocalcaemia, but exogenous continuous PTH infusion could correct the hypocalcemia (Günther *et al.,* 2000). Interestingly, there were no compensatory increases in PTHrP or $1,25(OH)_2$ vitamin D_3. These findings indicate that Gcm2 mice have a normal response (and not resistance) to PTH and that the PTH in the serum of Gcm2-deficient mice was active. The auxillary source of PTH was determined by combined expression and ablation studies (Günther *et al.,* 2000). These revealed a cluster of PTH-expressing cells under the thymic capsule in both the Gcm2-deficient (−/−) and wild-type (+/+) mice. These thymic PTH-producing cells also expressed the CaSR, and long-term treatment of the Gcm2-deficient mice with $1,25(OH)_2$ vitamin D_3 restored the serum calcium concentrations to normal and reduced the serum PTH levels, thereby indicating that the thymic production of PTH can be downregulated (Günther *et al.,* 2000). However, it appears that this thymic production of PTH cannot be upregulated as serum PTH levels are not high despite the hypocalcaemia in the Gcm2-deficient mice. This absence of upregulation would be consistent with the very small size of the thymic PTH-producing cell cluster, when compared to the size of normal parathyroid glands. The development of the thymic PTH-producing cells likely involves Gcm1, which is the other mouse homolog of Drosophilia Gcm (Kim *et al.,* 1998). Gcm1 expression, which could not be detected in parathyroid glands, colocalized with PTH expression in the thymus (Günther *et al.,* 2000). Thus, Gcm2 specifically controls the differentiation of the cells of third pharyngeal pouch into parathyroid glands, and Gcm1 regulates an auxillary developmental pathway that involves differentiation of PTH-producing cells in the thymus. Gcm genes are likely to have similar roles in human parathyroid development, as a recent report indicates that an intragenic deletion of Gcm2 in a patient is associated with hypoparathyroidism. These findings may also help to explain the high incidence of PTH-producing tumors in the thymus.

X-Linked Recessive Hypoparathyroidism

Hypoparathyroidism with an X-linked recessive transmission pattern has been reported in two multigenerational kindreds (Peden, 1960; Whyte and Weldon, 1981). Only males were affected, and they suffered from infantile epilepsy and hypocalcemia. The hypoparathyroidism is due to a defect in parathyroid gland development. Linkage studies utilizing X-linked RFLPs in these two families assigned the mutant gene to chromosome X*q*26–*q*27 (Thakker *et al.,* 1990). A novel approach utilizing mitochondrial DNA analysis established a common ancestry in these two X-linked hypoparathyroid kindreds (Mumm *et al.,* 1997). A common ancestry for these two kindreds from Eastern Missouri had been suspected, but it could not be established despite five generations of extensive genealogical records (Whyte and Weldon, 1981). The mitochondrial genes are transmitted through the maternal line exclusively. If relatedness among the two kindreds involved the maternal lines, analysis of mitochondrial genetic markers would reveal common features. The DNA sequence of the mitochondrial (mt) D-loop was compared among individuals in both kindreds. The mt DNA sequence was identical among affected males and their maternal lineage for individuals in both kindreds, but differed at 3 to 6 positions when compared with the mitochondrial DNA of the fathers. These results demonstrated that the two kindreds with X-linked recessive hypoparathyroidism are indeed related and that an identical gene defect is likely to be responsible for the disease. Additional studies have refined the location of this gene to be between factor IX (FIX) and DXS1205 (Trump *et al.,* 1998). Analysis of a yeast artificial chromosome (YAC) contig of this region (Zucchi *et al.,* 1996) indicates that the region is 1.5 million bp in size and contains at least three candidate genes. The specific gene defect responsible for this form of X-linked hypoparathyroidism has yet to be identified. The results of this study also demonstrate that the mitochondrial genetic approach may be of importance in detecting common ancestry in other X-linked diseases.

Complex Syndromes Associated with Hypoparathyroidism

Hypoparathyroidism may occur as part of a complex syndrome which may either be associated with a congenital development anomaly or with an autoimmune syndrome. The congenital developmental anomalies associated with hypoparathyroidism include the DiGeorge, the HDR (Hypoparathyroidism, Deafness, and Renal anomalies), the Kenney–Caffey, and the Barakat syndromes and also syndromes associated with either lymphoedema or dysmorphic features and growth failure (Table I).

DiGeorge Syndrome

Patients with the DiGeorge syndrome (DGS) typically suffer from hypoparathyroidism, immunodeficiency, congenital heart defects, and deformities of the ear, nose, and mouth (Bilezikian and Thakker, 1998). The disorder arises from a congenital failure in the development of the derivatives of the third and fourth pharyngeal pouches with resulting absence or hypoplasia of the parathyroids and thymus. Most cases of DGS are sporadic but an autosomal dominant inheritance of DGS has been observed and an association between the syndrome and an unbalanced translocation and

deletions involving 22*q*11.2 have also been reported (Scambler *et al.,* 1991), and this is referred to as DGS type 1 (DGS1). In some patients, deletions of another locus on chromosome 10*p* have been observed in association with DGS (Monaco *et al.,* 1991), and this is referred to as DGS type 2 (DGS2). Mapping studies of the DGS1 deleted region on chromosome 22*q*11.2 have defined a 250 kb minimal critical region (Gong *et al.,* 1996), and cloning of the translocation breakpoint on 22*q*11.21 from a DGS1 patient (Augusseau *et al.,* 1986) has revealed that there are probably 2 genes (rnex40 and nex2.2–nex3), transcribed in opposite directions, which are disrupted by this breakpoint (Budarf *et al.,* 1995). The coding region of one of these genes, designated *rnex40,* has homology to the mouse and rat androgen receptors and contains a leucine zipper motif, suggesting that the DGS1 candidate gene may be a DNA-binding protein. Eleven nucleotides of the rnex40 gene are deleted at the translocation junction, making it likely that loss of function of this gene is responsible for at least part of the DiGeorge phenotype (Budarf *et al.,* 1995). Another partial transcript, referred to as nex2.2–nex3, was also identified from this breakpoint. Both rnex40 and nex2.2–nex3 are deleted in all DGS1 patients with 22*q*11 deletions and studies aimed at assessing the presence of hemizygosity and mutations in these 2 genes in DGS1 patients who do not have detectable 22*q*11 deletions are required to demonstrate the role of these genes in the etiology of the DGS1. Such studies have been performed for a human homolog of a yeast gene that encodes a protein involved in the degradation of ubiquinated proteins, referred to as UDF1L (Yamagishi *et al.,* 1999). UDF1L is located on 22*q*11 and has been found to be deleted in all of 182 patients with the 22*q*11 deletion syndrome (Yamagishi *et al.,* 1999), which includes patients with the DGS1, the velo-cardio-facial (VCFS), and conotruncal anomaly face (CAFS) syndromes (Scambler *et al.,* 1991; Gong *et al.,* 1996). However, a smaller deletion of approximately 20 kb that removed exons 1 to 3 of UDF1L was detected in one patient (Yamagishi *et al.,* 1999). This patient, who had a *de novo* deletion resulting in haplo-insufficiency of UDF1L, suffered from neonatal onset cleft palate, small mouth, low-set ears, broad nasal bridge, an interrupted aortic arch, a persistent truncus arteriosus, hypocalcemia, T lymphocyte deficiency, and syndactyly of her toes (Yamagishi *et al.,* 1999). These results indicate that abnormalities of the UDF1L gene may contribute to the etiology of early-onset DGS1 in man. However, heterozygous mice that are deleted for one udf1l allele (Udf1l+/−) do not have cardiac defects (Lindsag *et al.,* 1999). This is in contrast to the situation in heterozygous mice (Df1/+) that are deleted (Magnaghi *et al.,* 1998) for the region that is homologous to the human 22*q*11 segment. The Df1/+ mice develop cardiovascular abnormalities, which are due to defective development of the fourth pharyngeal arch arteries, and are of the same type as DGS1 patients (Lindsay *et al.,* 1999). However, the Df1/+ mice have normal serum calcium, phosphate and PTH concentrations and also have normally functioning B and T cells (Lindsay *et al.,* 1999). These findings indicate that the genes responsible for hypoparathyroidism and immune deficiency may either lie outside the Df1 region, or that heterozygous mutations may be insufficient to produce these defects in mice, or that the genetic background may alter the expression of the mutation. Interestingly, another candidate gene for DGS1 does lie outside the Df1 region, and this is Hira, which is a transcription factor that interacts with Pax3, that in turn is expressed in cardiac and neural crest cells (Magnaghi *et al.,* 1998). Thus, there may be more than one gene involved in the development of the complex manifestations of early onset DGS1. However, it is important to note that patients with late-onset DGS1 (Scire *et al.,* 1994; Sykes *et al.,* 1997) develop symptomatic hypocalcemia in childhood or during adolescence with only subtle phenotypic abnormalities. These late-onset DGS1 patients have similar microdeletions in the 22*q*11 region, and the molecular definition of these variants of the DiGeorge syndrome may well provide additional insights into the regulation of PTH secretion and/or parathyroid gland development.

Hypoparathyroidism, Deafness, and Renal Anomalies Syndrome

The combined inheritance of hypoparathyroidism, deafness and renal dysplasia as an autosomal dominant trait was reported in one family in 1992 (Bilous *et al.,* 1992). Patients had asymptomatic hypocalcaemia with undetectable or inappropriately normal serum concentrations of PTH, and normal brisk increases in plasma cAMP in response to the infusion of PTH. The patients also had bilateral, symmetrical, sensorineural deafness involving all frequencies. The renal abnormalities consisted mainly of bilateral cysts that compressed the glomeruli and tubules and lead to renal impairment in some patients. Cytogenetic abnormalities were not detected and abnormalities of the PTH gene were excluded (Bilous *et al.,* 1992). However, cytogenetic abnormalities involving chromosome 10*p*14–10*p*ter were identified in two unrelated patients with features that were consistent with HDR. These two patients suffered from hypoparathyroidism, deafness and growth and mental retardation; one patient also had a solitary dysplastic kidney with vesico-ureteric reflux and a uterus bicornis unicollis (Fryns *et al.,* 1981) and the other patient, who had a complex reciprocal, insertional translocation of chromosomes 10*p* and 8*q,* had cartilaginous exostoses (Van Esch *et al.,* 1999). Neither of these patients had immunodeficiency or heart defects, which are key features of DGS2 (see above), and further studies defined two non-overlapping regions; thus, the DGS2 region was located on 10*p*13–*p*14 and HDR on 10*p*14–10*p*ter. Deletion mapping studies in two other HDR patients further defined a critical 200-kb region that contained GATA3 (Van Esch *et al.,* 2000), which belongs to a family of zinc-finger transcription factors that are involved in vertebrate embryonic development. DNA sequence analysis in other HDR patients identified mutations that resulted in a haploinsufficiency and loss of GATA3 function (Van Esch *et al.,* 2000). The HDR phenotype is consistent

with the expression pattern of GATA3 during human and mouse embryogenesis in the developing kidney, otic vesicle, and parathyroids. However, GATA3 is also expressed in the developing central nervous systen (CNS) and the hematopoietic organs in man and mice, and this suggests that GATA3 may have a more complex role. Indeed, homozygous GATA3 knockout mice have defects of the CNS and a lack of T-cell development, although the heterozygous GATA3 knockout mice appear to have no abnormalities (Pandolfi *et al.,* 1995). It is important to note that HDR patients with GATA3 haploinsufficiency do not have immune deficiency, and this suggests that the immune abnormalities observed in some patients with 10*p* deletions are most likely to be caused by other genes on 10*p*. Similarly, the facial dysmorphism, growth and development delay, commonly seen in patients with larger 10*p* deletions were absent in the HDR patients with GATA3 mutations, further indicating that these features were likely due to other genes on 10*p* (Van Esch *et al.,* 2000). These studies of HDR patients clearly indicate an important role for GATA3 in parathyroid development and in the etiology of hypoparathyroidism.

Mitochondrial Disorders Associated with Hypoparathyroidism

Hypoparathyroidism has been reported to occur in three disorders associated with mitochondrial dysfunction: the Kearns-Sayre syndrome (KSS), the MELAS syndrome and a mitochondrial trifunctional protein deficiency syndrome (MTPDS). KSS is characterized by progressive external ophthalmoplegia and pigmentary retinopathy before the age of 20 years and is often associated with heart block or cardiomyopathy. The MELAS syndrome consists of a childhood onset of mitochondrial encephalopathy, lactic acidosis, and stroke-like episodes. In addition, varying degrees of proximal myopathy can be seen in both conditions. Both the KSS and MELAS syndromes have been reported to occur with insulin-dependent diabetes mellitus and hypoparathyroidism (Moraes *et al.,* 1989; Zupanc *et al.,* 1991). A point mutation in the mitochondrial gene tRNA leucine (UUR) has been reported in one patient with the MELAS syndrome who also suffered from hypoparathyroidism and diabetes mellitus (Morten *et al.,* 1993). Large deletions, consisting of 6741 and 6903 bp and involving >38% of the mitochondrial genome, have been reported in other patients who suffered from KSS, hypoparathyroidism, and sensorineural deafness (Zupanc *et al.,* 1991; Isotani *et al.,* 1996). Rearrangements (Wilichowski *et al.,* 1997) and duplication (Abramowicz *et al.,* 1996) of mitochondrial DNA have also been reported in KSS. Mitochondrial trifunctional protein deficiency is a disorder of fatty-acid oxidation that is associated with peripherial neuropathy, pigmentary retinopathy, and acute fatty liver degeneration in pregnant women who carry an affected fetus. Hypoparathyroidism has been observed in one patient with trifunctional protein deficiency (Dionisi-Via *et al.,* 1996). The role of these mitochondrial mutations in the etiology of hypoparathyroidism remains to be further elucidated.

Kenney–Caffey Syndrome

Hypoparathyroidism has been reported to occur in over 50% of patients with the Kenney–Caffey syndrome, which is associated with short stature, osteosclerosis and cortical thickening of the long bones, delayed closure of the anterior fontanel, basal ganglia calcification, nanophthalmos, and hyperopia (Fanconi *et al.,* 1986; Franceschini *et al.,* 1992). Parathyroid tissue could not be found in a detailed postmortem examination of one patient (Boynton *et al.,* 1979) and this suggests that hypoparathyroidism may be due to an embryological defect of parathyroid development. A molecular genetic analysis using PTH gene RFLP analysis revealed no abnormalities (Bergada *et al.,* 1988) and mutations at other loci, for example in developmental genes, need to be investigated.

Additional Familial Syndromes

Single familial syndromes in which hypoparathyroidism is a component have been reported (Table 1). The inheritance of the disorder in some instances has been established and molecular genetic analysis of the PTH gene has revealed no abnormalities. Thus, an association of hypoparathyroidism, renal insufficiency and developmental delay has been reported in one Asian family in whom autosomal recessive inheritance of the disorder was established (Shaw *et al.,* 1991). An analysis of the PTH gene in this family revealed no abnormalities (Parkinson *et al.,* 1993). The occurrence of hypoparathyroidism, nerve deafness and a steroid-resistant nephrosis leading to renal failure, which has been referred to as the *Barakat syndrome* (Barakat *et al.,* 1977), has been reported in four brothers from one family, and an association of hypoparathyroidism with congenital lymphoedema, nephropathy, mitral valve prolapse and brachytelephalangy has been observed in two brothers from another family (Dahlberg *et al.,* 1983). Molecular genetic studies have not been reported from these two families. A syndrome in which hypoparathyroidism was associated with severe growth failure and dysmorphic features has been reported in 12 patients from Saudi Arabia (Sanjad *et al.,* 1991). Consanguinity was noted in 11 of the 12 patients' families, the majority of which originated from the Western province of Saudi Arabia. This syndrome, which is inherited as an autosomal recessive disorder has also been identified in families of Bedonin origin and homozygosity and linkage disequilibrium studies have located this gene to chromosome 1*q*42–*q*43 (Parvari *et al.,* 1998). Molecular genetic investigations of these disorders will help to identify additional genes that regulate the development of the parathyroid glands.

Blomstrand's Disease

Blomstrand's chondrodysplasia is an autosomal recessive human disorder characterized by early lethality, dramatically advanced bone maturation and accelerated chondrocyte differentiation (Blomstrand *et al.,* 1985). Affected infants, who

usually have consanguineous unaffected parents (Young *et al.,* 1993; Leroy *et al.,* 1996; Loshkajian *et al.,* 1997; den Hollander *et al.,* 1997; Oostra *et al.,* 1998), develop pronounced hyperdensity of the entire skeleton with markedly advanced ossification that results in extremely short and poorly modeled long bones. Mutations of the PTH/PTHrP receptor that impair its function are associated with Blomstrand's disease (Jobert *et al.,* 1998; Zhang *et al.,* 1998; Karaplis *et al.,* 1998). Thus it seems likely that affected infants will in addition to the skeletal defects, also have abnormalities in other organs, which will include secondary hyperplasia of the parathyroid glands, presumably due to hypocalcemia.

Pluriglandular Autoimmune Hypoparathyroidism

Hypoparathyroidism may occur in association with candidiasis, pernicious anemia, allopecia, vitiligo, and autoimmune Addison's disease, and the disorder has been referred to as either the autoimmune polyendocrinopathy–candidiasis–ectodermal dystrophy (APECED) syndrome or the polyglandular autoimmune type 1 syndrome (Ahonen *et al.,* 1990). This disorder has a high incidence in Finland, and a genetic analysis of 58 patients from 42 Finnish families indicated autosomal recessive inheritance of the disorder (Ahonen, 1985). In addition, the disorder has been reported to have a high incidence among Iranian Jews, although the occurrence of candidiasis was less common in this population (Zlotogora and Shapiro, 1992). Linkage studies of 14 Finnish families mapped the APECED gene to chromosome 21*q*22.3 (Aaltonen *et al.,* 1994). Further positional cloning studies led to the isolation of a novel gene from chromosome 21*q*22.3. This gene, referred to as AIRE (autoimmune regulator), encodes a 545-amino-acid protein that contains motifs suggestive of a transcriptional factor and includes a nuclear localization signal, two zinc-finger motifs, a proline-rich region and three LXXLL motifs (Nagamine *et al.,* 1997; Finnish-German APECED Consortium, 1997). Six AIRE mutations have been reported in the APECED families and a codon 257 (Arg→Stop) mutation was the predominant abnormality in 82% of the Finnish families (Nagamine *et al.,* 1997; Finnish-German APECED Consortium, 1997). The identification of the genetic defect causing APECED will not only facilitate genetic diagnosis but will also enhance the elucidation of the mechanisms causing autoimmune disease.

Pseudohypoparathyroidism (PHP)

Patients with pseudohypoparathyroidism are characterised by hypocalcemia and hyperphosphatemia due to PTH resistance (Bilezikian and Thakker, 1998; Yu *et al.,* 1995; van Dop, 1989; Weinstein, 1998). Instead of PTH deficiency these patients have elevated levels of serum PTH which is biochemically and biologically normal. Complete resistance to PTH, demonstrated by no increase in urinary cyclic AMP and urinary phosphate excretion after PTH infusion, is referred to as PHP type I. The occurrence of PHP type I with the somatic features of Albright's hereditary osteodystrophy (AHO) is referred to as PHP type Ia, whereas the presence of biochemical features without somatic features is referred to as PHP type Ib. The occurrence of somatic features (AHO) without the biochemical abnormalities is referred to as pseudo-pseudohypoparathyroidism (PPHP). The absence of a normal rise in urinary excretion of cyclic AMP excretion after an infusion of PTH in PHP type Ia and PPHP indicated a defect at some site of the PTH receptor-adenylyl cyclase system. This receptor system is regulated by at least two G proteins, one of which stimulates (Gsα) and another of which inhibits (Giα) the activity of the membrane-bound enzyme that catalyzes the formation of the intracellular second messenger cyclic AMP.

Inactivating mutations of the Gsα gene (referred to as GNAS1), which is located on chromosome 20*q*13.2, have been identified in PHP type Ia and PPHP patients (Yu *et al.,* 1995; van Dop, 1989; Weinstein, 1998). A mutational 'hotspot' involving a 4-bp deletion (Δ GACT) of codon 189 and the first nucleotide of codon 190 has been identified (Yu *et al.,* 1995). These mutations, which are heterozygous, lead to an ≈50% reduction in $G_s\alpha$ activity/protein, and are thought to explain, at least partially, the resistance toward PTH and other hormones (e.g., thyroid stimulating hormone (TSH), gonadotrophins and glucagon) that mediate their actions through G protein-coupled receptors (Yu *et al.,* 1995; van Dop, 1989; Weinstein, 1998). However, a similar reduction in $G_s\alpha$ activity/protein is also found in patients with PPHP, who show the same physical features as individuals with PHP-Ia, but lack the endocrine abnormalities. Thus, *GNAS1* mutations do not fully explain the PHP-Ia or PPHP phenotypes (Yu *et al.,* 1995; van Dop, 1989; Weinstein, 1998; Schuster *et al.,* 1993; Miric *et al.,* 1993; Weinstein *et al.,* 1990), and studies of PHP-Ia and PPHP that occurred within the same kindred revealed that the hormonal resistance is parentally imprinted. Thus, PHP-Ia occurred in a child only when the mutation was inherited from a mother affected with either PHP-Ia or PPHP (Davies and Hughes, 1993; Wilson *et al.,* 1994). These findings in man gained support by observations in heterozygous *Gnas* knockout mice that lacked exon 2. Mice that had inherited the mutant allele from a female showed undetectable $G_s\alpha$ protein in the renal cortex and decreased blood calcium concentration due to PTH resistance. In contrast, offspring that had inherited the mutant allele lacking exon 2 from a male, showed no evidence of endocrine abnormalities (Yu *et al.,* 1998). Tissue- or cell-specific $G_s\alpha$ expression is thus likely to be involved in the pathogenesis of PHP-Ia and PPHP, and this may also help to explain the dominant phenotype that arises from heterozygous *GNAS1* mutations. Expression of the *GNASI* gene has been shown to be further complicated by alternative splicing which results in several different mRNAs, some of which are derived only from either the paternal or the maternal allele. This complexity of the *GNASI* gene may contribute to the unique phenotypic

abnormalities observed in patients with PHP as the alternative splicing gives rise to at least three different gene products which are transcribed either from the maternal or the paternal allele, or from both alleles (Hayward *et al.,* 1998a, b; Peters *et al.,* 1999). The first of these products is $G_s\alpha$ which is encoded by exons 1 through 13 of the *GNASI* gene and mediates the biological functions of a large variety of G protein-coupled receptors, including the PTH/PTHrP receptor. The second product is $XL_{\alpha s}$ which comprises of a novel first exon (XL) spliced onto exons 2 through 13. The encoded XLαs, which is an ≈92-kDa protein, that shares considerable amino acid sequence identity with the carboxyl-terminal portion of $G_s\alpha$ (Kehlenbach *et al.,* 1994), may not function as a stimulatory G protein. $XL_{\alpha s}$ expression occurs at numerous sites and is particularly high in endocrine and neuroendocrine cells (Kehlenbach *et al.,* 1994). Furthermore XLαs appears to be transcribed only from the paternal allele (Hayward *et al.,* 1998a,b; Peters *et al.,* 1999). The third product is NESP55 (Hayward *et al.,* 1998a), which is transcribed only from the maternal allele (Hayward *et al.,* 1998b; Peters *et al.,* 1999), is encoded by yet another exon of the *GNASI* gene that is located upstream of exon XL and the $G_s\alpha$-specific exons 1 through 13. NESP55, which is thought to act as a neuroendocrine secretory protein (Ischia *et al.,* 1997), shares no amino acid sequence homology with either $XL_{\alpha s}$ or $G_s\alpha$, but its mRNA does contain $G_s\alpha$-specific exons within its 3′ noncoding region. The complexity of the *GNASI* gene and its use of different, allele-specific promoters, makes it plausible to postulate that mutations in the $G_s\alpha$-specific exons 1 to 13 (Yu *et al.,* 1995; van Dop, 1989; Weinstein, 1998; Schuster *et al.,* 1993; Miric *et al.,* 1993; Weinstein *et al.,* 1990), will affect not only the functional properties of $G_s\alpha$, but also those of $XL_{\alpha s}$ and of NESP55.

GNAS1 mutations have not been detected in PHP type Ib (PHP-Ib), which has been considered to be due to a defect of the PTH/PTHrP receptor. However, it is important to note that PHP-Ib patients generally have a normal or increased osseous response to PTH, as assessed by bone turnover and osteoclastic resorption (Yu *et al.,* 1995; ven Dop, 1989; Murray *et al.,* 1993; Farfel, 1999), and the normal growth plate development in these patients is consistent with a normal chondrocyte response to PTHrP. These observations made it unlikely that defects in the PTH/PTHrP receptor were the cause of PHP-Ib, and indeed studies of the PTH/PTHrP receptor gene and mRNA in PHP-Ib patients have failed to identify mutations (Schipani *et al.,* 1995; Bettoun *et al.,* 1997; Suarez *et al.,* 1995; Fukumoto *et al.,* 1996). In order to identify the location of the PHP-Ib gene a genome-wide search was therefore undertaken in four unrelated kindreds and this mapped the PHP-Ib locus to chromosome 20*q*13.3, a location that also contains the GNAS1 gene (Jüppner *et al.,* 1998). In addition, parental imprinting of the genetic defect was observed and this is similar to the findings in kindreds with PHP-type Ia and/or PPHP. Two possible explanations for these observations have been proposed. First, PHP-Ib maybe due to a defect in a tissue- or cell-specific enhancer, or promoter of the *GNAS1* gene and this may affect, directly or indirectly, the expression levels of the $G_s\alpha$-specific transcripts and/or the transcripts encoding $XL_{\alpha s}$ and NESP55; or second, PHP-Ib may be caused by a defect in a gene close to the GNAS1 gene which is transcribed only from the maternal allele and affects PTH/PTHrP receptor or Gsα expression and/or function in some renal cells.

Conclusions

Application of the methods of molecular genetics to the study of the hypoparathyroid disorders has resulted in considerable advances that have identified some genes and their encoded proteins that are involved in the regulation of PTH synthesis and secretion, and in mediating its actions in different target issues. In addition, the identification of mutations has helped to provide molecular explanations and insights into a variety of familial and sporadic disorders of calcium homeostasis and bone development. Genetic mapping studies have also helped to identify the chromosomal locations of some hypoparathyroid disorders, and future positional cloning approaches, which will progress with greater rapidity owing to the Human Genome Sequencing project, will provide additional insights into the mechanisms that regulate PTH action and calcium homeostasis.

Acknowledgments

I am grateful to the Medical Research Council (UK) for support, to B. Harding for preparing the figures, and to Miss Julie Allen for typing the manuscript and expert secretarial assistance.

CHAPTER 63

Jansen's Metaphyseal Chondrodysplasia and Blomstrand's Lethal Chondrodysplasia

Two Genetic Disorders Caused by PTH/PTHrP Receptor Mutations

Harald Jüppner,[*,†] Ernestina Schipani,[*] and Caroline Silve[‡]

[*]Department of Medicine, Endocrine Unit, and [†]MassGeneral Hospital for Children, Massachusetts General Hospital, and Harvard Medical School, Boston, Massachusetts 02114; and [‡]INSERM Unit 426, Faculté de Médecine Xavier Bichat, 75018 Paris, France

Introduction

The PTH/PTHrP receptor (also referred to as type I PTH/PTHrP receptor or PTH1R) mediates the actions of two ligands, parathyroid hormone (PTH) and parathyroid hormone-related peptide (PTHrP), and stimulates at least two distinct second messenger pathways, cAMP/PKA and IP_3/Ca^{2+}/PKC (Jüppner *et al.,* 1991; Abou-Samra *et al.,* 1992; Schipani *et al.,* 1993). This receptor is most abundantly expressed in kidney, bone, and growth plates and at lower levels in a large variety of other tissues (Tian *et al.,* 1993; Urena *et al.,* 1993). The PTH-dependent endocrine actions that are mediated through the PTH/PTHrP receptor, i.e., the regulation of mineral ion homeostasis, had been explored through studies in intact and parathyroidectomized animals. The role of the PTH/PTHrP receptor in mediating the PTHrP-dependent autocrine/paracrine regulation of chondrocyte growth and differentiation became apparent only through the analysis of genetically manipulated mice. For example, animals that are "null" for PTHrP or the PTH/PTHrP receptor die *in utero* or shortly thereafter and show a profound acceleration of growth plate mineralization. In contrast, mice overexpressing PTHrP under the control of a growth plate-specific promoter are viable, but showed a severe delay in chondrocyte maturation, which leads to impaired bone growth and elongation (Karaplis *et al.,* 1994; Amizuka *et al.,* 1994; Weir *et al.,* 1996; Lanske *et al.,* 1996; Vortkamp *et al.,* 1996). These studies in mice thus provided important clues regarding the phenotypic abnormalities that were to be expected in humans with PTH/PTHrP receptor mutations and consequently led to the identification of different activating and inactivating PTH/PTHrP receptor mutations in two genetic disorders, Jansen's metaphyseal chondrodysplasia (JMC) and Blomstrand's lethal chondrodysplasia (BLC). Since the biological consequences of these PTH/PTHrP receptor

mutations require a detailed understanding of the PTH- and PTHrP-dependent actions that are mediated through this G protein-coupled receptor, we will first review the physiological roles of these two peptide hormones.

Parathyroid Hormone

Besides 1,25$(OH)_2$ vitamin D_3 (1,25$(OH)_2D_3$), PTH is the most important endocrine regulator of extracellular calcium homeostasis in mammals (Kronenberg *et al.,* 1993; Jüppner *et al.,* 1999). PTH is predominantly expressed in the parathyroid glands. However, lower protein and mRNA levels were recently identified in the hypothalamus and the thymus of *glial cells missing 2* (*gcm2*)-ablated mice (Günther *et al.,* 2000). These findings confirmed earlier studies in rats (Nutley *et al.,* 1995), but it remains unlikely that PTH derived from tissues other than the parathyroid glands is normally involved in the regulation of mineral ion homeostasis. Its synthesis and secretion by the parathyroid glands is dependent predominantly on the extracellular concentration of calcium (Brown, 1983; Silver and Kronenberg, 1996), which is monitored by a calcium-sensing receptor (Brown *et al.,* 1993, 1999) and to a lesser extent by 1,25$(OH)_2D_3$ and phosphate (Silver and Kronenberg, 1996; Almaden *et al.,* 1996; Slatopolsky *et al.,* 1996; Moallem *et al.,* 1998).

PTH acts primarily on kidney and bone, where it binds to cells expressing the PTH/PTHrP receptor and thereby initiates a series of processes that serve to maintain blood calcium and phosphate concentrations within narrow limits (Fig. 1). In kidney, the mRNA encoding the PTH/PTHrP receptor is expressed primarily in the convoluted and straight proximal tubules, the cortical portion of thick ascending limb, and the distal convoluted renal tubules (Riccardi *et al.,* 1996; Lee *et al.,* 1996; Yang *et al.,* 1997), i.e., in those renal segments which respond to PTH with an increase in cAMP accumulation (Chabardes *et al.,* 1975, 1980; Morel *et al.,* 1981).

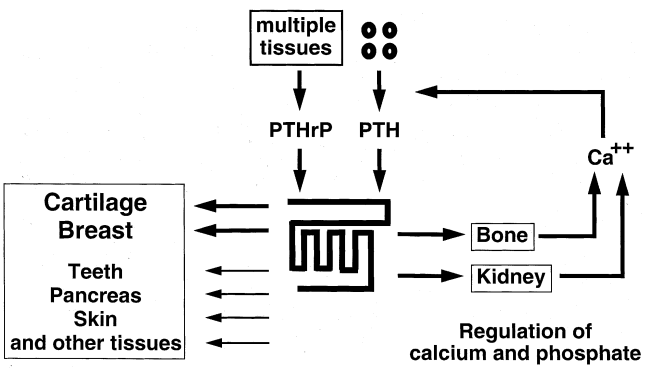

Figure 1 The PTH/PTHrP receptor is abundantly expressed in kidney and bone were it mediates the PTH-dependent regulation of calcium and phosphate homeostasis. It is also expressed in numerous other tissues, particularly in the growth plate chondrocytes, where it mediates the regulation of cellular proliferation and differentiation during development.

The most important PTH-mediated actions in the kidney affect the synthesis of 1,25$(OH)_2D_3$ from its precursor 25OHD_3, the excretion of phosphate, and the reabsorption of calcium. The stimulation of 1α-hydroxylase activity, an action which appears to be at least partially cAMP-dependent (Garabedian *et al.,* 1972; Fraser and Kodicek, 1973; Horiuchi *et al.,* 1977; Kong *et al.,* 1999; Fu *et al.,* 1997; Takeyama *et al.,* 1997), is largely restricted to the proximal convoluted tubule. The resulting increase in 1,25$(OH)_2D_3$ production enhances the absorption of calcium and phosphate from the intestine. The PTH-dependent inhibition of renal tubular phosphate reabsorption has been extensively documented in a variety of *in vivo* and *in vitro* studies (for reviews, see Stewart and Broadus, 1987; Amiel *et al.,* 1998; Murer *et al.,* 1999; Silve and Friedlander, 2000). Thus to increase renal phosphate excretion, PTH reduces the abundance of the type II sodium-phosphate cotransporter (Npt-2, also referred to as NaPi-2a) on the apical surface of proximal tubules, particularly of the proximal straight tubules (pars recta). This effect of PTH is mediated by both cAMP-dependent and -independent mechanisms and is associated with an increased internalization and subsequent lysosomal degradation of Npt-2 (Bell *et al.,* 1972; Goldfarb *et al.,* 1978; Pfister *et al.,* 1998, 1999; Lotscher *et al.,* 1999; for review, see Murer *et al.,* 2000). PTH/PTHrP receptor protein expression has been demonstrated by immunohistochemical and immunoelectron microscopic analysis, and by functional studies, on both basolateral and luminal membranes in proximal tubular cells *in vitro* and in intact proximal tubules (Reshkin *et al.,* 1991; Kaufmann *et al.,* 1994; Amizuka *et al.,* 1997; Traebert *et al.,* 2000). Apical receptors may be preferentially coupled to cAMP-independent signaling pathway, while basolateral receptor activation initiates both cAMP-dependent and cAMP-independent effects. Recently, megalin, a multifunctional clearance receptor expressed on the apical surface of proximal tubular cells has been shown to regulate the renal catabolism of PTH and to potentially antagonize PTH/PTHrP receptor activity (Hilpert *et al.,* 1999). In the distal convoluted tubule, PTH stimulates, possibly through second messengers other than cAMP, the reabsorption of calcium (Friedman *et al.,* 1996, 1999). PTH also decreases the glomerular filtration, inhibits the proximal reabsorption of bicarbonate and of amino acids, and stimulates gluconeogenesis (Amiel *et al.,* 1998; Jaeger *et al.,* 1987). Consistent with the findings regarding the second messenger systems that mediate the proximal and distal actions of PTH, recently established clonal cell lines derived from proximal segments of rat renal tubules showed a PTH-dependent accumulation of cAMP accumulation and a rapid increase in intracellular free calcium. In contrast to the characteristics of these "proximal" tubular cells, where PTH stimulation led to a rapid release of intracellular calcium from intracellular stores, the increase in this second messenger in the "distal" tubular cells was dependent largely on extracellular calcium (Friedman *et al.,* 1996, 1999). These findings indicated that distinct portions of the nephron respond differently to challenge with PTH.

Similar to its renal tubular effects, the PTH-dependent actions on bone are complex and often difficult to study. As outlined below in more detail, the hormone can influence, either directly or indirectly, the proliferation and differentiation of several bone cell precursors. Furthermore, the effects resulting from PTH stimulation of mature osteoblasts appear to be different depending on the intensity and duration of the stimulus, the type of bone (trabecular versus cortical), and the hormonal impregnation of bone. As a result, the hormonal effects observed *in vitro* often fail to reflect the conditions *in vivo.* For example, PTH stimulates both bone formation and osteoclastic bone resorption; however, the continuous administration of PTH *in vivo* is thought to favor bone resorption over bone formation, whereas intermittent doses of the hormone results in net anabolic effects (Tam *et al.,* 1982; Lane *et al.,* 1998; for review, see Finkelstein, 1996; Neer *et al.,* 2001). Rapid changes in blood PTH concentration may occur *in vivo,* since small changes in ionized calcium can generate significant variations in PTH secretion (Brown *et al.,* 1999) and these may contribute to the observed circadian rhythm of PTH concentration in the circulation (Kripke *et al.,* 1978; Harms *et al.,* 1989, 1994). Along with other endocrine factors, notably $1,25(OH)_2D_3$, PTH modulates the responsiveness of bone cells (Crowell *et al.,* 1981; Turner *et al.,* 1995).

The initial, PTH-dependent effect on bone is a rapid release of calcium from areas of the matrix that allow rapid exchange with the extracellular fluid (ECF). These events are followed, after a delay of several hours, by PTH-induced changes in bone cell metabolism. After stimulating osteoblast activity and thus bone formation (Silve *et al.,* 1982), activated osteoblasts increase the activity of already present osteoclasts as well as the differentiation of osteoclast precursors into mature bone-resorbing cells. The coupling between bone-forming osteoblasts and bone-resorbing osteoclasts is thought to depend, at least in part, on the ability of PTH to induce changes in the synthesis and/or activity of several different osteoblast-specific proteins, including insulin-like growth factor 1 (IGF1) (Canalis *et al.,* 1989). However, the most important of these "coupling" factors is RANKL (also referred to as osteoclast-differentiation factor (ODF), TRANCE, or osteoprotegerin ligand), a tumor necrosis factor (TNF)-related protein which is anchored on the surface of osteoblasts. RANKL interacts with the receptor RANK, which is expressed on preosteoclasts and mature osteoclasts, and facilitates the differentiation of precursor cells into osteoclasts and stimulates the activity of these bone-resorbing cells (Quinn *et al.,* 1998; Yasuda *et al.,* 1998). PTH thus acts on two distinct tissues, kidney and bone, to increase through different mechanisms the blood concentration of calcium and to thereby prevent significant hypocalcemia.

Parathyroid Hormone-Related Peptide

PTHrP was first discovered as the major cause of the humoral hypercalcemia of malignancy syndrome (Stewart *et al.,* 1980; Moseley *et al.,* 1987; Suva *et al.,* 1987; Strewler *et al.,* 1987; Mangin *et al.,* 1988). Within its amino-terminal portion, PTHrP shares partial amino acid sequence homology with PTH, and as a result of these limited structural similarities, amino-terminal fragments of both peptides have largely indistinguishable biological properties, at least with regard to the regulation of mineral ion homeostasis (Kemp *et al.,* 1987; Horiuchi *et al.,* 1987; Fraher *et al.,* 1992; Everhart-Caye *et al.,* 1996). Shortly after its initial isolation from several different tumors, PTHrP and its mRNA were found in large variety of fetal and adult tissues, suggesting that this peptide has an important biological role throughout life (Ikeda *et al.,* 1988; Broadus and Stewart, 1994; Yang and Stewart, 1996). However, it was not until the generation of genetically manipulated mice that the major physiological roles of PTHrP became apparent. These roles include the regulation of chondrocyte proliferation and differentiation during the process of endochondral bone formation (Karaplis *et al.,* 1994; Amizuka *et al.,* 1994; Weir *et al.,* 1996; Lanske *et al.,* 1996; Vortkamp *et al.,* 1996) and epithelial–mesenchymal interactions during organogenesis of certain epithelial organs, including skin, mammary gland, and teeth (Wysolmerski *et al.,* 1994, 1996, 1998; Philbrick *et al.,* 1998) (for review, see Wysolmerski and Stewart, 1998; Strewler, 2000). During fetal development, the expression of mRNA transcripts encoding PTHrP or the PTH/PTHrP receptor is closely linked, both spatially and temporally, implying that the ligand and its receptor are involved in paracrine/autocrine signaling events at these sites (Karaplis *et al.,* 1994; Wysolmerski *et al.,* 1998; Philbrick *et al.,* 1998; Lee *et al.,* 1995). These observations are furthermore consistent with the hypothesis that the PTH/PTHrP receptor mediates most of the actions of PTHrP.

Other recently described PTHrP-dependent effects are likely to involve mid-/carboxyl-terminal peptide fragments that are generated through alternative splicing and/or posttranslational processing and involve distinct, only incompletely characterized cell surface receptors and/or direct interactions with the nucleus (Wu *et al.,* 1996; Kovacs *et al.,* 1996; Lanske *et al.,* 1999; Henderson *et al.,* 1995; Nguyen and Karaplis, 1998; Massfelder *et al.,* 1997). While these non-amino-terminal PTHrP fragments are unlikely to be of biological importance for adult mineral ion metabolism, recent evidence suggests that large carboxyl-terminal fragments of PTH such as PTH(7–84) act, directly or indirectly, as antagonists of the calcemic actions of PTH(1–84) (Slatopolsky *et al.,* 2000; Nguyen-Yamamoto *et al.,* 2001). Through yet undefined mechanisms, carboxyl-terminal fragments of PTH may thus contribute to the regulation of calcium homeostasis.

The PTH/PTHrP Receptor: A Receptor for Two Distinct Ligands

The isolation of cDNAs encoding the PTH/PTHrP receptor from several different species, including humans, and subsequent expression of these cDNAs in various mammalian cell lines has confirmed and extended three key

observations: (1) the recombinant PTH/PTHrP receptor binds amino-terminal fragments of PTH and PTHrP with similar or indistinguishable affinity; (2) both ligands stimulate with similar potency the formation of at least two second messengers, cAMP and inositol phosphate, and (3) identical receptors are expressed in renal tubular cells and in osteoblasts (Jüppner *et al.,* 1991; Abou-Samra *et al.,* 1992; Schipani *et al.,* 1993). Furthermore, similar to the widely expressed PTHrP, the mRNA encoding the PTH/PTHrP receptor is found in a large variety of fetal and adult tissues (Tian *et al.,* 1993; Urena *et al.,* 1993; Riccardi *et al.,* 1996; Lee *et al.,* 1994, 1995, 1996) and at particularly abundant concentrations in proximal tubular cells, in osteoblasts, and in prehypertrophic chondrocytes of growth plates (Karaplis *et al.,* 1994; Weir *et al.,* 1996; Lanske *et al.,* 1996; Vortkamp *et al.,* 1996).

PTH/PTHrP receptor belongs to the class B family of heptahelical G protein-coupled receptors (GPCR) which also comprises the receptors for secretin, calcitonin, glucagon, and several other peptide hormones (Jüppner, 1994; Mannstadt *et al.,* 1999; Gardella and Jüppner, 2000). These hormone receptors share no homology with other G protein-coupled receptors, for example the members of the class A and class C family of receptors, and the organization of genes those encoding the latter receptors are distinctly different from encoding the class B receptors. All class B receptors are characterized by an amino-terminal, extracellular domain that comprises approximately 150 amino acids and by eight conserved extracellular cysteine residues, as well as several other conserved amino acids which are dispersed throughout the amino-terminal domain, the membrane-spanning helices, and the connecting loops.

The organization of the PTH/PTHrP receptor gene which comprises in mammals 14 coding exons, appears to be similar in all vertebrates (Kong *et al.,* 1994; McCuaig *et al.,* 1994). The ~2.5-kb transcript encoding the full-length PTH/PTHrP receptor is the predominant mRNA species in most tissues (Tian *et al.,* 1993; Urena *et al.,* 1993), but several larger and smaller sized transcripts have also been detected, suggesting the presence of splice variants of the PTH/PTHrP receptor. In contrast to alternatively spliced mRNAs that encode functional calcitonin and CRF receptors lacking portions of the seventh membrane-spanning helix (Shyu *et al.,* 1996; Grammatopoulos *et al.,* 1999), no alternatively spliced, functionally active PTH/PTHrP receptors have yet been identified (Jobert *et al.,* 1996; Joun *et al.,* 1997).

Transcripts encoding identical PTH/PTHrP receptors are derived from at least three different promoters that located upstream of one of three different untranslated exons (Kong *et al.,* 1994; McCuaig *et al.,* 1994; Bettoun *et al.,* 1997; Manen *et al.,* 1998). Little is known about the factors that control the activity of these promoters, some of which appear to be species- and tissue-specific (Amizuka *et al.,* 1997; Bettoun *et al.,* 1998), and their activity may be different throughout development and adult life (Bettoun *et al.,* 1998; Amizuka *et al.,* 1999). Transcripts derived from the P1 and the P2 promoter have been observed in rodents and humans (McCuaig *et al.,* 1994; Joun *et al.,* 1997; McCuaig *et al.,* 1995). P1-derived transcripts are found mainly, at least in rodents, in vascular smooth muscles and in peritubular endothelial cells of the adult kidney (Amizuka *et al.,* 1997). In contrast, transcripts derived from the ubiquitous P2 promoter can be detected in numerous fetal and adult tissues, including cartilage and bone (Amizuka *et al.,* 1999). The P2 promoter activity is equivalent in humans and mice, while the activity of the P1 promoter is prominent only in rodents and appears to be weak or absent in humans. A third promoter, P3, has been identified thus far only in humans, where it is thought to control PTH/PTHrP receptor expression in several different tissues, including kidney and bone (Manen *et al.,* 1998; Bettoun *et al.,* 1998). Methylation appears to play a role in controlling human PTH/PTHrP receptor gene promoter activity (Bettoun *et al.,* 2000). A differential regulation of P2 activity in osteoblasts and chondrocytes following vitamin D3 administration has been demonstrated in rodents (Amizuka *et al.,* 1999).

A second PTH-receptor, termed type 2 PTH receptor or PTH2-receptor, which belongs to the same family of G protein-coupled receptors as the PTH/PTHrP receptor, is less broadly expressed, with little if any expression in kidney and bone (Usdin *et al.,* 1996, 1999). The human PTH2-receptor is efficiently activated by PTH, but not by PTHrP (Usdin *et al.,* 1995; Gardella *et al.,* 1996; Behar *et al.,* 1996), while the rat receptor homolog is not activated by either of these two ligands (Hoare *et al.,* 1999). Instead, both PTH2-receptor isoforms are efficiently and equally activated by TIP39, a recently identified hypothalamic peptide, which shows limited amino acid sequence homology with PTH and PTHrP. It is therefore likely that TIP39 represents the primary agonist for the PTH2-receptor (Usdin *et al.,* 1999; Usdin, 1997). Although TIP39 does not activate the PTH/PTHrP receptor, the full-length peptide as well as several fragments that are truncated at the amino-terminus can bind to the latter receptor and furthermore inhibit PTH- and PTHrP-stimulated cAMP accumulation (Hoare *et al.,* 2000a,b; Jonsson *et al.,* 2001). It appears unlikely, however, that TIP39 has a role in the regulation of mineral ion homeostasis.

Role of PTHrP and the PTH/PTHrP Receptor in Endochondral Bone Formation

PTHrP was initially discovered as the cause of the humoral hypercalcemia of malignancy syndrome. However, its most prominent physiological role was revealed only through the homologous ablation of its gene in mice (Karaplis *et al.,* 1994) and through the development of transgenic animals which express PTHrP under the control of a growth plate-specific promoter (Weir *et al.,* 1996).

Homozygous PTHrP gene-ablated animals die during the perinatal period and show striking skeletal changes, which include domed skulls, short snouts, and mandibles

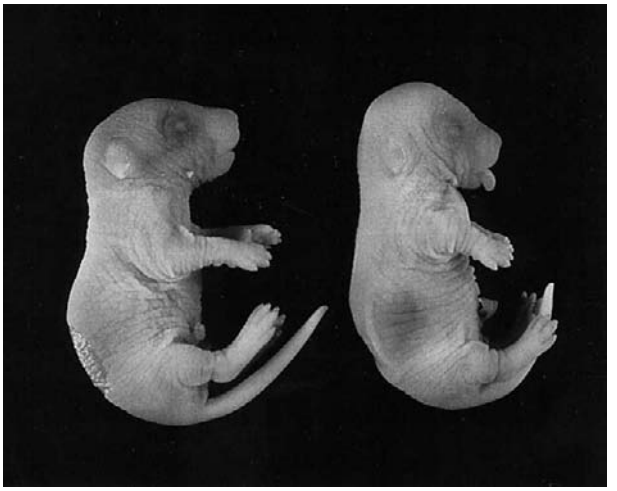

Figure 2 Phenotype of a homozygous PTHrP-ablated mouse (day 18.5 of embryonic development). Note the chondrodysplasia characterized by a domed skull, short snout and mandible, protruding tongue, narrow thorax, and disproportionately short limbs. From Karaplis *et al.* (1994), with permission. (See also color plate.)

and disproportionately short extremities, yet no obvious developmental defects in other organs (Fig. 2, see also color plate). These skeletal changes are caused by a dramatic acceleration of chondrocyte differentiation that leads to premature growth plate mineralization (Karaplis *et al.,* 1994) (Fig. 3). Heterozygous animals, lacking only one copy of the PTHrP gene, show normal growth and development, and are fertile, but develop, despite apparently normal calcium and phosphorus homeostasis, mild osteopenia later in life (Amizuka *et al.,* 1996). Growth plate abnormalities that are, in many aspects, the opposite of those found in PTHrP-ablated mice are observed in animals that overexpress PTHrP under the control of the α1(II) collagen promoter (Weir *et al.,* 1996). Throughout life these animals are smaller in size than their wild-type litter mates, and show a disproportionate foreshortening of limbs and tail, which is most likely due to a severe delay in chondrocyte differentiation and endochondral ossification. Thus, too little or too much PTHrP expression in the growth plate leads to short-limbed dwarfism, although through entirely different mechanisms.

From these and other studies, it is now well established that PTHrP facilitates the continuous proliferation of chondrocytes in the growth plate, and that it postpones their programmed differentiation into hypertrophic chondrocytes. Consistent with this role of PTHrP in endochondral bone formation, earlier *in vitro* studies had shown that PTH (used in these studies instead of PTHrP) affects chondrocyte maturation and activity (Lebovitz and Eisenbarth, 1975; Smith *et al.,* 1976). More recent studies confirmed these findings by showing that PTH and PTHrP stimulate, presumably through cAMP-dependent mechanisms (Jikko *et al.,* 1996), the proliferation of fetal growth plate chondrocytes, inhibit the differentiation of these cells into hypertrophic chondrocytes, and stimulate the accumulation of cartilage-specific proteoglycans that are thought to act as inhibitors of mineralization (Takano *et al.,* 1985; Koike *et al.,* 1990; Iwamoto *et al.,* 1994). In the absence of these cartilage-specific PTHrP effects, growth plates of homozygous PTHrP gene-ablated mice have a thinner layer of proliferating chondrocytes, while the layer of

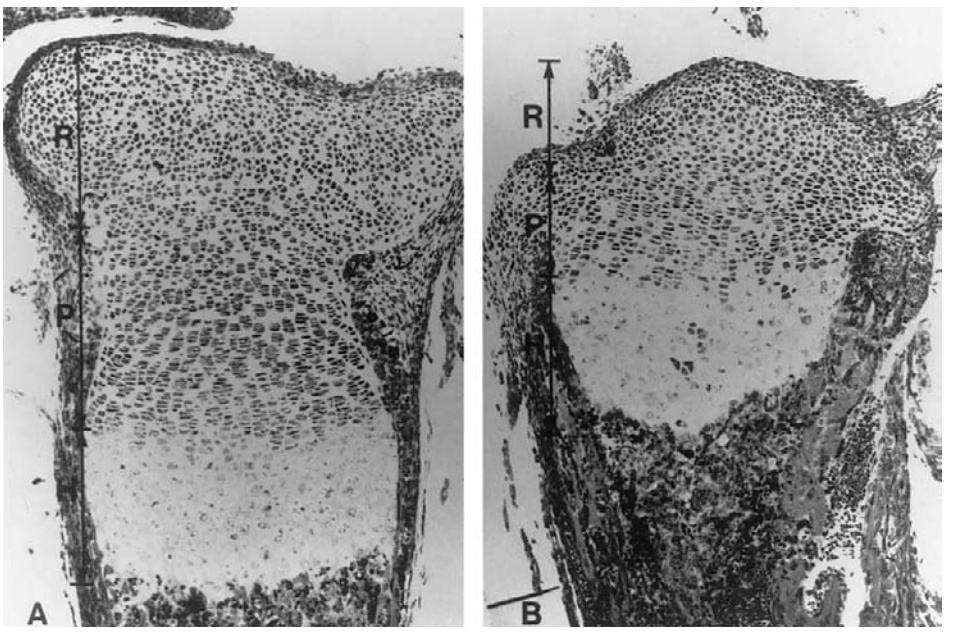

Figure 3 Low-magnification photomicrographs of the proximal tibiae of a wild-type mouse (A) and a homozygous PTHrP-ablated mouse (B) (E 18.5). Note that the tibial epiphysis of the PTHrP-ablated mouse is shortened, the zones of reserve and proliferative chondrocytes are markedly reduced. From Amizuka *et al.* (1994), with permission.

hypertrophic chondrocytes is relatively normal in thickness, but somewhat disorganized. Taken together these findings suggested that the lack of PTHrP accelerates the normal differentiation process of growth plate chondrocytes; i.e., resting and proliferating chondrocytes undergo fewer cycles of cell division and differentiate prematurely into hypertrophic cells, which then undergo apoptosis before being replaced by invading osteoblasts.

The phenotypic changes in mice which are "null" for either PTHrP or the PTH/PTHrP receptor are similar, and current evidence indicates that the autocrine/paracrine actions of PTHrP within the growth plate are mediated through the PTH/PTHrP receptor (Karaplis *et al.,* 1994; Lanske *et al.,* 1996; Chung *et al.,* 1998). Furthermore, mice missing either PTHrP or its receptor are resistant to the actions of *Indian Hedgehog (Ihh),* a developmentally important protein which is most abundantly expressed in growth plate chondrocytes that are about to differentiate into hypertrophic cells. *Ihh* binds directly to *patched,* a membrane receptor, which interacts with *smoothened* and thereby suppresses the constitutive activity of the latter protein (Stone *et al.,* 1996; Marigo *et al.,* 1996). The ectopic expression of *Ihh* in the chicken wing cartilage stimulates the production of PTHrP and thereby blocks the normal chondrocyte differentiation program (Vortkamp *et al.,* 1996); whether PTHrP represses, as part of a feedback loop, the expression of *Ihh* remains to be established. PTHrP and *Ihh* are thus critically important components of normal bone growth and elongation (Lanske *et al.,* 1996; Vortkamp *et al.,* 1996). However, not all actions of PTHrP appear to be mediated through the PTH/PTHrP receptor, since the ablation of the PTHrP gene or the PTH/PTHrP receptor gene leads to subtle, but distinctly different, abnormalities in early bone development (Lanske *et al.,* 1999). This suggests that some actions of PTHrP in bone involve either distinct receptors or the peptide's direct nuclear actions (Henderson *et al.,* 1995; Nguyen and Karaplis, 1998; Massfelder *et al.,* 1997).

Role of PTHrP in Regulating Epithelial–Mesenchymal Interactions

Studies with transgenic mice, in which PTHrP expression is targeted through a human keratinocyte-specific promoter (K14) to the developing epidermis and mammary gland, demonstrated that PTHrP plays also a critical role in hair follicle development and branching morphogenesis of the mammary gland (Wysolmerski *et al.,* 1994, 1996). These conclusions were further supported by findings in PTHrP-null mice that had been rescued from neonatal death by targeting PTHrP expression to chondrocytes through the α1(II) collagen promoter (Weir *et al.,* 1996). These rescued mice lack mammary epithelial ducts, due to a failure of the initial round of branching growth that is required for transforming the mammary bud into the primary duct system; ablation of both copies of the PTH/PTHrP receptor gene recapitulated the phenotype of PTHrP-ablated animals (Wysolmerski *et al.,* 1998).

Using similar approaches, it was furthermore demonstrated that PTHrP is required for normal tooth eruption. Teeth appeared to develop normally in rescued PTHrP knockout mice, but became trapped by the surrounding bone and underwent progressive impactation (Philbrick *et al.,* 1998). In these tissues, PTHrP mRNA was identified by *in situ* hybridization in epithelial cells, while the PTH/PTHrP receptor mRNA was found on mesenchymal or stromal cells. These observations led to the concept that the communication between epithelium and mesenchyme involves the PTH/PTHrP receptor, and that PTHrP-signaling is essential for normal development of these tissues (Wysolmerski and Stewart, 1998).

Jansen's Metaphyseal Chondrodysplasia (JMC)

JMC, first described in 1934 (Jansen, 1934), is a rare autosomal dominant form of short-limbed dwarfism associated with laboratory abnormalities that are typically observed only in patients with either primary hyperparathyroidism or with the humoral hypercalcemia of malignancy syndrome (reviewed in Jüppner, 1996; Parfitt *et al.,* 1996). These biochemical changes, i.e., hypercalcemia, renal phosphate wasting, and increased urinary cAMP excretion, occur despite low or undetectable concentrations of PTH in the circulation and of PTHrP concentrations that are not elevated (Frame and Poznanski, 1980; Holt, 1969; Kessel *et al.,* 1992; Rao *et al.,* 1979; Silverthorn *et al.,* 1983; Schipani *et al.,* 1999; Kruse and Schütz, 1993). Severe hypercalcemia, which is often asymptomatic, and hypophosphatemia had been noted in Jansen's first patient (De Haas *et al.,* 1969) and in a subsequently described child with the same disorder (Cameron *et al.,* 1954). It was not until the description of a third patient, however, that the association between the abnormalities in endochondral bone formation and in mineral ion homeostasis was formally considered (Gram *et al.,* 1959). At that time the biochemical abnormalities could not be readily distinguished from those observed in primary hyperparathyroidism, but the surgical exploration of the patient revealed no obvious abnormalities of the parathyroid glands. It was therefore concluded that the changes in mineral metabolism were either "secondary to the underlying bone defect" or "related to an undefined metabolic disorder that gave rise to both metaphyseal and biochemical changes" (Gram *et al.,* 1959). Most reported cases of JMC are sporadic, but the description of two unrelated affected females that gave birth to affected daughters (Lenz, 1969; Holthusen *et al.,* 1975; Charrow and Poznanski, 1984) suggested an autosomal dominant mode of inheritance; this conclusion was subsequently confirmed for one of these families at the molecular level (Schipani *et al.,* 1996).

At birth some patients with JMC have dysmorphic features, which can include high skull vault, flattening of the of the nose and forehead-low set ears, hypertelorism, high-arched palate, and micro- or retrognathia (for a review, see

Jüppner, 1996). Although body length is within normal limits at birth, growth becomes increasingly abnormal, eventually leading to the development of short stature. Additional signs may include kyphoscoliosis with a bell-shaped thorax and widened costochondral junctions, metaphyseal enlargement of the joints, waddling gait, prominent supraorbital ridges, and frontonasal hyperplasia. The legs are usually bowed and short, while the arms are relatively long.

Radiological studies have shown considerable, age-dependent differences in the osseous manifestations of JMC. In younger patients, severe metaphyseal changes, especially of the long bones are present (Fig. 4). The metaphyses are enlarged and expanded, giving a club-like appearance to the ends of the long bones with a wide zone of irregular calcifications. Patches of partially calcified cartilage that protrude into the diaphyses are also present and appear relatively radiolucent. These findings, which are characteristically observed throughout early childhood, are similar to the lesions observed in rickets. However, distinct from the findings in rickets, metacarpal and metatarsal bones are also involved.

Later in childhood, the changes are no longer reminiscent of rickets. Until the onset of puberty, almost all tubular bones show irregular patches of partially calcified cartilage that protrude into the diaphyses; the spine and vertebral bodies show no obvious abnormalities (Frame and Poznanski, 1980; Kessel *et al.,* 1992; Kao *et al.,* 1979; Silverthorn *et al.,* 1983; Schipani *et al.,* 1999; Kruse and Schütz, 1993; Cameron *et al.,* 1954; Charrow and Poznanski, 1984). After adolescence, the cartilaginous tissue in the metaphyses gradually disappears and turns into bone, leading to bulbous deformities (see Fig. 4). The ends of most tubular bones remain expanded, deformed, and radiolucent, but a more normal trabecular pattern gradually emerges (Frame and Poznanski, 1980; Kessel *et al.,* 1992; Kao *et al.,* 1979; Silverthorn *et al.,* 1983; Schipani *et al.,* 1999; Kruse and Schütz, 1993; Cameron *et al.,* 1954; Charrow and Poznanski, 1984).

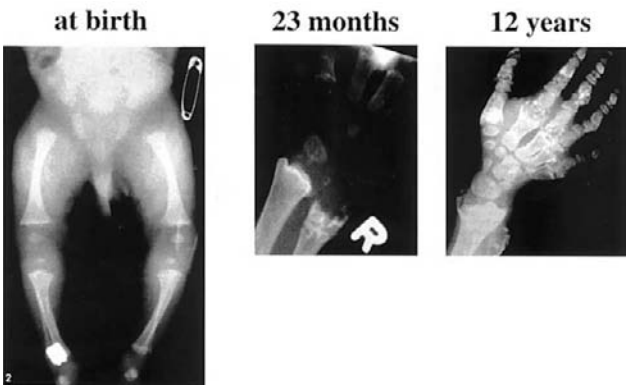

Figure 4 A patient with Jansen's disease and his radiological findings at different ages. (A) Patients with Jansen's metaphyseal chondrodysplasia (from Jansen, 1934, De Haas *et al.,* 1969; Silverthorn *et al.,* 1983); photograph of the latter patient kindly provided by Drs. Kooh and Cole, Hospital for Sick Children, Toronto, Canada). (B) X-rays from a patients with Jansen's disease at birth, 23 months, and 12 years of age. From Silverthorn *et al.* (1983), with permission.

In addition, sclerosis and thickening of the base of the skull and of the calvaria is noted in most cases. The former changes are thought to be the cause of cranial auditory and optical nerve compression, which has been observed later in life in some affected individuals. Loss of the normal cortical outline, areas of subperiosteal bone resorption, and generalized osteopenia are reminiscent of the changes seen in hyperparathyroidism. Furthermore, there is an increased in trabecular bone volume and a thinning of cortical bone (Parfott *et al.,* 1996). The two only reports that investigated the histological changes in the growth plates, described a severe delay in endochondral ossification of the metaphyses, including a lack of the regular columnar arrangement of the maturing cartilage cells, a lack of excess osteoid (which is usually indicative of active rickets or osteomalacia), little or no vascularization of cartilage, and no evidence for osteitis fibrosa (Cameron *et al.,* 1954; Jaffe, 1972).

One female patient with JMC was reported to be unable to breast-feed and to have, similar to her affected daughter, a dry and scaly skin (Schipani *et al.,* 1995). As discussed above, PTHrP and the PTH/PTHrP receptor are expressed in breast and skin, and this ligand/receptor system appears to have an important role in these two tissues. Tooth development and enamel formation appear normal in patients with JMC. Intelligence appears to be normal in all reported cases.

Most laboratory findings in JMC are reminiscent of those observed in patients with primary hyperparathyroidism or with the syndrome of humoral hypercalcemia of malignancy. In the newborn, blood phosphorus levels are typically at the lower end of the normal range, while alkaline phosphatase activity is almost invariably elevated. Hypercalcemia is usually absent at birth, but develops during the first months of life, and persists throughout life, but is more pronounced during infancy and childhood. Hypercalciuria is usually present and can be associated with an increased incidence of nephrocalcinosis (Kessel *et al.,* 1992). $1,25(OH)_2D_3$ levels have been reported to be normal or at the upper end of the normal range. Serum alkaline phosphatase activity and osteocalcin concentration are elevated throughout life, indicating that osteoblast activity is increased; compatible with an increased osteoclastic activity, urinary hydroxyproline excretion is elevated (Schipani *et al.,* 1999; Kruse and Schütz, 1993).

Jansen's Disease Is Caused by Activating PTH/PTHrP Receptor Mutations

Because of the findings in the various genetically manipulated mice described above, and because of the abundant expression of the PTH/PTHrP receptor in the three organs that are most obviously affected in JMC; i.e., kidney, bone, and metaphyseal growth plates, activating receptor mutations were considered as a cause of this rare disease. Indeed, in

several unrelated patients with this disorder, a heterozygous nucleotide exchange, which changes a histidine at position 223 to arginine, was identified in exon M2 of the PTH/PTHrP receptor gene (Schipani *et al.,* 1995; 1996, 1999; Minagawa *et al.,* 1997). In other patients, two additional heterozygous nucleotide exchanges were identified which change either a threonine at position 410 to proline (exon M5), or isoleucine at position 458 to arginine (exon M7) (Schipani *et al.,* 1996, 1999) (Fig. 5). The three mutated residues are predicted to be located at or close to the intracellular surface of the cell membrane and are strictly conserved in all mammalian members of this receptor family (Jüppner, 1994; Mannstadt *et al.,* 1999), suggesting an important functional role for these three residues. With the exception of one family where a mother-to-daughter transmission of the H223R mutation was documented (Schipani *et al.,* 1996), each of the three mutations was excluded in the healthy parents and siblings, and in genomic DNA from a significant number of unrelated healthy individuals. This suggests that JMC is usually caused by *de novo* mutations. To date, the T410P and the 1458R mutation was found in one patient each, while the H223R mutation was identified in eight patients, and is thus the most frequent PTH/PTHrP receptor mutation in JMC.

To test *in vitro* the functional consequences of the identified missense mutations in JMC, each of the three different nucleotide exchanges was introduced into the cDNA encoding the wild-type human PTH/PTHrP receptor (Schipani *et al.,* 1995, 1996, 1999; Minagawa *et al.,* 1997). COS-7 cells transiently expressing PTH/PTHrP receptors with either the H223R, the T410P, or the 1458R mutation showed significantly higher basal accumulation of cAMP, then cells expressing the wild-type PTH/PTHrP receptor (see Fig. 5). Cells expressing PTH/PTHrP receptors with either of the three point mutations showed no evidence for increased basal accumulation of IP3, indicating that this signaling pathway is not constitutively activated (Schipani *et al.,* 1995, 1996, 1999). Interestingly, the D578H mutation in the luteinizing hormone receptor, which is at a position equivalent to the T410P mutation in the PTH/PTHrP receptor, led to constitutive activity of both signaling pathways, cAMP and IP3 (Liu *et al.,* 1999). It is therefore plausible that the lack of constitutive IP3 generation by three activating mutations in the PTH/PTHrP receptor could be related to insufficient sensitivity of the methods that were used to explore this second messenger system.

When challenged with increasing concentrations of either PTH or PTHrP, cells expressing the mutant H223R and T410P receptors showed, in comparison to cells expressing the wild-type PTH/PTHrP receptor, reduced maximal cAMP accumulation. In contrast, cells expressing the 1458R mutant showed the same maximal cAMP accumulation as cells transfected with the wild-type receptor (Schipani *et al.,* 1999). Agonist-dependent IP accumulation was observed with COS-7 cells expressing the I458R and the T410P mutant, but not with cells expressing the H223R mutant. Despite the differences in the *in vitro* response to PTH or PTHrP, patients with either of the three PTH/PTHrP receptor mutations showed no obvious differences in their clinical and/or biochemical presentation.

Activating mutations in other G protein-coupled receptors have been implicated in several other human diseases, but none of these involve members of the class B receptor family. These disorders include rare forms of retinitis pigmentosa or congenital stationary blindness (activating mutations in rhodopsin) (Robinson *et al.,* 1992; Dryja *et al.,* 1993), thyroid adenomas or non-autoimmune hyperthyroidism (activating TSH receptor mutations) (Parma *et al.,* 1993; Duprez *et al.,* 1994; Paschke *et al.,* 1994; Kopp *et al.,* 1995; Tonacchera *et al.,* 1996; Grüters *et al.,* 1998; Khoo *et al.,* 1999; Nogueira *et al.,* 1999; Russo *et al.,* 1999; Trultzsch *et al.,* 1999), gonadotropin-independent male precocious puberty (Shenker *et al.,* 1993; Latronico *et al.,* 1995; Kraalj *et al.,* 1995;

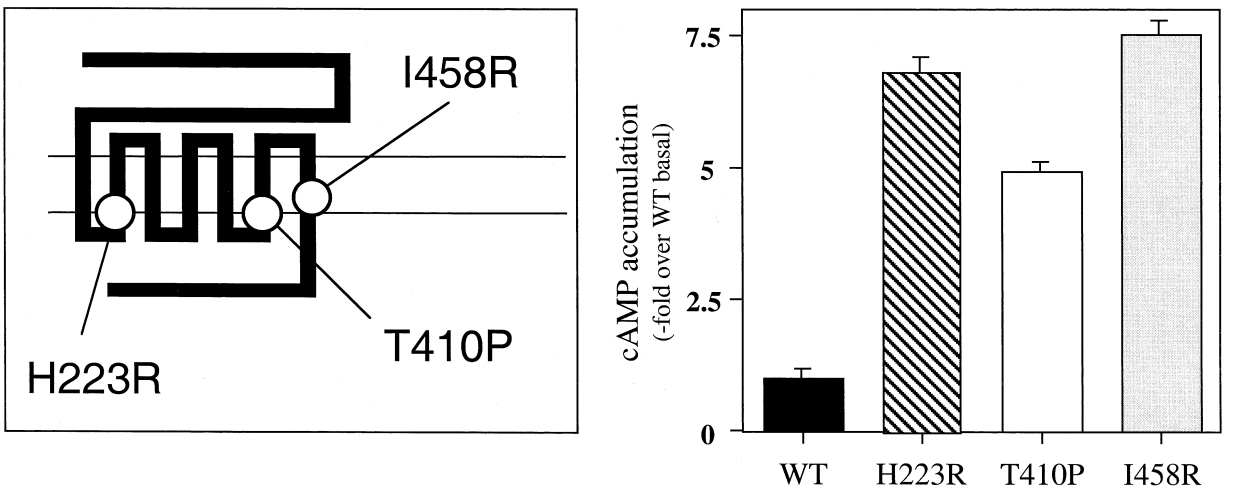

Figure 5 Schematic representation of the PTH/PTHrP receptor and basal, agonist-indepenent cAMP accumulation of wild-type and mutant receptors. The approximate location of the three different missense mutations that were identified in patients with Jansen's disease are indicated (left). Basal cAMP accumulation of COS-7 cells expressing wild-type ■ and mutant PTH/PTHrP receptors (H223R, ▨; T410P, ▭; 1458R, ▭ (right). Modified from Schipani *et al.* (1996, 1999).

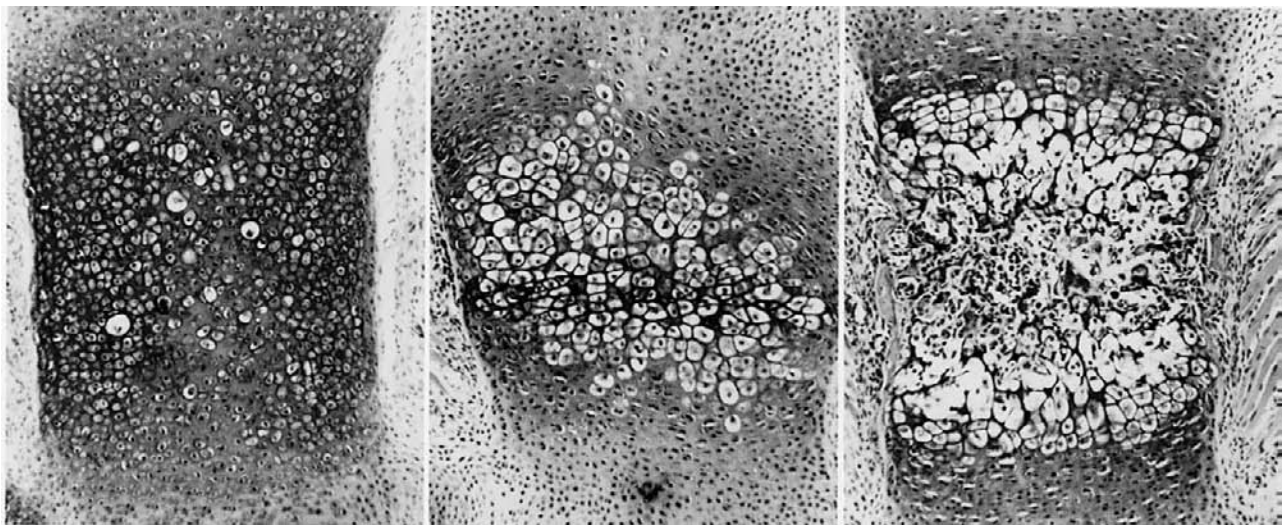

Figure 6 Histological sections, stained with hematoxylin and eosin, of decalcified sternum from a newborn wild-type mouse (left) and transgenic littermates that were heterozygous (middle) or homozygous (right) for expression of a constitutively active PTH/PTHrP receptor under the control of the type II collagen promoter. From Schipani *et al.* (1997). (See also color plate.)

Shenker, 1998), and Leydig-cell tumors (activating mutations in the luteinizing hormone receptor) (Liu *et al.,* 1999), and autosomal dominant forms of familial hypocalcemia (activating calcium-sensing receptor mutations) (Pollak *et al.,* 1994; Pearce, 1995; Pearce and Brown, 1996; Baron *et al.,* 1996; Rearce *et al.,* 1997; Brown *et al.,* 1998; Watanabe *et al.,* 1998; Okazaki *et al.,* 1999). Cell membrane receptors exhibiting constitutive signaling have also been described in the pathogenesis of Kaposi's sarcoma and primary effusion lymphomas (constitutive signaling of the Kaposi's sarcoma herpesvirus-G protein-coupled receptor (KSHV-GPCR) via activation of phosphoinositide-specific phospholipase) (J. A. Burger *et al.,* 1999; M. Burger *et al.,* 1999).

To prove that the growth plate abnormalities in Jansen's disease are indeed caused by constitutively active PTH/PTHrP receptors, transgenic mice were generated that express the H223R mutant under the control of the rat α1(II) collagen promoter, thereby targeting receptor expression to proliferating chondrocytes (Schipani *et al.,* 1997). Two transgenic mouse lines were established, both of which showed delayed mineralization and decelerated differentiation of proliferative chondrocytes into hypertrophic chondrocytes, a delay in vascular invasion and a prolonged presence of hypertrophic chondrocytes (Fig. 6, see also color plate). In one of these mouse lines, the defect in endochondral bone formation was apparent only at the microscopic level, while the second line showed shortened and deformed limbs that are reminiscent of the findings in patients with Jansen's disease. Based on these results in transgenic mice it appears likely that the growth abnormalities in JMC are caused by the expression of mutant, constitutively active PTH/PTHrP receptor in growth plate chondrocytes.

In an attempt to better understand how the PTH/PTHrP receptor can modulate bone development and turnover, transgenic mice were recently generated in which the human PTH/PTHrP receptor with the H223R mutation is expressed under the control of the type I collagen promoter. Constitutive activity of this receptor was thus targeted to mature osteoblasts and osteoblast precursors. When compared to control littermates, long bones of transgenic mice were reduced in length. The histological analysis of these bones revealed findings that are reminiscent of the skeletal abnormalities in patients with hyperparathyroidism and with Jansen's disease (Parfitt *et al.,* 1996), i.e., a thinner and more porous cortex in the diaphysis, an increased trabeculation of the metaphysis, and a reduction in bone marrow space (Fig. 7, see also color plate). Besides increased osteoblast function in trabecular bone and at the endosteal surface of cortical bone, osteoblastic activity in the periosteum was inhibited. Furthermore, mature osteoblasts as well as a heterogeneous population of preosteoblasts were increased in the trabecular compartment by a mechanism of increased proliferation and decreased apoptosis, and expression of the constitutively active PTH/PTHrP receptor in osteoblasts resulted in a dramatic increase in osteoclast number. The net effect of these actions was a substantial increase in trabecular bone volume and a decrease in cortical bone mass. These studies identified the PTH/PTHrP receptor as an important mediator of both bone forming and bone resorbing actions of PTH, and point out the complexity and heterogeneity of the osteoblast population and/or their regulatory microenvironment (Calvi *et al.,* 2001).

Blomstrand's Lethal Chondrodysplasia

Blomstrand's lethal chondrodysplasia is a recessive human disorder characterized by early lethality, advanced bone maturation and accelerated chondrocyte differentiation, and most likely severe abnormalities in mineral ion homeostasis. The first patient was described by Blomstrand and

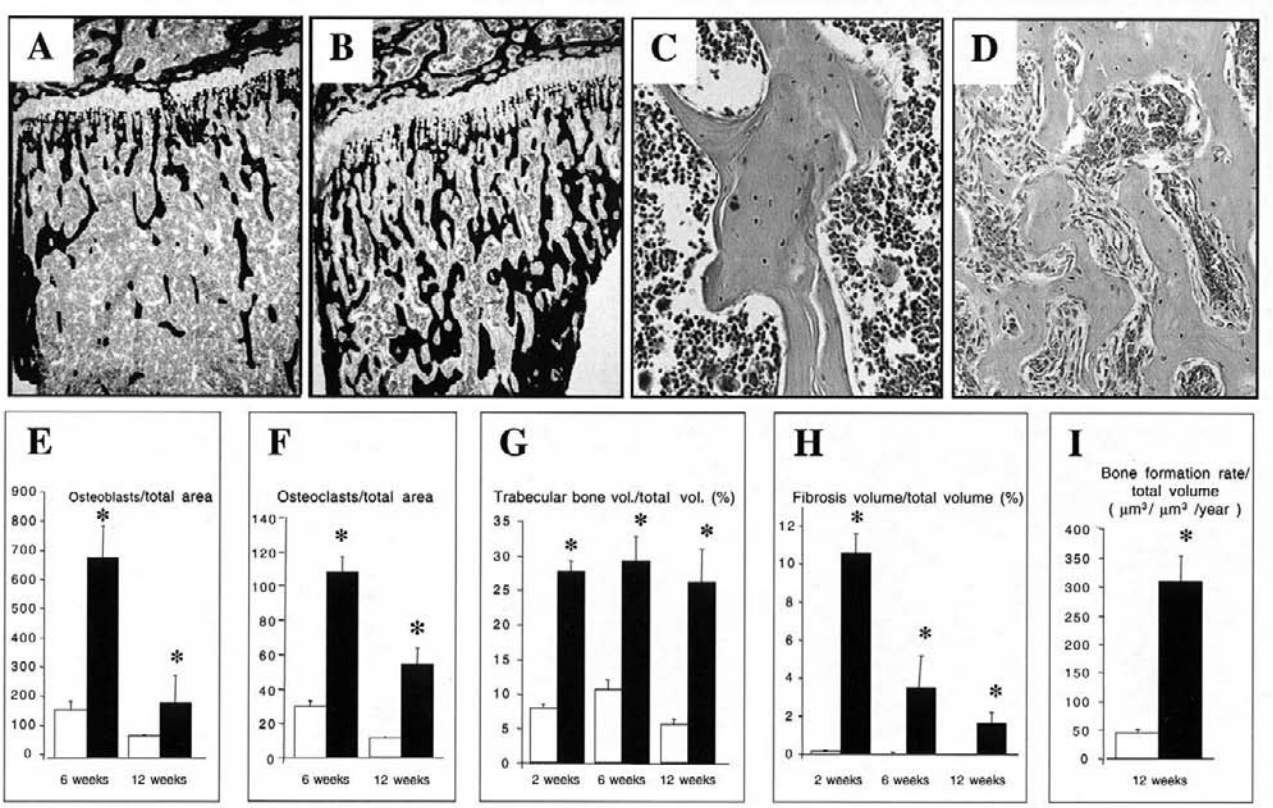

Figure 7 Histology and histomorphometric analysis of trabecular bone from wild-type and CL2 transgenic mice. Histologic sections of tibiae, stained by the method of von Kossa, from 12-week-old wild-type mice (A) and CL2 transgenic littermates (B). High-power light microscopy of decalcified sections, stained with hematoxylin and eosin, of the metaphyseal area from the proximal tibia of 12-week-old wild-type (C) and CL2 transgenic littermates (D). Histomorphometric analysis performed in wild-type (white bars) and CL1 transgenic littermates (black bars) (E–I). Ages of animals are indicated on the *x*-axis; asterisks indicate a statistically significant difference between two groups of mice ($P < 0.05$); error bars represent the SEM. Modified from Calvi *et al.* (2001). (See also color plate.)

colleagues in 1985; descriptions of several other patients followed (Young *et al.,* 1993; Leroy *et al.,* 1996; Loshkajian *et al.,* 1997; den Hollander *et al.,* 1997; Oostra *et al.,* 1998, 2000; Galera *et al.,* 1999; Karperien *et al.,* 1999). The disorder was shown to occur in families of different ethnic backgrounds and appears to affect males and females equally. Most affected infants are born to consanguineous parents [only in one instance were unrelated parents reported to have two offspring that are both affected by Blomstrand's disease (Loshkajian *et al.,* 1997)], suggesting that BLC is an autosomal recessive disease. Infants with BLC are typically born prematurely and die shortly after birth. Birth weight, when corrected for gestational age, appears to be normal, but may be overestimated because most infants are hydroptic; also the placenta can be immature and edematous. Nasal, mandibular, and facial bones are hypoplastic; the base of the skull is short and narrow; the ears are low set; the thoracic cage is hypoplastic and narrow with short thick ribs and hypoplastic vertebrae. In contrast, the clavicles are relatively long and often abnormally shaped, the limbs are extremely short, and only the hands and feet are of relatively normal size and shape. Internal organs show no apparent structural or histological anomalies, but preductal aortic coarctation was observed in most published cases. The lungs are hypoplastic and the protruding eyes typically show cataracts. Defects in mammary gland and tooth development, previously overlooked, were demonstrated in two recently studied fetuses with BLC. In these fetuses, nipples were absent, and no subcutaneous ductal tissue could be identified by histochemical analysis. Tooth buds were present, but developping teeth were severely impacted within the surrounding alveolar bone, leading to distortions in their architecture and orientation (Wysolmerski *et al.,* 2001).

Radiological studies of patients with BLC reveal pronounced hyperdensity of the entire skeleton and markedly advanced ossification (Fig. 8). As mentioned above, the long bones are extremely short and poorly modeled, show markedly increased density, and lack metaphyseal growth plates. Endochondral bone formation is dramatically advanced and is associated with a major reduction in epiphyseal resting cartilage, preventing the development of epiphyseal ossification centers (Fig. 9, see also color plate). The zones of chondrocyte proliferation and of column formation are lacking, and the zone that normally comprises the layer of hypertrophic chondrocytes is poorly defined, narrow, and irregular (Oostra *et al.,* 2000). Cortical bone is thickened and

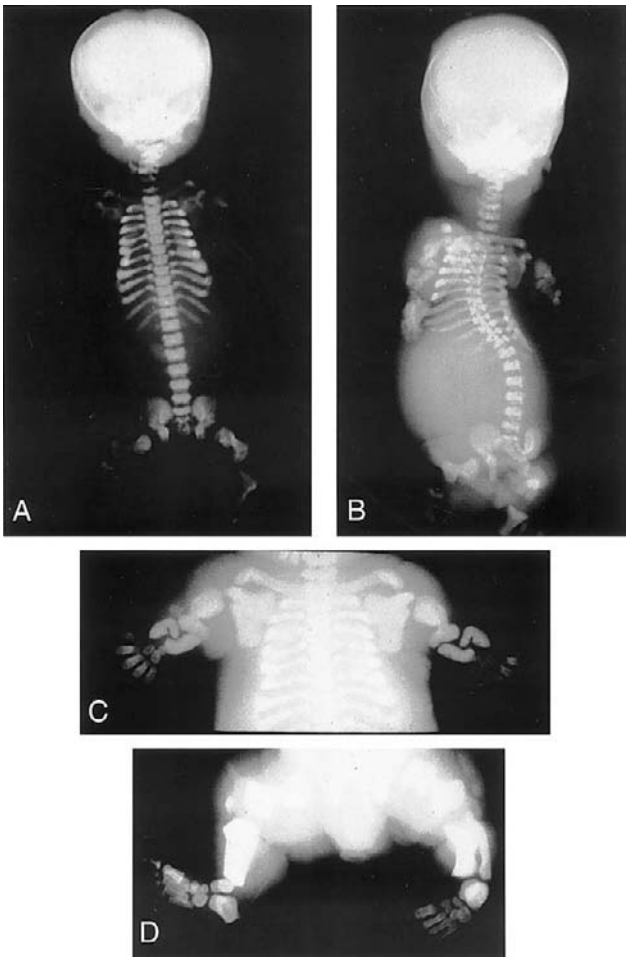

Figure 8 Radiological findings in two fetuses with Blomstrand's lethal chondrodysplasia (BLC). Anterio-posterior (A) and lateral (B) views of a male fetus at 26 weeks of gestation; upper (C) and lower (D) limbs of a female fetus with BLC at 33 weeks of gestation. Particularly striking is the dramatic acceleration of endochondral bone formation of all skeletal elements. No secondary ossification centers of ossification are seen in the long bones. The limbs are coarsely shaped and extremely short, while carpal and tarsal bones have a comparatively normal shape and size. Note also that the clavicles are relatively long, but show abnormal bending. From Loshkajian *et al.* (1997), with permission.

bone trabeculae are coarse with reduced diaphyseal marrow spaces. Capillary ingrowth, bone resorption, and bone formation are reported by some authors as being unaltered (Leroy *et al.,* 1996), while others describe these bone remodeling events as deficient (Loshkajian *et al.,* 1997).

Blomstrand's Disease Is Caused by Inactivating PTH/PTHrP Receptor Mutations

Recently, four different defects in the PTH/PTHrP receptor gene were described in genomic DNA from patients affected by BLC (Fig. 10). The first reported case, a product of non-consanguineous parents, was shown to have two distinct abnormalities in the PTH/PTHrP receptor gene (Jobert *et al.,* 1998). Through a nucleotide exchange in exon M5 of the maternal PTH/PTHrP receptor allele, a novel splice acceptor site was introduced which led to a mutant mRNA encoding an abnormal receptor that lacks a portion of the fifth membrane-spanning domain (amino acids 373 to 383 (Δ373–383)). This receptor mutant fails, despite seemingly normal cell surface expression, to respond to PTH or PTHrP with an accumulation of cAMP (Fig. 11) and inositol phosphate (data not shown). For yet unknown reasons, the paternal PTH/PTHrP receptor allele from this patient is very poorly expressed, suggesting an unidentified mutation in one of the different promoter regions or in a putative enhancer element.

A second patient with BLC, the product of a consanguineous marriage, was shown to have a nucleotide exchange that leads to a proline-to-leucine mutation at position 132 (P132L) (Zhang *et al.,* 1998; Karaplis *et al.,* 1998). This residue in the amino-terminal, extracellular domain of the PTH/PTHrP receptor is invariant in all mammalian members of this family of G protein-coupled receptors, indicating that the identified mutation is likely to have significant functional consequences. Indeed, COS-7 cells expressing this mutant PTH/PTHrP receptor showed, despite apparently normal cell surface expression, dramatically

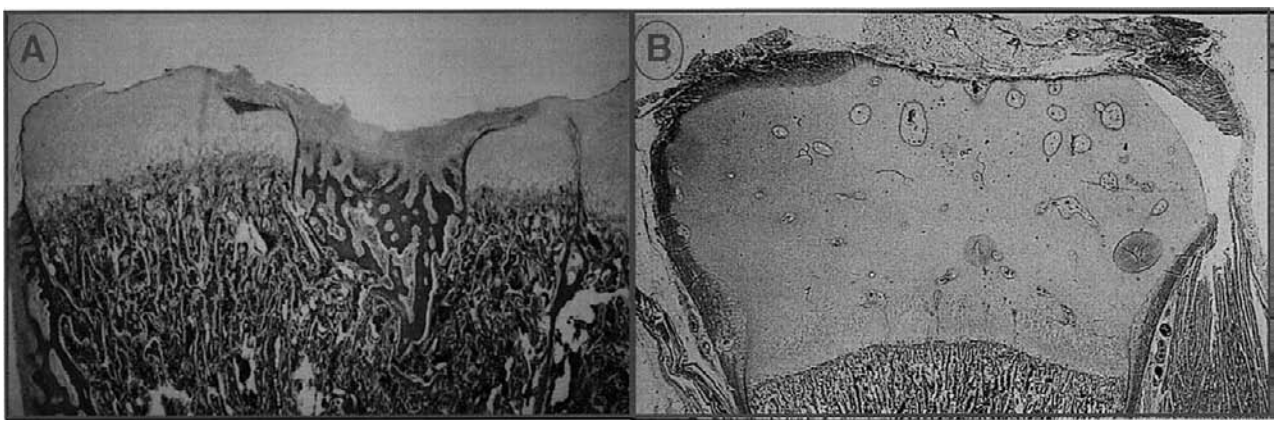

Figure 9 Section of the upper tibia end from a patient with BLC (A) and an age-matched control. Note the severely reduced size of the growth plate, the irregular boundary between the growth plate and the primary spongiosa, and the increased cortical bone thickness. From Loshkajian *et al.* (1997), with permission, and Anne-Lise Delezoide, personal collection. (See also color plate.)

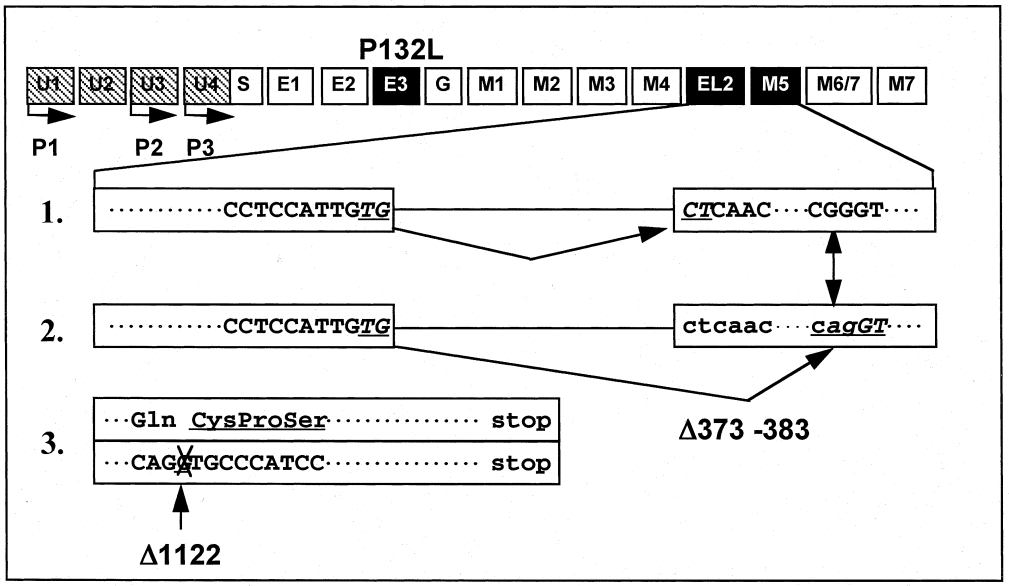

Figure 10 Schematic representation of the PTH/PTHrP receptor gene and location of the nucleotide changes identified in patients with Blomstrand's disease. Untranslated and translated exons gene (top) are indicated by stripped and open boxes respectively, and introns are indicated by solid lines. The mRNAs derived from the P1 or the P2 promoter are indicated by the solid and dotted lines, respectively, below the untranslated exons; the transcript derived from the P3 promoter starts within exon U4/S. The homozygous P132L mutation identified in one patient with Blomstrand's disease is indicated above exon M3 (Zhang *et al.,* 1998; Karaplis *et al.,* 1998). Three partial nucleotide sequences are shown (bottom): (1) wild-type exon EL2 and exon M5 (normal splice-donor and splice-acceptor sites at the junction between exon EL2/intron N11 and intron N11/exon M5, respectively, are underlined); (2) the mutation in exon M5 (nucleotide 1176 of the human cDNA is shown in bold) introduces a novel splice-acceptor site in the maternal allele which leads to the deletion of amino acid residues 373–383 of the human PTH/PTHrP receptor (Jobert et al., 1998); (3) the nucleotide deletion in exon EL2 (nucleotide 1122 of the human cDNA) was identified in another patient with Blomstrand's chondrodysplasia; the "arrow" indicates the amino acid (glutamine at position 364 of the human PTH/PTHrP receptor) after which the protein sequence is altered due to a shift in reading frame (Karperien *et al.,* 1999).

impaired binding of radiolabeled PTH and PTHrP analogs, greatly reduced agonist-stimulated cAMP accumulation (see Fig. 11), and showed no measurable inositol phosphate response. It is important to note, however, that cells expressing the P132L mutant receptor showed some agonist-induced second messenger response and showed little, but detectable, specific binding of radiolabeled PTHrP.

A homozygous deletion of G at position 1122 (exon EL2) was identified in a third case of BLC (Karperien *et al.,* 1999). This mutation led to a shift in the open reading frame, which

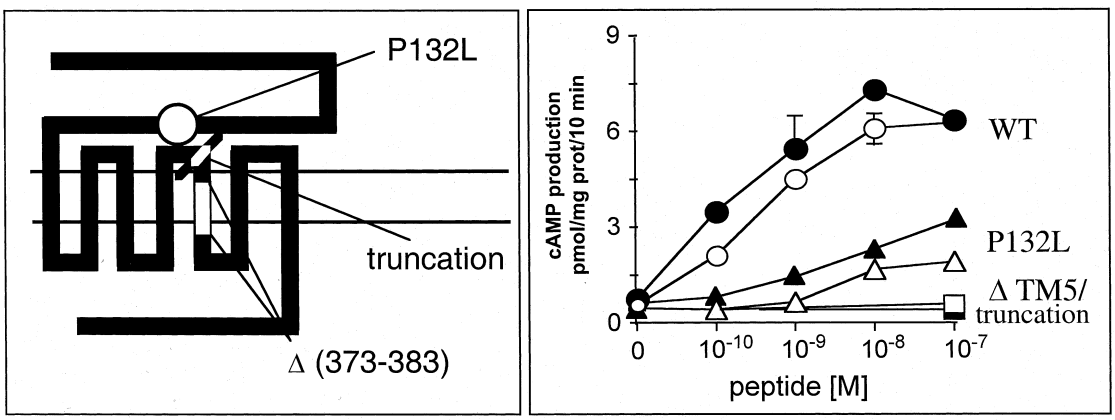

Figure 11 Schematic representation of the PTH/PTHrP receptor and functional evaluation of the wild-type and mutant receptors in COS-7 cells. Approximate location of loss-of-function mutation identified in patients with Blomstrand's disease (left) and cAMP accumulation in response to PTH (closed symbols) or PTHrP (open symbols) by wild-type and mutant PTH/PTHrP receptors. Modified from Karperien *et al.* (1999) and Zhang *et al.* (1998).

resulted in a truncated protein that completely diverged from the wild-type receptor sequence after amino acid 364, and thus lacked transmembrane domains 5, 6, and 7, the connecting intra- and extracellular loops, and the cytoplasmic tail (Δ365–593). Functional analysis of the D365–593 recombinant mutant receptor in COS-7 cells demonstrated a total absence of PTH-stimulated accumulation of intracellular cAMP, which was confirmed in studies performed with the patient's dermal fibroblasts (see Fig. 11).

As for the other cases of BLC, these findings provided a plausible explanation for the severe abnormalities in endochondral bone formation. The abnormalities in mammary gland and tooth development furthermore support the conclusion that the PTH/PTHrP receptor has in humans and mice identical roles in the development of these organs. Compatible with the role of PTH/PTHrP receptor and PTHrP in organogenesis, both were demonstrated to be expressed in the developing breast and tooth of human control fetuses (Wysolmerski *et al.,* 2001). It is also worth noting that abnormalities in skeletal development in the fetuses carrying the P132L mutation, which inactivates the PTH/PTHrP receptor incompletely, are less severe than those observed in most cases, particularly with regard to the bones of the lower limbs (Young *et al.,* 1993; Karperien *et al.,* 1999; Oostra *et al.,* 2000). This led to the proposal that two forms of BLC can be distinguished clinically and on the basis of the *in vitro* characteristics of the mutant PTH/PTHrP receptors (Oostra *et al.,* 2000). Taken together the findings in patients with BLC suggested that this rare human disease is the equivalent of the mouse PTH/PTHrP receptor "knockout" (Lanske *et al.,* 1996).

Inactivating mutations have been described in several other G protein-coupled receptors (reviewed in Spiegel, 1998, 1999). For example, genetic forms of growth hormone deficiency were shown to be caused by mutations in the growth hormone-releasing hormone receptor (Wajnrajch *et al.,* 1996; Godfrey *et al.,* 1993), mutations in the thyrotropin receptor are the cause of inherited hypothyroidism (Stein *et al.,* 1994; Gu *et al.,* 1995; Biebermann *et al.,* 1998), and mutations in the calcium-sensing receptor have been associated with familial hypocalciuric hypercalcemia and neonatal severe primary hyperparathyroidism (reviewed in Brown, 1999).

Conclusions

The findings in PTHrP- and PTH/PTHrP receptor-ablated mice, and in transgenic animals overexpressing PTHrP in the growth plate, predicted that human disorders caused by mutations in either of these two proteins would be associated with severe abnormalities in endochondral bone formation and in the regulation of mineral ion homeostasis. These insights from genetically manipulated animals led to the identification of activating and inactivating PTH/PTHrP receptor mutations in two rare genetic disorders, Jansen's and Blomstrand's diseases, respectively. In addition to resolving the pathogenesis of puzzling human disorders, these naturally occurring PTH/PTHrP receptor mutations have provided important new insights into the importance of this G protein-coupled receptor in mammalian development. The availability of mutant, constitutively active PTH/PTHrP receptors has furthermore provided novel tools for studying bone and cartilage development independent of PTH and PTHrP.

CHAPTER 64

Pseudohypoparathyroidism

Michael A. Levine

Department of Pediatrics, Division of Pediatric Endocrinology, The Johns Hopkins University School of Medicine, Baltimore, Maryland 21287

Overview

The term *pseudohypoparathyroidism* (PHP) refers to a group of metabolic syndromes in which biochemical hypoparathyroidism (i.e., hypocalcemia and hyperphosphatemia) is due not to deficiency of parathyroid hormone (PTH) but rather to unresponsiveness of target tissues to the biological actions of PTH. Plasma levels of PTH are increased in patients with PHP, a feature that distinguishes these patients from those with true hypoparathyroidism, in whom parathyroid insufficiency is associated with low plasma levels of PTH. Thus PHP differs fundamentally from true hypoparathyroidism.

In their original report of PHP, Fuller Albright and his associates described the failure of patients with this syndrome to show a phosphaturic response to injected parathyroid extract (Albright *et al.,* 1942). These observations led to the speculation that biochemical hypoparathyroidism in PHP was due to an inability of the target organs, bone and kidney, to respond to PTH.

PTH Signal Transduction

PTH regulates mineral metabolism and skeletal homeostasis by modulating activity of specialized target cells that are present in bone and kidney. PTH action first requires binding of the hormone to specific receptors that are expressed on the plasma membrane of target cells. The classical PTH receptor is a ~75-kDa glycoprotein that is often referred to as the PTH/PTHrP or type 1 PTH receptor (PTH1R). Molecular cloning of cDNA's encoding PTH receptors from several species (Schipani *et al.,* 1993; Abou Samra *et al.,* 1992; Juppner *et al.,* 1991; Adams *et al.,* 1995) has indicated that the PTH1R expressed on bone and that expressed in kidney cells are identical. The PTH1R binds both PTH and parathyroid hormone-related protein (PTHrP), a factor made by diverse tumors that cause humorally mediated hypercalcemia, with equivalent affinity, which accounts for the similar activities of both hormones. In addition to the classical PTH receptor (PTH1R), two other receptor proteins, termed the type 2 and type 3 PTH receptors, with unique characteristics, have been identified. The human type 2 PTH receptor (PTH2R) has 52% amino-acid sequence identity to the human PTH1R, but is not expressed in conventional PTH target tissues (i.e., bone and kidney). The PTH2R interacts with PTH but not PTHrP (Behar *et al.,* 1996;Usdin *et al.,* 1995) and is most highly expressed in regions of the brain that lack PTH mRNA (Usdin *et al.,* 1995). The recently identified hypothalamic peptide, tuberoinfundibular peptide, of 39 amino acids (TIP39), binds the PTH2R with subnanomolar affinity (0.59 nM) and strongly activates adenylyl cyclase, suggesting that TIP39 may represent the natural ligand for this receptor. Although TIP39 binds binds to the PTH1R with moderate affinity (59 n*M*), it produces little or no stimulation of cAMP accumulation (Clark *et al.,* 1998; Hoare *et al.,* 2000a). The type 3 receptor (PTH3R) can interact with both PTH and PTHrP, and activates adenylyl cyclase but not phospholipase C (Hoare *et al.,* 2000b; Rubin and Juppner, 1999). However, as PTH does not appear to exist in fish, it is likely that a PTHrP-like peptide is the endogenous ligand for the PTH3R. All three PTH receptors are members of a large family of receptors that bind hormones, neurotransmitters, cytokines, light photons, taste, and odor molecules. These receptors consist of a single polypeptide chain that is predicted by hydrophobicity plots to span the plasma membrane with seven alpha helices (i.e., heptahelical), forming three extracellular and three or four intracellular loops and a cytoplasmic carboxyl-terminal tail. The heptahelical receptors are coupled

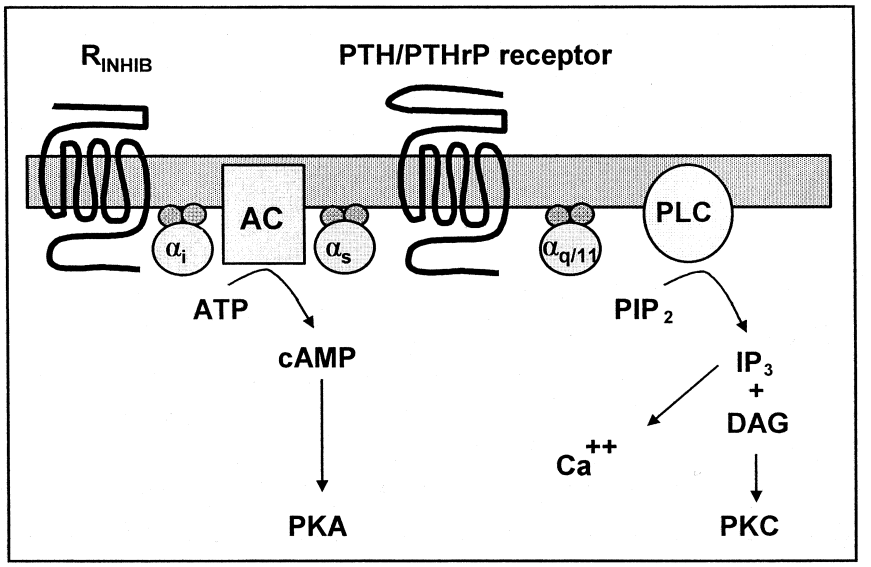

Figure 1 Cell surface receptors for PTH are coupled to two classes of G proteins. G_s mediates stimulation of adenylyl cyclase (AC) and the production of cAMP, which in turn activates protein kinase A (PKA). G_q stimulates phospholipase C (PLC) to form the second messengers inositol-(1,4,5)-trisphosphate (IP_3) and diacylglycerol (DAG) from membrane-bound phosphatidylinositol-(4,5)-bisphosphate. IP_3 increases intracellular calcium (Ca^{2+}) and DAG stimulates protein kinase C (PKC) activity. Each G protein consists of a unique a chain and a $\beta\gamma$ dimer.

by heterotrimeric ($\alpha\beta\gamma$) G proteins (Neer, 1995) to signal effector molecules localized to the inner surface of the plasma membrane (Fig. 1).

The heterotrimeric G proteins share a common structure consisting of an α subunit and a tightly coupled $\beta\gamma$ dimer. The α subunit interacts with detector and effector molecules, binds GTP, and possesses intrinsic GTPase activity (Bohm *et al.,* 1997). Mammals have over 20 different G protein α chains encoded by 16 genes; additional protein diversity results from the generation of alternatively spliced mRNAs. The mammalian α subunits are between 40 and 90% identical in amino acid sequence, and their overall length varies between 350 and 395 residues. The 16 α-subunits can be divided into four classes based both on their degree of primary sequence homology and on functional similarities (G_s, G_i, G_q, G_{12}). Within the past several years the crystal structures of various G protein α subunits bound to GDP, GTPγS, or aluminum fluoride and of G protein heterotrimers have been defined. G protein α subunits are composed of a GTPase domain, which is very similar to the structure of the smaller ras-like proteins and other members of the GTPase superfamily, and a variable helical domain, which is less conserved and present only in the α subunits of heterotrimeric G proteins. The GTPase domain contains the conserved guanine nucleotide-binding site and the residues necessary for effector activation. Guanine nucleotides sit within a cleft between the two domains. The helical residues appears to be important for maintaining guanine nucleotide in the binding pocket, as disruption of interactions between the two domains leads to an increased rate of GDP release in the basal state.

The α subunits associate with a smaller group of β (at least 5) and γ (more than 11) subunits (Clapham and Neer, 1997). The β and γ subunits combine tightly with one another (Schmidt and Neer, 1991; Schmidt *et al.,* 1992) and the resultant $\beta\gamma$ dimers demonstrate specific associations with different α subunits (Rahmatullah and Robishaw, 1994; Rahmatullah *et al.,* 1995). Combinatorial specificity in the associations between various G protein subunits provides the potential for enormous diversity and may allow distinct heterotrimers to interact selectively with only a limited number of the more than 1000 G protein-coupled receptors (Taussig and Zimmermann, 1998; Wess, 1998). At present it is unknown whether specific G protein subunit associations occur randomly or if there are regulated mechanisms that determine the subunit composition of heterotrimers.

The activation state of the heterotrimeric G protein is regulated by a mechanism in which the binding and hydrolysis of GTP acts a molecular timing switch (Fig. 2). In the basal (inactive) state, G proteins exist in the heterotrimeric form with GDP bound to the α chain. The association of α with $\beta\gamma$ occludes the sites of interaction of both of these molecules with downstream effector molecules, and the inactive state is maintained by an extremely slow rate of dissociation of GDP from the α chain ($K \approx 0.01$/min). The interaction of a ligand-bound receptor with a G protein facilitates the release of tightly bound GDP and the subsequent binding of cytosolic GTP. The binding of GTP to the α chain induces conformational changes that facilitate the dissociation of the α-GTP chain from the $\beta\gamma$ dimer and the receptor. The free α-GTP chain assumes an active conformation in which a new surface is formed that enables the α chain to interact with target

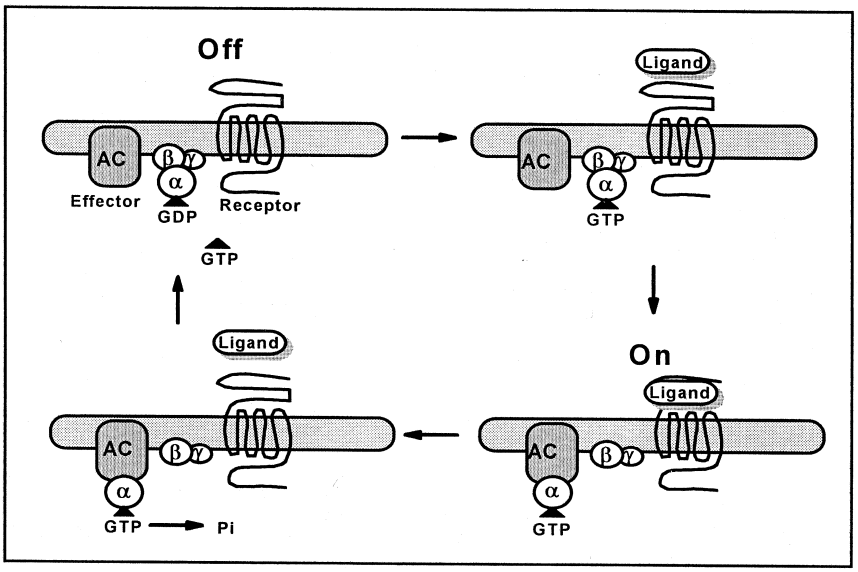

Figure 2 The cycle of hormone-dependent GTP binding and hydrolysis that regulates heterotrimeric G protein signal transduction. In the nonstimulated, basal (Off) state, GDP is tightly bound to the α chain of the heterotrimeric G protein. Binding of an agonist (Ligand) to its receptor (depicted with seven transmembrane spanning domains) induces a conformational change in the receptor and enables it to activate the G protein. The G protein now releases GDP and binds GTP present in the cytosol. The binding of GTP to the α chain leads to dissociation of the α-GTP from the $\beta\gamma$ dimer, and each of these molecules is now free to regulate downstream effector proteins. The hydrolysis of GTP to GDP by the intrinsic GTPase of the α chain promotes reassociation of α-GDP with $\beta\gamma$ and the inactive state is restored. The heterotrimeric G protein is ready for another cycle of hormone-induced activation.

enzymes and ion channels with 20- to 100-fold higher affinity than in the GDP bound state. Early studies had suggested that only the free α-GTP chain could regulate downstream signaling and that the $\beta\gamma$ dimers served only the passive role of localizing the α chain to the plasma membrane. However, more recent studies have shown that $\beta\gamma$ dimers also participate in the downstream signaling events through interaction with an ever-widening array of targets (Gautam *et al.,* 1998; Clapham and Neer, 1993); for example, $\beta\gamma$ dimers can influence activity of certain forms of adenylyl cyclase and phospholipase C, open potassium channels, participate in receptor desensitization, mediate mitogen-activated protein (MAP) kinase phosphorylation, and modulate leukocyte chemotaxis.

G protein signaling is terminated by the hydrolysis of α-GTP to α-GDP by a slow ($k_{cat} \approx 4$/min) GTPase that is characteristic of the α chain. This process promotes dissociation of the α chain from effector molecules and promotes reassociation with G protein $\beta\gamma$ dimers, thus preventing further interaction of these subunits with downstream effectors. The GTPase reaction is a high-energy transition state that requires association of the γ-phosphorous atom of GTP with the oxygen of a water molecule. Arginine^{-201} and glutamine^{-227} in Gα_s function as "fingers" to position the γ-phosphate of GTP. With hydrolysis of GTP to GDP, the α-GDP chain reassociates with the $\beta\gamma$ dimer and the beterotrimeric G protein is capable of participating in another cycle of receptor-activated signaling. Thus, the GTPase of the Gα chain provides a molecular "timing switch" that controls the duration, and thereby the intensity, of the signaling event. The intrinsic rates of GTP hydrolysis by G protein α chains differ widely, and interactions that influence the rate of the GTPase reaction can have profound consequences. Several factors can act as "GTPase-activating proteins" or GAPs (Ross *et al.,* 1998) to accelerate the slow intrinsic rate of GTP hydrolysis by Gα proteins. For example, RGS proteins (for "regulators of G protein signaling") act as GAPs for G_i, G_o G_z, and G_q by stabilizing the transition state of the GTPase reaction, thereby lowering the activation energy for this reaction. RGS proteins can stimulate a 40-fold increase in the catalytic rate of GTP hydrolysis of these α chains, and thus can markedly accelerate the termination of G protein signaling (see recent reviews (Siderovski *et al.,* 1999; Hepler, 1999) (Fig. 2)

Upon binding of either PTH or PTHrP, the PTH1R receptor activates G_s, leading to stimulation of adenylyl cyclase and generation of cAMP, and at about 10-fold higher concentration of ligand, the receptor also activates Gq, leading to stimulation of phospholipase C and generation of inositol-(1,4,5)-trisphosphate (IP3) and diacylglycerol (DAG) (Fig. 1). Thus, the PTH1R, as well as the calcitonin (Chabre *et al.,* 1992) and many other related receptors, can couple to both G_s and $G_{q/11}$. Each of these receptors has been shown to stimulate cAMP formation and phosphoinositide breakdown, the latter with an EC_{50} one order of magnitude higher than for adenylyl cyclase stimulation. One study examining the labeling of specific G proteins by GTP-γ-azidoanilide in response to PTH1R receptor stimulation

directly demonstrated coupling of PTH1R to G_s and G_q and minimal coupling to Gi_1 (Schwindinger *et al.,* 1998a). The best-characterized mediator of PTH action is cAMP, which rapidly activates protein kinase A (Bringhurst *et al.,* 1989). The relevant target proteins that are phosphorylated by protein kinase A and the precise mode(s) of action of these proteins remain uncharacterized, though proteins that activate genes responsive to cAMP and ion channel proteins are strong candidates. In contrast to the well-recognized biologic effects of cAMP in PTH target tissues, the physiological importance of metabolites of phosphotidylinositol hydrolysis and intracellular calcium as PTH-induced second messengers has not yet been established. A growing number of studies have revealed that the number of PTH receptors expressed, as well as the concentration of G protein and PTH, cooperates to determine the precise signal response.

General Pathophysiology

In addition to the clinical and biochemical features of hypoparathyroidism, the patients described by Albright exhibited a distinctive constellation of developmental and skeletal defects, subsequently referred to as Albright hereditary osteodystrophy (AHO), and including a round face; short, stocky physique; brachydactyly; heterotopic ossification; and mental retardation. The relationship between the biochemical abnormalities (hypocalcemia and hyperphosphatemia) and AHO could not be explained by Albright, and yet remains unclarified. Indeed, in certain families some affected members may show both AHO and PTH resistance whereas other family members may have AHO without evidence of any endocrine dysfunction, a disorder Albright termed "pseudo-pseudohypoparathyroidism" (pseudoPHP) to emphasize the physical similarities but biochemical differences between these patients and patients with PHP (Albright *et al.,* 1952).

The diagnostic classification of PHP is further extended by the existence of additional variants in which patients manifest PTH resistance and biochemical hypoparathyroidism but lack any of the features of AHO (Winter and Hughes, 1980; Drezner *et al.,* 1973). A classification of the many different forms of PHP is presented in Table I.

Characterization of the molecular basis for PHP commenced with the observations by Chase and Aurbach that cAMP mediates many of the actions of PTH on kidney and bone, and that administration of biologically active PTH to normal subjects leads to a significant increase in the urinary excretion of nephrogenous cAMP and phosphate (Chase *et al.,* 1969). The PTH infusion test remains the most reliable test available for the diagnosis of PHP, and enables distinction between several variants of the syndrome (Fig. 3). Patients with PHP type 1 fail to show an appropriate increase in urinary excretion of both nephrogenous cAMP and phosphate (Chase *et al.,* 1969), suggesting that an abnormality in the renal PTH receptor–adenylyl cyclase complex that produces cAMP is the basis for impaired PTH responsiveness. Subsequent studies by Bell *et al.,* in which administration of dibutyryl cAMP to patients with PHP type 1 produced a phosphaturic response, provided additional support for this hypothesis, and demonstrated that the renal response mechanism to cAMP was intact (Bell *et al.,* 1972). These studies have led to the conclusion that proximal renal tubule cells are unresponsive to PTH. By contrast, cells in other regions of the kidney appear responsive to PTH, as evidenced by the observation that urinary calcium excretion in patients with PHP type 1 is less than in patients with hormonopenic hypoparathyroidism after normalization of blood calcium levels in each group by vitamin D and oral calcium supplements (Mizunashi *et al.,* 1990; Shima *et al.,* 1988). Moreover, renal handling of calcium (and sodium) in response to exogenous PTH also appears to be normal in patients with PHP type 1 (Stone *et al.,* 1993). These results indicate that

Table I Characteristic Features of the Various Forms of Pseudohypoparathyroidism

	PHP type 1a	Pseudo-PHP	PHP type 1b	PHP type 1c	PHP type 2
Physical appearance	Albright hereditary, osteodystrophy may be subtle or (rarely) absent		Normal	Albright hereditary osteodystrophy	Normal
Response to PTH					
Urine cAMP	Defective	Normal	Defective	Defective	Normal
Urine phosphorous	Defective	Normal	Defective	Defective	Defective
Serum calcium level	Low or (rarely) normal	Normal	Low	Low	Low
Hormone resistance	Generalized	Absent	Limited to PTH target tissues	Generalized	Limited to tissues
$G\alpha_s$ activity	Reduced	Reduced	Normal	Normal	Normal
Inheritance	Autosomal dominant		Autosomal dominant (most cases)	Unknown	Unknown
Molecular defect	Heterozygous mutations in the *GNAS1* gene		Imprinting defect in *GNAS1* gene	Unknown	Unknown

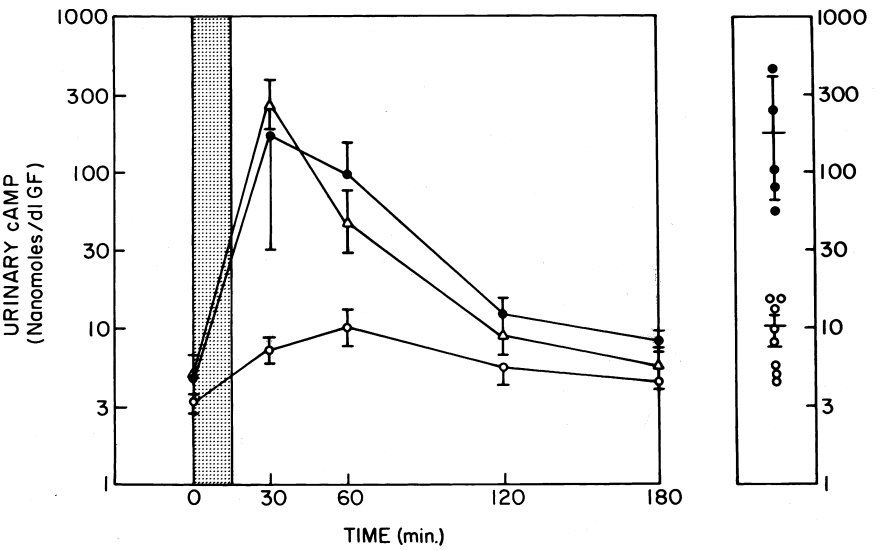

Figure 3 Urinary cAMP excretion in response to an infusion of bovine parathyroid extract (300 USP units). The peak response in normal subjects (△) as well as those with pseudo-PHP (●) is 50- to 100-fold times basal. Subjects with PHP type 1a (○) or PHP type 1b (not shown) show only a two- to five-fold increase. Urinary cAMP is expressed as nanomoles per 100 ml of GF, U_{cAMP} (nanomoles per 100 ml GF) = U_{cAMP} (nanomoles/dl) X S_{Cre} (mg/dl)/U_{Cre} (mg/dl). Reprinted with permission from Levine *et al.* (1986).

calcium reabsorption in the distal tubule is responsive to circulating PTH in subjects with PHP type 1, and imply that adequate amounts of cAMP are produced in these cells or that other second messengers (e.g., cytosolic calcium or diacylglycerol) may be responsible for PTH action (Fig. 1).

Administration of PTH to subjects with the less common form of the disorder, PHP type 2, produces a normal increase in urinary cAMP but fails to elicit an appropriate phosphaturic response (Drezner *et al.,* 1973). These observations have suggested that PTH resistance in PHP type 2 results from a biochemical defect that is either unrelated or distal to the PTH-stimulated generation of cAMP.

It has been generally assumed that bone cells in patients with PHP type 1 are innately resistant to PTH, but this remains unproved. In fact, cultured bone cells from a patient with PHP type 1 have been shown to increase intracellular cAMP normally in response to PTH treatment *in vitro* (Murray *et al.,* 1993). Evidence that bone cells are unresponsive to PTH is largely inferred from the observation that patients with PHP type 1 are hypocalcemic and that administration of PTH does not increase the plasma calcium level. However, clinical, radiological, or histological evidence of increased bone turnover and demineralization (Fig. 4) is common in patients with PHP type 1. One possible explanation for the variable bone responsiveness to PTH is the existence of two distinct cellular systems in bone upon which PTH exerts action: the remodeling system and the mineral mobilization or homeostatic system. The bone remodeling system appears to be more responsive to PTH in patients with PHP type 1 than the homeostatic system. This variability may reflect the lesser dependence of the remodeling system upon normal

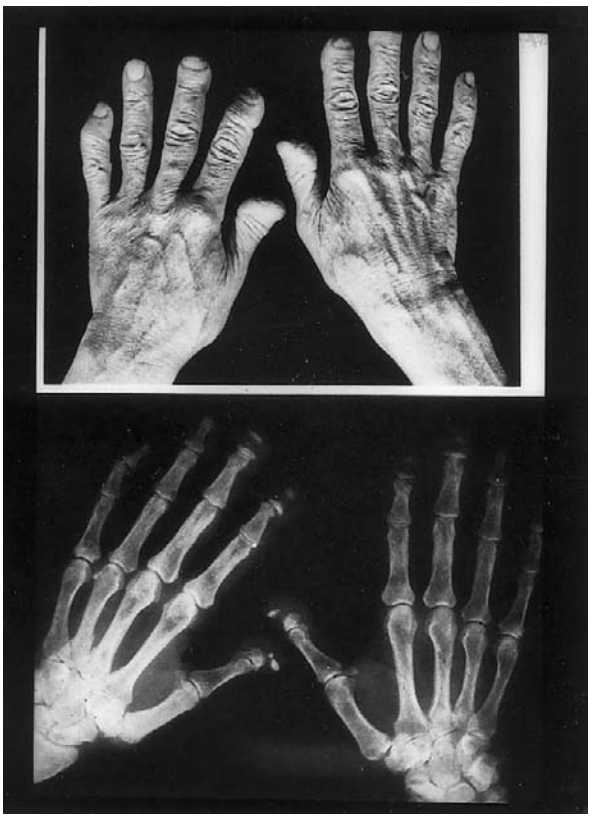

Figure 4 Photograph and radiograph of hands of a patient with marked hyperparathyroid bone disease. Marked periosteal bone erosion in terminal phalanges has resulted in "pseudoclubbing." From Levine *et al.,* (1982).

plasma levels of $1,25(OH)_2D$. Plasma levels of $1,25(OH)_2D$ are reduced in hypocalcemic patients with PHP type 1 (Drezner *et al.,* 1976) and could explain the concurrence of hypocalcemia and increased skeletal remodeling in many of these patients. Hypocalcemia leads to a compensatory overproduction of PTH, which could eventually overcome the $1,25(OH)_2D$ dependency for remodeling but not for PTH-stimulated calcium mobilization.

A role for $1,25(OH)_2D$ in modulating the responsiveness of the calcium homeostatic system to PTH is suggested by several observations. First, the calcemic response to PTH is deficient not only in patients with PHP type 1, but also in patients with other hypocalcemic disorders in which plasma levels of $1,25(OH)_2D$ are low. Moreover, normalization of the plasma calcium level in patients with PHP type 1 by administration of physiologic amounts of $1,25(OH)_2D$ or pharmacological amounts of vitamin D restores calcemic responsiveness (Drezner and Haussler, 1979). Second, patients with PHP type 1 who have normal serum levels of calcium and $1,25(OH)_2D_3$ without vitamin D treatment (so-called "normocalcemic" PHP) show a normal calcemic response to administered PTH (Drezner and Haussler, 1979). These findings suggest that $1,25(OH)_2D$ deficiency is the basis for the lack of a calcemic response to PTH in hypocalcemic patients with PHP type 1 and challenge the premise that bone cells are intrinsically resistant to the actions of PTH.

Subjects with PHP type 1 have increased serum levels of phosphate owing to an inability of PTH to decrease phosphate reabsorption in the kidney. Hypocalcemia *per se* may also contribute to the development of hyperphosphatemia, as very low levels of intracellular calcium impair renal phosphate clearance. Accordingly, restoration of plasma calcium levels to normal by chronic treatment with calcium and vitamin D can reduce elevated levels of serum phosphorous. Similar therapy has been shown to reverse the defective phosphaturic response to administered PTH in certain patients with PHP type 1, although the urinary cAMP response remains markedly deficient (Stogmann and Fischer, 1975). Therefore, persistence of a blunted urinary cAMP response to PTH in PHP type 1 patients in whom chronic vitamin D therapy has led to normalization of plasma calcium levels and restoration of a phosphaturic response need not imply, as has been at least suggested (Stogmann and Fischer, 1975), that there is no relationship between cAMP production and phosphate clearance.

Hyperphosphatemia has several important metabolic consequences. Elevated plasma phosphate levels can decrease plasma calcium levels both by increasing the deposition of extracellular calcium into bone and soft tissues and by decreasing the mobilization of calcium from the skeleton. Furthermore, elevated plasma phosphate concentrations can reduce 1-α-hydroxylase activity in renal tubular cells and decrease synthesis of $1,25(OH)_2D$. This effect may be of equal or greater significance than the defective renal cAMP response to PTH as a cause of deficient production of $1,25(OH)_2D$. It is therefore likely that reduced synthesis of $1,25(OH)_2D$ in PHP type 1 arises as a consequence of two defects related to PTH resistance: (1) decreased renal phosphate clearance, which results in elevated plasma phosphate levels that inhibit activity of renal 1-α-hydroxylase; and (2) decreased PTH activation of the enzyme. The overall evidence suggests that the disturbances in calcium, phosphorous, and vitamin D metabolism in most patients with PHP type 1 result directly or indirectly from reduced responsiveness of both bone and kidney to PTH. Hypocalcemia results from impaired mobilization of calcium from bone, reduced intestinal absorption of calcium (via deficient generation of $1,25(OH)_2D$), and urinary calcium loss. Of these defects, the diminished movement of calcium out of bone stores into the extracellular fluid probably has the greatest role in producing hypocalcemia. Intensive treatment with calcitriol ($1,25(OH)_2D$) or other vitamin D analogs improves intestinal calcium absorption and bone calcium mobilization, restores plasma calcium to normal, and reduces circulating PTH levels. Thus, although PTH resistance appears to be the proximate biochemical defect, the major abnormalities in mineral metabolism found in patients with PHP type 1 can be largely explained on the basis of deficiency of circulating $1,25(OH)_2D$.

Molecular Classification of Pseudohypoparathyroidism

Hormone action may be divided conceptually into prereceptor, receptor, and postreceptor events; defects in each of these steps have been proposed as the basis of hormone resistance in PHP (Fig. 1). For example, a circulating inhibitor of PTH action has been proposed as a cause of PTH resistance on the basis of studies showing an apparent dissociation between plasma levels of endogenous immunoreactive and bioactive PTH in subjects with PHP type 1. Despite high circulating levels of immunoreactive PTH, the levels of bioactive PTH in many patients with PHP type 1 have been found to be within the normal range when measured with highly sensitive renal (de Deuxchaisnes *et al.,* 1981) and metatarsal (Bradbeer *et al.,* 1988) cytochemical bioassay systems. Furthermore, plasma from many of these patients has been shown to diminish the biological activity of exogenous PTH in these *in vitro* bioassays (Loveridge *et al.,* 1982). Currently, the nature of this putative inhibitor or antagonist remains unknown. The observation that prolonged hypercalcemia can remove or reduce significantly the level of inhibitory activity in the plasma of patients with PHP has suggested that the parathyroid gland may be the source of the inhibitor. In addition, analysis of circulating PTH immunoactivity after fractionation of patient plasma by reversed-phase high-performance liquid chromatography has disclosed the presence of aberrant forms of immunoreactive PTH in many of these patients (Mitchell and Goltzman, 1985). Although it is

conceivable that a PTH inhibitor may cause PTH resistance in some patients with PHP, it is more likely that circulating antagonists of PTH action arise as a consequence of the sustained secondary hyperparathyroidism that results from the primary biochemical defect.

By contrast, molecular studies have provided confirmation that defects in the PTH1R-G protein-coupled signaling pathway are responsible for PTH resistance in many patients with PHP type 1. Patients with PHP type 1a show decreased responsiveness to a variety of hormones that utilize cAMP as a second messenger, and cells from these patients have a 50% reduction in expression or activity of the α chain of Gs, the G protein that couples receptors to adenylyl cyclase (Fig. 1). Mutations in the *GNAS1* gene, which encodes $G\alpha_s$, have been identified in most cases of PHP type 1a. Patients with PHP type 1c also show resistance to multiple hormones, but have apparently normal levels of $G\alpha_s$. Multihormone resistance in these patients may be due to defects in other components of the signal transduction system that are not tissue specific, including some forms of adenylyl cyclase (Barrett *et al.,* 1989). Patients with PHP type 1a or 1c also have AHO. By contrast, hormone resistance is limited to PTH target tissues in patients with PHP type 1b. These patients have normal levels of $G\alpha_s$ in accessible cells and lack features of AHO. Defective imprinting of the *GNAS1* gene appears to be the basis for selective deficiency of $G\alpha_s$ in the proximal renal tubule.

Finally, patients with PHP type 2 have a normal urinary cAMP response to PTH but fail to generate a phosphaturic response. These subjects may have a defect in cAMP-dependent protein kinase A, one of its substrates or targets, or in another PTH signaling pathway (e.g., phospholipase C).

Pseudohypoparathyroidism Type 1a and Pseudopseudohypoparathyroidism

Cell membranes from patients with PHP type 1a show an approximately 50% reduction in expression or activity of $G\alpha_s$ protein (Levine *et al.,* 1986) (Fig. 5). This generalized deficiency of $G\alpha_s$ may impair the ability of PTH, as well as many other hormones and neurotransmitters, to activate adenylyl cyclase and thereby may account for multihormone resistance (Fig. 6). In addition to hormone resistance, patients with PHP type 1a also manifest the peculiar constellation of developmental and somatic defects that are collectively termed AHO (Fig. 7; see Clinical Features below) (Albright *et al.,* 1942).

Early studies of PHP type 1a led to the identification of families in which some individuals had signs of AHO but lacked apparent hormone resistance (i.e., pseudo-PHP). The observation that PHP type 1a and pseudo-PHP can occur in the same family first suggested that these two disorders might reflect variability in expression of a single genetic lesion. Support for this view comes from studies indicating that within a given kindred, subjects with either pseudo-PHP or PHP type 1a have equivalent functional $G\alpha_s$ deficiency (Fig. 5) (Levine *et al.,* 1986, 1988), and that a transition from hormone responsiveness to hormone resistance may occur (Barr *et al.,* 1994). It, therefore, seems appropriate to apply the term AHO to both of these variants in acknowledgment of the clinical and biochemical characteristics that patients with PHP type 1a and pseudo-PHP share (Mann *et al.,* 1962).

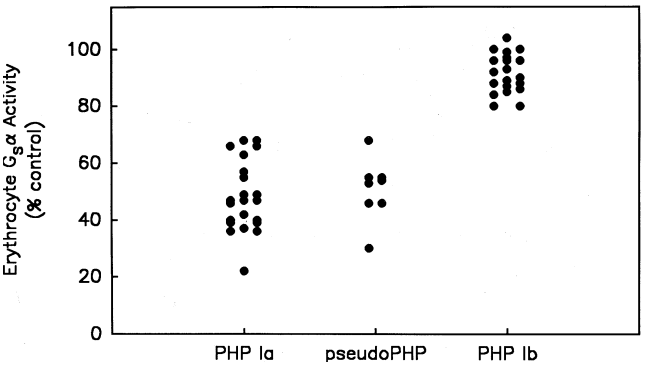

Figure 5 $G\alpha_s$ activity of erythrocyte membranes. $G\alpha_s$ is quantified in complementation assays with S49 cyc$^-$ membranes, which genetically lack $G\alpha_s$ but retain all other components necessary for hormone-response adenylyl cyclase activity. Activity is reduced approximately 50% in patients with AHO and subjects with either PHP type 1a or pseudo-PHP, but is normal in patients with PHP type 1b.

Molecular Defect in Albright Hereditary Osteodystrophy

The discovery that $G\alpha_s$ deficiency results from inactivating mutations in the *GNAS1* gene, located at 20*q*13.2–*q*13.3 (Levine *et al.,* 1991), first provided confirmation of autosomal dominant transmission of AHO and subsequently facilitated studies to address the unusual pattern of inheritance of PHP type 1a and pseudo-PHP. *GNAS1* is a complex gene (Kozasa *et al.,* 1988) composed of at least 16 exons, including 3 alternative first exons (Hayward *et al.,* 1998a,b; Swaroop *et al.,*

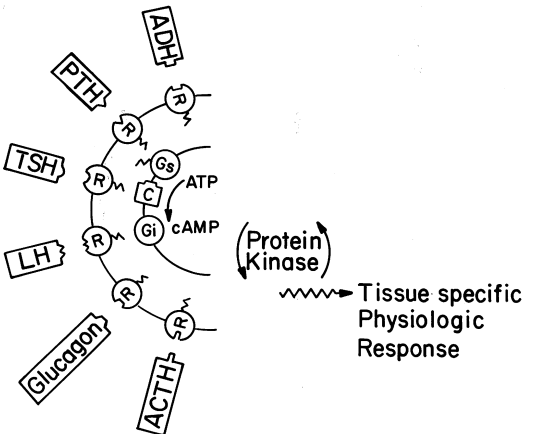

Figure 6 Model of multihormone resistance in subjects with $G\alpha_s$ deficiency.

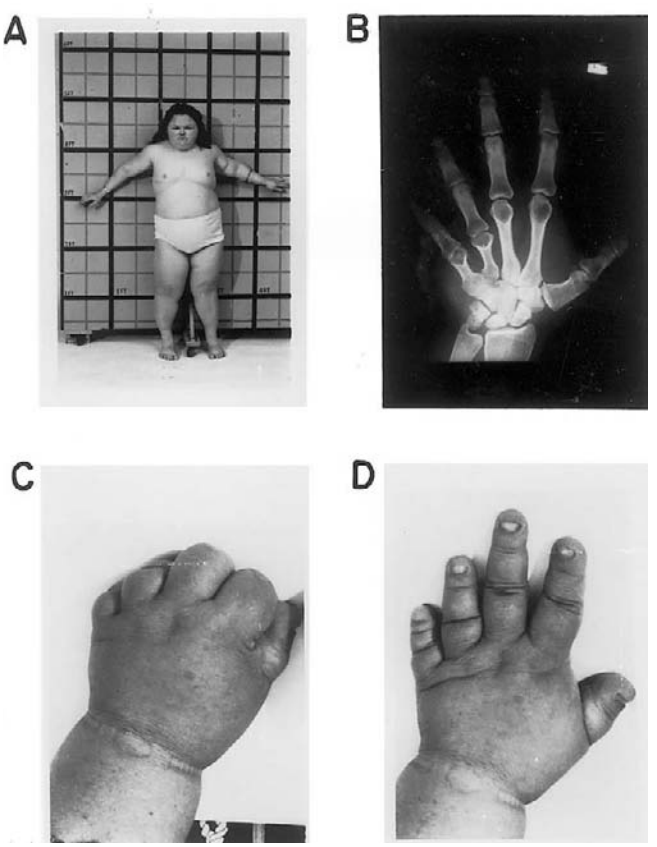

Figure 7 Typical features of Albright hereditary osteodystrophy. (A) A young woman with characteristic features of AHO; note the short stature, disproportionate shortening of the limbs, obesity, and round face. (B) Radiograph of patient's hand showing marked shortening of fourth and fifth metacarpals. (C) Archibald sign, with dimples in place of knuckles. (D) Brachydactyly of the hand, note thumb sign and shortening of the fourth and fifth digits.

1991) (Fig. 8). Alternative splicing of nascent transcripts derived from exons 1–13 generates four mRNAs that encode $G\alpha_s$ proteins. Deletion of exon 3 results in the loss of 15 codons from the mRNA, while use of an alternative splice site in exon 4 results in the insertion of a single additional codon into the mRNA. This produces two $G\alpha_s$ isoforms with apparent molecular weights of 45 kDa and two isoforms with apparent molecular weights of 52 kDa (Kozasa *et al.,* 1988). The long and short forms of $G\alpha_s$ exhibit tissue-specific patterns of expression (Bhatt *et al.,* 1988) and can both can stimulate adenylyl cyclase and open calcium channels (Mattera *et al.,* 1989). However, biochemical characterization of these isoforms has revealed subtle differences in the binding constant for GDP, the rate at which the forms are activated by agonist binding, efficiency of adenylyl cyclase stimulation, and the rate of GTP hydrolysis. The significance of these differences remains unknown (Jones *et al.,* 1990; Mattera *et al.,* 1989; Graziano *et al.,* 1989), but these distinctions imply the existence of as yet undefined roles for these G proteins (Novotny and Svoboda, 1998).

Additional complexity in the processing of the *GNAS1* gene arises from the use of first exons other than exon 1, which encodes sequences necessary for interaction with $G\beta\gamma$ and attachment to the plasma membrane (Evanko *et al.,* 2000). Accordingly, it is unlikely that these proteins can function fully as transmembrane signal transducers to couple receptors to intracellular signal generators. In one case, $G\alpha_s$ transcripts are produced with an alternative first exon (exon 1A) that lacks an initiator ATG codon. Smaller, $G\alpha_s$ proteins are predicted to be translated from an inframe ATG in exon 2, if translation occurs at all. Because these proteins lack amino acid sequences encoded by exon 1 (Ishikawa *et al.,* 1990) that are necessary for binding to $\beta\gamma$ subunits, it is unlikely that they function as conventional α chains. In two other instances unique transcripts are generated using additional coding exons that are present upstream of exon 1, the first exon present in transcripts used to generate functional $G\alpha_s$ protein. The more 5′ of these exons encodes the neuroendocrine secretory protein NESP55, a chromogranin-like protein, and is generated from a transcript that contains sequences derived from exon 2–13 of *GNAS1* in the 3′ nontranslated region (Leitner *et al.,* 1999; Ischia *et al.,* 1997). Accordingly, NESP55 shares no protein homology with $G\alpha_s$. Eleven kilobases further downstream is a second alternative exon, XLαs, that when spliced in-frame to exons 2–13 results in a transcript that encodes a larger, 51-kDa $G\alpha_s$ isoform. (Kehlenbach *et al.,* 1994). The XLαs protein is able to interact with $\beta\gamma$ chains through sequences in the carboxyl terminal region of the XL domain, which shows high homology to the exon 1-encoded portion of $G\alpha_s$ that promotes binding to $\beta\gamma$ dimers (Pasolli *et al.,* 2000; Klemke *et al.,* 2000). XLαs is targeted to the plasma membrane (Pasolli *et al.,* 2000), and can activate adenylyl cyclase (Klemke *et al.,* 2000). However, it is apparently unable to interact with heptahelical receptors (Klemke *et al.,* 2000) and thus its signal transduction properties are unique. Both NESP55 and XLαs are most highly expressed in neuroendocrine tissues.

Molecular studies of DNA from subjects with AHO have disclosed inactivating mutations in the *GNAS1* gene (Lin *et al.,* 1992; Iiri *et al.,* 1994; Luttikhuis *et al.,* 1994; Patten *et al.,* 1990; Weinstein *et al.,* 1990; Miric *et al.,* 1993; Schwindinger *et al.,* 1994; Farfel *et al.,* 1996; Shapira *et al.,* 1996; Fischer *et al.,* 1998; Jan de Beur *et al.,* 1998; Nakamoto *et al.,* 1998; Warner *et al.,* 1998; Ahmed *et al.,* 1998; Yu *et al.,* 1999) that account for a 50% reduction in expression or function of $G\alpha_s$ protein in accessible tissues (Table II). All patients are heterozygous, and have one normal *GNAS1* allele and one defective allele. Mutations in the *GNAS1* gene are heterogeneous, and include missense mutations (Patten *et al.,* 1990; Miric *et al.,* 1993; Schwindinger *et al.,* 1994; Farfel *et al.,* 1996; Warner *et al.,* 1998), point mutations that disrupt efficient splicing (Weinstein *et al.,* 1990) or terminate translation prematurely (Jan de Beur *et al.,* 1998), and small deletions (Weinstein *et al.,* 1990; Miric *et al.,* 1993; Weinstein *et al.,* 1992; Shapira *et al.,* 1996; Yu *et al.,* 1999; Fischer *et al.,* 1998) (Fig. 9). Although private mutations have been found in nearly all of the kindreds studied, a four-base deletion in exon 7 has been detected in multiple families (Weinstein *et al.,* 1992; Yu *et al.,* 1995; Ahmed

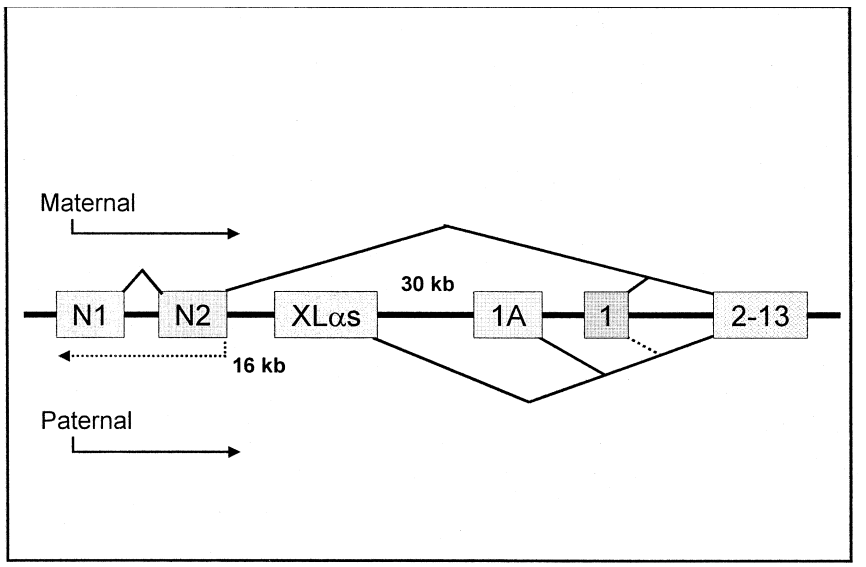

Figure 8 The *GNAS1* gene complex. The gene consists of 13 exons that encode the signaling protein $G\alpha_s$; upstream of exon 1 are three alternative exons, labeled exon 1A, XLαs, and NESP55. These three alternative first exons are spliced to exons 2–13 of the gene to produce unique transcripts and, at least in the case of NESP55 and XLas, distinct proteins (see text). Differentially methylated regions are located near the NESP55, XLas, and 1A exons and correspond to regulated expression via genomic imprinting. NESP55 is transcribed exclusively from the maternal allele, while XLas and exon 1A transcripts are derived exclusively from the paternal allele. Transcripts encoding Gas are generated from both alleles except in imprinted tissue (e.g., proximal renal tubule), where only the maternal allele is trancriptionally active.

et al., 1998; Yokoyama *et al.,* 1996; Walden *et al.,* 1999; Nakamoto *et al.,* 1998) and an unusual missense mutation in exon 13 (A366S; see below) has been identified in two unrelated young boys (Iiri *et al.,* 1994), suggesting that these two regions may be genetic "hot spots."

Most gene mutations lead to reduced expression of $G\alpha_s$ mRNA (Levine *et al.,* 1988; Carter *et al.,* 1987), but in some subjects the mutant allele produces normal levels of $G\alpha_s$ mRNA (Levine *et al.,* 1988; Carter *et al.,* 1987; Mallet *et al.,* 1982) that encode dysfunctional $G\alpha_s$ proteins (Schwindinger *et al.,* 1994; Farfel *et al.,* 1996; Iiri *et al.,* 1994; Warner *et al.,* 1998; Wu *et al.,* 2001). The replacement of arginine by histidine at codon 385 in the carboxyl terminal tail of $G\alpha_s$ selectively "uncouples" G_s from receptors and prevents receptor activation (Schwindinger *et al.,* 1994). Substitution of arginine by histidine at position 231 also prevents receptor activation of G_s, but by an entirely different mechanism (Farfel *et al.,* 1996). The replacement of arginine-231 hinders binding of GTP to the α chain, and thereby inhibits receptor-induced dissociation of $G\alpha_s$ from $G\beta\gamma$. Likewise, substitution of arginine at position 258 with tryptophan leads to increased GDP release and impaired receptor-mediated activation (Warner *et al.,* 1998).

Multiple Hormone Resistance in Pseudohypoparathyroidism Type 1a

Although biochemical hypoparathyroidism is the most commonly recognized endocrine deficiency in PHP type 1a, early clinical studies described additional hormonal abnormalities, such as hypothyroidism (Marx *et al.,* 1971; Werder *et al.,* 1975) and hypogonadism (Wolfsdorf *et al.,* 1978). Because available evidence suggests that $G\alpha_s$ is present in all tissues, generalized deficiency of this protein could be the basis for not only PTH resistance, the hallmark of PHP type 1a, but could also explain the decreased responsiveness of diverse tissues (e.g., kidney, thyroid gland, gonads, and liver) to hormones that act via activation of adenylyl cyclase (e.g., PTH, thyroid-stimulating hormone (TSH), gonadotropins, and glucagon) (Levine *et al.,* 1983a; Tsai *et al.,* 1989; Shima *et al.,* 1988). Primary hypothyroidism occurs in most patients with PHP type 1a (Levine *et al.,* 1983a). Typically, patients lack a goiter or anti-thyroid antibodies and have an elevated serum TSH with an exaggerated response to thyrotropin-releasing hormone (TRH). Serum levels of T_4 may be low or low normal. Hypothyroidism may occur early in life prior to the development of hypocalcemia, and elevated serum levels of TSH are not uncommonly detected during neonatal screening (Levine *et al.,* 1985; Weisman *et al.,* 1985; Yokoro *et al.,* 1990). Unfortunately, early institution of thyroid hormone replacement does not seem to prevent the development of mental retardation (Weisman *et al.,* 1985).

Reproductive dysfunction occurs commonly in subjects with PHP type 1a, particularly in women. Female patients with PHP type 1a may have delayed puberty, oligomenorrhea, and infertility (Levine *et al.,* 1983a). Plasma gonadotropins may be elevated, but are more commonly normal (Namnoum *et al.,* 1998). Some patients show an exaggerated serum gonadotropin response to GnRH (Wolfsdorf *et al.,* 1978; Downs *et al.,* 1983). Features of hypogonadism may be less obvious

Table II *In Vitro* Hormone Responsiveness of Tissues from Patients with PHP Type 1

Tissue	Form of PHP	Adenylyl cyclase response	Notes	Reference
Kidney	PHP type 1a (presumed) $n = 1$	Responsive to PTH. No normal controls.	[ATP] is high. Kidney obtained from autopsy.	Marcus *et al.,* 1971
Kidney	PHP type 1a $n = 1$	Abnormal response to PTH when [ATP] is low and no guanine nucleotides are present.	High [ATP] or addition of GTP normalizes response to PTH and replicates same activity as kidney from Marcus *et al.* (1971).	Downs *et al.,* 1983; Drezner and Burch, 1978
Cultured skin fibroblasts	PHP type 1a ($n = 5$) PHP type 1b ($n = 2$)	Normal responses to PGE_1, sodium fluoride, and cholera toxin in cells and membranes from both groups.		Bourne *et al.,* 1981
Cultured skin fibroblasts	PHP type 1a ($n = 5$)	Decreased response to PGE_1, sodium fluoride, guanine nucleotides.	Normal response to forskolin.	Levine *et al.,* 1983b
Cultured skin fibroblasts	PHP type 1b	Decreased cAMP response to PTH.	Decreased levels of PTH receptor mRNA; increases in some with dexamethasone.	Silve *et al.,* 1986; Silve *et al.,* 1990; Suarez *et al.,* 1995;
Cultured bone cells	PHP type 1b ($n = 1$)	Normal response to cholera toxin and PTH.		Murray *et al.,* 1993
Thyroid	PHP type 1a (presumed) ($n = 1$)	Basal and sodium fluoride-stimulated activities are normal; response to TSH is reduced.	Response is not affected by [ATP] or presence of GTP.	Mallet *et al.,* 1982
Platelets	PHP type 1a ($n = 3$) PHP type 1b ($n = 4$)	Maximal PGI_2-induced cAMP response is reduced in platelets from both groups.		Motulsky *et al.,* 1982
EBV-transformed lymphoblasts	PHP type 1a ($n = 3$) PHP type 1b ($n = 2$)	Adenylyl cyclase activity is normal in both groups.		Farfel *et al.,* 1982

in men with variable serum testosterone levels ranging from normal to frankly reduced. Testes may show evidence of a maturation arrest or may fail to descend normally. Fertility appears to be decreased in men with PHP type 1a. Deficiency of prolactin secretion (basal and in response to secretagogues such as TRH) had been reported in some patients with PHP type 1 (Carlson *et al.,* 1977), but later studies have not confirmed these early findings (Levine *et al.,* 1983a).

Obesity is common in subjects with PHP type 1a, as well as in patients with pseudoPHP. Obesity may reflect a defective lipolytic response to hormonal stimulation due to $G\alpha_s$ deficiency (Carel *et al.,* 1999; Kaartinen *et al.,* 1994). Others have hypothesized that $G\alpha_s$ deficiency results in reduced signaling of the melanocortin 4 receptor that is responsible for the disinhibition of satiety and hyperphagia observed in PHP 1a (Ong *et al.,* 2000).

Abnormal hormone responsiveness may occur in some tissues without obvious clinical sequelae. For example, the hepatic glucose response to glucagon is normal although plasma cAMP concentrations fail to increase normally (Levine *et al.,* 1983a; Brickman *et al.,* 1986). In other tissues significant hormone resistance does not occur despite the apparent reduction in $G\alpha_s$. Diabetes insipidus is not a feature of PHP type 1a, and urine is concentrated normally in response to vasopressin in patients with PHP type 1a (Moses *et al.,* 1986). Although there is a report of adrenal insufficiency in a single individual with PHP type 1a (Ridderskamp and Schlaghecke, 1990), hypoadrenalism is not a typical feature of PHP type 1a and adrenocortical responsiveness to corticotropin (ACTH) is normal (Levine *et al.,* 1983a).

PRIMARY SENSORY ABNORMALITIES

Patients with PHP type 1a frequently manifest distinctive olfactory (Weinstock *et al.,* 1986), gustatory (Henkin, 1968), and auditory (Koch *et al.,* 1990) abnormalities that are apparently unrelated to endocrine dysfunction. The molecular basis of these neurosensory deficits has become more obscure with the discovery of unique G proteins that regulate signal transduction pathways related to vision (Lerea *et al.,* 1986; Lochrie *et al.,* 1985), olfaction (Jones and Reed, 1989), and taste (McLaughlin *et al.,* 1992).

Henkin first reported gustatory disturbances in patients with PHP type 1 (Henkin, 1968), but biochemical methods that allow distinction between types 1a and 1b had not yet been developed. These patients had elevated thresholds for detection and recognition of sour and bitter taste. In addition, the olfactory threshold for detection and recognition of all vapors tested was similarly elevated. Treatment with calcium, parathyroid extract, or both did not restore taste or olfaction to normal. The subsequent identification of an odorant-sensitive adenylyl cyclase in frog and rat olfactory

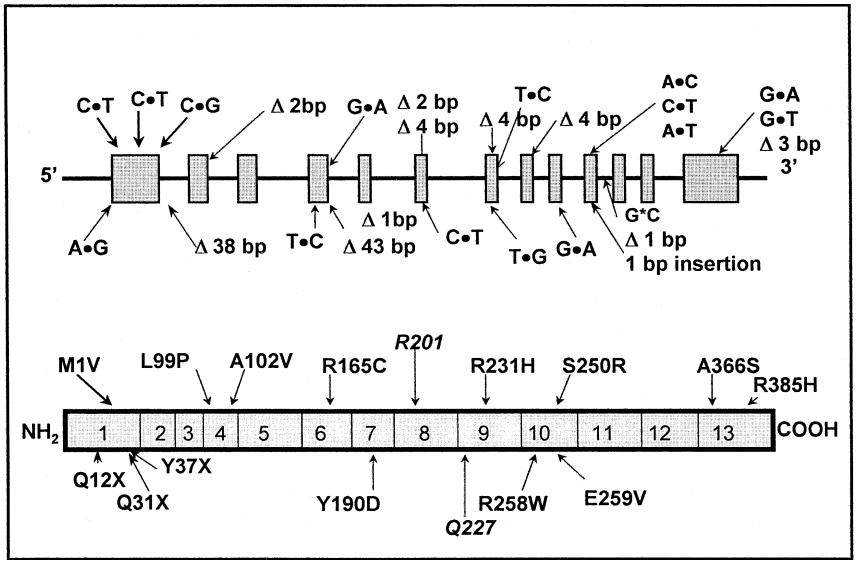

Figure 9 Mutations in the *GNAS1* gene. (Top) the human *GNAS1* gene, which spans over 20 k pairs and contains at least 13 exons and 12 introns. Unique mutations that result in *loss of* $G\alpha_s$ *function* have been identified in affected members of many unrelated AHO families; missense mutations are denoted by the symbol *. (Botton) The position of these missense mutations above the protein structure. Two polymorphisms are denoted by the symbol +, and the position of the unchanged amino acid is denoted beneath the predicted $G_{s\alpha}$ protein. The site of two missense mutations that result in gain of function (replacement of either Arg^{201} or Gln^{227}) in patients with MAS (Weinstein *et al.,* 1991; Schwindinger *et al.,* 1992; Shenker *et al.,* 1994, 1993; Levine *et al.,* 1994) or in sporadic tumors (Landis *et al.,* 1989; Lyons *et al.,* 1990) are depicted in italics. The mutation in exon 1 eliminates the initiator methionine codon and prevents synthesis of a normal $G_{s\alpha}$ protein (Patten *et al.,* 1990). The 4 base-pair deletions in exon 7 (Weinstein *et al.,* 1992) and exon 8 (Miric *et al.,* 1993), and the 1 base-pair deletion in exon 10 all shift the normal reading frame and prevent normal mRNA and/or protein synthesis. Mutations in intron 3 and at the donor splice junction between exon 10 and intron 10 cause splicing abnormalities that prevent normal mRNA synthesis (Weinstein *et al.,* 1990). The mutations indicated with an asterisk represent missense mutations (Miric *et al.,* 1993; Schwindinger *et al.,* 1994; Iiri *et al.,* 1994); the resultant amino acid substitutions are indicated in the schematic diagram of the $G\alpha_s$ protein at the bottom of the figure. Some of these mutations may prevent normal protein synthesis by altering protein secondary structure, but the arg → his substitution in exon 13 appears to encode an altered protein that cannot couple normally to receptors (Schwindinger *et al.,* 1994) and the ala → ser mutation encodes an activated $G\alpha_s$ protein that is unstable at 37°C (Iiri *et al.,* 1994).

neuroepithelium (Sklar *et al.,* 1986; Pace *et al.,* 1985) that was stimulated by a G_s-like protein (Pace and Lancet, 1986) prompted further investigation of olfactory function in patients with PHP type 1. Using quantitative tests to assess the ability of patients to identify common odorants, several early studies showed variably decreased olfactory ability in subjects with PHP type 1a by comparison to patients with PHP type 1b who have normal $G\alpha_s$ activity (Weinstock *et al.,* 1986; Ikeda *et al.,* 1988). Subsequent analyses, using comprehensive tests of odor detection, identification, and memory, demonstrated that patients with PHP type 1a as well as patients with PHP type 1b have olfactory dysfunction relative to matched controls and that patients with pseudo-PHP (PPHP) have relatively normal olfactory function (Doty *et al.,* 1997). These studies imply that other mechanisms (e.g., ones associated with PTH or PTHrP resistance) are responsible for the olfactory deficits of this disorder, and are consistent with the existence of a unique G protein in olfactory neuroepithelial cells, termed G_{olf} (Jones and Reed, 1989), that couples odorant receptors to a unique form of adenylyl cyclase (type III (Bakalyar and Reed, 1990)).

Koch *et al.* (1990) found that PHP type 1a patients with $G\alpha_s$ deficiency had symmetrical sensorineural hearing losses. The authors speculated that loss of the G protein–adenylyl cyclase complex causes progressive damage to cochlear hair cells induced by a disorder of the electrolyte composition of the inner ear fluids.

Alterations in visual function have also been described in patients with PHP type 1a. For example, decreased color discrimination and enhanced contrast sensitivity have been observed in patients with PHP type 1a (Jackowski *et al.,* 1992). The pathophysiological basis for these photoreceptor alterations is unknown, as $G\alpha_s$ seems to play no role in retinal phototransduction. Light activation of the specialized receptor proteins rhodopsin and opsin that are expressed in rods and cones, respectively, is coupled to stimulation of cyclic GMP phosphodiesterase by G proteins that were originally termed transducins (Lerea *et al.,* 1986; Lochrie *et al.,* 1985). Although these G proteins share substantial similarity

to G_s in subunit structure and mechanism of action, their expression is limited to retinal photoreceptor cells and they subserve unique signaling functions.

Neurological Abnormalities

Mild to moderate mental retardation is common in patients with PHP type 1a. Farfel and Friedman assessed intelligence in 25 patients with PHP type 1 whose $G\alpha_s$ activity had been determined (Farfel and Friedman, 1986). The authors found an association between mental deficiency and $G\alpha_s$ deficiency and speculated that reduced cyclic adenosine monophosphate (cAMP) levels in cortical tissue may lead to mental retardation. Other factors that might contribute to mental retardation in patients with PHP type 1a include hypothyroidism and hypocalcemia; however, efforts to control these have not prevented cognitive dysfunction in all patients, suggesting that $G\alpha_s$ deficiency may cause a primary abnormality of neurotransmitter signaling. Seizure disorders are also frequently reported. These may reflect atypical seizures due to hypocalcemia (cerebral tetany) or exacerbation of epileptic seizures. These seizures may occur prior to recognition of hypocalcemia (Faig *et al.,* 1992; Bonadio, 1989). There have been reports of psychosis in patients with AHO (Furukawa, 1991). As with patients with hormonopenic hypoparathyroidism, patients with PHP type 1 who have extensive calcifications of the basal ganglia may develop movement disorders (Klawans *et al.,* 1976; Blin *et al.,* 1991; Dure and Mussell, 1998; Vaamonde *et al.,* 1993; Uncini *et al.,* 1985; Tambyah *et al.,* 1993).

Phenotypic Variability in AHO

Molecular studies have provided a basis for $G\alpha_s$ deficiency, but they do not explain the striking variability in biochemical and clinical phenotype in subjects with AHO. Why do some $G\alpha_s$-coupled pathways show reduced hormone responsiveness (e.g., PTH, TSH, gonadotropins), whereas other pathways are clinically unaffected (ACTH in the adrenal gland and vasopressin in the renal medulla)? Perhaps even more intriguing is the paradox that $G\alpha_s$ deficiency can be associated with hormone resistance and AHO (PHP type 1a), AHO only (pseudo-PHP), progressive osseous heteroplasia (POH) (Shore *et al.,* 1999), or no apparent consequences at all (Miric *et al.,* 1993). These observations, when considered in the context of studies showing that the number of G_s molecules in cell membranes greatly exceeds the number of either receptor or adenylyl cyclase molecules (Levis and Bourne, 1992), raise issue with the hypothesis that a 50% deficiency of $G\alpha_s$ can impair hormone responsiveness. Indeed, *in vitro* studies of tissues and cells from subjects with PHP type 1a have often demonstrated normal hormonal responsiveness despite a 50% reduction in $G\alpha_s$ expression (Levine, 1996).

Several observations now suggest a molecular basis for the variable phenotypes that arise from identical *GNAS1* gene defects. First, clinical genetic studies have documented that PHP type 1a and pseudo-PHP frequently occur in the same family, but are not present in the same generation (Fig. 10). Second, analysis of published pedigrees has indicated that in nearly all cases maternal transmission of $G_s\alpha$ deficiency leads to PHP type 1a, whereas paternal transmission of the defect leads to pseudo-PHP (Fig. 10) (Wilson *et al.,* 1994; Levine *et al.,* 1986; Davies and Hughes, 1993; Nakamoto *et al.,* 1998). These findings are inconsistent with models in which chance determines phenotype or in which a second gene is interactive with the defective *GNAS1* gene, as both PHP type 1a and pseudo-PHP would be expected to occur with equal frequency and in the same sibship. An alternative explanation for the variable phenotypes that occur is that *GNAS1* expression

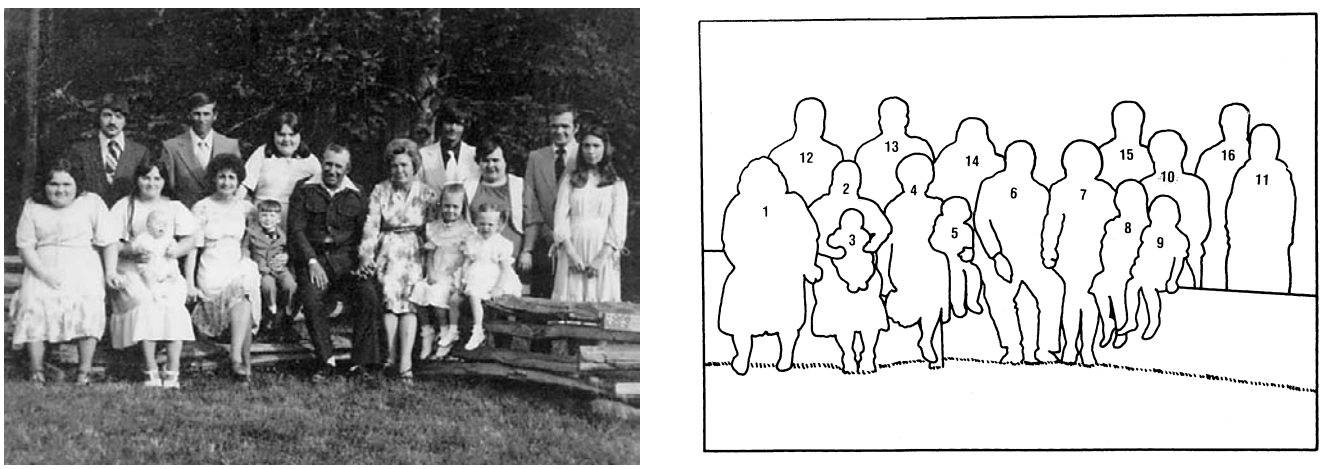

Figure 10 A large kindred containing members with AHO showing variable expression of the same mutation in the *GNAS1* gene (Weinstein *et al.,* 1990). There is increasing severity of $G\alpha_s$ deficiency with each generation. Subjects 1, 2, 14, and 10 have PHP type 1a with typical features of AHO and multihormone resistance. Their sisters, subjects 4 and 11, are unaffected. Subject 3, the son of patient 2, is the most severely affected member of the family and has multiple developmental defects. Subjects 5, 8, and 9, the children of unaffected sisters 4 and 11, respectively, are also normal. Patient 6, the father of the six women, is normal, whereas subject 7, the mother, carries the same gene defect yet her only manifestation of AHO is shortening of the distal phalanx of one thumb (i.e., pseudo-PHP). From Levine *et al.* (1982).

is modified by genomic imprinting (Davies and Hughes, 1993). Genomic imprinting is an unusual mode of regulation of gene expression that results in the expression of only one parental allele in somatic tissues. Thus, genomic imprinting can account for functional differences that arise as a consequence of the parental origin of a gene allele. Recent studies have indeed confirmed that the *GNAS1* gene is imprinted, but in a far more complex manner than had been anticipated. Three unique, alternative first exons, and their respective promoters, are located within the 35-kb upstream of the *GNAS1* exon 1 (Fig. 8). These promoters each have differentially methylated regions (DMR) that show allele-specific methylation that correspond to patterns of genomic imprinting and monoallelic transcription. The most 5′ of these exons encodes NESP55, which is expressed exclusively from the maternal allele and which is methylated at the DMR on the paternal allele. By contrast, the XLαs exon, which is only 11 kb downstream, is paternally expressed and shows methylation of the DMR on the maternal allele (Hayward *et al.,* 1998a,b). The exon 1A DMR is only 2 kb downstream from XLαs and is similarly methylated on the maternal allele and expressed from only the paternal allele (Liu *et al.,* 2000a). Despite the reciprocal imprinting in both the paternal and the maternal directions of the *GNAS1* gene, expression of Gα_s appears to be biallelic in all human tissues that have been examined thus far (Campbell *et al.,* 1994; Hayward *et al.,* 1998a,b), although monoallelic expression exclusively from the maternally derived allele has been documented in some tissues (e.g., renal proximal tubule) in murine models of PHP type 1a. These models have been developed through disruption of a single *Gnas* gene in murine embryonic stem cells (Yu *et al.,* 1998; Schwindinger *et al.,* 1998b), and although the heterozygous (*Gnas* +/−) knockout mice have reduced levels of Gα_s protein, they lack many of the features of the human disorder. Biochemical analyses of *Gnas* (+/−) mice demonstrate that Gα_s expression derives from only the maternal allele in some tissues (e.g., renal cortex) but from both alleles in most other tissues (e.g., renal medulla) (Weinstein *et al.,* 2000; Ecelbarger *et al.,* 1999; Yu *et al.,* 1998). Accordingly, mice that inherit the defective *Gnas* gene maternally express only that allele in imprinted tissues, such as the PTH-sensitive renal proximal tubule, with the result that there is no functional Gα_s protein. By contrast, the 50% reduction in Gα_s expression that occurs in nonimprinted tissues, which express both *Gnas* alleles, may account for more variable and moderate hormone resistance in these sites (e.g., the thyroid). Thus, variable hormonal responsiveness implies that haploinsufficiency of Gα_s is tissue-specific; that is, in some tissues a 50% reduction in Gα_s is still sufficient to facilitate normal signal transduction. Confirmation of this proposed mechanism in patients with AHO will require demonstration that the human Gα_s transcript is paternally imprinted in the renal cortex.

In AHO, inherited *GNAS1* gene mutations reduce expression or function of Gα_s protein. By contrast, in the McCune–Albright syndrome, post-zygotic somatic mutations in the *GNAS1* gene enhance activity of the protein (Schwindinger *et al.,* 1992; Weinstein *et al.,* 1991). These mutations lead to constitutive activation of adenylyl cyclase, and result in proliferation and autonomous hyperfunction of hormonally responsive cells. The clinical significance of Gα_s activity as a determinant of hormone action is emphasized by the description by Iiri *et al.* (1994) of two males with both precocious puberty and PHP type 1a. These two unrelated boys had identical *GNAS1* gene mutations in exon 13 (A366S) that resulted in a temperature-sensitive form of Gα_s (Fig. 9). This Gα_s is constitutively active in the cooler environment of the testis, while being rapidly degraded in other tissues at normal body temperature. Thus, different tissues in these two individuals could show hormone resistance (to PTH and TSH), hormone responsiveness (to ACTH), or hormone independent activation (to luteinizing hormone (LH)).

Pseudohypoparathyroidism Type 1b

Patients with PHP type 1b lack features of AHO, manifest hormone resistance that is limited to PTH target organs (Table I), and have normal Gα_s activity (Fig. 5) (Levine *et al.,* 1983a). Although patients with PHP type 1b fail to show a nephrogenous cAMP response to PTH (Fig. 3), they often manifest osteopenia or skeletal lesions similar to those that occur in patients with hyperparathyroidism, including osteitis fibrosa cystica (Fig. 4) (Kidd *et al.,* 1980). Cultured bone cells from one patient with PHP type 1b and osteitis fibrosa cystica were shown to have normal adenylyl cyclase responsiveness to PTH *in vitro* (Murray *et al.,* 1993). These observations have suggested that at least one intracellular signaling pathway coupled to the PTH receptor may be intact in patients with PHP type 1b.

Specific resistance of target tissues to PTH, and normal activity of Gα_s, had implicated decreased expression or function of the PTH1R as the cause for hormone resistance. In addition, cultured fibroblasts from some, but not all, PHP type 1b patients were shown to accumulate reduced levels of cAMP in response to PTH (Silve *et al.,* 1986, 1990) and contain decreased levels of mRNA encoding the PTH/PTHrP receptor (Suarez *et al.,* 1995). Several lines of evidence suggest that the primary defect in PHP type 1b is *not* in the gene encoding the PTH1R, however. First, pretreatment of cultured fibroblasts from subjects with PHP type 1b with dexamethasone was found to normalize the PTH-induced cAMP response and to increase expression of PTH1R mRNA (Suarez *et al.,* 1995). Second, molecular studies have failed to disclose mutations in the coding exons (Schipani *et al.,* 1995) and promoter regions (Bettoun *et al.,* 1997) of the PTH1R gene or its mRNA (Fukumoto *et al.,* 1996). Furthermore, linkage studies have demonstrated discordance between inheritance of PHP type 1b and PTH1R alleles, thus excluding defects even in regions of the gene that have not yet been examined by sequence analysis (Jan de Beur *et al.,* 2000). Third, mice (Lanske *et al.,* 1996) and humans (Jobert *et al.,* 1998) that are heterozygous for inactivation of the gene encoding the PTH1R do not manifest PTH resistance or hypocalcemia.

Finally, inheritance of two defective PTH1R genes results in Blomstrand chondrodysplasia, a lethal genetic disorder characterized by advanced endochondral bone maturation (Jobert *et al.,* 1998). Thus, it is likely that the molecular defect in PHP type 1b resides in other gene(s) that regulate expression or activity of the PTH1R.

Although most cases of PHP type 1b appear to be sporadic, familial cases have been described in which transmission of the defect is most consistent with an autosomal dominant pattern (Allen *et al.,* 1988; Winter and Hughes, 1980) In some of these kindreds, there appears to be a pattern of inheritance consistent with imprinting as observed in PHP type 1a (Juppner *et al.,* 1998; Wu *et al.,* 2001). Molecular genetic studies of multiplex PHP type 1b kindreds have used linkage analysis to map the location of the PHP type 1b gene to a small region of chromosome 20*q*13.3 near the *GNAS1* gene (Juppner *et al.,* 1998; Jan de Beur *et al.,* 2001a). Although it is possible that the PHP type 1b locus corresponds to a unique gene involved in PTH responsiveness that resides upstream of *GNAS1* (Juppner *et al.,* 1998), more recent observations imply that defective imprinting of *GNAS1* may account for selective deficiency of $G\alpha_s$ in the renal proximal tubule in PHP type 1b. Upstream of the first exon for $G\alpha_s$ is a DMR that is normally methylated on the maternal allele and unmethylated on the paternal allele, which is expressed (Fig. 8). Remarkably, subjects with PHP type 1b show a loss of methylation on the maternal allele, which permits biallelic expression of alternative transcripts that contain exon 1A as the first exon (Liu *et al.,* 2000b; Jan de Beur *et al.,* 2001b). It is conceivable that loss of maternal-specific imprinting of the exon 1A region, and consequent transcription of both alleles, may interfere with normal expression of $G\alpha_s$ transcripts from the maternal allele in imprinted tissues such as the renal proximal tubules, thereby leading to PTH resistance.

Pseudohypoparathyroidism Type 1c

Resistance to multiple hormones has been described in several patients with AHO who have do not have a demonstrable defect in G_s or G_i (Levine *et al.,* 1983a; Farfel *et al.,* 1981; Izraeli *et al.,* 1992). This disorder is termed PHP type 1c. The nature of the lesion in such patients is unclear, but it could be related to some other general component of the receptor–adenylyl cyclase system, such as the catalytic unit (Barrett *et al.,* 1989). Alternatively, these patients could have functional defects of G_s (or G_i) that do not become apparent in the assays presently available.

Pseudohypoparathyroidism Type 2

PHP type 2 is the least common form of PHP, and does not appear to have a clear genetic or familial basis. Patients do not have features of AHO. Renal resistance to PTH in PHP type 2 patients is manifested by a reduced phosphaturic response to administration of PTH, despite a normal increase in urinary cAMP excretion (Drezner *et al.,* 1973). These observations suggest that the PTH receptor–adenylyl cyclase complex functions normally to increase cyclic AMP in response to PTH, and are consistent with a model in which PTH resistance arises from an inability of intracellular cAMP to initiate the chain of metabolic events that result in the ultimate expression of PTH action.

Although supportive data are not yet available, a defect in cAMP-dependent protein kinase A has been proposed as the basis for this disorder (Drezner *et al.,* 1973). Alternatively, the defect in PHP type 2 may not reside in an inability to generate a physiological response to intracellular cAMP: a defect in another PTH-sensitive signal transduction pathway may explain the lack of a phosphaturic response. One candidate is the PTH-sensitive phospholipase C pathway that leads to increased concentrations of the intracellular second messengers inositol 1,4,5-trisphosphate and diacylglycerol (Civitelli *et al.,* 1988; Dunlay and Hruska, 1990) and cytosolic calcium (Gupta *et al.,* 1991; Civitelli *et al.,* 1989; Reid *et al.,* 1987; Yamaguchi *et al.,* 1987) (Fig. 1).

In some patients with PHP type 2 the phosphaturic response to PTH has been restored to normal after serum levels of calcium have been normalized by treatment with calcium infusion or vitamin D (Kruse *et al.,* 1989). These results point to the importance of Ca^{2+} as an intracellular second messenger. Finally, a similar dissociation between the effects of PTH on generation of cAMP and tubular reabsorption of phosphate has been observed in patients with profound hypocalcemia due to vitamin D deficiency (Rao *et al.,* 1985), suggesting that some cases of PHP type 2 may in fact represent vitamin D deficiency.

Clinical Features

Hypocalcemia

The *sine qua non* of PHP is target tissue resistance to the action of PTH, and the major clinical manifestations of PHP are the consequence of reduced concentrations of ionized calcium in blood and extracellular fluid. Hypocalcemia may produce neuromuscular, ectodermal, cardiac, and ocular changes. The primary hallmark of hypocalcemia is *tetany,* a condition characterized by increased neuromuscular excitability. Symptoms of tetany include carpopedal spasm, convulsions, circumoral and acral paresthesias, muscle cramps, and stridor. Laryngeal spasm occurs most commonly in young children and may be the presenting manifestation of severe hypocalcemia. Tetany may be potentiated by hypomagnesemia and can be mimicked by hypokalemia. Hypocalcemia may cause seizures with abnormal EEG patterns, or may also unmask a previously unsuspected seizure disorder or greatly aggravate known epilepsy. Latent tetany may be detected by tapping over the facial nerve to produce a facial twitch (Chvostek sign) or by inflating a blood pressure cuff above systolic pressure for 3 min to produce carpal spasm (Trousseau sign). A slightly positive Chvostek sign may occur in 15% of normal adults. Importantly, both of

these signs can be absent even in patients with severe hypocalcemia. The natural history of PHP is quite variable. Although PHP is congenital, hypocalcemia is not present from birth, and PTH resistance seems to arise gradually during childhood. The initial manifestations of tetany typically occur between 3 and 8 years of age, but the significance of these findings may not be appreciated and the diagnosis of hypocalcemia may be delayed for months or even years. Increasing levels of serum phosphate, PTH, and $1,25(OH)_2D_3$ were documented to precede the onset of hypocalcemia in one child as he advanced from 3 to $3\frac{1}{2}$ years of age (Tsang *et al.,* 1984). These findings seem to imply that the earliest manifestation of PTH resistance is the inability to induce a phosphaturic response. Indeed, we have found some very young infants that we identified through genetic screening to have mild hypercalcemia as an apparent response to increasing levels of PTH and $1,25(OH)_2D$, implying that skeletal responsiveness to PTH is maintained even as renal resistance evolves (unpublished observations). In a second report serial PTH infusions were used to evaluate hormone responsiveness. This child was shown to have a normal cAMP response at age 3 months when serum levels of calcium, phosphorous, and PTH were normal, but was found to have an abnormal cAMP response when retested at age 2.6 years after he had developed tetany and was found to be hypocalcemic (Barr *et al.,* 1994). At the time of his second PTH infusion, the child had markedly elevated serum concentrations of phosphorous and PTH and was receiving thyroxine for recently diagnosed hypothyroidism (Barr *et al.,* 1994). Some affected children show few symptoms of tetany and the diagnosis of PHP is recognized only later in life after hypocalcemia is inadvertently discovered or when features of AHO become obvious. Hypocalcemia may not always provide a clue to the clinical diagnosis of PHP, however, as some PHP patients are able to maintain a normal serum calcium level without treatment (i.e., normocalcemic PHP) (Drezner and Haussler, 1979).

As in other forms of hypoparathyroidism, patients may have coarse, brittle hair, dermatitis with eczema, and brittle nails. Chronic hypocalcemia and hyperphosphatemia may lead to soft tissue calcifications in patients with PHP. Posterior subcapsular cataracts develop frequently, and computerized tomography of the brain reveals calcification of the basal ganglion (Illum and Dupont, 1985) and frontal lobes in most patients. Occasional patients may also have calcifications in the heart (Schuster and Sandhage, 1992).

Skeletal Remodeling

PTH responsiveness of the skeleton appears to be variable in subjects with PHP. In contrast to the well-documented resistance of the kidney to PTH, there is less compelling evidence to support the notion that bone cells are resistant to PTH in PHP. There is a spectrum of bone disease in PHP: some subjects have apparently normal appearing bone while others have radiological or histological evidence of significant bone resorption (Burnstein *et al.,* 1985). Patients with PHP type 1a typically have little or no evidence of diffuse skeletal involvement, while patients with PHP type 1b often demonstrate evidence of osteopenia or hyperparathyroid bone disease, including osteitis fibrosa cystica (Fig. 4). Cultured bone cells from one patient with PHP type 1b and osteitis fibrosa cystica were shown to have normal adenylyl cyclase responsiveness to PTH *in vitro* (Murray *et al.,* 1993).

Patients with PHP may develop additional abnormalities in bone metabolism, including osteomalacia (Burnstein *et al.,* 1985), rickets (Dabbaugh *et al.,* 1984), renal osteodystrophy (Hall *et al.,* 1981), and osteopenia (Breslau *et al.,* 1983). These skeletal abnormalities result from excessive PTH or deficient $1,25(OH)_2D_3$.

Albright Hereditary Osteodystrophy

Subjects with PHP type 1a or pseudo-PHP typically manifest a characteristic constellation of developmental defects, termed Albright hereditary osteodystrophy, that includes short stature, obesity, a round face, shortening of the digits (brachydactyly), subcutaneous ossification, and dental hypoplasia (Fig. 7) (Albright *et al.,* 1942, 1952). Considerable variability occurs in the clinical expression of these features even among affected members of a single family, and all of these features may not be present in every case (Faull *et al.,* 1991). On rare occasion, it may be impossible to detect any features of AHO in an individual with $G\alpha_s$ deficiency (Fig. 10) (Weinstein *et al.,* 1990; Miric *et al.,* 1993).

Although patients with AHO may be of normal height and weight, approximately 66% of children and 80% of adults are below the 10th percentile for height. This reflects a disproportionate shortening of the limbs, as arm span is less than height in the majority of patients. Obesity is a common feature of AHO and about one-third of all patients with AHO are above the 90th percentile of weight for their age, despite their short stature (Fitch, 1982) (Fig. 7A). Patients with AHO typically have a round face, a short neck, and a flattened bridge of the nose. Numerous other abnormalities of the head and neck have also been noted. Ocular findings include hypertelorism, strabismus, nystagmus, unequal pupils, diplopia, microphthalmia, and a variety of abnormal findings on funduscopic exam that range from irregular pigmentation to optic atrophy and macular degeneration. Head circumference is above the 90th percentile in a significant minority of children (Fitch, 1982). Dental abnormalities are common in subjects with PHP type 1a and include dentin and enamel hypoplasia, short and blunted roots, and delayed or absent tooth eruption (Croft *et al.,* 1965).

Brachydactyly is the most reliable sign for the diagnosis of AHO, and may be symmetrical or asymmetrical and involve one or both hands or feet (Fig. 7). Shortening of the distal phalanx of the thumb is the most common abnormality; this is apparent on physical exam as a thumb in which the ratio of the width of the nail to its length is increased (so-called "Murder's thumb" or "potter's thumb," Fig. 7D). Shortening of the metacarpals causes shortening of the digits, particularly the fourth and fifth. Shortening of the metacarpals may also be recognized on physical exam as dimpling over the knuckles of a clenched fist (Archibald sign, Fig. 7C). Often a definitive diagnosis requires careful examination of radiographs of the

hands and feet (Fig. 7B). A specific pattern of shortening of the bones in the hand has been identified, in which the distal phalanx of the thumb and third through fifth metacarpals are the most severely shortened (Poznanski *et al.,* 1977; Graudal *et al.,* 1988). This may be useful in distinguishing AHO from other unrelated syndromes in which brachydactyly occurs, such as familial brachydactyly, Turner syndrome, and Klinefelter syndrome (Poznanski *et al.,* 1977).

In addition to brachydactyly, several other skeletal abnormalities are present in AHO. Numerous deformities of the long bones have been reported, including a short ulna, bowed radius, deformed elbow or cubitus valgus, coxa vara, coxa valga, genu varum, and genu valgus deformities (Fitch, 1982). The most common abnormalities of the skull are hyperostosis frontalis interna and a thickened calvarium. The skeletal abnormalities of AHO may not be apparent until a child is 5 years old (Steinbach *et al.,* 1965). Bone age is advanced 2–3 years in the majority of patients (Fitch, 1982). Spinal cord compression has been reported in several patients with AHO (Alam and Kelly, 1990).

Patients with AHO develop heterotopic ossifications of the soft tissues or skin (osteoma cutis) that are unrelated to abnormalities in serum calcium or phosphorous levels. Osteoma cutis is present in 25 to 50% of patients and is typically noted in infancy or early childhood. Occasionally, ossification of the skin is the presenting feature of AHO (Prendiville *et al.,* 1992; Izraeli *et al.,* 1992). Blue-tinged, stony hard papular or nodular lesions that range in size from pinpoint up to 5 cm in diameter often occur at sites of minor trauma and may appear to be migratory on serial examinations (Prendiville *et al.,* 1992). Biopsy of these lesions reveals heterotopic ossification with spicules of mineralizing osteoid and calcified cartilage. More extensive and progressive ossification that affects the deep connective tissues occurs in subjects with progressive osseous heteroplasia (POH), a rare genetic disorder with apparent autosomal dominant inheritance (Kaplan *et al.,* 1994). In its most specific characterization, POH does not share any other phenotypic features with AHO or display hormonal resistance. Recently, a mutation in *GNAS1* has been identified in a girl with POH-like heterotopic ossification, normal PTH responsiveness, and no features of AHO except mild brachydactyly of the fourth and fifth metacarpals (Eddy *et al.,* 2000). The discovery of *GNAS1* mutations in an overlap syndrome of AHO and POH subsequently led to the analysis of *GNAS1* in several POH kindreds. Heterozygous inactivating mutations in *GNAS1,* including the 4-bp deletion in exon 7 that is a mutational "hot spot" in AHO, were identified and paternal transmission of POH was confirmed by documenting inheritance of defective *GNAS1* alleles from fathers (Shore *et al.,* 1999). The mechanism by which heterozygous loss of function mutations in *GNAS1* leads to heterotopic bone formation is unclear. The association of POH with mutations in *GNAS1* further widens the phenotypic expression of $G\alpha_s$ deficiency, but the molecular modifiers that account for the variable phenotypes associated with identical gene defects in different families are unknown (see below).

The presence of these developmental and skeletal abnormalities does not necessarily indicate that a patient has AHO and $G\alpha_s$ deficiency. Features of AHO, particularly shortened metacarpals or metatarsals, may occur in normal subjects, as well as in patients with hormone deficient hypoparathyroidism (Moses *et al.,* 1974; Isozaki *et al.,* 1984; Le Roith *et al.,* 1979), renal hypercalciuria (Moses and Notman, 1979), and primary hyperparathyroidism (Sasaki *et al.,* 1985). Moreover, several features of AHO, for example obesity, round face, brachydactyly, and mental retardation, are common to other disorders (e.g., Prader–Willi syndrome, acrodysostosis, Ullrich–Turner syndrome, Gardener's syndrome), many of which are associated with unrelated chromosomal defects. In some instances overlapping clinical features between AHO and other syndromes may lead to confusion. For example, AHO in a mother and her daughter has been associated with a proximal 15*q* chromosomal deletion resembling that found in Prader-Willi syndrome (Hedeland *et al.,* 1992). A growing number of reports have described small terminal deletions of chromosome 2*q* in patients with variable AHO-like phenotypes. Terminal deletion of 2*q*37 [del(2)(*q*37.3)] is the first consistent karyotypic abnormality that has been documented in patients with an AHO-like syndrome (Wilson *et al.,* 1995; Phelan *et al.,* 1995). These patients have normal endocrine function and normal $G_{s\alpha}$ activity, however (Phelan *et al.,* 1995). Thus, high-resolution chromosome analysis, biochemical/molecular analysis, and careful physical and radiological examination are essential in discriminating between these phenocopies and AHO.

GENETICS

AHO, including PHP type 1a and pseudo-PHP, is inherited in an autosomal dominant manner via transmission of defects in the *GNAS1* gene (see above). The inheritance of other forms of PHP is less well characterized. Transmission of PHP type 1b is most consistent with an autosomal dominant pattern and appears to be linked to inheritance of a defective maternal *GNAS1* allele (Juppner *et al.,* 1998; Jan de Beur *et al.,* 1997, 2001b). Clinical and molecular evidence implicate genomic imprinting as the basis for development of hormone resistance in individuals with PHP types 1a and 1b who have mutations in *GNAS1*. PHP type 2 is typically a sporadic disorder, although one case of familial PHP type 2 has been reported (Van Dop, 1989).

Diagnosis of Pseudohypoparathyroidism

Clinical Evaluation

The diagnosis of PHP should be considered in any patient who has biochemical hypoparathyroidism. A low serum calcium level may be found during an evaluation of unexplained paresthesias or seizures, or may be discovered after multichannel analysis of a blood specimen obtained as part of a routine examination. PHP should be strongly suspected if the

serum concentration of PTH is elevated, although occasionally serum levels of PTH are "inappropriately" normal in subjects with PHP owing to confounding hypomagnesemia (Allen *et al.,* 1988) or other factors (Attanasio *et al.,* 1986). Hypocalcemia may be precipitated or worsened during times of "stress" on calcium homeostasis, such as during early pregnancy, lactation, or during an episode of acute pancreatitis. Although hypocalcemia is present in most patients with PHP by the end of the first decade of life, occasional patients do not develop hypocalcemia until they are in their 50s (Hamilton, 1980).

Cataracts and intracranial calcification, particularly of the basal ganglion, occur commonly in patients with all forms of chronic hypoparathyroidism, including PHP. The presence of these calcifications does not help to discriminate among the various causes of hypocalcemia and hyperphosphatemia (Litvin *et al.,* 1981), but does indicate that the mineral defects have been present for at least 5 to 10 years. Intracranial calcifications are readily detected when CT scanning is employed (Sachs *et al.,* 1982; Korn-Lubetzki *et al.,* 1980) and may occasionally be associated with symptoms such as Parkinson's disease (Pearson *et al.,* 1981). Other unusual presenting manifestations of PHP include neonatal hypothyroidism (Levine *et al.,* 1985; Weisman *et al.,* 1985), unexplained cardiac failure (Miano *et al.,* 1981), Parkinson's disease (Pearson *et al.,* 1981), and spinal cord compression (Cavallo *et al.,* 1980). Finally, relatives of patients with PHP should be evaluated for signs of PHP as expression of the disorder can be very subtle.

A diagnosis of PHP can be made with reasonable certainty when hypocalcemia is accompanied by hyperphosphatemia and elevated circulating levels of PTH. Further corroboration of the diagnosis requires demonstration of normal renal function and normal serum levels of magnesium and 25-(OH)-vitamin D. A positive family history lends further support to the diagnosis. The presence of AHO and manifestations of multihormone resistance, such as hypothyroidism or hypogonadism, favors a diagnosis of PHP type 1a (Levine *et al.,* 1983a). When most or all of these features are present, more sophisticated tests may not be necessary to confirm the clinical diagnosis. Serum calcium levels can fluctuate in patients with PHP, and may spontaneously change from low to normal and *vice versa,* thus contributing to the confusion regarding the distinction between PHP and pseudo-PHP (Breslau *et al.,* 1980; Drezner and Haussler, 1979). However, the abnormal cAMP response to administered PTH (below) does not become normal in PHP patients who become normocalcemic with or without treatment. Thus, the PTH infusion remains the most reliable test for distinguishing between these two variants (Fig. 3).

Biochemical Tests

The biochemical hallmark of PHP is the failure of the target organs, bone and kidney, to respond normally to PTH. Additional tests have been developed to identify subjects with PHP type 1a; these research tests, which are based on analysis of $G\alpha_s$ protein or the *GNAS1* gene, are only rarely indicated under typical clinical circumstances. The definitive diagnosis of PHP at the present time depends on the demonstration of a deficient cAMP, $1,25(OH)_2D_3$, or phosphate response to an active preparation of PTH. The classical tests of Ellsworth and Howard, and of Chase, Melson, and Aurbach involved the intravenous infusion of 200–300 USP units of bovine parathyroid extract (parathyroid injection, USP; Lilly) and subsequent measurement of urinary excretion of nephrogenous (or total) cAMP (Fig. 3) and phosphate. This relatively crude PTH preparation is no longer available, and has been replaced by synthetic peptides corresponding to the amino terminal region of human PTH (e.g., hPTH(1–34) peptide). Several diagnostic protocols have been described in which the response to an infusion of synthetic hPTH(1–34) peptide is used to differentiate among disorders of PTH responsiveness (Furlong *et al.,* 1986; McElduff *et al.,* 1987; Mallette, 1988). A standard protocol involves the infusion of this PTH fragment, 200 units in an adult and 3 units/kg body weight (200 units maximum) in children over the age of 3 years, intravenously over 10 min (Mallette, 1988; Mallette *et al.,* 1988) (Fig. 11). Test subjects should be in a fasting state and active urine output should be initiated and maintained by the ingestion of 200 ml of water per hour 2 hr prior to the infusion of PTH and continuing through the study. A baseline urine collection should be made in a 60-min period preceding the PTH infusion. Starting at time 0 urine should be collected in separate collections at the 0- to 30-, 30- to 60-, and 60- to 120–min time periods. Blood samples should be obtained at time 0 and at 2 hr after the start of PTH infusion for measurement of serum creatinine and phosphorus concentrations. Urine

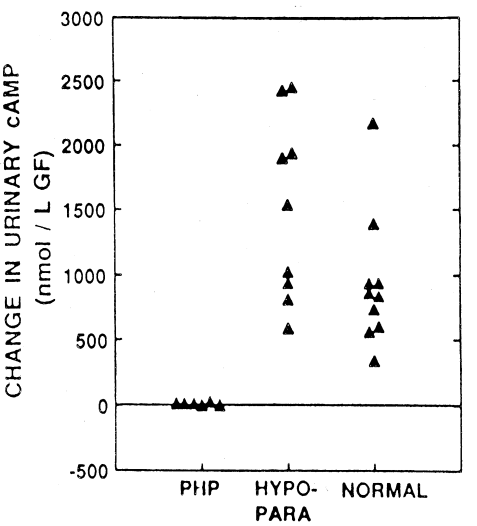

Figure 11 Change in urinary cAMP excretion in response to PTH infusion in patients with pseudohypoparathyroidism, and hypoparathyroidism and normal subjects. Reprinted with permission from Mallette *et al.* (1988)). The mean increase in cAMP excretion in the first 30-min collection period was 6.3 nmol/liter GF with individual values ranging from 0 to 20. In patients with hypoparathyroidism the increase was 1512 with the minimum being over 500 nmol/liter GF. In normal subjects the mean rise of cAMP was 937 nmol/L GF with a minimum increase of about 300.

samples should be analyzed for cAMP, phosphorus, and creatinine concentrations.

The preferred unit for expression of urinary cAMP is nmols/100 ml (or per liter) of glomerular filtrate (nmol/dl GF). The cAMP response during the first 30 min after the start of PTH infusion better differentiates patients with PHP type 1 from those with hypoparathyroidism and from normal subjects than other parameters of cAMP metabolism (Mallette *et al.,* 1988) (Fig. 11). The change in urinary cAMP/mg creatinine during the same 30-min period also discriminates well between patients with PHP and normal subjects or patients with hypoparathyroidism (Mallette *et al.,* 1988). Several metabolic abnormalities such as hypo- and hypermagnesemia and metabolic acidosis may interfere with the renal generation and excretion of cAMP in response to PTH (Rude *et al.,* 1976; Slatopolsky *et al.,* 1976; Beck and Davis, 1975; Beck *et al.,* 1975). The maximal urinary cAMP response to PTH increases after suppression of endogenous PTH in patients with PHP type 1, but nevertheless does not reach that of the normal range (Stone *et al.,* 1993) These abnormalities should be corrected if possible, but probably do not interfere with the interpretation of the test.

Calculation of the phosphaturic response to PTH as the percentage decrease in tubular maximum for phosphate reabsorption (percentage fall in TmP/GF) during the first hour after PTH infusion yields the best separation between normal subjects and patients with PHP or hypoparathyroidism (Mallette *et al.,* 1988) (Fig. 12). However, distinction between groups is also possible when the results are expressed as the fall in percentage tubular reabsorption of phosphorus (decrease in % TRP). A nomogram has been developed that facilitates calculation of $TmPO_4$/GFR (Walton and Bijvoet, 1975). TmP/GF is elevated in patients with PHP and hypoparathyroidism. Patients with hormone-deficient hypoparathyroidism have a steep fall in TmP/GF during the first hour after beginning the infusion of PTH. This fall does not occur in patients with PHP (for further details see references by Mallette *et al.* (1988; Mallette *et al.,* 1988)). Although a normal phosphate response may occur in PHP type 1 patients with serum calcium or PTH levels in the normal range (Stone *et al.,* 1993), in patients with PHP type 2 the phosphaturic response to PTH is not changed despite at least a 10-fold increase in cAMP excretion. Unfortunately, interpretation of the phosphaturic response to PTH is often complicated by random variations in phosphate clearance, and it is sometimes not possible to classify a phosphaturic response as normal or subnormal regardless of the criteria employed. More perplexing yet is the observation that biochemical findings that resemble PHP type 2 have been found in patients with various forms of vitamin D deficiency (Rao *et al.,* 1985). In these patients, marked hypocalcemia is accompanied by hyperphosphatemia due presumably to an acquired dissociation between the amount of cAMP generated in the renal tubule and its effect on phosphate clearance.

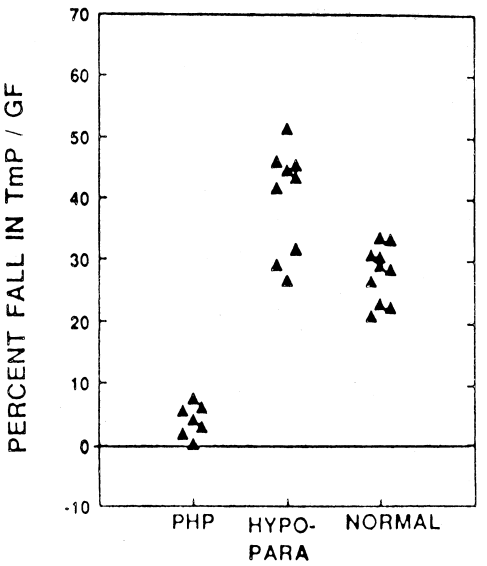

Figure 12 Percentage fall in TmP/GF from the baseline value in the first hour after infusion of PTH in patients with pseudohypoparathyroidism, and hypoparathyroidism and in normal subjects. Reprinted with permission from Mallette *et al.* (1988).

The plasma cAMP response to PTH can also be used to differentiate patients with PHP type 1 from normal subjects and from patients with hypoparathyroidism (Furlong *et al.,* 1986; Sohn *et al.,* 1984; Stirling *et al.,* 1991). Patients with PHP type 2 can be expected to have normal responsiveness, however. This test offers few advantages over protocols that assess the urinary excretion of cAMP, as changes in plasma cAMP in normal subjects and patients with hypoparathyroidism are much less dramatic than changes in urinary cAMP, and urine must still be collected if one wishes to assess the phosphaturic response to PTH. One reasonable indication for measuring the plasma cAMP response to PTH is the evaluation of patients in whom proper collection of urine is not possible, such as young children (Stirling *et al.,* 1991).

The plasma $1,25(OH)_2D_3$ response to PTH has been used to differentiate between hormone-deficient and hormone-resistant hypoparathyroidism (Miura *et al.,* 1990; McElduff *et al.,* 1987). In contrast to normal subjects and patients with hypoparathyroidism, patients with PHP had no significant increase in circulating levels of $1,25(OH)_2D_3$. This proposed test demonstrates nicely the difference in the pathophysiology between hypoparathyroidism and PHP. Its clinical relevance is probably limited to distinguishing type 1 from type 2 PHP where the expected increase in the latter form of PHP might be a more reliable parameter than the phosphaturic response to PTH.

Treatment

Urgent treatment of acute or severe symptomatic hypocalcemia in patients with PHP (or other forms of hypoparathyroidism) is best accomplished by the infusion of calcium intravenously. Vitamin D is not required. The

goal is alleviation of symptoms and prevention of laryngeal spasm and seizures. Hyperphosphatemia, alkalosis, and hypomagnesemia should be corrected. The serum calcium should be increased to the mid-normal range. The desired serum calcium levels can usually be obtained by injecting 1–3 g of calcium gluconate (93–279 mg of elemental calcium, 10–30 ml of 10% calcium gluconate) over a 10-min period followed by continuous infusion of calcium (up to 100 mg/hr) using a solution of 5% dextrose in water containing 100 ml of 10% calcium gluconate (930 mg of elemental calcium) per liter. A 10% solution of calcium chloride is available for intravenous use but it is very irritating to the veins. The serum calcium level should be measured at frequent intervals, and the amount of intravenous calcium should be adjusted accordingly. Electrocardiographic monitoring is advisable when patients are receiving digitalis-like drugs because increasing serum calcium levels can predispose to digitalis toxicity. Oral calcium and vitamin D therapy should be started as soon as possible and gradually adjusted to replace the need for intravenous calcium (Lebowitz and Moses, 1992).

The long-term treatment of hypocalcemia in patients with PHP involves the administration of oral calcium and vitamin D or analogs. Patients with PHP may require less intensive therapy than patients with PTH deficiency.

The goals of therapy are to maintain serum-ionized calcium levels in the normal range, to avoid hypercalciuria, and to suppress PTH levels. Patients with hypoparathyroidism have increased urinary calcium excretion in relation to serum calcium and are therefore prone to hypercalciuria (Litvak *et al.,* 1958). By contrast, patients with PHP have significantly lower urinary calcium in relation to serum calcium (Litvak *et al.,* 1958; Yamamoto *et al.,* 1988) and can tolerate serum calcium levels that are within the normal range without developing hypercalciuria (Mizunashi *et al.,* 1990).

Once normocalcemia has been attained attention should be directed toward suppression of PTH levels to normal. This is important because elevated PTH levels in patients with PHP are frequently associated with increased bone remodeling. Hyperparathyroid bone disease, including osteitis fibrosa cystica (Kidd *et al.,* 1980; Steinbach *et al.,* 1965; Kolb and Steinbach, 1962) and cortical osteopenia (Fig. 4) (Breslau *et al.,* 1983), can occur in patients with PHP type 1. These subjects may have elevated serum levels of alkaline phosphatase (Kolb and Steinbach, 1962) and urine hydroxyproline (Breslau *et al.,* 1983). In this regard calcitriol has an advantage over other vitamin D preparations since it may inhibit PTH release directly (Slatopolsky *et al.,* 1984) in addition to the indirect inhibition caused by elevating the serum calcium. Since thiazide diuretics effectively increase renal calcium reabsorption in patients with PHP (Breslau and Moses, 1978), these agents along with a low sodium diet can be utilized as an additional means of attaining higher serum calcium levels and better suppression of PTH without inducing hypercalciuria.

Oral calcium is usually administered in amounts from 1 to 3 g of elemental calcium per day in divided doses. To assure optimal absorption, oral calcium supplements should be taken with water or other fluids and with food in the stomach (Shangraw, 1989). Many considerations are involved in the selection of a calcium supplement, and none are unique to the treatment of PHP. Calcium carbonate is an inexpensive form of calcium that is very convenient owing to its high content of elemental calcium (40%). When taken with food, absorption of calcium from calcium carbonate is adequate even in achlorhydric patients. Due to the low content of elemental calcium in calcium lactate (13%) and calcium gluconate (9%), patients must take many tablets to obtain adequate amounts of calcium. Thus, these salts are inconvenient and are often not acceptable to the patients. Calcium citrate is 21% calcium and is well absorbed even in the absence of stomach acidity (Harvey *et al.,* 1988). Although more expensive than many other forms of calcium, calcium citrate has the advantage of causing fewer gastrointestinal side effects. For those who prefer a liquid calcium supplement, calcium glubionate is very palatable and contains 252 mg calcium/10 ml. Ten to 30 ml of a 10% calcium chloride solution (360 to 1080 mg calcium) every 8 hr may be very effective in patients with achlorhydria (Komindr *et al.,* 1989). Hyperchloremic acidosis may occur, which can be prevented by giving half of the calcium as chloride and half as carbonate simultaneously (Komindr *et al.,* 1989). Calcium phosphate salts should be avoided.

All patients with PHP who are hypocalcemic will require vitamin D or analogs in addition to calcium. Calcitriol, the active form of vitamin D, is the most popular physiological treatment choice in patients with PHP. Patients with PHP require about 75% as much calcitriol to maintain normocalcemia as do patients with hypoparathyroidism (Okano *et al.,* 1982). Almost all patients with PHP can be effectively treated with calcitriol in the amount of 0.25 μg twice a day to 0.5 μg four times a day. Because of the expense of calcitriol and the need to administer the drug several times per day, other vitamin D preparations may be preferred. PHP patients respond well to pharmacological doses of ergocalciferol and calcidiol. Ergocalciferol is the least expensive choice for vitamin D therapy, and provides a long duration of action (with corresponding prolonged potential toxicity). Patients with PHP require lower doses of vitamin D than patients with hypoparathyroidism (Okano *et al.,* 1982), an observation that reflects the response of bone and renal distal tubular cells to endogenous PTH (Breslau, 1989). Treatment with calcium and vitamin D usually decreases the elevated serum phosphate to a high normal level because of a favorable balance between increased urinary phosphate excretion and decreased intestinal phosphate absorption. In general, phosphate-binding gels such as aluminum hydroxide are not necessary.

Attention should be directed to a number of special situations. Because thiazide diuretics can increase renal calcium reabsorption in patients with PHP (Breslau and Moses, 1978), the inadvertent institution or discontinuation of these drugs may respectively increase or decrease plasma calcium levels. By contrast, furosamide and other

loop diuretics can increase renal clearance of calcium and depress serum calcium levels. The administration of glucocorticoids antagonizes the action of vitamin D (and analogs) and may also precipitate hypocalcemia. The development of hypomagnesemia may also interfere with the effectiveness of treatment with calcium and vitamin D (Rosler and Rabinowitz, 1973).

Estrogen therapy and pregnancy have particularly interesting effects on calcium homeostasis in patients with PHP. Estrogen therapy can reduce serum calcium concentrations in women with PHP type 1 (Breslau and Zerwekh, 1986) as well as women with hypoparathyroidism (Verbeelen and Fuss, 1979). In contrast, at the time of the menses, when estrogen levels are low, some well-treated hypoparathyroid women may develop symptomatic hypocalcemia with the cause remaining unknown (Mallette, 1992). The same phenomenon occurs occasionally in women with PHP. Hypocalcemic symptoms are relieved in 30–60 min by ingestion of 200–400 mg of elemental calcium.

Paradoxically, during the high-estrogen state of pregnancy, the patients of Breslau and Zerwekh remained normocalcemic without therapeutic amounts of calcium and vitamin D (Zerwekh and Breslau, 1986). During pregnancy serum $1,25(OH)_2D_3$ concentrations increased two- to three fold while the PTH levels were nearly half of what was present before pregnancy. After delivery serum calcium and $1,25(OH)_2D_3$ levels decreased and PTH rose (Breslau and Zerwekh, 1986). As placental synthesis of 1,25-dihydroxy vitamin D is not compromised in patients with PHP (Zerwekh and Breslau, 1986), the placenta may have contributed to the maintenance of normocalcemia during pregnancy in these patients. In contrast, patients with hypoparathyroidism may require treatment with larger amounts of vitamin D and calcium in the latter half of pregnancy (Caplan and Beguin, 1990).

Patients with AHO may require specific treatment for unusual problems related to their developmental and skeletal abnormalities. Patients with PHP type 1a should be treated for their associated hypogonadism and hypothyroidism. Ectopic calcification occurs in about 30% of patients with AHO (Fitch, 1982), but rarely causes a problem. However, at times large extraskeletal osteomas may occur (Prendiville *et al.,* 1992). These may require surgical removal to relieve pressure symptoms. Surgery may also be required to relieve neurological symptoms caused by ossification of ligaments (Firooznia *et al.,* 1985). Skeletal abnormalities such as deformed elbows, coxa valga and vara, and bowed tibia may require orthopedic evaluation and treatment. More commonly, treatment is directed at bone abnormalities of the feet. The symptoms are caused by deformities such as painful hyperkeratotic lesions beneath prominent metatarsal heads, bursitis of effected metatarsal phalangeal joints, dislocated toes that do not fit well into shoes, ulcerative lesions from malalignment, or pressure and exostoses (Kalajian, 1978). Measures which have been recommended to relieve pedal symptoms include reduction of hyperkeratotic lesions, padding of the plantar aspects of the feet to accommodate the lesions, soft orthotic devices that can be placed in shoes to cushion weight bearing, custom-made molded shoes, and various medical and physical therapies to relieve acute capsulitis and bursitis (Kalajian, 1978).

Conclusion

The discovery, and biochemical characterization, of the components of the PTH receptor signal transduction pathway have facilitated development of molecular approaches to the investigation of the pathophysiology of PTH resistance. Ultimately, the insights gained from studies of these unusual patients will provide new information concerning the physiological regulation of PTH responsiveness in classical target tissues, such as bone and kidney, as well as in nonclassical targets.

As with many other human disorders for which the disease gene has been identified, it is predicted that ability to diagnose these disorders on a molecular level will extend the clinical spectrum of disease. This prediction has already been fulfilled in AHO where defects in the *GNAS1* gene encoding $G\alpha_s$ have been found to produce highly variable phenotypes. More recent studies, exploring the basis for phenotypic variability in PHP type 1a and the molecular basis for PHP type 1b, have led to the unanticipated discovery of a remarkably complex mechanism of genomic imprinting that regulates *GNAS1* expression and which will provide the focus for much exciting future work.

CHAPTER 65

Other Skeletal Diseases Resulting from G Protein Defects

Fibrous Dysplasia of Bone and McCune–Albright Syndrome

Lee S. Weinstein

Metabolic Diseases Branch, National Institute of Diabetes, Digestive, and Kidney Diseases, National Institutes of Health, Bethesda, Maryland 20892

Summary

Fibrous dysplasia (FD) is a benign focal bone lesion composed of fibrous connective tissue with interspersed spicules of immature woven bone and, occasionally, islands of cartilaginous tissue. The lesions usually expand concentrically from the medullary cavity toward the cortex, resulting in thinning of the surrounding cortical bone. These lesions may be asymptomatic but often present with local swelling, pain, deformity, or fracture. Involvement of the craniofacial bones may lead to symptoms of nerve entrapment. In the majority of cases patients present with a single focus of FD, referred to as monostotic fibrous dysplasia (MOFD). A minority of patients have multiple bone lesions, referred to as polyostotic fibrous dysplasia (POFD). Of the patients with POFD, a small number have either pigmented "café-au-lait" lesions on the skin and/or endocrinopathies resulting in autonomous hypersecretion of multiple hormones. This constellation is the McCune–Albright syndrome (MAS). With rare exceptions, all three syndromes occur sporadically and are not transmitted from generation to generation. It was previously proposed that MOFD is a disease entity distinct from POFD and MAS. Recent molecular biological examination of patient tissues or cells have determined that virtually all cases of MAS are due to widespread distribution of cells in which an activating mutation of the G_s α-subunit gene is present. This defect results in elevation of intracellular cyclic adenosine monophosphate (cAMP), resulting in a myriad of abnormalities in these patients. The same mutations have been identified in both MOFD and POFD lesions, suggesting that these really represent a more limited presentation of MAS. It is likely that elevated cAMP in mesenchymal precursor cells leads to overexpression of the Fos protein, a *trans*-activating protein that is the product of an immediate–early gene. Overexpression of Fos, as well as other abnormalities resulting from constitutive activation of G_s in these cells disrupts the normal program of proliferation and differentiation of these cells, resulting in FD. These changes also lead to increased expression of interleukin-6 (IL-6) from these cells, which stimulates osteoclast recruitment and activity. Although nonsurgical therapeutic options have been limited, recent early success with the bisphosphonate pamidronate raise hope that medical therapy may halt and even reverse FD.

Clinical Presentation

FD was first described as a distinct entity and named about 50 years ago (Lichtenstein and Jaffe, 1942). The majority of patients with FD have a single bone lesion (MOFD).

The remainder have multiple lesions (POFD) and, of these, a small fraction have MAS. It has been stated that the relative incidence of these three entities is 70% MOFD, 30% POFD, and less than 3% MAS (Nager *et al.,* 1982). However, if one considers the cooccurrence of FD and any other manifestation characteristic of MAS to be a form-fruste of MAS, then the relative incidence of MAS is significantly higher. The most commonly affected bones include the femur (most often the femoral neck and intertrochanteric region), tibia, humerus, ribs, and craniofacial bones (most often the maxilla) (Schlumberger, 1946; Harris *et al.,* 1962; Nager *et al.,* 1982). Other long bones such as the radius, ulna, and fibula are involved less frequently while the bones of the hands, feet, and spine are usually spared. FD is the most common benign bone lesion of the ribs (Schlumberger, 1946).

The most common symptoms associated with FD (more often associated with POFD) include deformities (often producing a limp), pathological fractures, pain, and nerve compression (Schlumberger, 1946; Harris *et al.,* 1962; Danon and Crawford, 1987). Deformities may include leg length discrepancy, outward bowing of the proximal femur (shepherd's-crook deformity), facial assymmetry, orbital displacement and visible or palpable bony enlargement. In some cases deformity of the chest wall may lead to restrictive pulmonary disease (Nager *et al.,* 1982; Schlumberger, 1946). Because of the lack of normal trabecular bone and the thinning of the surrounding cortical bone, pathologic fractures occur frequently and are often recurrent. Pain is caused by rapidly expanding lesions, pathological fractures, and secondary arthritic changes in nearby joints. The most common neurological complications include blindness, deafness and equilibrium disturbances due to compression of the occipital and auditory nerves. High output cardiac failure due to arteriovenous shunting through bone lesions has also been reported (Fischer *et al.,* 1970). Often, particularly in patients with MOFD, FD, may be asymptomatic and first diagnosed as an incidental radiologic finding (Schlumberger, 1946).

Usually FD is identified in the first decade of life either by the onset of symptoms or by screening patients who have other manifestations of MAS. It often progresses in early life but usually becomes quiescent after the third decade (Harris *et al.,* 1962; Danon and Crawford, 1987). It has been reported that advanced bone age in childhood may be associated with FD, even in the absence of endocrine abnormalities (Benedict, 1962; Mauras and Blizzard, 1986). In a small number of cases FD may significantly progress and be initially diagnosed during puberty, pregnancy, or the use of oral contraceptives (Stevens-Simon *et al.,* 1991; Schlumberger, 1946). Often active disease is associated with mildly to moderately increased serum alkaline phosphatase and other biochemical markers of bone turnover. In a small number of cases FD may undergo malignant degeneration, most often to osteosarcoma and occasionally to chondrosarcoma, fibrosarcomas, or other types of sarcoma (Tanner *et al.,* 1961; Yabut *et al.,* 1988; Ruggieri *et al.,* 1994). There is no concensus about whether prior radiotherapy increases the probability of malignant transformation. In contrast to POFD, MOFD usually has a benign clinical course (Schlumberger, 1946). The clinical manifestations of MAS will be summarized below (see Mc-Cune–Albright syndrome).

In some patients with FD, there is the coexistence of FD and intramuscular myxomas (Mazabraud's syndrome) (Mazabraud and Girard, 1957; Lever and Pettingale, 1983; Prayson and Leeson, 1993; Gober and Nicholas, 1993; Aoki *et al.,* 1995). Myxomas occur more frequently in patients with POFD and MAS. Generally these tumors are located in the vicinity of the FD, the thigh being the most common location. In contrast to sporadic myxomas, the myxomas in this syndrome tend to be large and often are multiple. They can easily be misdiagnosed as malignant sarcomas.

McCune–Albright Syndrome

MAS was first described as a specific syndrome distinct from neurofibromatosis and hyperparathyroidism in the 1930s (Albright *et al.,* 1937; McCune, 1936). The classical clinical triad which has generally defined the syndrome is the cooccurrence of sexual precocity, POFD, and areas of skin hyperpigmentation (café-au-lait spots). However, multiple other endocrine abnormalities, including thyroid nodules and hyperthyroidism, adrenal hyperplasia and hypercortisolism, pituitary tumors with acromegaly and hyperprolactinemia and hypophosphatemic rickets or osteomalacia, can also be present (Danon and Crawford, 1987; Mauras and Blizzard, 1986; Schwindinger and Levine, 1993). Other nonendocrine abnormalities are also occasionally present, affecting the liver, heart, thymus, spleen, bone marrow, gastrointestinal tract, and the brain (Weinstein *et al.,* 1991; Shenker *et al.,* 1993). However, many patients may present with only two of the features of the classic triad or one of these features and another endocrine or nonendocrine abnormality (Grant and Martinez, 1983; Rieth *et al.,* 1984; Danon and Crawford, 1987). These patients are also considered to have MAS. In any patient with characteristic café-au-lait spots, clinical evidence of FD, or any of the above endocrine abnormalities, particularly at a young age, the diagnosis of MAS should be considered.

The café-au-lait spots appear as single or multiple brown hyperpigmented flat macules that may be difficult to notice at birth, but become more obvious with age or with sun exposure (Danon and Crawford, 1987; Mauras and Blizzard, 1986). Albright originally stated that café-au-lait spots in MAS have irregular borders like the "coast of Maine," in contrast to those in neurofibromatosis in which the borders are smooth like the "coast of California" (Albright *et al.,* 1937). However, this distinction may be difficult to make and is not reliable in differentiating these two diseases. Often the café-au-lait spots are on one side of the body which usually corresponds to the side with bone involvement. The areas of pigmentation generally do not cross the midline. They are often arranged in a segmental pattern which follows the developmental lines of Blaschko (Happle, 1986). Melanocytes cultured from these lesions have increased numbers of

dendrites and melanosomes and increased levels of tyrosinase, the rate-limiting enzyme for the production of melanin (Kim *et al.,* 1999). These latter changes are likely due to increased intracellular cAMP concentrations. Rarely, MAS is also associated with alopecia (Schwartz *et al.,* 1996).

Sexual precocity may present as early as the first months of life. In girls premature menses is usually the first sign and occurs before breast development (Danon and Crawford, 1987; Mauras and Blizzard, 1986; Feuillan, 1993). Serum estrogen levels increase and decrease cyclically and correspond to the presence of large ovarian follicles which enlarge and regress in a cyclic manner (Comite *et al.,* 1984; Rieth *et al.,* 1984; Feuillan, 1993). There is no evidence of ovulation from the follicles and sometimes they remain as ovarian cysts. Measurements of serum gonadotropin pulsatility and the response to luteinizing-hormone-releasing hormone (LHRH) show suppression of gonadotropin secretion except in older girls who have developed secondary central puberty (Foster *et al.,* 1984). Usually females undergo normal development during adolescence and show normal reproductive function in adult life. Boys can also present with precocious puberty although less commonly than girls. Usual signs include testicular enlargement, secondary sex characteristics, and often evidence of spermatogenesis (Danon and Crawford, 1987; Mauras and Blizzard, 1986). In one case testicular enlargement was present without other evidence of puberty, which resulted from maturation of the tubules but not the Leydig cells (Giovanelli *et al.,* 1978). As in girls the sexual precocity is gonadotropin-independent. Sexual precocity in either sex is usually associated with advanced bone age. As expected, long-acting analogs of LHRH have been shown to be ineffective in the treatment of prepubertal patients (Comite *et al.,* 1984; Feuillan, 1993). Cyproheptadine has shown some success while the aromatase inhibitor testolactone has shown to have beneficial effects in girls (Feuillan *et al.,* 1993; Feuillan, 1993). Preliminary reports suggest that tamoxifen (Eugster *et al.,* 1999) and ketoconazole (Syed and Chalew, 1999) may also be useful for treatment of precocious puberty in MAS

Thyroid abnormalities can occur at any age, even soon after birth (Danon and Crawford, 1987; Mauras and Blizzard, 1986). The patient often presents with a nodular goiter and multinodular disease is often detected by ultrasound. The nodules are almost always benign and usually show increased radioiodine uptake (Feuillan *et al.,* 1990). In most cases with nodular disease hyperthyroidism is also present (Feuillan *et al.,* 1990; Mastorakos *et al.,* 1997). This may range from severe hyperthyroidism with many clinical manifestations to "biochemical" hyperthyroidism in which the thyroid hormone levels are in the upper normal range but the thyroid-stimulating hormone (TSH) is suppressed. Response of TSH to TSH-releasing hormone (TRH) has also demonstrated suppression of TSH. More minor sonographic abnormalities may also be present in patients who are euthyroid (Lair-Milan *et al.,* 1996). Hyperthyroidism may also contribute to accelerated bone growth. Thyroid pathology reveals no evidence of lymphocytic infiltration and thyroid antibodies are almost always undetectable. If hyperthyroidism is clinically significant patients can be treated with antithyroid drugs, radioiodine, or surgery.

Hypercortisolism in MAS is not as common as sexual precocity and hyperthyroidism (Danon and Crawford, 1987; Mauras and Blizzard, 1986). Often the major manifestation of hypercortisolism in children is decreased growth rate. Hypercortisolism can also result in clinically severe abnormalities and present very early in life. MAS patients with hypercortisolism may have an increased incidence of severe nonendocrine manifestations which include unexplained sudden death after adrenalectomy (Shenker *et al.,* 1993). Hormonal evaluation in these patients show that the adrenal glands are hypersecreting cortisol even in the absence of ACTH (Danon and Crawford, 1987; Mauras and Blizzard, 1986). Pathology usually is that of adrenal nodular hyperplasia although adrenal adenoma has also been reported (Benjamin and McRoberts, 1973; Kirk *et al.,* 1999). Most patients will require bilateral adrenalectomy.

Growth hormone excess (acromegaly) and hyperprolactinemia are also present in a small number of MAS patients (Danon and Crawford, 1987; Mauras and Blizzard, 1986). The clinical and biochemical features of acromegaly in MAS are similar to those of acromegaly in general, including elevated serum growth hormones which increase after administration of growth-hormone-releasing hormone (GHRH) or TRH and are not suppressed by glucose. In young children acromegaly will accelerate bone growth. Sometimes the deformities resulting from craniofacial FD may appear similar to those of acromegaly. Since the clinical manifestations are usually subtle and slowly progressive, all cases of MAS or FD should be periodically screened for the presence of acromegaly. Acromegaly in MAS may be associated with hyperprolactinemia. In some cases this may result in hypogonadism and galactorrhea although pubertal development is usually normal (Danon and Crawford, 1987; Mauras and Blizzard, 1986). Hyperprolactinemia in the absence of acromegaly has not been reported in MAS. Associated pathology is most commonly pituitary adenoma or nodular hyperplasia. In one case mammosomatotroph hyperplasia was associated with acromegaly and hyperprolactinemia (Kovacs *et al.,* 1984). Pituitary adenomas and hyperplasia have not been associated with excess secretion of any other pituitary hormones in MAS. The treatment options include surgical excision, radiotherapy, bromocryptine or pergolide, or long-acting somatostatin analogs. Surgery may be technically difficult or impossible if FD is present in the base of the skull. In these cases, radiotherapy may be contraindicated because of possible increase of malignancy in the surrounding bone.

Hyperphosphaturic hypophosphatemic rickets or osteomalacia has been associated with MAS and POFD (Ryan *et al.,* 1968; McArthur *et al.,* 1979; Cole *et al.,* 1983; Lever and Pettingale, 1983; Danon and Crawford, 1987; Mauras and Blizzard, 1986; Hahn *et al.,* 1991; Zung *et al.,* 1995). These patients show inappropriately decreased reabsorption of phosphate from the renal proximal tubule in the absence

of hyperparathyroidism. It has been postulated that a phosphaturic factor is secreted from areas of FD, similar to the mechanism of tumor-associated hyperphosphaturic hypophosphatemic rickets (Dent and Gertner, 1976; McArthur *et al.,* 1979). Others suggest that the hypophosphatemia is caused by a primary defect in the renal proximal tubule (Tanaka and Suwa, 1977; Lever and Pettingale, 1983). MAS patients with hypophosphatemia were demonstrated to have increased basal urinary cAMP, although some of this increase may possibly be related to increased glomerular filtration of cAMP (Zung *et al.,* 1995). The urinary cAMP response to exogenous PTH infusion was significantly blunted while the phosphaturic response was normal. The abnormal renal adenylyl cyclase activity is more consistent with a defect in the proximal renal tubule which leads to an abnormality in the production of cAMP, although the mechanism for hypophosphatemic rickets in MAS has not been clearly established. Osteomalacic changes have also been shown to be a common feature of fibrous dysplastic bone lesions in patients without the other clinical features of MAS (Bianco *et al.,* 2000). The hypophosphatemia is treated with vitamin D and oral phosphate therapy. Usually the osteomalacia or rickets is corrected but the hypophosphatemia is more resistant to therapy (Lever and Pettingale, 1983).

Hyperparathyroidism has been reported to occur with FD (primarily MOFD) in a few patients (Benedict, 1962; Firat and Stutzman, 1968; Ehrig and Wilson, 1972; Hammami *et al.,* 1997). Parathyroid adenoma was usually found surgically, and correction of hyperparathyroidism did not result in regression of the bone lesions. It is possible that most, if not all, of these patients have the autosomal dominant syndrome of hyperparathyroidism and fibroosseous tumors, a distinct clinical and genetic entity that has been subsequently recognized (Jackson *et al.,* 1990; Szabo *et al.,* 1995). Consistent with this, in the one case in which $G_s\alpha$ mutations were looked for, none were identified (Hammami *et al.,* 1997). Hyperparathyroidism has not been associated with MAS and it not clear if there is a true association between hyperparathyroidism and FD.

While the vast majority of MAS patients have abnormalities restricted to the bone, skin, and endocrine organs and have an excellent prognosis (Harris *et al.,* 1962; Lee *et al.,* 1986; Danon and Crawford, 1987), there are a small number of patients who present with one or more nonendocrine abnormalities which may lead to markedly increased morbidity and mortality (Shenker *et al.,* 1993). Patients with these features often present with the early development of extensive POFD or hypercortisolism (Harris *et al.,* 1962; Shenker *et al.,* 1993). Liver abnormalities include severe neonatal jaundice, elevated liver enzymes, and evidence of cholestatic and biliary abnormalities on liver biopsy (Shenker *et al.,* 1993; Silva *et al.,* 2000). Cardiac abnormalities may include cardiomegaly, persistent tachycardia, and unexplained sudden death in young patients. Atypical myocyte hypertrophy has also been noted on histological examination (Shenker *et al.,* 1993). The role that endocrine abnormalities, restrictive pulmonary disease, arteriovenous shunting, or a primary abnormality of myocardium and cardiac conduction plays in the pathogenesis of the cardiac manifestations is still unclear (Shenker *et al.,* 1993). Other abnormalities that are rarely associated with MAS include thymic hyperplasia, myelofibrosis with extramedullary hematopoiesis, gastrointestinal polyps, pancreatitis, breast and endometrial cancer, microcephaly, and other neurological abnormalities (Danon and Crawford, 1987; Shenker *et al.,* 1993).

Genetics

All forms of FD (MOFD, POFD, MAS), with very rare exceptions, occur sporadically without evidence of disease in more than a single family member. There is one report of POFD in multiple family members (Reitzik and Lownie, 1975). Two other reports suggest the inheritance of disease from mother to daughter. In the first family a mother was diagnosed as possible MAS while her daughter had POFD (Hibbs and Rush, 1952). In the second family a mother and daughter had both hyperparathyroidism and FD (Firat and Stutzman, 1968). It is possible that this latter family has the autosomal dominant syndrome of hyperparathyroidism and fibroosseous tumors (Jackson *et al.,* 1990; Szabo *et al.,* 1995). Recently two brothers with POFD born of nonconsanguinous unaffected parents were reported (Sarkar *et al.,* 1993). In one report, one of dizygotic twins had MAS (Caldwell and Broderick, 1947) while in another report one of monozygotic twins had MAS while the other had craniofacial FD (Lemli, 1977). These two instances are consistent with sporadic occurrence of the disease. There are no reported instances of MAS in more than one family member.

Radiological Findings

Nuclear scintigraphy with 99m-technetium methylene diphosphonate is the most sensitive method to survey the skeleton for FD (Pfeffer *et al.,* 1990). This should be performed in patients in whom MAS may be suspected due to an endocrine abnormality and/or pigmented skin lesion. It can also be used to survey the skeleton once FD has been diagnosed to determine extent of disease. On standard radiographs the lesions are typically cystic lesions which appear to expand from the medullary cavity to the cortex, usually expanding and thinning the surrounding cortical bone (Schlumberger, 1946; Mauras and Blizzard, 1986; Lucas *et al.,* 1995). In some cases the surrounding cortex becomes sclerotic, particularly if there has been a previous fracture. The lesions are usually radiolucent or exhibit a ground-glass appearance. Bone trabeculae are occasionally seen traversing the radiolucent lesions (Schlumberger, 1946). If a large amount of cartilage is present within the lesion calcifications may be visible (see Pathology) (Ishida and Dorfman, 1993). The lesions can also be sclerotic or mixed if there is a large amount of osseous tissue (Lucas *et al.,* 1995). FD is usually present in the metaphyses and diaphyses of long bones,

typically sparing the epiphyses (Albright *et al.,* 1937; Schlumberger, 1946; Mauras and Blizzard, 1986; Lucas *et al.,* 1995). Other lesions with a similar radiographic appearance include Paget's disease, osteitis fibrosa cystica, bone cysts, giant cell tumor, fibroma, chondroma, and other types of bone tumors (Schlumberger, 1946; Lucas *et al.,* 1995). Patients with POFD or MAS may show advanced bone age (Benedict, 1962; Mauras and Blizzard, 1986). Decreased bone density or radiographic features of rickets or osteomalacia is seen in patients with hypophosphatemia or hypercortisolism (Cole *et al.,* 1983; Danon and Crawford, 1987; Mauras and Blizzard, 1986)

Magnetic resonance imaging (MRI) has recently been shown to be useful in defining the extent of disease (Inamo *et al.,* 1993; Gober and Nicholas, 1993). MRI may be more sensitive and may delineate the borders of the lesions better than standard X-rays, particularly in areas in which standard X-rays are not very sensitive, such as the spine (Inamo *et al.,* 1993). Usually the lesions are hypodense on T1-weighted images but usually become brighter on T2- or STIR-weighted images (Inamo *et al.,* 1993; Gober and Nicholas, 1993; Jee *et al.,* 1996). It has been suggested that lesions that have a large amount of cartilage, decreased cellularity, or cystic changes have high signal intensity on T2-weighted images, while those that have a large amount of bone, increased cellularity, or sclerotic changes have low signal intensity on T2-weighted images. In one case MRI was also useful in identifying intramuscular myxomas, which are low signal intensity on T1-weighted images and high signal intensity on T2- or STIR-weighted images (Gober and Nicholas, 1993).

Pathology

The most prominent histological feature of FD is fibrous tissue composed of immature mesenchymal cells which appear to expand concentrically from the medullary cavity to the cortical bone (Fig. 1, see also color plate). Long, spindle-shaped fibroblasts are arranged in parallel arrays or in whirls and are embedded in a matrix with parallel collagen fibrils (Greco and Steiner, 1986). In some areas there appears to be a myxomatous matrix. The fibroblastic cells are of the osteoblastic lineage, as they express alkaline phosphate and other proteins associated with osteoblast differentiation (Riminucci *et al.,* 1997). Embedded in this fibrous tissue are spicules of immature woven bone mostly surrounded by flat lining cells similar to the fibroblasts in the fibrous areas (Greco and Steiner, 1986). These lining cells have retracted cell bodies, forming pseudolacunar spaces (Riminucci *et al.,* 1997, 1999b). This retraction is presumed to be secondary to increased intracellular cAMP, as cAMP produces similar cell shape changes in cultured osteoblasts (Riminucci *et al.,* 1997). In a few areas the woven bone trabeculae are lined by more typical osteoblasts. It appears that the osseous components of FD are formed through a process similar to membranous ossification. Unlike normal woven bone, the collagen fibrils at the surface are arranged perpendicular to the bone-forming surface (so-called Sharpey's fibers) (Riminucci *et al.,* 1997, 1999b; Bianco *et al.,* 2000). The woven bone in FD contains large osteocytic lacunae each containing multiple osteocytes (hyperosteocytic bone) (Riminucci *et al.,* 1997). Bone trabeculae in FD contain osteonectin, but not osteopontin or bone sialoprotein, proteins that are present in the matrix of normal woven bone (Riminucci *et al.,* 1997). Changes consistent with osteomalacia may be present within the bony component of FD lesions (Bianco *et al.,* 2000). Unlike normal bone, there is no evidence of replacement of the woven bone by mature lamellar bone. Usually the border between FD and normal bone is sharp and well demarcated.

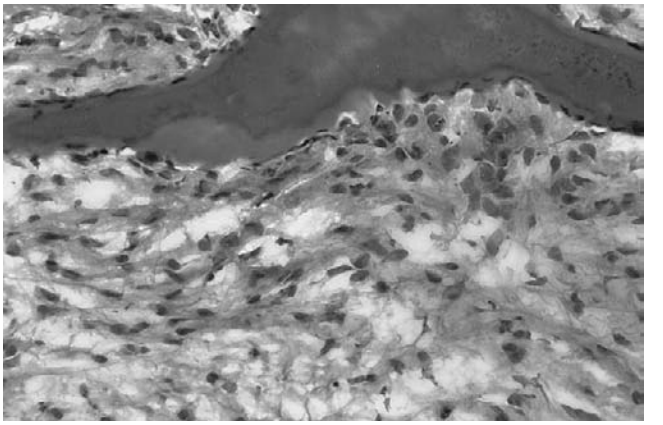

Figure 1 Histological section from a lesion of FD (H & E). Fibrous tissue containing elongated fibroblasts in a collagenous matrix dominate the section. One spicule of immature woven bone is present. Note that the bone spicule is surrounded in many areas by flattened cells which morphologically are different than cuboidal osteoblasts that normally are present in regions of bone formation. There are no cartilaginous elements in this section. (See also color plate.)

One recent study suggests that the histology of FD lesions is variable, with three major histological patterns depending on the location of the affected bone (Riminucci *et al.,* 1999b). The "Chinese writing" pattern, characterized by thin and disconnected bone trabeculae with interspersed fibrous tissue, is usually present in lesions located in the axial and appendicular skeleton. The "sclerotic/Pagetoid" pattern, characterized by dense, sclerotic trabecular bone forming an uninterrupted network and the presence of cement/arrest lines similar to the Schmorl's mosaic typically seen in Pagetic bone, is usually found in cranial bone lesions. The "sclerotic/hypercellular" pattern is present in FD lesions in gnathic (jaw) bones. This pattern is characterized by large trabeculae arranged in a parallel array with osteoblasts lining one side of the trabeculae. All three types of FD lesions have some common features, including the presence of retracted osteoblasts and Sharpey's fibers, that appear to be hallmarks for FD.

In some cases there are islands of hyaline cartilage which are surrounded by fibrous tissue, thus probably representing a metaplastic process (Greco and Steiner, 1986).

With few exceptions the cartilage appears normal and in some areas it undergoes endochondral ossification. In rare cases the cartilaginous component may be the dominant feature and this has been termed fibrocartilaginous dysplasia (Ishida and Dorfman, 1993). There may be some atypia suggesting chondrosarcoma but the presence of surrounding fibroosseous tissue is indicative of FD. Since endochondral ossification is often prominent, stippled or ring-like calcifications may be visible within these lesions on radiographs. Some lesions of FD contain calcified spherules, a typical feature of cemento-ossifying fibroma. These two benign fibrous lesions can sometimes be difficult to distinguish histologically and it has been suggested that they may represent a histological spectrum of a similar process (Voytek *et al.,* 1995). Other lesions which appear histologically similar to FD are osteitis fibrosa cystica, which is usually associated with hyperparathyroidism or chronic renal failure, and Paget's disease, which, unlike FD, usually develops in later life. In both of these diseases there is more active osteoclastic bone resorption within the lesions and no evidence of cartilaginous islands.

FD often invades the outer cortical bone through the action of increased numbers of surrounding osteoclasts (Riminucci *et al.,* 1997; Yamamoto *et al.,* 1996), resulting in cortical thinning and in some cases concentric bulging of the cortex. These osteoclasts have increased numbers of nuclei per cell (Yamamoto *et al.,* 1996). In rare cases these lesions may appear more aggressive, resulting in exophytic protuberances (Dorfman *et al.,* 1994) or even invasion into the surrounding soft tissue (Latham *et al.,* 1992). These lesions are benign and do not metastasize. Rarely, FD undergoes malignant degeneration, most often to osteosarcoma and less commonly to chondrosarcoma, fibrsarcoma, or malignant fibrohistiosarcoma (Yabut *et al.,* 1988; Ruggieri *et al.,* 1994)

Other tissues which may be abnormal pathologically in MAS include the skin, endocrine organs, liver, bone marrow, thymus, spleen and gastrointestinal tract. Histologically the pigmented macules appear similar to those seen in neurofibromatosis. However, in contrast to pigmented lesions from neurofibromatosis patients, those from MAS patients fail to develop giant pigmented granules within the melanocytes in response to dopa (Benedict, 1962). The affected endocrine tissues generally undergo a nodular hyperplasia or in some cases develop a hyperfunctioning adenoma (Danon and Crawford, 1987; Mauras and Blizzard, 1986; Weinstein *et al.,* 1991). The ovaries show the development of large follicular cysts with no evidence of ovulation. Endocrine organs may have pathological changes typically found in MAS in the absence of hormonal abnormalities (Danon and Crawford, 1987). In the small number of severely affected patients, numerous nonendocrine abnormalities have been described pathologically. These include cholestasis and biliary abnormalities in the liver, hypertrophy of the thymus and spleen, myeloid metaplasia with extramedullary hematopoiesis, subtle brain abnormalities, and gastrointestinal polyps (McCune and Bruch, 1937; Albright *et al.,* 1937; MacMahon, 1971; Danon and Crawford, 1987; Shenker *et al.,* 1993)

Pathogenesis

The first clues to the pathogenesis of the various syndromes in which FD is present originally came from observations of the skin and endocrine manifestations of MAS. It was first noted that in MAS the cutaneous hyperpigmentation often follows the developmental lines of Blaschko. Based upon this observation Happle proposed that the disease is likely to be caused by a dominant somatic mutation occurring early in development or a gametic half chromatid mutation (Happle, 1986). This early event would result in a mosaic with a widespead distribution of cells with a genetic abnormality. Since this disease is never inherited, it is likely that the mutation causing MAS is generally lethal if present in the germline. According to this model, the specific constellation of abnormalities within a given patient would be dependent on the distribution of mutant-bearing cells.

Evaluation of the endocrine abnormalities in MAS patients provided the second clue, which was important in hypothesizing where the specific genetic defect occurs. It was originally proposed that the hyperplasia and hyperfunction of diverse peripheral endocrine organs was the result of a hypothalamic defect (Hall and Warrick, 1972). Subsequent endocrine evaluations clearly demonstrated that in each case the abnormal endocrine glands were functioning autonomously (Danon *et al.,* 1975; Scully and McNeely, 1975; Mauras and Blizzard, 1986; D'Armiento *et al.,* 1983; Foster *et al.,* 1984; Feuillan *et al.,* 1990). An abnormality in these tissues resulting in excess intracellular cAMP could result in the diverse clinical manifestations of MAS since cAMP is known to stimulate the growth and/or function of endocrine organs which can be abnormal in MAS and the production of melanin pigment in melanocytes (Mauras and Blizzard, 1986; Lee *et al.,* 1986; Dumont *et al.,* 1989; Scully and McNeely, 1975). Mutations in the G_s α-subunit gene which lead to constitutive activation of G_s and cAMP production were identified in isolated human growth hormone-secreting pituitary tumors and thyroid tumors (Landis *et al.,* 1989; Lyons *et al.,* 1990; Suarez *et al.,* 1991), both of which are found in MAS. It therefore seemed likely that these same mutations may also be present in a more widespread distribution in MAS.

G proteins are a family of signal transduction proteins which transmit the signals between a large number of receptors for extracellular ligands and intracellular second messengers, such as enzymes and ion channels. Each G protein is a heterotrimer composed of a specific α, β, and γ subunit (Spiegel *et al.,* 1992). The α-subunit binds guanine nucleotide and interacts with specific receptors and effectors. In the inactive state, GDP is bound to the α-subunit and the GDP-bound α-subunit is associated with a tightly but noncovalently bound $\beta\gamma$ complex. When a ligand, such as a hormone, binds to its specific receptor, the occupied

receptor interacts with and activates the inactive heterotrimer, resulting in the exchange of GTP for GDP and dissociation of the α-subunit from the $\beta\gamma$ complex. Both GTP-bound α-subunit and $\beta\gamma$ subunits may regulate the activity of specific effectors. In the case of G_s, the G_s α-subunit ($G_s\alpha$) stimulates the activity of adenylyl cyclases, a family of enzymes which catalyze the formation of cAMP. The α-subunit has an intrinsic GTPase activity which hydrolyzes the bound GTP to GDP (Bourne *et al.,* 1990). This reaction functions as the "turn off" switch for the G protein. Therefore, modifications that inhibit the GTPase activity will result in constitutive activation and in the case of G_s will lead to overproduction of cAMP. ADP-ribosylation of amino acid residue Arg^{201} of $G_s\alpha$ by cholera toxin leads to constitutive activation of G_s by this mechanism (Spiegel *et al.,* 1992). Mutations which encode substitutions of amino acid residues Arg^{201} or Gln^{227} in $G_s\alpha$ have been found in human thyroid and growth hormone-secreting pituitary tumors and shown to result in constitutive activation (Landis *et al.,* 1989; Masters *et al.,* 1989; Graziano and Gilman, 1989). Targeted expression of the catalytic subunit of cholera toxin in somatotrophs in transgenic mice resulted in pituitary hyperplasia (Burton *et al.,* 1991).

Activating $G_s\alpha$ mutations coding for substitutions of residue Arg^{201} have been identified in tissues from many MAS patients (Weinstein *et al.,* 1991; Shenker *et al.,* 1993, 1994). In each case, one specific mutation (Arg^{201} to His or Cys) is detected in multiple tissues and in variable abundance, consistent with a widespread distribution of a population of cells harboring a somatic mutation. More recently an Arg^{201}-to-Ser mutation was identified in a POFD patient (Candeliere *et al.,* 1997) and an Arg^{201}-to-Gly mutation was identified in an MAS patient (Riminucci *et al.,* 1999a). A possible germline Arg^{201}-to-Leu mutation has also been reported in a severely affected patient with multiple skeletal, endocrine, and developmental abnormalities (Mockridge *et al.,* 1999). Substitutions of Gln^{227} have not been found in MAS. In each tissue the mutant allele was always present in equal or lower abundance than the wild-type allele, consistant with the mutation being dominant. These mutations are present in hyperplastic or adenomatous endocrine tissues, as well as in a café-au-lait lesions from MAS patients (Schwindinger *et al.,* 1992; Kim *et al.,* 1999). These mutations are also found in many nonendocrine tissues, some of which are abnormal (e.g., liver, heart, thymus) while others are normal (Weinstein *et al.,* 1991; Shenker *et al.,* 1993; Silva *et al.,* 2000). The role of these mutations in the pathogenesis of these nonendocrine manifestations needs to be defined. In Albright hereditary osteodystrophy (AHO), loss-of-function mutations of $G_s\alpha$ are associated with bone abnormalities and resistance to multiple hormones that stimulate cAMP production (Patten *et al.,* 1990; Weinstein *et al.,* 1990). After the discovery of these mutations in MAS tissues, elevated cAMP production has been demonstrated in MAS tissues *in vitro* and *in vivo* (Zung *et al.,* 1995; Yamamoto *et al.,* 1996; Marie *et al.,* 1997; Kim *et al.,* 1999).

Activating $G_s\alpha$ mutations have also been detected at high levels in bone lesions from MAS, POFD, and MOFD patients (Malchoff *et al.,* 1994; Shenker *et al.,* 1994, 1995; Alman *et al.,* 1996; Bianco *et al.,* 2000). Therefore all forms of FD can be considered to have the same underlying pathogenesis. Recent studies suggest that FD results from abnormal proliferation and differentiation of bone marrow stromal (CFU-F) cells (Bianco and Robey, 1999). Transplantation of skeletal progenitor cells derived from human FD lesions into immunocompromised mice leads to a lesion similar to that observed in human FD, with abnormal woven bone ossicles and lack of interspersed adipocytes or hematopoiesis (Bianco *et al.,* 1998, 2000). Interestingly, these lesions formed only when both normal and mutant cells were transplanted, suggesting that the formation of FD requires the presence of normal as well as mutant precursor cells (Bianco *et al.,* 1998).

The development of mature osteoblasts from pluripotential mesenchymal precursors in the marrow stroma involves a series of defined steps: commitment to the osteoblast lineage, a proliferative phase in which preosteoblasts divide and secrete collagen and other matrix proteins, and a postproliferative phase in which the cells express osteoblast-specific gene products (e.g., alkaline phosphatase, osteopontin, and osteocalcin) and form mineralized bone (Stein and Lian, 1993). In *in vitro* models of osteoblast differentiation, parathyroid hormone and forskolin, both stimulators of cAMP production, inhibit the differentiation of osteoprogenitor cells (Bellows *et al.,* 1990; Turksen *et al.,* 1990) while treatment with oligonucleotides antisense to $G_s\alpha$ promotes their differentiation (Nanes *et al.,* 1995). The cells present in lesions of FD appear poorly differentiated morphologically and have an increased proliferation rate (Marie *et al.,* 1997) and express markers of early, but not late, osteoblast differentiation (Marie *et al.,* 1997; Riminucci *et al.,* 1997). It therefore appears that in these cells the regulation of the normal differentiation program is disrupted.

Elevation of cAMP in osteoprogenitor cells may lead to FD by affecting a number of genes downstream in the signaling cascade (Fig. 2). Activated G_s has been shown to chronically increase the expression of c-*fos* and other oncogenes through the activation of cAMP-dependent protein kinase (protein kinase A (PKA)) (Gaiddon *et al.,* 1994). cAMP binds to the regulatory subunits of PKA and these subunits dissociate from the catalytic subunits. The catalytic subunits of PKA translocate to the nucleus and phosphorylate cAMP-responsive transcription factors such as cAMP response element binding protein (CREB) and the related cAMP response element modulator (CREM) proteins. Once phosphorylated, CREB and CREM can then bind to the promoters of cAMP-responsive genes, such as c-*fos,* resulting in increased transcription (Sassone-Corsi, 1995). Fos, the product of c-*fos,* binds with Jun, the product of the c-*jun* oncogene to form a heterodimer known as AP-1. AP-1 binds to the promoters of many genes and regulates their expression. AP-1-binding complexes are expressed at high levels in the proliferative phase of osteoblast develop-

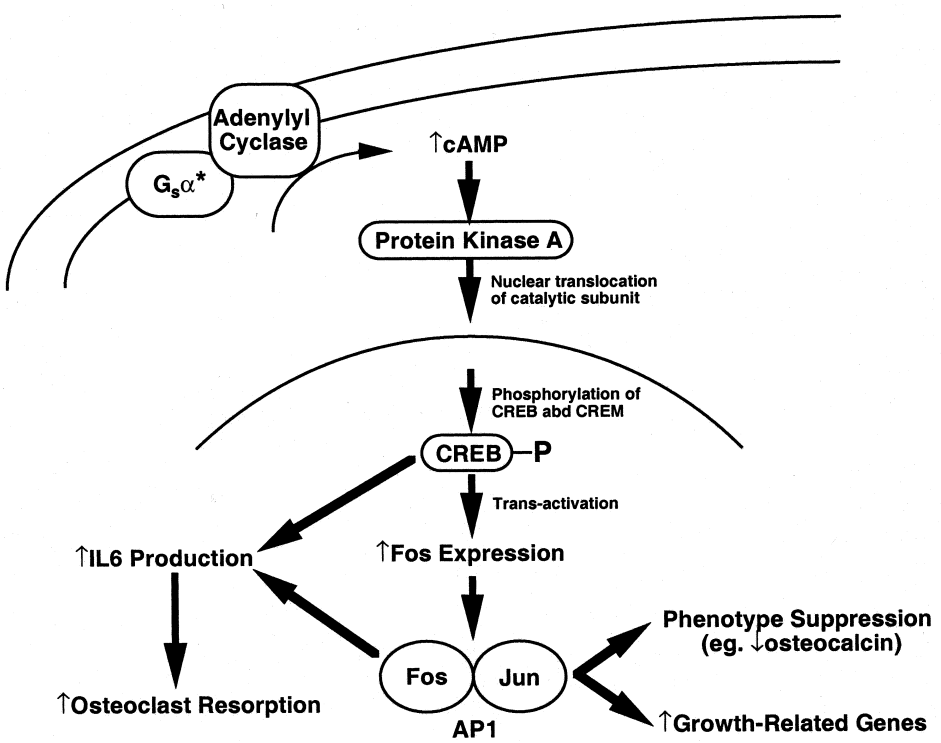

Figure 2 Possible mechanisms by which activated G_s in osteogenic cells may lead to FD. G_s activation increases the activity of the effector adenylyl cyclase, leading to increased intracellular cAMP levels. Binding of cAMP to the regulatory subunits of cAMP-dependent protein kinase (protein kinase A) allows release of its catalytic subunits, which translocate to the nucleus and phosphorylate proteins such as CREB and CREM. Phosphorylated CREB binds to promoters of cAMP-responsive immediate–early genes (e.g., c-*fos*) and increases their expression. Fos, the product of c-*fos,* binds with Jun to form AP-1. AP-1 is a transcription factor which increases the expression of growth-related genes and decreases the expression of osteoblast-specific genes, such as osteocalcin (phenotype suppression). CREB-P and AP-1 also stimulate the transcription of the IL-6 gene. IL-6 may be important in recruiting osteoclasts and stimulating osteoclastic bone resorption.

ment and markedly decrease upon the onset of differentiation (Stein and Lian, 1993). In the osteocalcin gene promoter AP-1 sites are found within two activating regions of the promoter, the vitamin D-responsive element (VDRE) and the osteocalcin (OC) box. It has been demonstated that the binding of AP-1 to these regions suppresses both the basal (OC box) and the vitamin D-induced expression (VDRE) of osteocalcin (Stein and Lian, 1993). This is one example of how high expression of AP-1 during the proliferative stage of osteoblast development can suppress the expression of a late marker of osteoblast differentiation.

Several lines of evidence suggest that overexpression of Fos is important in bone development *in vivo* and in the pathogenesis of FD. Fos has recently shown to be overexpressed in lesions of FD by *in situ* hybridization in specimens from eight patients, one of which was shown to have an activating $G_s\alpha$ mutation (Candeliere *et al.,* 1995). The abnormal expression of Fos was localized to the fibroblastic cells, which are presumed to be osteoblastic precursors. Overexpression of Fos in transgenic mice results in abnormal bone remodeling and bone lesions which are in many ways reminiscent of FD (Rüther *et al.,* 1987). Osteosarcomas which overexpress Fos develop in these animals after several months (Grigoriadis *et al.,* 1993). Fos is also overexpressed in many human osteosarcomas (Wu *et al.,* 1990). In contrast, mice with no expression of Fos develop osteopetrosis (Johnson *et al.,* 1992; Wang *et al.,* 1992).

Cells isolated from FD lesions also have markedly increased production if IL-6 (as well as IL-11). Increased local concentrations of IL-6 presumably recruit osteoclasts, allowing the FD lesion to expand by resorbing the surrounding normal cortical bone (Yamamoto *et al.,* 1996). Several lines of evidence show that the increased IL-6 production is the direct result of increased intracellular cAMP concentrations (Yamamoto *et al.,* 1996; Motomura *et al.,* 1998), and this is consistent with the presence of both cAMP-responsive elements and AP1 sites within the IL-6 promoter (Motomura *et al.,* 1998) (Fig. 2). The beta chain of platelet-derived growth factor (PDGF-B) has been shown to be abnormally expressed at high levels in FD and other aggressive fibrous bone lesions (Alman *et al.,* 1995). PDGF-B results in fibroblast proliferation and may be important in osteoclast activation. The increased levels of sex steroid receptors present in abnormal cells derived from areas of FD (Kaplan *et al.,* 1988; Pensler *et al.,* 1990) and the ability of sex steroids to increase PDGF-B expression (Alman *et al.,*

1995) may at least in part account for the progression of FD which is rarely observed during puberty, pregnancy, or the use of oral contraceptives (Stevens-Simon *et al.,* 1991).

Management

I will not discuss in detail the specific management of the various endocrine manifestations of MAS. They are generally managed with variable success by surgical removal of hyperplastic or adenomatous tissue or by specific medical therapy (e.g., somatostatin analog or bromocryptine for pituitary tumor, radioiodine or thionamides for hyperthyroidism, aromatase inhibitors for precocious puberty). One must be cautious that a small subset of patients, in which there are widespread manifestations including hypercortisolism, are at risk for perioperative sudden death. This complication may be secondary to either cardiomyopathy and arrythmia resulting from excess cAMP production in cardiac tissue or hormonal abnormalities (Shenker *et al.,* 1993). There is no specific therapy for the skin manifestations.

FD is often minimally symptomatic or asymptomatic and usually does not progress after the third decade. Generally fractures heal well with conservative management (Harris *et al.,* 1962). On occasion surgery is required for nonhealing fractures, severe pain or deformity, particularly on weight-bearing bones, or imminent signs of nerve compression (Harris *et al.,* 1962; Grabias and Campbell, 1977; Nager *et al.,* 1982; Edgerton *et al.,* 1985). Usually surgery involves excision or curretage and replacement with bone grafts. Until recently there were no other therapeutic options. Radiotherapy is contraindicated since it is generally ineffective and may increase the risk of sarcomatous degeneration, although this is controversial (Tanner *et al.,* 1961; Yabut *et al.,* 1988; Ruggieri *et al.,* 1994). Calcitonin, etidronate and clodronate have been administered to a few patients with no significant clinical improvement (Hjelmstedt and Ljunghall, 1979; Grant *et al.,* 1982; Cole *et al.,* 1983). Several uncontrolled trials have shown pamidronate to be effective in the treatment of FD, particularly with respect to improving bone pain and reversing some of the radiological abnormalites (Liens *et al.,* 1994; Chapurlat *et al.,* 1997; Lala *et al.,* 2000; Zacharin and O'Sullivan, 2000). Growth-plate widening was observed in one young patient, which reversed after the treatment was stopped (Liens *et al.,* 1994). More recent studies show pamidronate to be safe in children and adolescents.

CHAPTER 66

Osteogenesis Imperfecta

David W. Rowe

Department of Genetics and Developmental Biology, University of Connecticut Health Center, Farmington, Connecticut 06030

Introduction

Osteogenesis imperfecta (OI) is a highly variable heritable disease of bone characterized by recurring bone fractures. It is the most common single gene defect causing bone disease and its typical clinical presentation and natural history have been well chronicled in many review articles and book chapters. The disease has received attention from basic scientists because it has become the paradigm for mutations affecting a well-defined extracellular matrix protein. The results of these biochemical and molecular studies have provided the foundation for understanding the broad spectrum of heritable diseases of connective tissue, and OI will continue to be the disease that provides the breakthroughs for this class of heritable diseases. The purpose of this chapter is to provide an update to the well-described clinical classifications and point out recent advances in the diagnosis and therapy of the disease. Most of the chapter will review the consequences of mutations of type 1 collagen on the structure of the collagen fibers, the biology of the osteoblast and the pathophysiology of the resulting bone disease. It will emphasize how this information influences our understanding of osteoporosis and other heritable diseases of connective tissue. In addition outstanding problems requiring further research attention, particularly relating to cell and somatic gene therapy, will be presented.

Clinical Classifications and Variants of OI

The most widely used clinical classification for OI continues to be the one developed by Sillence that is based on disease severity (Sillence, 1988). For purposes of correlating clinical phenotype with the underlying genetic and pathophysiological basis of the disease, grouping the classes into deforming and nondeforming bone disease can be helpful even though this, too, is an arbitrary distinction. Three degrees of deforming OI, types II, III, and IV, are associated with decreasing severity of growth retardation and limb deformity and all result from a mutation affecting the structure of the type 1 collagen molecule (Table I). The consequences of this mutation on the structure of the extracellular matrix and the biology of bone cell are very similar, varying only in their degree of severity. In contrast most cases of nondeforming OI, type I, are the result of mutations affecting the production of an otherwise normal type I collagen molecule.

Deforming OI

The criteria for identifying individuals as OI type II, III, or IV are somewhat arbitrary. Although this classification helps to stratify patients according to their disease severity, the typing does not necessarily predict the natural history of the disease or the type of underlying genetic mutation. Furthermore, with the implementation of bisphosphonate in children, disease severity and natural history are being greatly improved and eventually may force a revaluation of this classification system.

Most infants that succumb to OI in the perinatal period are considered OI type II. The hallmarks of type II include shortened and deformed limbs in the presence of normal birth weight and length. The cranium is unusually soft and molded and may be fractured at birth. Intracranial bleeding may have occurred. The sclerae are deep blue. The limbs are deformed and short, raising the consideration of hypophosphatasia, achondrogenesis, and thanatophoric dwarfism in the diagnosis. Multiple fractures are seen on X-ray and the extremities appear broad and crumpled. The critical problem is neonatal pulmonary insufficiency that may lead to death in the first postnatal week. Faulty thoracic musculoskeletal development also limits respiratory function in the majority of cases.

Table I An All Inclusive Clinical and Molecular Classification of Osteogenesis Imperfecta

Molecular classification	Clinical classification	Clinical severity	Molecular mechanism
Dominant negative OI	Type II	Perinatal lethal	Glycine substitutions preferentially located in C terminal helical domain of either collagen chain.
	Type III	Progressive deforming	Glycine substitutions preferentially located in mid-helical domain of either collagen chain.
	Type IV	Moderately deforming	Glycine substitutions preferentially located in mid-helical domain of the a2 collagen chain.
	Type V	Moderately deforming	Non-type I collagen gene mutation.
	Type VI	Moderately deforming	Non-type I collagen gene mutation.
	Type I	Nondeforming	Glycine substitutions preferentially located in N terminal helical domain of either collagen chain.
	Sp1-associated osteoporosis	Osteoporosis associated risk factor	Excessive alpha-1 chain production may lead to accumulation of alpha-1(I) trimer molecules with the bone matrix.
	Noncollagen mutations	Mutation of proteins that interact with the collagen microfibril	Murine knock out studies suggest that noncollagenous proteins of bone may contribute to formation of a stable bone matrix. The osteoporosis of Marfan's may be an example.
Haploid insufficiency	Type I	Classical mild OI	Complete nonfunctional *Col1A1* allele usually due premature stop codon.
	Osteoporosis	Associated risk factor for osteoporosis	Partial inactivation of a *Col1A1* allele either due to a mutation affecting processing of the transcript or the activity of the promoter.

However, prolonged survival has been documented in occasional type II cases.

Infants born with fractures and deformity that survive the perinatal period are grouped as OI type III. The natural history of type III includes the presence of multiple fractures, significant molding of the calvarium, and deformity of the extremities at birth. Fractures may continue to occur in infancy and childhood precluding a normal pattern of ambulation. Deformity of the thoracic cage (pectus carinatum, pectus excavatum) may be present in early childhood and may advance as the scoliosis and vertebral compression increase. Type III OI subjects develop scoliosis at an early age. Vertebral compression, most commonly of the central or "codfish" type, begin shortly after birth and progress relentlessly prior to puberty (Ishikawa *et al.,* 1996). The volume of the thoracic cage decreases with age and eventually, cardiorespiratory insufficiency, including right-sided cardiac failure may occur. As adults these individuals are very short, frequently less than 4 ft in height. Skeletal involvement is associated with a severe defect in remodeling so that the appendicular bones are usually very narrow, although in some cases, a "broad bone" X-ray appearance is seen. In either event, the epiphyseal zone is markedly dysplastic which effectively limits endochondral and therefore, somatic bone growth. Because of severe limb deformity and a marked degree of osteopenia at an early age, type III subjects are wheelchair bound. Because of molding of the base of the skull, type III subjects are at risk for the development of basilar invagination that may cause brain-stem compression with both respiratory and neurologic complications and sudden death. Charnas reported communicating hydrocephalus in 17/76 subjects with OI (Charnas and Marini, 1993). Seizure disorders were observed in 5/76 cases. Brain-stem compression requiring surgical decompression or reinforcement of the craniocervical junction is extremely complex, requiring mechanical support, trans-oral clivectomy and decompression of the posterior fossa where respiratory center function is compromised (Bhangoo and Crockard, 1999; Sawin and Menezes, 1997).

Infants that appear normal at birth but develop deformity upon ambulation generally fall into the OI type IV group although this form can merge into features seen in OI type I. Moderate short stature is common, but ambulation is generally possible although with the aid of rods and braces. Radiologically, the extent of skeletal dysplasia in type IV disease is more severe than found in type I cases, but less than in type III OI. There is more severe osteoporosis with significant cortical and trabecular bone loss. Cystic changes may appear in the long bones. Vertebral compression fractures occur frequently. In addition to more severe scoliosis, there is moderate deformity of the pelvis and lower extremities that limits ambulation without support. Dentinogenesis imperfecta (DI) is most frequent in OI types III and IV and, overall, affects about 15% of OI patients among the different phenotypes (Lund *et al.,* 1998; Petersen and Wetzel, 1998). It appears as a bluish-brown translucent discoloration. Deciduous teeth tend to be more severely affected than permanent teeth. These teeth are soft because of a defect in underlying dentin (type I

collagen) so that the enamel layer is lost, which leads to extreme dental erosion even in children. Expert dental care is essential in affected children. Hearing loss, present in all OI phenotypes (Garretsen *et al.,* 1997), has its onset in childhood (Kuurila *et al.,* 2000) or during second or third decade. Both conductive, mixed and sensorineural hearing loss have been documented in OI (Shapiro *et al.,* 1982). The lesions are a combination of bony trauma (i.e., fractures of the stapes crura and footplate) and damage to neural structures in the inner ear. These lesions are not identical to those of otosclerosis.

Until recently there were no examples of OI resulting from mutations in genes other than type 1 collagen. As a result of forming an integrated research, diagnostic, and treatment team with the opportunity to examine the broad spectrum of patients with deforming OI, Gloreaux has identified at least two additional OI-like diseases (OI types V and VI) that are not a result of a mutation in the type I collagen genes. Type V OI has radiologic features of type IV OI with subtle differences including calcification of the interossieus membrane and a metaphyseal band adjacent to the growth plate. The disease is inherited as an autosomal dominant and no mutations with the type I collagen genes have been found (Glorieux *et al.,* 2000). Unlike OI type V which has been found in nonrelated families, OI type VI is restricted to an inbred Eskimo population. In this case linkage studies have been possible and have excluded type 1 collagen genes. The importance of these new clinical phenotypes is that it demonstrates that molecules other than type 1 collagen are essential for formation of a stable bone matrix and will eventually lead to a discovery of the role that these gene products play in bone biology. Murine knockout studies have also pointed to the importance of other matrix proteins to the formation of bone including osteonectin (Delany *et al.,* 2000) and biglycan (Xu *et al.,* 1998).

Another unifying feature of all the deforming forms of OI is the strong dominant negative properties of the mutation. In those cases where affected individuals choose to have children, the disease is passed on in an autosomal dominant manner. However, in most cases the disease results from a random and isolated mutation in the germ cell of a parent. Usually this event is a one-time occurrence and the likelihood of another affected individual is extremely small. However, in 5 to 10% of cases one of the parents sustained a somatic mutation during his or her embryonic development such that a proportion of their somatic and germ cells have an OI mutation (Cole and Dalgleish, 1995; Lund *et al.,* 1997). The mosaic parent does not have features of OI and most of their children have normal bones. However, if the child is conceived with the a germ cell carrying the OI mutation, then full-blown OI results. As a result of this possibility for recurrence, families with one child with OI who wish to have more children are advised to undergo prenatal testing (Raghunath *et al.,* 1994) or sensitive ultrasound analysis with the possibility that a subsequent child might be affected (Lachman, 1994; Tretter *et al.,* 1998).

Mild Nondeforming OI

Although this class of OI patients is relatively common, it is not unusual to be unappreciated by the family or their physician. In cases with blue sclera (Sillence *et al.,* 1993), mild short stature ligamentous laxity, mild scoliosis, and a strong family history of recurring fractures and osteoporosis, the diagnosis is not difficult. Radiographs are not diagnostic and fractures usually heal without deformity. In many cases there is not a high degree of morbidity and once puberty is attained, fractures are rare. Perhaps the most important reason for identifying these individuals is to initiate anti-osteoporosis therapy soon as menopausal symptoms have developed because these individuals are particularly susceptible to accelerated bone loss when sex steroids are lost (Bischoff *et al.,* 1999). Other patients who fit into this category can have symptoms that overlap with mild Ehlers Danlos syndrome. The overlap appears to be related to where the mutation is placed within the collagen molecule, making this type of mutation of interest to the structural biologist (Feshchenko *et al.,* 1998; Raff *et al.,* 2000). However, the importance to the clinician is to recognize that the two genetic phenotypes can coexist so that measures to strengthen the skeleton are initiated when appropriate.

Probably the most difficult situation that arises within this class of patients is child abuse. Although OI is frequently invoked as a potential explanation for the infants and young child with multiple fractures, it is rare that any of the clinical features that are characteristic of OI are present (Steiner *et al.,* 1996) and instead there usually is no family history of recurring fractures, short stature, or abnormal radiographs. Because OI can result from a new mutation within the type I collagen genes and potentially other extracellular matrix genes, lack of a family history does not exclude the diagnosis. Recently the term temporary brittle bone disease has been invoked to explain certain forms of multiple fractures in a setting without an obvious perpetrator (Paterson *et al.,* 1993) but the concept has not gained acceptance (Ablin and Sane, 1997; Chapman and Hall, 1997). A recent report finds that infants and children with this diagnosis have reduced bone mass by radiographic absorptiometry or computed tomography (Miller and Hangartner, 1999) but a credible mechanism for this clinical diagnosis is not yet available. Because analysis of bone density is so difficult in the infant, there are no accepted criteria for normal or diminished bone mass and instead diagnostic decisions are made by emotion and opinion and frequently in an antagonistic environment. This topic is probably best addressed in literature prepared by the osteogenesis imperfecta foundation (OIF) at (http://www.oif.org/tier2/childabuse.htm).

The relationship of mutations within the type I collagen genes and osteoporosis has been difficult to establish. In families where OI mutations and osteoporosis have been identified, careful clinical scrutiny usually identifies features of the disease (Shapiro *et al.,* 1992; Spotila *et al.,* 1991). Nonglycine substitutions in the helical domain have been found

in a few instances, but the significance of these findings is difficult to interpret (Spotila *et al.,* 1994). Quantitative trait linkage (QTL) studies of populations of individuals with osteoporosis have failed to demonstrate linkage to either type I collagen gene (Cardon *et al.,* 2000; Devoto *et al.,* 1998; Koller *et al.,* 1998; Niu *et al.,* 1999). However, a Sp1 polymorphism has shown a statistical association to individuals with osteoporosis (Grant *et al.,* 1996) in a number of convincing studies (Sainz *et al.,* 1999; Uitterlinden *et al.,* 1998; Weichetova *et al.,* 2000), although there appears to be certain population where this association cannot be demonstrated (Han *et al.,* 1999; Hustmyer *et al.,* 1999; Liden *et al.,* 1998; Nakajima *et al.,* 1999). Particularly intriguing is the observation that the Sp1 polymorphism, which is located at a transcriptional regulatory region in the first intron of the *Col1A1* gene, leads to a subtle increase in expression this genetic unit (Mann *et al.,* 2001). If this proves to be case at the protein level, the excess collagen α-1-(I) chains which are not incorporated into a heterotrimeric collagen molecule would form an α-1(I) trimer molecule. In mouse and man, severe OI results when both *COL1A2* genes failed to generate α-2(I) collagen chains because the bone matrix is composed of α-1(I) trimer molecules (see below). Osteopenia is observed when one of the two *COL1A2* genes does not function and a mixture of hetero and homotrimeric molecules accumulate. The Sp1 polymorphism suggests that an even more subtle imbalance between heterotrimer to homotrimer production can contribute to osteoporosis (Heegaard *et al.,* 2000; Keen *et al.,* 1999; McGuigan *et al.,* 2000) but that it is only one of a number of genetic and environmental factors contributing to diminished bone mass. This mild contribution will be missed by standard QTL studies and may be restricted to a specific population. If this explanation proves to be correct, a similar weak contribution from subtle mutations within the structural regions of type 1 collagen or mutations that affect regulation of either on the two collagen genes can be anticipated.

Needed Advances in Clinical Diagnosis and Management

In most cases the diagnosis of OI can be made on clinical grounds alone. Unfortunately radiographs are generally insensitive to the diminished bone mass associated with type 1 OI. DEXA has been shown to be effective in detecting the diminished bone mass associated with type 1 OI in adults although its application to children and particularly infants has not been adequately developed. Such standards would be particularly helpful in evaluating individuals with suspected abuse. pQCT might be more sensitive in young children to discriminate individuals with normal or diminished bone mass (Fredericks *et al.,* 1990; Keen *et al.,* 1999). Other clinical tests which may be helpful in the diagnosis OI are serum level of procollagen propeptide fragments reflecting the rate of type I collagen formation (Kauppila *et al.,* 1998; Lund *et al.,* 1998; Proszynska *et al.,* 1996) and the generation of collagen derived cross-links reflecting removal (Bank *et al.,* 2000). Here again standards need to be developed for age and sex, degree of sexual maturation, or menopause to make these tests of bone turnover useful in OI.

In many instances it is advantageous to know the underlying molecular abnormalities for purposes of genetic counseling and in some cases for predicting natural history. Frequently, molecular testing is also used to help in the evaluation of children with recurring fractures. Currently there are two sites in the United States that offer this service. One site http://www.pathology.washington.edu/clinical/byers.html) performs a screening test on fibroblasts derived from an affected individual for biochemical abnormalities of the collagen molecules followed by confirmation at the genetic level by DNA sequencing. The other site (http://www.som.tulane.edu/gene_therapy/matrix/) carries out a screening genomics analysis on DNA derived from peripheral blood or cultured fibroblasts and then identifies the mutation by DNA sequencing of abnormal migrating DNA fragments. Both sites have an excellent track record for finding mutations although not all the patients with OI yield an identified mutation. Tests that assess the intrinsic ability of bone cells to make a normal bone matrix are needed to assist in evaluation of individuals with otherwise unexplained bone fractures or osteoporosis.

Given the complexity in the clinical management of OI, a multidisciplinary clinical team approach to treatment is of greatest value for both the patient and the field. Not only are there significant orthopedic and medical issues, but problems of daily living are pervasive. Proper handling during infancy, mainstreaming within schools, driving an automobile, attending college, scoliosis and pulmonary insufficiency, neurological symptoms, pregnancy and genetic risk, and acceleration of bone disease after menopause are complex problems that are difficult for an individual clinician to manage and require an experienced and broad-based treatment team. Many of these issues are covered on the OIF web site (http://www.oif.org) and in their literature. The development of an OI registry that defines the underlying genetic mutation, characterizes the clinical phenotype, and tracks the response to intervention needs to be developed to broaden the experience of all clinicians who have to make diagnostic and treatment decisions. Such a resource might facilitate multicenter therapeutic trials as the most efficient manner of evaluating the efficacy of a treatment modality.

Animal Models of OI

Naturally arising forms of OI have been described in cows (Agerholm *et al.,* 1994) and dogs (Campbell *et al.,* 1997) and recently an experimentally produced form of OI has been introduced into sheep (Weiss, 2000). If these models are perpetuated into lines of affected animals, they will have value for evaluating orthopedic strategies. Because the maintenance of large animal models is extremely expensive, they will not be useful for the initial development of new medical or genetic strategies. However, once an intervention has the possibility of a clinical trial then a larger animal model will probably be a requirement for FDA approval.

To date, the mouse has contributed the most to our understanding of the disease and is the initial platform for evaluating new therapies. Lethal OI has been produced experimentally by insertion of a collagen transgene containing a glycine point mutation (Stacey *et al.,* 1988) or an internal deletion within the helical domain of the molecule (Khillan *et al.,* 1991). While transgene insertions are relatively easy to produce, there is significant variability in the clinical severity even within the same pedigree (Pereira *et al.,* 1994), reducing their value as an experimental model. OI mutations within the endogenous collagen gene yield a more reproducible phenotype. The oim/oim mouse arose from a spontaneous mutation within the *Col1A2* gene. Because the mutation produces a nonfunctional alpha-2(I) chain, the disease results from an accumulation of alpha-1(I) trimer molecules (Chipman *et al.,* 1993). It has been widely used even though this is a recessive form of OI that is quite unlike the more common dominantly inherited forms of OI. Recently a glycine substitution has been knocked into the *Col1A1* gene to produce a moderately severe form of OI (brit mouse) which has a stable phenotype and is very representative of the common forms of OI (Forlino *et al.,* 1999). The only murine model of type I OI is the heterozygous Mov 13 mouse in which one of the two *Col1A1* genes is nonfunctional due to a retroviral insertion within the first intron. The heterozygous mouse was initially thought to have normal bone and was used for generating a double knockout of the *Col1A1* gene, which has an embryonic lethal phenotype (Lohler *et al.,* 1984). However, more sensitive testing did demonstrate diminished bone mass and under production of type 1 collagen (Bonadio *et al.,* 1990). Unfortunately the mice succumb to leukemia in their early adulthood, limiting their value to basic bone research. A viable model for OI type 1 needs to be produced by genetic knock-in.

Murine models of mild OI (heritable osteoporosis) resulting from mutations other than type I collagen include the knockout mutations of biglycan (Xu *et al.,* 1998) and osteonectin (Delany *et al.,* 2000). Whether these cases represent a mutation that affects the structural stability of the extracellular matrix or indirectly affects the biology of the osteoblast is yet to be determined but these mice reveal the complexity of bone formation. The one naturally arising model that may be related to human forms of OI unrelated to the type 1 collagen gene is the fro/fro mouse (Muriel *et al.,* 1991; Sillence *et al.,* 1993). Direct analysis of collagen produced by these mice has not been informative and ongoing linkage studies should identify the abnormal genetic unit.

Molecular Basis of OI

A comprehensive listing of the mutations within type I collagen genes resulting in OI (Dalgleish, 1997) is now maintained in the OI mutation database (http://www.le.ac.uk/genetics/collagen). They can be broadly correlated with clinical severity with the deforming forms of OI being associated with mutations that interrupt the helical stability of the collagen molecule while most forms of type I OI being associated with underproduction of an otherwise normal type I collagen.

Deforming OI

Essentially all of these mutations act in a dominant negative manner; i.e., it is the presence of the abnormal gene product that causes the disease. Because of this mechanism the disease develops either as a sporadic new mutation or is inherited in an autosomal dominant manner. Those cases in which recurrence is observed represent germinal mosaicism in one parent and not recessive inheritance. The only known exception to this statement is a null mutation within the *Col1A2* gene (see below).

The three-dimensional structure of the collagen fibril can be altered by a substitution for glycine in the collagen (gly-x-y) triplet, inframe deletion, an inframe insertion, or exon skipping. Depending on the helical location of a mutation, these produce a variety of clinical pictures that range from lethal (OI type II) to severely deforming (OI type III) to mildly deforming (OI type IV). Glycine substitution in the helical domain of the collagen α-1(I) chain is the most common defect. Glycine, the smallest amino acid, is a critical component that must fit in a sterically restricted space where the three chains of the triple helix come together. Substitutions can occur in either base of the GGN codon for glycine and do not alter the length of the chain but disrupt helical stability. The eight potential amino acid substitutions are cysteine, alanine, arginine, aspartic acid, cysteine, glutamic acid, serine, valine, and tryptophan. How the substitution affects the conformation of the collagen helix is still not well understood and current biochemical analysis does not always predict clinical severity. Since the helix assembles from the C-terminal propeptide, a mutation in the C terminal helical and propeptide region results in greater instability and more severe disease while mutations located in the mid-helical domain tend to be less severe. However, mutations within the mid-helical domain can have a severe phenotype, suggesting that subdomains within the helix are critical for function beyond just contributing to an intact helical structure. Mutations located at the N-terminal domain of either chain can be extremely mild and fall into the category of type I OI.

Because the exons that encode the helical domain maintain the reading frame, mutations in the consensus donor or acceptor site can lead to exon skipping, producing a shortened helix that has the same effect on helical stability as a glycine substitution (Byers *et al.,* 1983). Much less common are mutations that delete a portion of the gene and along with it a number of inframe exons (Mundlos *et al.,* 1996) or mutations that insert a segment of intron that remains inframe with the entire transcript. In the latter case, a nonhelical segment is inserted within the helical domain disrupting the structure of the collagen helix (Wang *et al.,* 1996).

The one exception to the statement that severe disease results from a dominant negative mutation in either type I collagen gene is a null mutation of the *Col1A2* gene. Forma-

tion of the heterotrimeric collagen molecule requires that the α-2(I) chain account for 50% of the available chains at the time the procollagen molecule is assembled. When this requirement is not met, either because of underproduction of the α-2(I) chain or overproduction of the α-1(I) chain, then homotrimeric molecules are formed. Severity of disease depends on the balance between homotrimeric and heterotrimeric molecules within the bone matrix. This may explain why there is a spectrum of disease severity from OI type III when both *Col1A2* alleles are affected, to measurable osteopenia and fragility in the heterozygous state (McBride *et al.,* 1998; Saban *et al.,* 1996), to an association with osteoporosis due to the sp1 polymorphic alteration in the *Col1A1* gene. This variation in disease severity acts in a recessive manner or as quantitative trait in which gene dosage contributes to the severity of bone disease.

Nondeforming OI

The most common mutation causing type I OI reduces the output of otherwise normal type I collagen. Because of the 2:1 requirement for formation of heterotrimeric collagen, the level of *Col1A1* production directly influences the accumulation of normal type I collagen molecules. Reduced output from a single *Col1A1* allele reduces the production of heterotrimeric collagen and the unincorporated α-2(I) chains are degraded intracellularly. The genetic mechanism for a clinical phenotype resulting from complete inactivation of one allele is referred to as haploid insufficiency. In fact a spectrum of disease severity related to gene dosage is observed in the Mov 13 mouse. The homozygous Mov 13 is an embryonic lethal that does not reach the stage of skeletal development (Lohler *et al.,* 1984), while the heterozygous Mov 13 is a model for OI type I (Bonadio *et al.,* 1990). Similarly, the severity of osteopenia in type I OI is probably related to the degree that one of the *Col1A1* alleles underperforms. It would not be surprising to find that a more subtle underproduction from a *Col1A1* allele could be a contributing quantitative trait to the development of osteoporosis.

Mutations introducing a premature stop codon are the most frequent cause for a null *Col1A1* allele (Redford-Badwal *et al.,* 1996; Slayton *et al.,* 2000; Willing *et al.,* 1994). Premature stop codons arising in all but the terminal exon of a gene usually lead to rapid destruction of the transcript rather than producing a truncated protein. Termed nonsense mediated RNA decay, recently discovered nuclear proteins are able to recognize a premature stop codon and target it for rapid destruction (Serin *et al.,* 2001). This appears to be an important mechanism for preventing a truncated protein from expression, thus saving the cell from proteins with unintended function. Mutations of these surveillance genes are incompatible with development (Medghalchi *et al.,* 2001). Demonstrating that a truncated α-1(I) chain is produced from a *Col1A1* transcript *in vitro* serves as the basis for uncovering the presence and location of the stop codon (Bateman *et al.,* 1999). Otherwise finding the mutation by a molecular approach is laborious and can be missed.

A second mechanism for producing a null *Col1A1* allele is retention of an intron within the mature transcript. Intron retention instead of exon skipping can result when a mutation of a splice donor site is located in a small intron such that the combination of the intron and the flanking upstream and downstream exon is regarded as an acceptable exon (Stover *et al.,* 1993). However, the presence of the mutant donor site retains the transcript within the splicing apparatus of the nucleus (S35 domain) and it is eventually destroyed (Johnson *et al.,* 2000). While this is an uncommon cause of a null allele, it has provided insight into the normal pathway for splicing a complex transcript such as collagen and demonstrated that splicing of otherwise normal but small collagen introns is relatively slow. Because splicing of approximately 25% of the *Col1A1* introns are candidates to be affected this mechanism, it would not be surprising to find polymorphic changes within the gene that contribute to the rate of splicing and that are associated with mild osteoporosis.

Other causes for diminished transcriptional activity from a collagen gene are extremely rare. The Mov 13 mutation affects the transcriptional activity of the *Col1A1* gene by a mechanism that is unlikely to be seen in humans. Because there are elements within the collagen promoter necessary for activity in osteoblasts (Dodig *et al.,* 1996), mutation in these regions may exist but have not been identified to date. Mutation within the 3′ untranslated region affecting polyadenylation have been reported, and mutations in the 5′ untranslated region would be predicted have a phenotype but have not been observed.

Finally, a nonfunctional collagen gene can result from synthesis of a procollagen chain which is unable to incorporate within the triple helical molecule. Frameshift mutations within the terminal exon of either collagen gene have been identified that lead to synthesis of full sized procollagen chain which is rapidly degraded intracellularly when it fails to incorporate into the collagen molecule (Willing *et al.,* 1993). In the case of the *Col1A1* product, mild OI is observed, but when it occurs in the *Col1A2* product, homotrimeric molecules are formed, causing a more severe bone phenotype (see above).

Consequences of OI Producing Mutations

Formation on the Extracellular Matrix and Osteoid Mineralization

Many approaches have been employed to characterize the triple helical structure and intramolecular organization of collagen fibrils in normal and OI subjects. X-ray diffraction analysis of collagen-like peptides show the destabilizing effect of a glycine point mutation (Beck *et al.,* 2000) and studies using NMR and circular dichroism lead to a similar conclusion (Baum and Brodsky, 1999; Liu *et al.,* 1998;

Melacini *et al.,* 2000). At the intramolecular level, X-ray diffraction has shown small fibers with less well-defined lateral growth and more fiber disorganization in tissue obtained from OI subjects (McBride *et al.,* 1997). At the biochemical level, mutations that interrupt the helix decrease the thermal stability of procollagen molecules and render the molecule more susceptible to proteolytic attack by tissue proteases (Bachinger *et al.,* 1993). This may explain the observation that mutant collagen molecules are not uniformly distributed through matrix but are found on the surface of bone (Bank *et al.,* 2000). Because 25% of the collagen produced by cells containing a *Col1A1* mutation are normal and 50% of the collagen produced by cells containing a *Col1A2* mutation are normal, tissue proteases probably select against the mutant molecules (Bateman and Golub, 1994) allowing for a substrata of relatively normal collagen fibers to accumulate.

Transmission and scanning EM have shown that the periodicity of OI fibrils are normal but the fibrils are disorganized and have wide variation in fiber diameter (Eyden and Tzaphlidou, 2001). Fibril formation can be studied *in vitro* from components synthesized by cultured cells (Hashizume *et al.,* 1999; Holmes *et al.,* 1992, 2001; Hulmes *et al.,* 1995). The importance of other proteins that modify the size and organization of otherwise normal type I collagen fibrils has been revealed by EM studies. These changes can affect the mechanical properties of the collagen fibers formed *in vitro* (Christiansen *et al.,* 2000; Ottani *et al.,* 2001). For example the copolymerization of type V collagen within the type I collagen fibril influences the size and structure of the type I collagen fibril (Kypreos *et al.,* 2000; Mizuno *et al.,* 2001). Another modifier of the collagen fiber size is the incorporation of unprocessed type I procollagen producing another form of Ehlers-Danlos syndrome (EDS) that can overlap with features of type I OI. The EDS-OI-like symptoms appear to result from impairing cleavage of the procollagen propeptide secondary to glycine substitution disruption in the N-terminal helical domain. A similar problem might be expected with a mutation affecting cleavage of the C-terminal propeptide (Holmes *et al.,* 1996). Induced mutations in certain noncollagenous proteins such as decorin (Danielson *et al.,* 1997), fibromodulin (Ezura *et al.,* 2000; Svensson *et al.,* 1999), and microfibrillin (Kielty *et al.,* 1998) can affect the structure or organization of type I collagen fibers, indicating that physical interaction between the two components plays an important role in this process. It would not be surprising that OI mutations may affect some of these binding interactions, adding to the complexity of the bone phenotype.

The interaction of the mineralizing phase of new bone formation with the matrix has been studied by high-voltage electron microscopy (Landis *et al.,* 1996a,b), Fourier transform infrared microspectroscopic analysis (Cassella *et al.,* 1994, 2000), and small angle X-ray scattering (Fratzl *et al.,* 1996). These methods demonstrate that while the absolute amount of and composition of hydroxyapatite within a OI bone is probably not abnormal, the crystal structure is deformed and probably contributes to the overall weakened nature of the bone (Camacho *et al.,* 1999). Thus while the primary defect is in helix formation, the ultimate determination of bone strength reflects how the helix influences the interaction of noncollagenous proteins and mineral and at this point the critical features of the molecule that control these interactive events are not fully understood.

Intrinsic Properties of the OI Osteoblast

The presence of intracellular mutant procollagen molecules and the physiological response to the abnormal extracellular osteoid combine to have a profound impact on the biology of the osteoblast, which further influences the severity and natural history of disease. It has been appreciated for some time that the rough endoplasmic reticulum of OI fibroblasts are grossly dilated (Lamande *et al.,* 1995) and the secretion of fully formed procollagen is impaired (Fitzgerald *et al.,* 1999; Lamande and Bateman, 1999). The role that hsp47 chaperone protein has in determining the trafficking of normal and mutant molecules within these cells is likely to be an important determinant for the biology of the affected osteoblast (Kojima *et al.,* 1998). In fact, gene knockout of the hsp47 protein is an embryonic lethal in which type I procollagen is produced that is susceptible to protease digestion (Nagai *et al.,* 2000), suggesting that this chaperone protein plays an essential role in normal triple helix formation (Thomson and Ananthanarayanan, 2000). The retention of the mutant procollagen molecule also leads to posttranslational overmodification of the lysine residues in the helical domain that may further affect the quality of fibril formation.

The inherent ability of an OI fibroblast or bone cell to produce collagen and proliferate *in vitro* is impaired and probably is a consequence of the retained procollagen molecules with the distended rough ER. *In vitro* studies of osteoblasts derived from OI humans (Fedarko *et al.,* 1995, 1996) or OIM mice (Balk *et al.,* 1997) show diminished markers of osteoblastic differentiation as well as reduced rate of cell proliferation. However, the cells can be driven into osteoblastic differentiation when given exogenous BMPs. The explanation for this observation is not clear but may reflect the quality or quantity of the extracellular matrix that is made by the preosteoblastic cell that is necessary for osteoblast differentiation *in vitro.* Possibly the high rate of bone turnover that is characteristic of this disease (see below) may lead to exhaustion and/or premature senescence of stem cells capable of generating vigorous osteoblastic cells *in vitro.* If stem cell exhaustion is also present in intact bone, then an additional factor of a limited osteoblast number will contribute to the severity of the bone disease.

Physiological Demands on the OI Osteoblast

Intact bone, probably through the osteocyte, is able to sense its mechanical environment and initiate a new round of bone formation when the load on the region exceeds its

ability to carry it. This fundamental principle of bone biology is continuously called upon in OI because the matrix that is produced is never able to support the load placed on the skeleton. This situation is illustrated in the histology of OI bone that shows a state of high turnover characterized by increased numbers of osteoblasts and osteocytes (Jones *et al.,* 1999) and an increased number of osteoclasts. Dynamic labeling shows that increased number of double labeled surfaces of normal thickness (Rauch *et al.,* 2000). Biochemical markers for bone formation and resorption in growing children and adults do reflect the histological findings, although the measurements are variable because of differences in growth rate and the underlying mutation (Brenner *et al.,* 1994; Goans *et al.,* 1995; Lund *et al.,* 1998). Some of these variables can be overcome in murine models in which there is uniformity of the genetic defect and sufficient numbers of mice of similar age and sex.

Analysis of murine models is particularly instructive in appreciating the pathophysiology of the OI mutation. Because net total bone formation in OI bone is low and its intrinsic properties for matrix production in culture are impaired, the OI osteoblast or its lineage is viewed as underproductive. This view can lead to the conclusion that stimulation to increase its rate of matrix formation should be beneficial to the disease. However, the OI osteoblast lineage is under constant stimulation to proliferate to build up sufficient

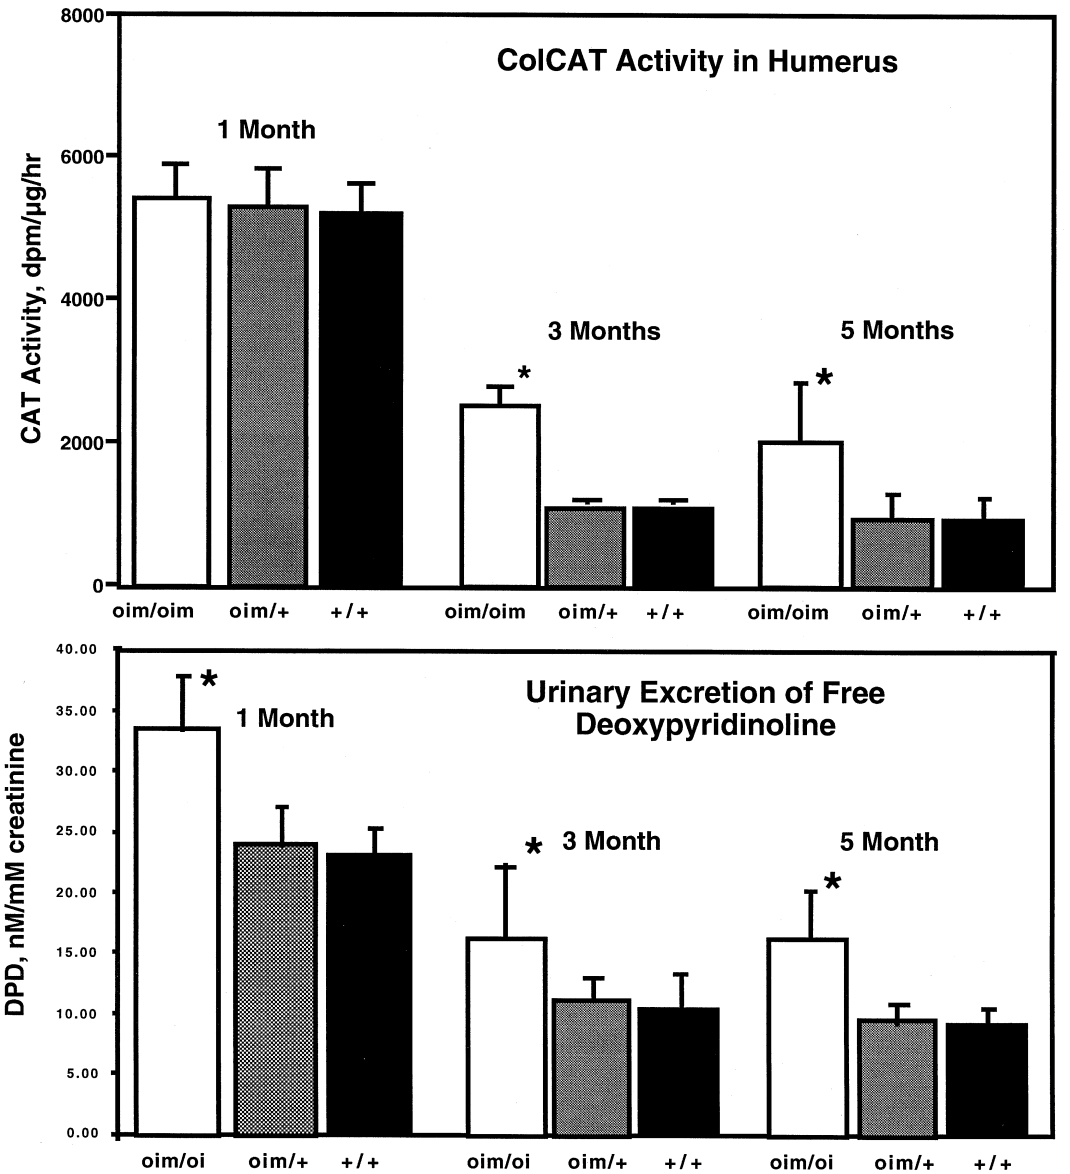

Figure 1 Relative balance of bone formation and resorption in OIM mice during the period of rapid somatic growth (1 month), adulthood (3 months), and older age (5 months). During somatic growth, the activity of the oim/oim osteoblast population does not exceed that of normal animals while bone resorption of the 1-month-old animal is greater than normal. Thus it is during the period of rapid bone growth that the deficit between bone formation and resorption is maximal. With stabilization of the skeleton, the continuous demand for new bone formation in the oim/oim mouse become evident and during this time the deficit between bone formation and resorption is less severe.

numbers of precursor cells to progress to full osteoblast differentiation and produce the matrix that was resorbed by the activated osteoclasts. The activated osteoblastic lineage can be demonstrated by measuring the content of *Col1A1* mRNA in OI bone or the activity of a type I collagen promoter transgene that is sensitive to osteoblastic activity. In both cases a high-level of transcriptional activity for type I collagen can be demonstrated relative to normal bone. The net effect is an uncoupling between the signals transmitted from the bone matrix to be bone lineage in which the bone cells do respond at the gene level but cannot deliver at the protein level. The lineage is already maximally stimulated in response to the activated osteoclastic pathways but the new matrix that is produced does not improve the mechanical properties of the bone.

Studies on the oim mouse model illustrates that it is the balance between matrix formation and resorption that determines bone strength in OI (Fig. 1). During periods of rapid linear growth, the deficit between formation and resorption is maximal because at this time bone turnover is enhanced even beyond the level that is responsive to mechanical forces. While normal bone has the reserve within the bone lineage to increase its rate of matrix formation, the OI bone lineage is already maximally stimulated so that it is during the period of linear growth that the deficit in net bone formation is most severe. This may explain why growth retardation and fractures are so severe in the rapidly growing child. With the completion of puberty and cessation of linear growth, bone remodeling slows and a balance between formation and resorption become more favorable. Thus puberty does not improve bone strength by stimulating the lineage but instead it stabilizes the skeleton and reduces the need for bone remodeling. When menopause reinstates a state of high bone resorption, the balance between formation and resorption again becomes unfavorable and fractures can return. In effect, the pathophysiology of OI can be viewed as a consequence of the activated osteoclast lineage and this probably explains the success of bisphosphonate treatment in OI.

Nondeforming OI secondary to an expressed collagen mutation probably represents a mild variant of deforming OI discussed above. However, OI type 1 resulting from haploid insufficiency of a *COL1A1* chain may have subtle differences. Analysis of the heterozygous Mov 13 mice show diminished bone volume and half-normal levels of col1a1 mRNA. This is consistent with human OI in which low levels of procollagen propeptide in blood reflect the null mutation in type I collagen-producing cells (Minisola *et al.,* 1994). Histomorphometry does show increase osteoblast cellularity and bone forming units and dynamic histomorphometry suggest a decrease in osteoid seams (McCarthy *et al.,* 1997). Excessive osteoclastic activity does not appear to be present. In both mouse and man with type I OI, significant skeletal remodeling becomes apparent upon sexual maturation so that the mechanical properties of the bone approach normal (Bonadio *et al.,* 1993; Jepsen *et al.,* 1997). While further analysis of a murine model that is healthy into adulthood is necessary, it would appear that the deficit between bone formation and resorption in type I OI is much less than in deforming forms of OI, particularly after the adult skeleton is established. Thus it is during adulthood that a relatively normal bone matrix is accumulated and fractures are uncommon. It is only during growth and in the menopause that this relationship is unfavorable, again underscoring the value of bisphosphonates for improving bone strength during these periods.

Therapy of OI

Antiresorptive Agents

Probably the most significant advance for OI since the previous edition of this text is the use of bisphosphonate in infants, growing children, and adults. Unlike previous agents that relied primarily on anecdotal evidence for success, a number of prospective studies have now shown that bisphosphonate can reduce fracture frequency, increase bone mineral content, and improve the radiographic assessment of the bone shape in growing children (Astrom and Soderhall, 1998; Glorieux *et al.,* 1998). Linear growth is not impaired and fractures heal at their expected rate. The findings are most dramatic in infants from one to three years of age in which the severity of the classification of the disease can be improved (Plotkin *et al.,* 2000). In both groups remarkable improvement is seen in the quality of life that includes motor function and muscle strength. Children begin to ambulate and adults find that their activities of daily living are easier to perform. Bone pain and diaphoresis, which is a major complaint often overlooked by physicians as well as families, is greatly diminished by the treatment. Equally positive results are being observed and adults although comprehensive studies have not yet been reported. Initial studies have used cyclical intravenous administration of pamidronate and currently prospective studies using oral forms of bisphosphonates are ongoing (Glorieux, 2000).

The success of bisphosphonate appears to be related to the unremitting osteoclastic activity. The effect of the drug can be monitored by measuring the level of collagen-derived cross-links in blood or urine. Clinical symptoms of bone pain and diaphoresis also correlate with the inhibitory effect of the drug on osteoclastic activity, suggesting that it is the process of high bone turnover and associated high blood flow, not unlike a pagetic lesion, that underlie these symptoms. Even though the matrix it now accumulates still contains the mutant collagen molecules, the balance between formation and degradation is improved and the accumulation of matrix improves bone strength relative a bone without matrix. The experience in children indicates that linear growth and repair of fractures is not compromised by the use of the bisphosphonate. Murine studies show less bowing and a diminished fractured frequency, even though bone strength by direct mechanical testing cannot be demonstrated. Further work is needed using animal models to confirm that the drug is acting primarily at the level of the osteoclast and

does not have other actions that contribute to clinical improvement. For example, if the bisphosphonate acts to reduce the level of bone turnover it might have the additional benefit of extending the longevity of the osteoblast lineage or allowing the resident osteoblast to achieve full differentiation and time to remodel the existing matrix from woven to lamellar bone.

Anabolic Agents

Growth hormone, IGF1 and PTH have the potential to increase bone mass. Except for a treatment protocol with growth hormone in children with deforming OI, most of the experience with these agents has been antidotal. Like all children who are initially started on growth hormone, OI children do experience an initial acceleration of growth rate. Because the treatment duration has been limited, a bone mass increase in excess to the increase in body size has not been reported, although stable ^{42}Ca isotopic studies demonstrate a improvement in mineral incorporation while on treatment (Vieira *et al.,* 1999, 2000). Given the underlying physiological basis of OI, it would be surprising that an agent which stimulates more bone turnover as part of its anabolic action would have a long-term beneficial effect. The osteoblast lineage is already maximally stimulated and the addition of agents which enhance osteoclastic activity will only contribute to the deficit between formation and degradation. The transient increasing growth rate that is seen in children with growth hormone occurs because the growth plate is stimulated to proliferate. If the bone that contains the growth plate cartilage (collar region and primary spongiosa) is no more structurally sound than before the stimulus, damage to the growth plate might be anticipated. Potentially the combination of growth hormone and bisphosphonate might provide a compromise that is acceptable and studies of with this combination are underway. However, this is another therapeutic setting requiring animal experimentation for concept validation. Furthermore, production of mice lines that are phenocopies of human OI with varying degrees of severity may point to the type of OI patient most appropriate for a particular combination of anabolic and/or antiresorptive drug (Antoniazzi *et al.,* 1996).

Cell and Gene Therapy

Because bisphosphonates do not correct the primary cause for OI and the effectiveness of their long-term use are still uncertain, steps to correct the underlying genetic mutation are being evaluated in both humans and mice. The possibility that gene therapy is a feasible strategy in OI came from the analysis of individuals who are somatic mosaic for an OI mutation but do not have evidence of bone disease. Those studies suggest that the deleterious effect of OI cells can be neutralized by the presence of normal cells so that if it were possible to introduce normal cells into an individual with OI, the severity of bone disease would be reduced. Furthermore, because bone turnover is high and the endogenous osteoblast lineage is activated in OI, introduction of normal cells into this environment would rapidly populate the bone with cells having a normal proliferative rate and making a normal matrix that would outproduce the effort from the resident OI cells. This treatment strategy requires the ability to introduce cells from the osteoblast lineage into OI subjects with the attendant problems of immune rejection unless a tissue-matched donor can be identified. Recent human transplant studies with bone marrow cells have been performed in a limited number of children with severe OI (Horwitz *et al.,* 1999, 2001). The success of these initial studies is difficult to assess at this time and again point to the importance of proof of principle experiment in animals before human experimentation is undertaken.

Assuming that the immune problems related to bone cell transplantation will be a major impediment for long-term engraftment of bone, a strategy needs to be developed in which the endogenous OI bone cells are engineered to correct the primary defect in type I collagen production *in vitro* followed by reintroduction into the affected host. This will require a two-step process in which the output from the mutant collagen allele is inhibited and a replacement collagen gene for the inactivated mutant gene is inserted. Once corrected, the engineered cells have to have the ability to engraft bone, proliferate, and participate in new bone formation. Each of these problems is a major research undertaking (Fig. 2).

Allele-specific suppression of a mutant collagen gene is potentially possible at either the genetic or the RNA level. Targeting the endogenous gene with a triplex-forming oligonucleotide (Faruqi *et al.,* 2000) or with a chimeric RNA–DNA oligonucleotide (Kren *et al.,* 1999) can correct a specified sequence. Although not all genes may be equally susceptible to this type of modification, if the change can be made it will be permanent and restore the output of collagen production to a normal level. This is a recently developed genetic approach that is likely to undergo further improvement which could make it the method of choice. More effort has been made at reducing the output at the level of RNA. While antisense constructs to a RNA transcript is unlikely to have allele specific discrimination, other strategies such as hammerhead (Klebba *et al.,* 2000), and hairpin (Lian *et al.,* 1999) ribozymes, U1snRNA (Beckley *et al.,* 2001), RNA transplicing (Caudevilla *et al.,* 1999; Mansfield *et al.,* 2000), and RNase P (Kawa *et al.,* 1998) do have such a potential. A detailed description on the background and mechanism of each antiRNA effector is beyond the scope of this chapter but is contained in the referenced articles. It is unlikely that any one approach will have sufficient strength and specificity to inhibit the mutation-containing transcript sufficiently to have a major impact on disease severity (Dawson and Marini, 2000). However, combining two or more of these antiRNA efforts that act at different compartments within the cell and by a different molecular mechanism may attain this goal.

Unlike correction at the level of the mutant gene, the antiRNA approach will require the introduction of a procollagen cDNA expression construct to replace the lost activity of the suppressed transcript. Expression of a collagen gene

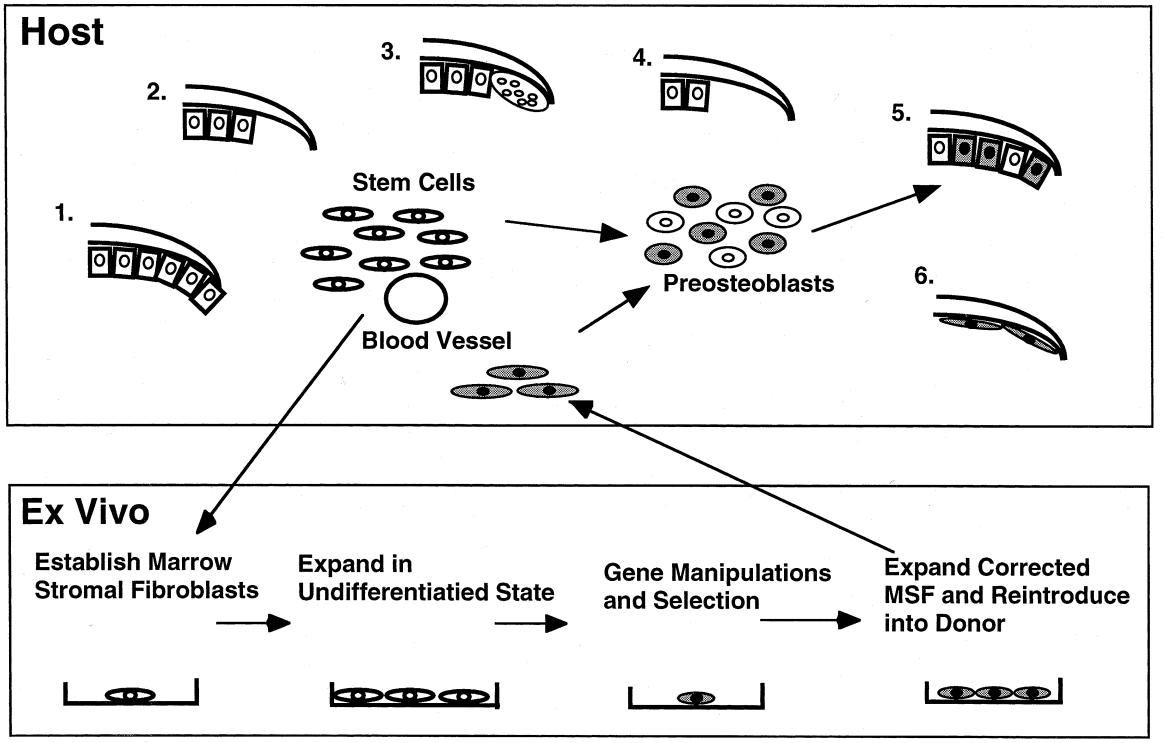

Figure 2 Strategy for somatic gene therapy for OI. The host bone is undergoing rapid and continuous bone turnover in which activated osteoblasts (1) start a cycle of bone remodeling (2). Osteoclasts remove damaged bone matrix (3) followed by a new wave of bone formation (4 and 5). Cells that contribute to the new round of bone formation are captured, probably by bone marrow aspiration, and grown in a culture dish under nondifferentiating conditions. Genetic manipulations include elimination and replacement of the mutant gene followed by expansion of the population of corrected cells. These cells are reintroduced into the host (darkened cells) and they begin to participate in the cycle of new bone formation. Over time the corrected cells outpopulate the endogenous cells and the quality of the bone matrix improves (5 and 6).

poses problems that differ from gene replacement for an enzyme or clotting factor. In bone, type I collagen production can account for 20% of total protein synthesis so that an extremely strong promoter is required to drive the replacement cDNA. In addition the cDNA has to be regulated so that α-1(I) chain production in excess of α-2(I) chains does not occur (see discussion of α-1(I) trimer above). Probably a type I collagen promoter fragment is the most appropriate promoter to achieve regulated expression. Another consideration is the vector to deliver the correcting construct. Although a collagen cDNA has been strongly expressed from an adenoviral construct at a high multiplicity of infection (Niyibizi *et al.,* 2000), this approach does not achieve permanent expression. Retrovectors have the size capacity and permanent integration needed to contain and express a collagen promoter–collagen cDNA construct. However, expression of the transgene can be suppressed after the transduced cells are reintroduced into the host (Cherry *et al.,* 2000). Modification of the retrovector that remove sequences responsible for suppression appear to overcome this problem, allowing for osteoblast-specific expression of the transgene throughout the life of the mouse (Stover *et al.,* 2001). It still remains to be demonstrated that this vector approach can achieve the level of collagen cDNA expression equivalent to one endogenous collagen allele.

Despite the genetic engineering problems, the most severe hurdle for somatic gene therapy for OI is the reintroduction of osteoprogenitor cells that are capable of homing to bone and participating in new bone formation. While there is no question regarding the ability of marrow stromal cells to differentiate into mature osteoblasts *in vitro* or in subcutaneous implant (Dennis *et al.,* 1999; Krebsbach *et al.,* 1997), demonstration that this is possible when administered systemically is still unconvincing. Most studies in man and mouse can demonstrate a low degree (1–5%) of engraftment of bone or bone marrow stroma as assessed by a transgenic or unique endogenous genetic marker (Ding *et al.,* 1999; Onyia *et al.,* 1998; Pereira *et al.,* 1998). In many cases, the marker gene does not discriminate whether this cell arises from a mesenchymal or macrophage lineage. Even when a relatively pure population of stromal cells are used for transplantation, small contamination from the myeloid lineage could belie stromal cell engraftment. Only one study has demonstrated expression of a transgene that is a marker of a differentiated osteoblast (Nilsson *et al.,* 1999) although the level of engraftment and its contribution to bone formation is hard to assess.

The underlying genetic abnormality also determines the success of stromal cell transplantation. When the disease is non-cell autonomous (i.e., the transplanted cells are

engineered to secrete a deficient soluble factor), an improvement in the disease phenotype occurs irrespective of where the cells established residence. This is most obvious when the transplanted cells express a cytokine (Brouard *et al.,* 1998) or clotting factor (Chuah *et al.,* 2000). This mechanism probably explains the recent success of bone marrow transplantation for vitamin D-resistant rickets (Miyamura *et al.,* 2000). Clinical improvement of a disease that is cell autonomous, such as OI, requires that the cells populate the affected bone, proliferate, differentiate, and participate in bone turnover. This is a standard that has not yet been met in any murine studies. The one exception is when the transplanted cells have undergone prolonged expansion *ex vivo* (Dahir *et al.,* 2000; Oyama *et al.,* 1999). For mouse this type of treatment rapidly leads to cell immortalization, making interpretation of a transplantation experiment difficult.

As new phamacologic or genetic therapies are developed, it will be increasingly necessary to establish a set of criteria that is used to judge its success relative to current therapies. While bisphosphonates still need further evaluation to fully appreciate their most effective use in different age and disease classifications, they do represent a significant advance in the treatment of OI and probably have to be regarded as the threshold that a new therapy has to exceed. Particularly as it relates to somatic gene therapy for OI, criteria need to be established that (a) demonstrate successful engraftment and (b) document improvements in bone health that are equivalent to or exceed medical therapy (Table II, column A). Whether the transplanted individual is mouse or man, it must be demonstrated that the transplanted cells populate the bone, expand in number over time, participate in the new bone formation, and provide a continuous source of new bone cells over the life of the transplanted subject. These studies are easier to perform in the mouse when the transplanted cells are engineered to contain visual transgenes driven by bone-specific promoters. Not only does the transgenic marker identify the source of the cell, it can reflect its level of participation in new bone formation. Moreover, this approach can be used to determine whether donor stem cells removed from the transplanted bone are still able to generate differentiated osteoblastic cells *in vitro.* If the transplanted cells are participating in new bone formation, the quality and quantity of the bone should improve over time. Radiographs should show remodeled bones with improved architecture and bone density measurements at well-defined sites will be increased in humans. μCT can be used to assess bone mass and architecture in mice. Bone histomorphometry and dynamic labeling studies should confirm these clinical measures of bone health. Particularly in the mouse, it should be possible to demonstrate improved mechanical properties of the bone after the intervention. Biochemical studies can also contribute to the impression of success by demonstrating that markers of new bone formation remain elevated while the level of markers reflecting bone degradation gradually subside.

Table II Criteria for Successful Therapy of OI

	A. Weight of criteria		B. Cell therapy	
Criteria	Man	Mouse	Man	Mouse
Cellular evaluation				
Cell engraftment	+	+	+	+
New bone formation	+++	+++	NR	NR
Increasing cell number; graft persistence	+++	+++	NR	NR
Bone evaluation				
BMD, QCT	+++	+++	+	NR
X-ray	++	+	NR	NR
Bone histology	+++	+++	+	+
Structural properties	NA	+++	NA	NR
Biochemical	+	++	NR	NR
Clinical criteria				
Quality of life	+++	+	NR	NR
Growth, wt gain	+++	+	++	+
Muscle strength	++	++	NR	NR
Fracture rate	+	+	+	NR

Note. NR, not reported; NA, not ascertainable; Assessment of current trials of bisphosphonate and cell transplantation in man and mouse.

The clinical evaluation of transplanted individuals is equally important to the assessment of success. Bone pain and diaphoresis are major symptoms that are daily facts of life for many patients with OI. Muscle weakness can be profound and in growing children greatly delay acquisition of motor milestones. Successful interruption of the pathophysiological cycle of OI appears to greatly reduce these symptoms. Bone pain diminishes, diaphoresis is greatly reduced and muscle tone improves. Children begin to ambulate and adults find that their activities of daily living are easier to perform. Because the symptoms are so profound for individuals with OI, they need to be recorded in a prospective manner as a clinical outcome measure. These types of measurements are difficult to record in the mouse, although cage activity can be quantitated and probably would be informative. Certainly fracture frequency, linear growth, and weight gain are important to record, although they can be influenced by many other factors unrelated to the intervention.

Even disregarding the molecular steps necessary to correct the genetic abnormalities in OI stromal cells, the success of transplantation of normal cells into a normal or OI host is relatively ineffective at this time (Table II, column B). Given the experimental difficulties of performing these studies in a controlled and quantitative manner in humans, greater emphasis must be placed on studies in experimental animals in which the problems inherent to the procedure can be identified and solved. Ultimately these problems will be solved and this will open a new era of therapeutic opportunities for OI and other osteopenic bone diseases.

Acknowledgments

The author received grant support for OI related research from the Public Health Department, National Institute of Health, National Institute of Arthritis and Musculoskeletal Disease (AR30426 and AR44545), and the Childrens' Brittle Bone Foundation.

CHAPTER 67

Hereditary Deficiencies in Vitamin D Action

Uri A. Liberman

Division of Endocrinology and Metabolism, Rabin Medical Center, Beilinson Campus, and Department of Physiology and Pharmacology, Sackler Faculty of Medicine, Tel Aviv University, Petach Tikvah 49100, Israel

Introduction

Hereditary deficiencies in vitamin D action can be due to disturbances in the synthesis of the hormonal form of the vitamin, 1,25-dihydroxyvitamin D1,($25(OH)_2$D-calcitriol), or defects in the interaction of calcitriol and its target tissues.

Vitamin D derived from endogenous production in the skin or absorbed from the gut is transformed into its active form by two successive steps: hydroxylation in the liver to 25-hydroxyvitamin D [25(OH)D], followed by 1α-hydroxylation in the renal proximal tubule to $1,25(OH)_2$D. Some other cells exhibit 1α-hydroxylase activity: placental decidual cells, keratinocytes, macrophages from various origins, and some tumor cells. The role of the extrarenal production of $1,25(OH)_2$D is unknown, and under normal conditions it does not significantly contribute to the circulating levels of the hormone. Hydroxylation at carbon 24, to produce 24,25-dihydroxyvitamin D [$24,25(OH)_2$D] or 1,24,25-trihydroxyvitamin D, is performed in a wide range of normal tissues and is believed to be important in the removal of vitamin D metabolites. All these enzymes are mitochondrial mixed-function oxidases containing cytochrome P450, and having ferredoxin and heme-binding domains. Cloning of cDNA for porcine 25-hydroxylase and the mouse, rat, and human 24- and 1-hydroxylase, as well as the genes for the latter two enzymes, has been recently reported (Akeno *et al.,* 1997; Fu *et al.,* 1997a; Jehan *et al.,* 1998; Jones *et al.,* 1999; Monkawa *et al.,* 1997; Murayama *et al.,* 1999; Ohyama *et al.,* 1993; Shinki *et al.,* 1997; Takeyama *et al.,* 1997). Hereditary defects along the cascade of $1,25(OH)_2$D synthesis lead to a deficiency in the vitamin D hormonal form.

Isolated deficiency of 25(OH)D is a very rare autosomal recessive disorder, attributed to, but not proven to be caused by deficiency in the hepatic vitamin D-25 hydroxylase activity (Gill et al. 2000).

This discussion will therefore concentrate on hereditary defects in the renal 25-hydroxyvitamin D-1 α-hydroxylase activity. Regarding interaction with the target tissue, as detailed elsewhere in this book, calcitriol effects are mediated via a high-affinity intracellular receptor—the vitamin D receptor (VDR). VDR acts as a ligand-modulated transcription factor that belongs to the steroid, thyroid, and retinoic acid receptors gene family (Baker *et al.,* 1988; Burmester *et al.,* 1988; Evans, 1988; Ozur *et al.,* 1991). Thus hereditary defects in the interaction of calcitriol and its target tissues could evolve from defects in hormone binding to VDR, defects in the interaction of the VDR or the hormone–VDR complex with DNA, or defects in the transcription modulation function.

Though VDRs were demonstrated in most, if not all, tissues, leading to the increased recognition of multiple target organs and actions of the hormone, it seems that most, if not all, clinical signs and symptoms associated with deficient vitamin D actions are due to perturbations in mineral metabolism.

$1,25(OH)_2$D is the most powerful physiological agent that stimulates active transport of calcium, and to a lesser degree phosphorus and magnesium, across the small intestine (DeLuca, 1984; Mayer *et al.,* 1984). Thus, deficiencies in vitamin D action will lead to a decrease in the net flux of mineral to the extracellular compartment, causing hypocalcemia and secondary hyperparathyroidism. Hypophosphatemia will

ensue, as a result of both reduced absorption of phosphorus due to deficient calcitriol action on the gut and increased renal phosphate clearance due to secondary hyperparathyroidism. Low concentrations of calcium and phosphorus in the extracellular fluid will lead to defective mineralization of organic bone matrix. Defective bone matrix mineralization of the newly formed bone and growth plate cartilage will produce the characteristic morphological and clinical signs of rickets, while at sites of bone remodeling, it will cause osteomalacia. Deficiencies in vitamin D action may impair the differentiation of osteoblasts and thus their functional capacity to mineralize bone matrix; this may be an additional mechanism leading to rickets and osteomalacia (Owen *et al.,* 1991; Reichel *et al.,* 1989).

As all hereditary deficiencies in vitamin D action will lead to the same clinical, radiological, histological, and most of the biochemical aberrations, those common features will be discussed first.

Clinical Features of Rickets and Osteomalacia

Children with hereditary deficiencies in vitamin D action will appear normal at birth and usually develop the characteristic features of rickets within the first 2 years of life. Defects in bone mineralization are particularly evident in regions of rapid bone growth, including, during the first year of life, the cranium, wrist, and ribs. Rickets at this time will lead to widened cranial sutures, frontal bossing, posterior flattening of the skull (craniotabes), bulging of costochondral junction (rachitic rosary), indentation of the ribs at the diaphragmatic insertion (Harrison's groove), and widening of the wrists. After the first year of life with the acquisition of erect posture and rapid linear growth, the deformities are most severe in the legs. Bow legs (genu varum) or knock-knee (genu valgum) deformities of various severity develop as well as widening of the end of long bones. If not treated, rickets may cause severe lasting deformities, compromise adult height, and increase susceptibility to pathological fractures.

The specific radiographic features of rickets reflect the failure of cartilage calcification and endochondral ossification and therefore are best seen in the metaphysis of rapidly growing bones. The metaphyses are widened, uneven, concave, or cupped and because of the delay in or absence of calcification, the metaphyses could become partially or totally invisible (Fig. 1). In more severe forms or in patients untreated for prolonged periods, rarefaction and thinning of the cortex of the entire shaft, as well as bone deformities and greenstick fractures, will become evident.

The clinical features of osteomalacia are subtle and could be manifested as bone pain or low back pain of varying severity in some cases. The first clinical presentation could be an acute fracture of the long bones, public ramii, ribs, or spine. The radiographic manifestations could be mild, e.g., generalized, nonspecific osteopenia or more specific, such as pseudofractures, commonly seen at the medial edges of long bones shaft.

Figure 1 Radiographs of wrists and hands of a patient with VDDR. Note the signs of severe rickets and demineralization.

In hypocalcemic rickets and/or osteomalacia, as is the case in deficiencies in vitamin D action, there may exist radiographic features of secondary hyperparathyroidism such as subperiosteal resorption and cysts of the long bones.

The characteristic histological feature of rickets and osteomalacia is deficiency or lack of mineralization of the organic matrix of bone. Because in clinical practice a bone specimen can be obtained only from the iliac crest, the histological picture is osteomalacia. Osteomalacia is defined as excess osteoid (hyperosteoidosis) and a quantitative dynamic proof of defective bone matrix mineralization obtained by analysis of time-spaced tetracycline labeling (Parfitt, 1983; Teitelbaum and Bollough, 1979).

The biochemical parameters characterizing deficiencies in vitamin D action can be divided into those associated with vitamin D status, the primary disturbance in mineral homeostasis and the respective compensatory mechanisms, and changes in bone metabolism. Changes in mineral and bone metabolism will be similar in all states of deficient vitamin D action, while serum levels of vitamin D metabolites will characterize each of the two classes delineated in the introduction (Table I).

As previously discussed, deficiencies in vitamin D action will lead to hypocalcemia and secondary hyperparathyroidism. Thus, the characteristic biochemical features are low to low-normal concentrations of serum calcium (depending on compensatory parathyroid activity), low urinary calcium excretion, hypophosphatemia, increased serum immunoreac-

Table I Biochemical Features of Vitamin D-Dependent Rickets (VDDR) Types I and II

	Serum concentrations						
	Calcium	Phosphorus	Alkaline phosphatase	iPTH	25OHD	$1,25(OH)_2D$	$24,25(OH)_2D$
VDRR-I	↓	↓	↑	↑	N– ↑	↓	↑
VDRR-II	↓	↓	↑	↑	N– ↑	↑	↓

tive parathyroid hormone (iPTH) levels, increased urinary cyclic AMP excretion, and decreased tubular reabsorption of phosphate (the last two measures reflecting the biological activity of elevated iPTH). Biochemical markers associated with increased osteoid production such as bone-specific alkaline phosphatase and osteocalcin will be elevated in states of rickets and osteomalacia (Cole *et al.,* 1985). However, as $1,25(OH)_2D$ stimulates osteocalcin synthesis *in vivo* and *in vitro*, serum levels of this biochemical bone marker are unreliable measures in hereditary vitamin D-deficient states.

Hereditary Deficiency in $1,25(OH)_2D$ Production (Vitamin D-Dependent Rickets Type I)

Prader *et al.,* (1961) were the first to describe two young children who showed all the usual clinical features of vitamin D deficiency despite adequate intake of the vitamin, thus coining the name "pseudovitamin D deficiency." Complete remission was dependent on continuous therapy with high doses of vitamin D; thus the term "vitamin D-dependent rickets" (VDDR). However, remission of the disease could be achieved by continuous therapy with physiological (microgram) doses of 1α-hydroxylated vitamin D metabolites (Delvin *et al.,* 1981; Fraser *et al.,* 1973).

Family studies have revealed it to be an autosomal recessive disease. Linkage analysis in a subset of French-Canadian families assigned the gene responsible for the disease to chromosome 12q13 (De Brackeleer and Larochell, 1991; Labuda *et al.,* 1990). The gene encoding the 1α-hydroxylase of mouse kidney, human keratinocyte, and peripheral mononuclear cells was localized on chromosome 12q13.1–q13.3, which maps to the disease locus of VDDR-I (Fu *et al.,* 1997b; Kitanaka *et al.,* 1998; Smith *et al.,* 1999; St. Arnaud *et al.,* 1997, Wang *et al.,* 1998; Yoshida *et al.,* 1998). There are no direct measures of the renal enzyme proving defective 1α-hydroxylase activity. This is virtually impossible to obtain, because of both the difficulty in obtaining tissue and the low level of expression. There are, however, several indirect observations to support this etiology. First, circulating levels of 25-hydroxyvitamin D (25(OH)D) are normal or elevated, depending on previous vitamin D treatment. Second, serum concentrations of $1,25(OH)_2D$ are very low (Table I). Third, while massive doses (100–300 times the daily recommended dose) of vitamin D or 25(OH)D are required to maintain remission of rickets, physiological replacement doses of calcitriol are sufficient to achieve the same effect. Fourth, it was reported that cells isolated from the placenta of two women with this disease had deficient activity of the decidual enzyme 25(OH)D-1α-hydroxylase (Glorieux *et al.,* 1995). It is noteworthy that during the past 15 years or so, it was demonstrated that human decidual cells do produce $1,25(OH)_2D$ and that this enzyme was regulated by feedback mechanisms (Delvin and Arabian, 1987; Diaz *et al.,* 2000; Weisman *et al.,* 1979). Finally, the 1α-hydroxylase gene from more than 20 families with VDDR-I and some of their first-degree healthy relatives were analyzed by direct sequencing, site-directed mutagenesis, and cDNA expression in transfected cells. All patients had homozygous mutations while parents or other healthy siblings were heterozygous for the mutation. Most patients of French-Canadian origin had the same mutation causing a frameshift and a premature stop codon in the putative heme-binding domain. The same mutation was observed in additional families of diverse origins (Smith *et al.,* 1999). All other patients had either a base-pair deletion causing premature termination codon upstream from the putative ferredoxin and heme-binding domains, or missense mutations (Fu *et al.,* 1997b; Kitanaka *et al.,* 1999; Smith *et al.,* 1998; Wang *et al.,* 1998; Yoshida *et al.,* 1998). No 1α-hydroxylase activity was detected when the mutant enzyme was expressed in various cells. The sequence of the human 1α-hydroxylase gene from keratinocytes and peripheral blood mononuclear cells has recently been shown to be identical with the renal gene (Fu *et al.,* 1997b; Kitanaka *et al.,* 1999; Smith *et al.,* 1999; Wang *et al.,* 1998; Yoshida *et al.,* 1998), thus supporting the use of these accessible cells as a proxy to study the renal tubular enzymatic defect. Taken together, these observations support the notion that the etiology of this hereditary disease is a defect in the renal tubular 25(OH)D-1α-hydroxylase activity.

The beneficial therapeutic effect of high serum concentrations of 25(OH)D in patients treated with massive doses of vitamin D, while $1,25(OH)_2D$ levels remain low, may have several possible explanations. First, high levels of 25-(OH)D may activate the VDR whose affinity for this metabolite is approximately two orders of magnitude lower than for $1,25(OH)_2D$. Second, a metabolite of 25(OH)D may act directly on target tissues, and finally, high levels of 25(OH)D may drive the local production of $1,25(OH)_2D$ via a paracrine–autocrine pathway, assuming that the tissue enzyme is controlled differently than the renal and decidual enzyme.

The differential diagnosis of VDDR-I from other hereditary forms of hypocalcemic rickets and especially the one associated with defects in the vitamin D receptor–effector system is based on serum concentrations of calcitriol and

Table II Response to Treatment of Patients with Vitamin D-Dependent Rickets (VDDR) Types I and II

	Vitamin D or 25(OH)D		1α-Hydroxylated vitamin D metabolites	
	Physiological	Pharmacological	Physiological	Pharmacological
VDDR-I	−	+	+	Toxic
VDDR-II	−	− or +	−	− or +

Note. Physiological doses are those recommended or being used as replacement therapy. Pharmacological doses are 100 times and more of the physiological doses (see details in text).

the response to treatment with 1-α-hydroxylated vitamin D metabolites (Tables I and II).

A similar syndrome has been described and studied in a mutant strain of pigs where the mode of inheritance as well as the clinical and biochemical features are similar to the human disease (Fox *et al.,* 1985; Harmeyer *et al.,* 1982). Piglets affected by the disease have rickets, elevated 25(OH)D with low or undetectable $1,25(OH)_2D$ serum concentrations, normal specific tissue binding sites for tritiated $1,25(OH)_2D$, and no detectable activity of 25(OH)D-1α-hydroxylase in renal cortical homogenates. Thus, there is strong evidence that the disease state in the pig is caused solely by an inherited defect in the renal enzyme.

Hereditary Defects in the Vitamin D Receptor-Effector System (Vitamin D-Dependent Rickets Type II)

Introduction

This is a rare disorder and only ~60 patients have been reported (Balsan *et al.,* 1983; Bear *et al.,* 1981; Brooks *et al.,* 1978; Castells *et al.,* 1986; Chen *et al.,* 1984; Clemens *et al.,* 1983; Cockerill *et al.,* 1997; Eil *et al.,* 1981; Feldman *et al.,* 1982; Fraher *et al.,* 1986; Fujita *et al.,* 1980; Griffin and Zerwekh, 1983; Hawa *et al.,* 1996; Hewison *et al.,* 1993; Hirst *et al.,* 1985; Hochberg *et al.,* 1984; Liberman *et al.,* 1980, 1983b; Lin and Uttley, 1993; Lin *et al.,* 1996; Malloy *et al.,* 1997; Marx *et al.,* 1978, 1984; Mechica *et al.,* 1997; Rosen *et al.,* 1979; Saijo *et al.,* 1991; Simonin *et al.,* 1992; Sockalosky *et al.,* 1980; Takeda *et al.,* 1986, 1987, 1989; Tauchiya *et al.,* 1980; Yagi *et al.,* 1993; Whitfield *et al.,* 1996; personal communications).

Brooks *et al.* (1978) described an adult patient with hypocalcemic osteomalacia and elevated serum concentration of $1,25(OH)_2D$. Treatment with vitamin D, causing a further increase in serum calcitriol levels, cured the patient. The term vitamin D-dependent rickets type II (VDDR-II) was suggested to describe this disorder. However, reports on additional patients, about half of whom did not respond to vitamin D therapy, as well as *in vivo* and *in vitro* studies to be discussed below, seem to prove that vitamin D dependency is a misnomer. The term hereditary defects in the vitamin D receptor–effector system or end-organ resistance to $1,25(OH)_2D$ action is therefore more appropriate to describe the etiology and pathogenesis of this syndrome. However, due to convention and convenience, the term VDDR-II will be retained in this chapter.

Clinical and Biochemical Features

General Features

The clinical, radiological, histological, and biochemical features (except serum levels of vitamin D metabolites) are typical of hypocalcemic rickets and/or osteomalacia as previously discussed. Notable exceptions are two unrelated patients with hyperphosphatemia, despite elevated serum levels of iPTH (Liberman *et al.,* 1980; Yagi *et al.,* 1993), which can be the end result of long-standing and severe hypocalcemia, which paradoxically inhibits the phosphaturic response to PTH or represents an additional hereditary renal tubular defect.

In VDDR-II there is no history of vitamin D deficiency and no clinical or biochemical response to physiological doses of vitamin D or its 1α-hydroxylated active metabolites. Serum levels of 25(OH)D are normal or elevated (depending on preceding vitamin D therapy); $1,25(OH)_2D$ concentrations are markedly elevated before or during therapy with vitamin D preparations; and 24,25-dihydroxyvitamin D ($24,25(OH)_2D$)) circulating levels are inappropriately low (Table I).

The disease manifests itself as an active metabolic bone disease in early childhood. However, late onset at adolescence and adulthood was documented in several sporadic cases including the first report by Brooks *et al.* (1978) and Fujita *et al.* (1980). These patients represented the mildest form of the disease and had a complete remission when treated with vitamin D or its active metabolites. It is unclear if the adult onset patients belonged to the same hereditary entity, as no further studies on their VDR status have been published.

Ectodermal Anomalies

A peculiar clinical feature of VDDR-II patients, appearing in approximately two-thirds of the subjects, is total alopecia or sparse hair (Fig. 2). Alopecia usually appears during the first year of life and in one patient, at least, has been associated with additional ectodermal anomalies (Liberman *et al.,*

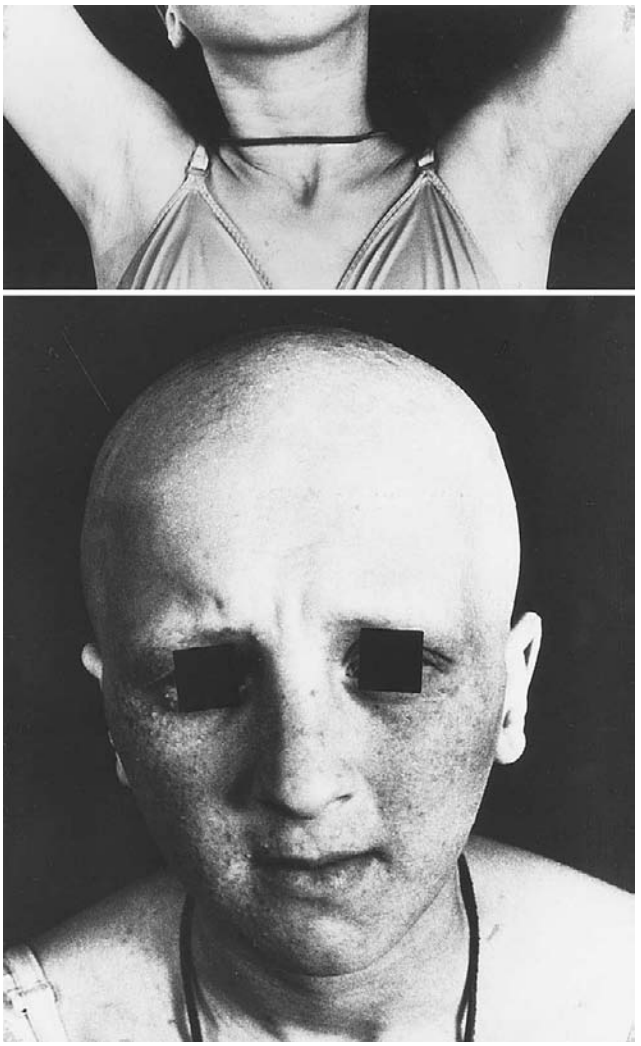

Figure 2 A patient with VDDR-II with total alopecia. Note, no scalp or axilla hair and no eyebrows or eyelashes.

1980). It seems that alopecia is a marker of a more severe form of the disease as judged by the earlier onset, the severity of the clinical features, the proportion of patients who do not respond to treatment with high doses of vitamin D or its active metabolites, and the extremely elevated levels of serum $1,25(OH)_2D$ recorded during therapy (Marx *et al.,* 1984, 1986). Though some patients with alopecia could achieve clinical and biochemical remission of their bone disease, none have shown hair growth. The notion that total alopecia is probably a consequence of a defective vitamin D receptor–effector system is supported by the following: alopecia has only been associated with hereditary defects in the VDR system, i.e., with end-organ resistance to the action of the hormone, and has not been recorded with hereditary deficiency in $1,25(OH)_2D$ synthesis, i.e., low circulating levels of the hormone; alopecia is present in kindreds with different defects in the VDRs; high-affinity uptake of tritiated $1,25(OH)_2D_3$ in the nucleus of the outer root sheath of the hair follicle of rodents has been demonstrated by autoradiography (Strumpf *et al.,* 1979); and the epidermis and hair follicle contain a calcium-binding protein that is partially vitamin D-dependent (Marx *et al.,* 1984). Finally, alopecia develops in homozygote VDR knockout mice (Li *et al.,* 1997; Yoshizawa *et al.,* 1997). Taken together, it could be hypothesized that an intact VDR–effector system is important for the differentiation of the hair follicle in the fetus, which is unrelated to mineral homeostasis.

VITAMIN D METABOLISM

Serum concentrations of $1,25(OH)_2D$ range from upper normal values to markedly elevated before therapy, but on vitamin D treatment may reach the highest levels found in any living system (100 times and more than the upper normal range) (Marx *et al.,* 1986). These values may represent the end results of four different mechanisms acting synergistically to stimulate strongly the renal 25(OH)D-1; α-hydroxylase. Three of the mechanisms are hypocalcemia, secondary hyperparathyroidism, and hypophosphatemia. The fourth mechanism may be a failure of the negative feedback loop by which the hormone inhibits the renal enzyme activity caused by the basic defect in the VDR–effector system. This was demonstrated in a patient with VDRR-II in remission (normal serum levels of calcium, phosphorus, and PTH) in whom a load of $25(OH)D_3$ had caused a marked increase in serum $1,25(OH)_2D_3$ concentration (Balsan *et al.* 1983; Marx *et al.,* 1984). It was reported recently that the 1α-hydroxylase gene expression was not suppressed by $1,25(OH)_2D_3$ in renal tubular cells from VDR knock out mice while it was suppressed in cells with normal VDR or heterozygote for the null mutation (Murayama *et al.,* 1999; Takeyama *et al.,* 1997).

$1,25(OH)_2D$ is a potent inducer of the enzyme 25(OH) D-24-hydroxylase *in vivo* and *in vitro*. Serum levels of $24,25(OH)_2D$ have been very low or inappropriately low in the face of the elevated concentrations of the hormone in patients with VDDR-II (Castells *et al.,* 1986; Fraher *et al.,* 1986; Liberman *et al.,* 1980; Marx *et al.,* 1984). This probably reflects defective stimulation of $24,25(OH)_2D$ production due to the basic deficiency in VDR activity. This assumption is supported by the observation that in mutant mice lacking the VDR, expression of 24(OH) ase was reduced to undetectable levels and the normal induction of the enzyme by $1,25(OH)_2D_3$ was not obtained (Takeyama *et al.,* 1997).

MODE OF INHERITANCE

In approximately half of the reported kindreds, parental consanguinity and multiple siblings with the same defect suggest autosomal recessive mode of inheritance (Marx *et al.,* 1984). Parents of patients who are expected to be obligate heterozygotes have been reported to be normal, i.e., no bone disease or alopecia and normal blood biochemistry. However, studies on cells (cultured dermal fibroblasts, Epstein–Barr transformed lymphoblasts, and mitogen-stimulated lymphocytes) obtained from parents of affected children revealed decreased bioresponses, decreased normal VDR protein and its mRNA, and a heterozygote genotype exhibiting both normal and mutant DNA alleles (Malloy *et al.,* 1989, 1990; Ritchie *et al.,* 1989; Takeda *et al.,* 1990). There is a striking

clustering of patients around the Mediterranean, including patients reported from Europe and America who originated from the same area. A notable exception is a cluster of some kindred from Japan (Fujita *et al.,* 1980; Tauchiya *et al.,* 1980, 1986, 1987, 1989; Yagi *et al.,* 1993).

Cellular and Molecular Defects

METHODS

The near ubiquity of a similar if not identical VDR–effector system among various cell types including cells originating from tissues easily accessible for sampling made feasible studies on the nature of the intracellular and molecular defects in patients with VDDR-II. The cells used were mainly fibroblasts derived from skin biopsies (Balsan *et al.,* 1983; Castells *et al.,* 1986; Chen *et al.,* 1984; Clemens *et al.,* 1983; Eil *et al.,* 1981; Feldman *et al.,* 1982; Fraher *et al.,* 1986; Griffin and Zerwekh, 1983; Hirst *et al.,* 1985; Hughes *et al.,* 1988; Liberman *et al.,* 1983b; Malloy *et al.,* 1989, 1990; Marx *et al.,* 1984; Ritchie *et al.,* 1989; Takeda *et al.,* 1989) and peripheral blood mononuclear (PBM) cells (Koren *et al.,* 1985; Ritchie *et al.,* 1989; Takeda *et al.,* 1986, 1990; Yagi *et al.,* 1993). PBM cells contain high-affinity receptors for $1,25(OH)_2D_3$ that are expressed constitutively in monocytes and are induced in mitogen-stimulated T-lymphocytes and Epstein–-Barr (EB) transformed lymphoblasts. All cells have been used to assess most of the steps in $1,25(OH)_2D_3$ action from cellular and subcellular uptake of the hormone to bioresponse as well as to elucidate the molecular aberrations in the VDR protein, RNA, and DNA levels.

The hormone–receptor interaction has been analyzed by several methods including binding characteristics of ^{3}H 1,25 $(OH)_2D_3$ to intact cells, nuclei or high salt cellular soluble extracts—so-called cytosol (Balsan *et al.,* 1983; Castells *et al.,* 1986; Chen *et al.,* 1984; Clemens *et al.,* 1983; Eil *et al.,* 1981; Feldman *et al.,* 1982; Fraher *et al.,* 1986; Hirst *et al.,* 1985; Hochberg *et al.,* 1984; Hughes *et al.,* 1988; Koren *et al.,* 1985; Liberman *et al.,* 1983a,b; Malloy *et al.,* 1989, 1990; Marx *et al.,* 1984; Ritchie *et al.,* 1989; Sone *et al.,* 1990; Takeda *et al.,* 1985; Yagi *et al.,* 1993), measurements of VDR protein content by monoclonal antibodies with radiological immunoassay or Western blot analysis (Malloy *et al.,* 1990; Ritchie *et al.,* 1989), immunocytochemical methods in whole cells (Barsony *et al.,* 1990), and characterization of the hormone–receptor complex on continuous sucrose gradient and nonspecific DNA–cellulose columns (Balsan *et al.,* 1983; Chen *et al.,* 1984; Clemens *et al.,* 1983; Eil *et al.,* 1981; Feldmam *et al.,* 1982; Hirst *et al.,* 1985; Hochberg *et al.,* 1984; Hughes *et al.,* 1988; Liberman *et al.,* 1983a,b; Malloy *et al.,* 1989; Marx *et al.,* 1984; Sone *et al.,* 1990).

The cloning and nucleotide sequencing of the human VDR gene made it feasible to study the molecular defects in patients with VDRR-II. The methods used included, among others, isolation of genomic DNA that encodes the structural portion of the human VDR, PCR amplification, screening, and sequencing of the amplified DNA fragments (Hughes *et al.,* 1988; Kristjansson *et al.,* 1993; Malloy *et al.,* 1990; Ritchie *et al.,* 1989; Sone *et al.,* 1990; Yagi *et al.,* 1993); cloning and sequencing of the VDR cDNA produced from isolated fibroblasts total RNA by reverse transcription and PCR amplification (Rut *et al.,* 1994; Saijo *et al.,* 1991; Weise *et al.,* 1993); recreation of the mutant receptor *in vitro* by introducing the appropriate base change in normal VDR cDNA by site-directed mutagenesis and measuring the biochemical and functional properties of the encoded VDR by transfecting an expression vector containing the mutant cDNA into mammalian cell lines (Hewison *et al.,* 1993; Hughes *et al.,* 1988; Malloy *et al.,* 1990; Ritchie *et al.,* 1989; Sone *et al.,* 1990; Yagi *et al.,* 1993); measurement of VDR mRNA by Northern blot analysis (Malloy *et al.,* 1990); and restriction enzyme mapping techniques (Yagi *et al.,* 1993).

TYPES OF DEFECTS

Studies with the above-mentioned methods in cells originating from a variety of patients with VDDR-II revealed heterogeneity of the cellular and molecular defects in the VDR–effector system. Based on the known functional properties of the VDR, three different classes of defects could be identified (Fig. 3).

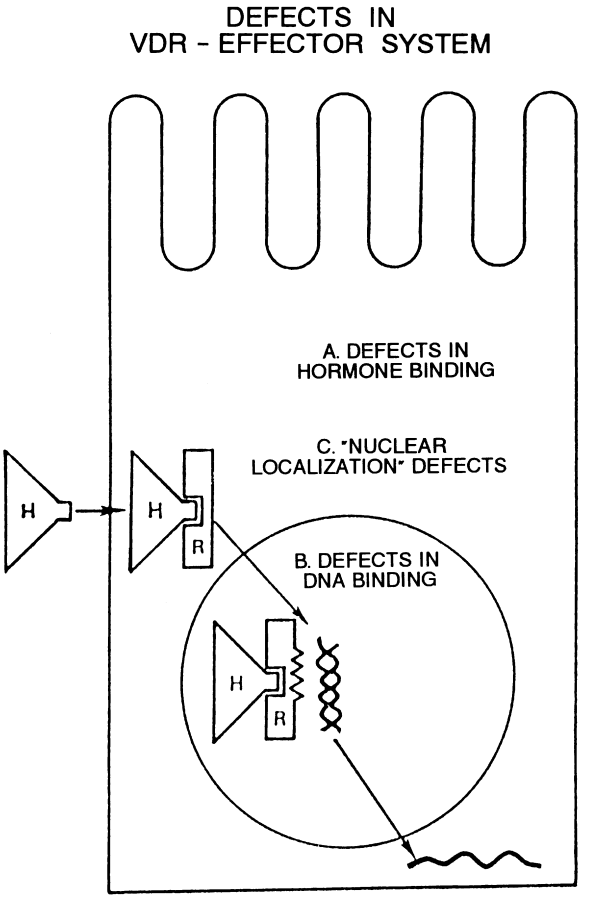

Figure 3 Three classes of defects in intracellular interaction of VDR, $1,25(OH)_2D$, nuclei, and/or DNA.

Deficient Hormone Binding There are three subgroups in this class: (i) No Hormone Binding. This is the most common abnormality observed and is characterized by unmeasurable specific binding of ^3H, $25(OH)_2D_3$ to either intact cells, nuclei, or cell extracts (Balsan *et al.,* 1983; Chen *et al.,* 1984; Cockeril *et al.,* 1997; Feldman *et al.,* 1982; Fraher *et al.,* 1986; Hawa *et al.,* 1996; Koren *et al.,* 1985; Kristjansson *et al.,* 1993; Liberman *et al.,* 1983a,b; Malloy *et al.,* 1990; Marx *et al.,* 1984; Mechica *et al.,* 1997; Ritchie *et al.,* 1989; Sone *et al.,* 1989). Studies in several kindreds with this defect (including an extended kindred with 8 patients studied) revealed undetectable levels of VDR by immunoblots on an immunoradiometric assay in most kindreds (Kristjansson *et al.,* 1993; Malloy *et al.,* 1990; Ritchie *et al.,* 1989; Weise *et al.,* 1993). DNA from these affected subjects exhibited a single base mutation in each kindred resulting in (a) conversion of a normal amino acid codon into a premature termination codon in the coding sequence of the VDR protein and (b) a frameshift in translation resulting in a premature stop codon. The truncated VDRs produced lacked hormone binding or both hormone and DNA binding domains (Fig. 4) (Cockeril *et al.,* 1997; Hawa *et al.,* 1996; Mechica *et al.,* 1997; Weise *et al.,* 1993). The recreated mutant VDR cDNA was expressed in mammalian cells, and the resulting mutant VDR was demonstrated to be the truncated protein that exhibited no specific hormone binding. Steady-state VDR mRNA levels were decreased or undetectable in patients' cells from one kindred (Malloy *et al.,* 1990; Ritchie *et al.,* 1989). An immunoradiometric assay for VDR did not detect the 148- and 291-amino-acid-long mutant VDR, though this portion of the receptor included both epitopes required for recognition (Weise *et al.,* 1993). These observations may indicate an unstable transcript and/or increased turnover. In cells cultured from parents of some patients, expected to be obligate heterozygotes, binding of ^3H, $25(OH)_2D_3$, VDR protein, and mRNA content of cells ranged from the lower limit of normal to about half the normal level.

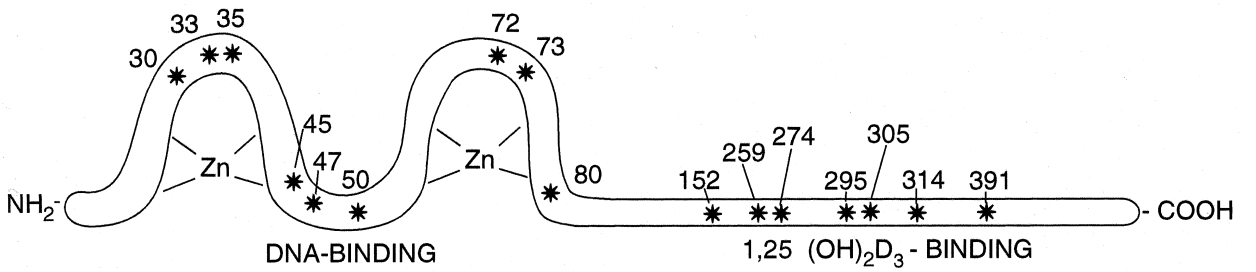
In one patient representing a kindred with no hormone binding, a missense mutation resulted in the substitution of the hydrophobic basic arginine-274 by the hydrophilic nonpolar leucine in the hormone binding region (Kristjansson *et al.,* 1993) (Fig. 4). In this patient, normal transcription in a transfection assay could be elicited by 1000-fold higher concentrations of calcitriol than needed for the wild-type receptor. However, no *in vivo* or *in vitro* stimulation of 25(OH)D-24-hydroxylase could be obtained by high concentrations of $1,25(OH)_2D_3$.

(ii) Defective Hormone Binding Capacity. In one patient representing one kindred, the number of binding sites in nuclei and high-salt soluble cell extracts was 10% of control, with an apparent normal affinity (Balsan *et al.,* 1983; Liberman *et al.,* 1983a,b).

(iii) Defective Hormone Binding Affinity. Binding affinity of tritiated calcitriol was reduced 20- to 30-fold, with normal capacity, in high-salt soluble dermal fibroblast extracts from one kindred (Castells *et al.,* 1986). An additional patient, representing a different kindred had a modest decrease of VDR affinity when measured at 0° C (Malloy *et al.,* 1997).

No studies on the molecular defect were performed in patients with the last two defects.

Deficient Binding to DNA Cell preparations derived from patients with this defect demonstrate normal or near normal binding capacity and affinity for ^3H $1,25(OH)_2D_3$ to nuclei of intact cells and to high-salt soluble cell extracts, as well as normal molecular size VDR of 48–50 kDa, as analyzed by immunoblot. Hormone receptor complexes, however, have



NORMAL	MUTANT
30 Arg (CGA)	Stop (TGA)
33 Gly (GGC)	Asp (GAC)
35 His (CAC)	Gln (CAG)
45 Lys (AAA)	Glu (GAA)
47 Phe (TTC)	Lle (ATC)
50 Arg (CGA)	Gln (CAA)
72 Arg (CGC)	Stop (TGA)
73 Arg (CGG)	Gln (CAA)
80 Arg (CGG)	Gln (CAG)

NORMAL	MUTANT
152 Gln (CAG)	Stop (TAG)
259 Gln (CAG)	Pro (CCG)
274 Arg (CGC)	Leu (CTC)
295 Tyr (TAC)	Stop (TAA)
305 His (CAC)	Gln (CAG)
314 Lle (ATC)	Ser (AGC)
391 Arg (CGC)	Cys (TGC)

Figure 4 Schematic presentation of the homozygous mutation in the VDR protein in VDDR-II. The asterisks depict sites of amino-acid substitutions due to point mutations and codon changes, using the numbering system of Baker *et al.* (1988).

decreased affinity to nonspecific DNA (peak elution from DNA–cellulose columns at 0.1 M KCl as compared with 0.2 M in normals) (Hirst *et al.,* 1985; Hughes *et al.,* 1988; Liberman *et al.,* 1986; Saijo *et al.,* 1991; Yagi *et al.,* 1993). A single nucleotide missense mutation within exon 2 or 3, encoding the DNA binding domain of the VDR, was demonstrated in genomic DNA isolated from dermal fibroblasts and/or EB-transformed lymphoblasts from 10 unrelated kindreds (Hughes *et al.,* 1988; Lin *et al.,* 1996; Malloy *et al.,* 1989; Mechica *et al.,* 1997; Rut *et al.,* 1994; Sone *et al.,* 1990; Saijo *et al.,* 1991; Yagi *et al.,* 1993). Eight different single nucleotide mutations were found in the ten kindreds (Fig. 4). Two apparently unrelated kindreds share the same mutation (Saijo *et al.,* 1991; Sone *et al.,* 1990).

All point mutations caused a single substitution of an amino acid that resides in the region of the two zinc fingers of the VDR protein that are essential for the functional interaction of the hormone–receptor complex with DNA. Interestingly, all these altered amino acids are highly conserved in the steroid receptor superfamily and seem to concentrate in three regions—the tip of the first zinc fingers (three mutations), the "knuckle" region, just C-terminal of the first zinc fingers (three mutations), and the C-terminal side of the second zinc fingers (two mutations). All of these single amino acid residue substitutions are associated with charge changes and thus affect hydrogen bonding. These aberrations, as well as changes in hydrophobicity, will have a deleterious effect on the interaction of the hormone–receptor complex with DNA.

Each of the mutants was recreated by introducing the appropriate base change into the normal VDR cDNA and then transfecting the mutated cDNA into mammalian cells. The functional properties of the resultant VDR expression product were indistinguishable from mutant DNA, i.e., normal hormone binding and deficient binding to nuclear extracts and nonspecific DNA (Hughes *et al.,* 1988; Saijo *et al.,* 1991; Sone *et al.,* 1990). Studies on cells obtained from parents of some of these patients revealed, as expected, a heterozygous state, i.e., expression of both normal and defective forms of VDR as well as normal and mutant gene sequences (Hughes *et al.,* 1988; Malloy *et al.,* 1989).

Deficient Nuclear Uptake The following features characterize the hormone–receptor–nuclear interaction in this defect—normal or near normal binding capacity and affinity of ^{3}H 1,25$(OH)_2D_3$ to high-salt soluble cell extracts with low to unmeasurable hormone uptake into nuclei of intact cells (Eil *et al.,* 1981; Hewison *et al.,* 1993; Liberman *et al.,* 1983b; Takeda *et al.,* 1989; Whitfield *et al.,* 1996). These features were demonstrated in skin-derived fibroblasts in all kindreds, in cells cultured from a bone biopsy of one patient (Liberman *et al.,* 1983b), and in EB-transformed lymphoblasts of one patient (Hewison *et al.,* 1993). Occupied VDR obtained from high-salt fibroblast extracts of two kindreds demonstrated normal binding to nonspecific DNA cellulose (Liberman *et al.,* 1986). Immunocytological studies in fibroblasts of a patient with this defect showed that immediately after 1,25$(OH)_2D_3$ treatment, VDR accumulated along the nuclear membrane with no nuclear translocation (Barsony *et al.,* 1990). Patients with this defect included a kindred with normal hair and several kindreds with total alopecia. Finally, almost all patients responded with a complete clinical remission to high doses of vitamin D and its active 1α-hydroxylated metabolites.

Attempts to characterize the molecular defect were carried in six kindreds. In three of them, no mutation in the coding region of the VDR gene was observed (Hewison *et al.,* 1993; pers. commun.). Studies in two kindreds revealed a normal molecular mass and quantitative expression of the VDR as judged by immunoblotting (Whitfield *et al.,* 1996). Complete sequencing of the VDR coding region revealed a different single nucleotide mutation in each kindred: ATC to AGC for isoleucine-314 to serine in one kindred, CGC to TCG altering arginine -391 to cysteine in the second kindred, and CAG to CCG altering glutamine-259 to proline in the third kindred (Fig. 4) (Cockeril *et al.,* 1997; Whitfield *et al.,* 1996), This region is considered to play a role in heterodimerization of VDR with RXR, and thus it has been suggested that these patients' receptors have defects that compromise RXR heterodimerization, which is essential for nuclear localization and probably for recognition of the vitamin D-responsive element as well. The fact that no mutation in the VDR coding region was observed in three additional kindreds with the same phenotypical defect may suggest that the genetic defect affects another component of the receptor effector system that is essential for the VDR function as a nuclear transcription factor. It has been recently shown that coactivation complexes are essential for the ligand-induced transactivation of VDR (Freedman, 1999). It is worthwhile to note that in one kindred originally described with this defect (Takeda *et al.,* 1989) a missense mutation at position 140 in exon 3, encoding the DNA binding domain was observed (Saijo *et al.,* 1991).

In Vitro Posttranscriptional and Transcriptional Effect of 1,25$(OH)_2D_3$

In vitro bioeffects of the hormone on various cells in patients with VDDR-II have been assayed mainly by two procedures, induction of 25(OH)D-24-hydroxylase and inhibition of mitogen stimulated PBM cells.

1,25$(OH)_2D_3$ induces 25(OH)D-24-hydroxylase activity in skin-derived fibroblasts (Balsan *et al.,* 1983; Castells *et al.,* 1986; Chen *et al.,* 1984; Clemens *et al.,* 1983; Feldman *et al.,* 1982; Fraher *et al.,* 1986; Gamblin *et al.,* 1985; Griffin *et al.,* 1983; Hewison *et al.,* 1993; Hirst *et al.,* 1985; Hughes *et al.,* 1988; Liberman *et al.,* 1983b; Malloy *et al.,* 1990; Ritchie *et al.,* 1989; Rut *et al.,* 1994; Sone *et al.,* 1990; Yagi *et al.,* 1993), mitogen-stimulated lymphocytes (Takeda *et al.,* 1990), and cells originating from bone (Balsan *et al.,* 1986) in a dose-dependent manner. In cells from normal subjects, maximal and half-maximal induction of the enzyme was achieved by 10^{-8} and 10^{-9} M concentrations of 1,25 $(OH)_2D_3$, respectively. Dermal fibroblast or PBM cells from VDDR-II patients with no calcemic response to maximal doses of

vitamin D or its metabolites in vivo did not show any 25(OH)D-24-hydroxylase response to very high concentration of $1,25(OH)_2D_3$ *in vitro,* while dermal fibroblasts from patients with a calcemic response to high doses of vitamin D or its metabolites *in vivo* showed inducible 24-hydroxylase with supraphysiological concentrations of 1,25 $(OH)_2D_3$, i.e., a shift to the right, *in vitro.* Physiological concentrations of $1,25(OH)_2D_3$ partially inhibit mitogen-induced DNA synthesis in peripheral lymphocytes with a half maximal inhibition achieved at 10^{-10} M of the hormone (Koren *et al.,* 1985; Takeda *et al.,* 1986). Mitogen stimulated lymphocytes from several kindreds with defects characterized as no hormone binding or deficient binding to DNA, with no calcemic response to high doses of vitamin D and its metabolites *in vivo*, showed no inhibition of lymphocyte proliferation *in vitro*, with concentrations of up to 10^{-6} M $1,25(OH)_2D_3$. (Fig. 5). Additional methods for measuring bioeffects of $1,25(OH)_2D_3$ on various cells *in vitro* were carried out only in few patients and included inhibition of dermal fibroblast proliferation (Clemens *et al.,* 1983), induction of osteocalcin synthesis in cells derived from bone (Balsan *et al.,* 1986), a mitogenic effect on dermal fibroblasts (Barsony *et al.,* 1989), and stimulation of cGMP production in cultured skin fibroblasts (Barsony and Marx, 1988). It is noteworthy that in all assays mentioned and without exception, each patient's cells showed severely deficient responses.

With the elucidation of the molecular defects in VDDR-II, the transactivation abilities of naturally occurring mutant or recreated mutant VDRs were evaluated in a transcriptional activation assay. The human osteocalcin gene promoter fused to chloramphenicol acetyltransferase (CAT) gene reporter plasmid was transfected into the patients or into normal fibroblasts (Hewison *et al.,* 1993; Hughes *et al.,* 1988; Malloy *et al.,* 1990; Ritchie *et al.,* 1989; Saijo *et al.,* 1991; Sone *et al.,* 1989; Yagi *et al.,* 1993). Treating normal transfected cells with $1,25(OH)_2D_3$, caused a concentration-dependent induction of transcription, measured by increased CAT activity. No induction of transcription was observed in cells originating from patients with defects characterized as no hormone binding (Kristjansson *et al.,* 1993; Malloy *et al.,* 1990; Ritchie *et al.,* 1989) or deficient binding to DNA (Hughes *et al.,* 1988; Saijo *et al.,* 1991; Sone *et al.,* 1990; Yagi *et al.,* 1993). Moreover, in a cotransfection assay, the addition of a normal human VDR cDNA expression vector to the transfected plasmid that directed synthesis of a normal VDR restored hormone responsiveness of resistant cells. Finally, in a patient characterized as deficient nuclear uptake defect no mutation was identified within the coding region of the VDR gene; no induction of 25(OH)D-24-hydroxylase activity by up to 10^{-6} M $1,25(OH)_2D_3$ was observed in cultured skin fibroblasts, but there was normal transactivation by $1,25(OH)_2D_3$ in the transcriptional activation assay (Hewison *et al.,* 1993).

CELLULAR DEFECTS AND CLINICAL FEATURES

Normal hair was described with most phenotypes of the cellular defects, the exception being patients with deficient hormone binding capacity and affinity, but this could be due to the fact that only one or two kindreds were described per subgroup. Normal hair is usually associated with a milder form of the disease, as judged by the age of onset, severity of the clinical features, and usually the complete clinical and biochemical remission on high doses of vitamin D or its metabolites.

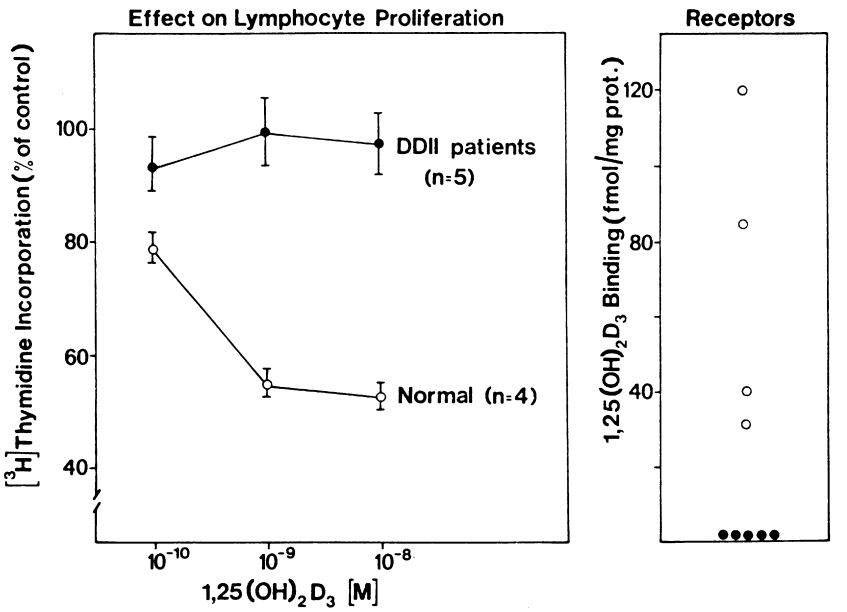


Figure 5 Effect of increasing concentrations of $1,25(OH)_2D_3$ on mitogen-induced lymphocyte proliferation from patients with VDDR-II (DD-II) and normal controls. The numbers of specific $[^3H]1,25(OH)_2D_3$ binding sites are depicted (right) in the same cell populations. VDRR-II patients tested here are with the defect characterized as no hormone binding.

One patient with normal hair seemed to display resistance both *in vivo* (no clinical remission on circulating calcitriol level up to 100 times the mean normal adult values) and *in vitro* (no induction of 25(OH)D-24-hydroxylase activity in dermal fibroblasts by up to 10^{-8} M $1,25(OH)_2D_3$ (Fraher *et al.,* 1986). However, it may be argued that the patient did not receive full treatment for a long enough period of time (only 10 weeks of total treatment with the various vitamin D metabolites). Only approximately half of the patients with alopecia have shown satisfactory clinical and biochemical remission to high doses of vitamin D or its active 1α-hydroxylated metabolites, but the dose requirement is ~10-fold higher than in patients with normal hair (Marx *et al.,* 1986).

It seems that patient defects characterized as deficient hormone binding affinity and deficient nuclear uptake achieve complete clinical and biochemical remission on high doses of vitamin D or its active 1α-hydroxylated metabolites. Most of the patients with other types of defects could not be cured with high doses of vitamin D or its metabolites. However, it should be emphasized that not all of the patients received treatment for a long enough period of time and with sufficiently high doses (see Treatment, below).

Diagnosis

Clinical features of early-onset rickets with no history of vitamin D deficiency, total alopecia, parental consanguinity, additional siblings with the same disease, serum biochemistry of hypocalcemic rickets, elevated circulating levels of $1,25(OH)_2D$, and normal to high levels of 25(OH)D (Table I) support the diagnosis of VDDR-II. The issue becomes more complicated when the clinical features are atypical, i.e., late onset of the disease, sporadic cases, and normal hair. Failure of a therapeutic trial with calcium and/or physiological replacement doses of vitamin D or its metabolites may support the diagnosis but the final direct proof requires the demonstration of a cellular, molecular, and functional defect in the VDR–effector system.

Based on the clinical and biochemical features, the following additional disease states should be considered: (1) extreme calcium deficiency—a seemingly rare situation, described in a group of children from a rural community in South Africa, who consumed an exceptionally low-calcium diet of 125 mg/day (Pettifor *et al.,* 1981). All had severe bone disease with histologically proven osteomalacia, biochemical features of hypocalcemic rickets with elevated serum levels of $1,25(OH)_2D$, and sufficient vitamin D. Calcium repletion caused complete clinical and biochemical remission. Nutritional history and the response to calcium supplementation support this diagnosis. (2) Severe vitamin D deficiency—during initial stages of vitamin D therapy in children with severe vitamin D-deficient rickets, the biochemical picture may resemble VDDR-II, i.e., hypocalcemic rickets with elevated serum calcitriol levels. This may represent a "hungry bone syndrome," i.e., high calcium demands of the abundant osteoid tissue becoming mineralized. This is a transient condition that may be differentiated from VDDR-II by a history of vitamin D deficiency and the final therapeutic response to replacement doses of vitamin D.

Treatment

In about half of the kindreds with VDDR-II, the bioeffects of $1,25(OH)_2D_3$ were measured *in vitro* (see above). An invariable correlation (with one exception) was documented between the *in vitro* effect and the therapeutic response *in vivo;* i.e., patients with no calcemic response to high levels of serum calcitriol showed no effects of $1,25(OH)_2D_3$ on their cells *in vitro* (either induction of 25(OH))D-24-hydroxylase or inhibition of lymphocyte proliferation) and vice versa. If the predictive therapeutic value of the *in vitro* cellular response to $1,25(OH)_2D_3$ could be substantiated convincingly, it may eliminate the need for time-consuming and expensive therapeutic trials with massive doses of vitamin D or its active metabolites. In the meantime, it is mandatory to treat every patient with VDDR-II irrespective of the type of receptor defect.

An adequate therapeutic trial must include vitamin D at a dose that is sufficient to maintain high serum concentrations of $1,25(OH)_2D_3$, as the patients can produce high hormone levels if supplied with enough substrate (Brooks *et al.,* 1978; Marx *et al.,* 1978). If high serum calcitriol levels are not achieved, it is advisable to treat with 1α-hydroxylated vitamin D metabolites in daily doses of up to 6 μg/kg or a total of 30–60 μg and calcium supplementation of up to 3 g of elemental calcium daily; therapy must be maintained for a period sufficient to mineralize the abundant osteoid (usually 3–5 months). Therapy may be considered a failure if no change in the clinical, radiological, or biochemical parameters occurs during continuous and frequent follow-up while serum $1,25(OH)_2D$ concentrations are maintained at ~100 times the mean normal range.

In some patients with no response to adequate therapeutic trials with vitamin D or its metabolites, a remarkable clinical and biochemical remission of their bone disease, including catch-up growth, was obtained by treatment with large amounts of calcium. This was achieved by long-term (months) intracaval infusions of up to 1000 mg of calcium daily (Balsan *et al.,* 1986; Bliziotes *et al.,* 1988; Weisman *et al.,* 1987). Another way to increase calcium input into the extra cellular compartment is to increase net gut absorption, independent of vitamin D, by increasing calcium intake (Sakati *et al.,* 1986). This approach is limited by dose and patient tolerability and was actually used successfully in only one patient.

Several patients have shown unexplained fluctuations in response to therapy or in presentation of the disease. One patient after a prolonged remission became completely unresponsive to much higher doses of active 1α-hydroxylated vitamin D metabolites (Balsan *et al.,* 1983), and another patient seemed to show amelioration of resistance to $1,25(OH)_2D_3$ after a brief therapeutic trial with $24,25(OH)_2D_3$ (Liberman *et al.,* 1980). In several patients, spontaneous healing occurred

in their teens (Hochberg *et al.,* 1984) or rickets did not recur for 14 years after cessation of therapy (Takeda *et al.,* 1989).

Animals Models

Some New World primates (marmoset and tamarins) that develop osteomalacia in captivity are known to have high nutritional requirements for vitamin D and maintain high serum levels of $1,25(OH)_2D$, thus exhibiting a form of end-organ resistance to $1,25(OH)_2D$ (Adams and Gacad, 1988; Liberman *et al.,* 1985; Shinki *et al.,* 1983; Takahashi *et al.,* 1985). Cultured dermal fibroblasts and EB-virus transformed lymphoblast have shown deficient hormone binding capacity and affinity (Adams and Gacad, 1988; Liberman *et al.,* 1985). It has been observed that marmoset lymphoblasts contain a soluble protein of 50–60 kDa that binds $1,25(OH)_2D_3$ with a low affinity but high capacity and thus may serve as a sink that interferes with the hormone binding and its cognate receptor (Gacad and Adams 1993). The same group described another protein present in the nuclear extract of these cells capable of inhibiting normal VDR–RXR binding to the vitamin D response element (Arbelle *et al.,* 1996).

It is of interest that these New World primates also exhibit a compensated hereditary end-organ resistance to the true steroid hormones including glucocorticoids, estrogens, and progestins (Lipsett *et al.,* 1985). This of course raises the interesting possibility that the defect in the hormone–receptor–effector system involves an element shared by all the members of this superfamily of ligand-modulated transcription factors.

Recently, VDR knockout mice have been created by targeted ablation of the first or second zinc finger (Li *et al.,* 1997; Yoshizawa *et al.,* 1997). Only the homozygotic mice were affected. Though phenotypically normal at birth, after weaning, however, they become hypocalcemic, develop secondary hyperparathyroidism, rickets, osteomalacia, and progressive alopecia. The female mice with ablation of the first zinc finger are infertile and show uterine hypoplasia and impaired folliculogenesis. Otherwise, both VDR cell mutant mice show clinical, radiological, histological, and biochemical features that are identical to the human disease VDRR-II. Supplementation with a calcium-enriched diet can prevent or treat most of the disturbances in mineral and bone metabolism in these animal models.

Concluding Remarks

Hereditary deficiencies in vitamin D action are rare disorders. The importance of studying these diseases stems from the fact that they represent a naturally occurring experimental model that helps to elucidate the function and importance of vitamin D and the VDR–effector system in humans *in vivo.*

VDRs are abundant and widely distributed among most tissues studied and multiple effects of calcitriol are observed on various cell functions *in vitro.* Yet, the clinical and biochemical features in patients with VDDR-I and -II seem to demonstrate that the only disturbances of clinical relevance are perturbations in mineral and bone metabolism. This demonstrates the pivotal role of $1,25(OH)_2D$ in transepithelial net calcium fluxes. Moreover, the fact that in patients with extreme end-organ resistance to calcitriol, calcium infusions correct the disturbances in mineral homeostasis and cure the bone disease may support the notion that defective bone matrix mineralization in VDRR-I and -II is secondary to disturbances in mineral homeostasis. Characterization of the molecular, cellular, and functional defects of the different natural mutants of the human VDR in VDDR-II demonstrates the essentiality of the VDR as the mediator of calcitriol action and the importance and function of its different domains. Furthermore, to function biologically, the VDR must associate with additional partners, i. e., $1,25(OH)_2D$, an RXR isoform, a specifically defined DNA region, and activator complexes. This notion has been based primarily on *in vitro*-created point mutations and *in vitro* functional assays. However, the acid test for the relevance of the structure–function relationship is the demonstration of *in vivo* effects in general and deficient function under pathological conditions in particular. Thus, studies in patients with hereditary deficiencies in vitamin D action are the essential link between molecular defects and physiological relevant effects.

CHAPTER 68

Oncogenic Osteomalacia

Kenneth W. Lyles

GRECC, Veterans Affairs Medical Center, and Department of Medicine, Sarah W. Stedman Center for Nutritional Studies, Duke University Medical Center, Durham, North Carolina 27710

Introduction

Osteomalacia is a metabolic bone disease with two major histomorphometric abnormalities: increased amounts of osteoid tissue and a reduced bone formation rate. Most cases of disease are caused by a defect in phosphate and/or vitamin D metabolism (Parfitt, 1990). In oncogenic osteomalacia (tumor-induced osteomalcia) renal phosphate wasting, low serum 1,25 dihydroxyvitamin D levels and osteomalacia occur in association with a variety of benign or malignant neoplasms, disappearing upon removal or irradiation of the neoplasm (Lyles *et al.,* 1980; Drezner, 1993). Patients with oncogenic osteomalacia have diffuse bone pain and complain of fatigue. The bone pain can be localized to the lower back, the pelvis, and/or the femurs. Occasionally the patients develop fractures of the ribs, pelvis, femoral neck, or tibia. The fractures may occur with minimal trauma or be pseudofractures which occur more commonly in patients with osteomalacia. In addition to skeletal pain and fatigue, patients may have a proximal myopathy, making it difficult for them to climb steps or rise from a squatting position.

The syndrome was first described by McCance in 1947, when a patient with vitamin D-resistant osteomalacia of 7 years duration was cured by the resection of a tumor of degenerated osteoid from the right femur. Oncogenic osteomalacia has similar clinical features with x-linked hypophosphatemic rickets (XLH) and autosomal dominant hypophosphatemic rickets (ADHR): hypophosphatemia, renal phosphate wasting, inappropriately low serum $1,25(OH)_2$ vitamin D levels, and osteomalacia. New knowledge about the genetic and molecular defects in these three renal phosphate wasting syndromes have shed light on our understanding of normal phosphate homeostasis. Recently a factor(s) is postulated to cause renal phosphate wasting in the genetic disorder x-linked hypophosphatemic rickets, possibly making its pathophysiology similar to that of oncogenic osteomalacia (Meyer *et al.,* 1989; Nesbitt *et al.,* 1992).

Hypophosphatemia, the *sine qua non* for the diagnosis of oncogenic osteomalacia, can have been present for months to years before the diagnosis of osteomalacia is entertained. The hypophosphatemia (a fasting serum phosphorus level of < 2.5 mg/dl) is caused by a reduced renal phosphate reabsorption threshold. The renal phosphate wasting is quantitated by measuring a renal tubular maximum for the reabsorption of phosphorus per liter of glomerular filtrate (TmP/GFR) (Walton and Bijvoet, 1975). Serum $1,25(OH)_2D_3$ levels are reduced in these patients. Since hypophosphatemia is a primary stimulus for increasing renal production of $1,25(OH)_2D_3$, a low $1,25(OH)_2D_3$ level in a patient with oncogenic osteomalacia indicates an impairment of vitamin D metabolism in the proximal renal tubules (Lyles and Drezner, 1995). Gastrointestinal absorption of both calcium and phosphorus is reduced, which, coupled with renal phosphate wasting, leads to a negative phosphate balance. Parathyroid hormone (a hormone that lowers the TmP/GFR) levels have been measured in many patients with oncogenic osteomalacia, and, with few exceptions (Shenker and Grenkin, 1984; Cheng *et al.,* 1989), the levels are normal. Some patients with oncogenic osteomalacia have aminoaciduria and/or glycosuria, indicating additional abnormalities in the proximal renal tubule (Leehey *et al.,* 1985). Radiographic abnormalities include osteopenia, pseudofractures, fractures, and coarsened trabeculae from the osteomalacia. In growing children, widened epiphyseal plates occur an indicator of rachitic disease (Drezner, 1993).

Tumors

Most tumors that cause oncogenic osteomalacia are of mesenchymal origin and are found in either bone or soft tissue. Patients with these tumors range in age from 17 to 88

years. Tumor locations include the lower limbs, nasopharynx, mandible, ethmoid sinus, skull, cervical spine, upper extremities, and the abdominal wall (Ryan and Reiss, 1984; Renton and Shaw, 1976). Most tumors are skeletal with involvement of long bones; however, occasionally widespread osteolytic lesions are found (Daniels and Weisenfeld, 1979; Moncrieff *et al.,* 1978). Many tumors are small, being only a few centimeters in size which can explain the difficulty in detection and the delay in diagnosis. Neoplasms causing osteomalacia generally are benign and tumor types can include: hemangiomas (Daniels and Weisenfeld, 1979; Yoshikawa *et al.,* 1964; Salassa *et al.,* 1970; Renton and Shaw 1975; Turner and Dalinka, 1979; Camus *et al.,* 1980; Schapira *et al.,* 1995), dermatofibromas (Cai *et al.,* 1994), hemangioperioytoma (Miyauchi *et al.,* 1988; Yoshikawa *et al.,* 1964; Renton and Shaw, 1975; Linovitz *et al.,* 1976; Morita, 1976; Crouzet *et al.,* 1980; Sweet *et al.,* 1980; Chacko and Joseph, 1981; Seshadri *et al.,* 1985; Gitelis *et al.,* 1986; McClure and Smith, 1987; Schultze *et al.,* 1989; Papotti *et al.,* 1988), bone and soft tissue giant cell tumors (Seshadri *et al.,* 1985; Papotti *et al.,* 1988; Krane, 1965; Drezner and Femgios, 1977; Prowse and Brooks, 1987), mesenchymal lung tumor (Schapira *et al.,* 1995), osteoblastoma (Fukumoto *et al.,* 1979), non-ossifying and ossifying fibromas (Linovitz *et al.,* 1976; Asnes *et al.,* 1981, Parker *et al.,* 1990; Leehey *et al.,* 1985), fibroangioma (Aschinberg *et al.,* 1977), and mixed connective tissue variants (Lejeune *et al.,* 1979; Reid *et al.,* 1987; McGuire *et al.,* 1989). Malignant neoplasms have also been associated with oncogenic osteomalacia and these types include: carcinoma of the prostate, (Lyles *et al.,* 1980; Hosking *et al.,* 1975; Murphy *et al.,* 1985; McMurtry *et al.,* 1993; Nakahama *et al.,* 1995), carcinoma of the breast, (Dent and Stamp, 1978), oat cell carcinoma, (Taylor *et al.,* 1984; VanHeyningen *et al.,* 1994), multiple myeloma, (Maldonado *et al.,* 1975; Rao *et al.,* 1987; Pope and Belchetz, 1993), osteosarcoma, (Cheng *et al.,* 1989; Nomura *et al.,* 1982; Wyman *et al.,* 1977), sarcoma (Stanbury, 1972), angiosarcoma (Linovitz *et al.,* 1976), malignant fibrous histiocytoma (Willhoite, 1975), chondrosarcoma (Firth *et al.,* 1985), and malignant neurinoma (Hauge, 1956). Most of the early reports of oncogenic osteomalacia in association with prostatic carcinoma were in men who were also receiving diethylstilbestrol therapy for their disease (Lyles *et al.,* 1980; McGuire *et al.,* 1989; Hosking *et al.,* 1975; Murphy *et al.,* 1985). This suggested that estrogen therapy, with its recognized ability to lower the renal phosphate reabsorption threshold (Nassim *et al.,* 1955; Citrin *et al.,* 1984), was necessary to make oncogenic osteomalacia manifest in patients with this neoplasm. More recently two additional reports have described oncogenic osteomalacia in patients with carcinoma of the prostate whose only endocrine therapy for their cancer was orchiectomy (McMurtry *et al.,* 1993; Nakahama *et al.,* 1995). Thus, prostatic carcinoma appears capable of causing this syndrome *de novo.* Other diseases not traditionally considered to be neoplastic in nature can cause a form of oncogenic osteomalacia, and these disorders include epidermal nevi (Aschinberg *et al.,* 1977; Carey *et al.,* 1986; Goldblum and Headington, 1993), neurofibromatosis (Saville *et al.,* 1955; Weinstein and Harris, 1990; Konishi *et al.,* 1991), Albright's syndrome (Lever and Pettingale, 1983), Paget's disease of bone (D'Amore *et al.,* 1990), and fibrous dysplasia (Dent and Gertner, 1976).

A wide variety of meschemychymal tumors cause oncogenic osteomalacia and their diversity underscores the histologic complexity of these tumors. Weidner and Cruz (1987) showed that the histologically polymorphous mesenchymal neoplasms can be classified into four distinct morphological patterns: (1) primitive—appearing, mixed connective tissue tumors, (2) osteoblastoma-like tumors, (3) nonossifying fibroma-like tumors, and (4) ossifying fibroma-like tumors. The most frequently occurring type of these tumors, the mixed connective tissue variant, is characterized by variable numbers of primitive stromal cells growing in poorly defined sheets with occasional clusters on osteoclastic-like giant cells and vascularity is often prominent. The primitive stromal cells are probably the source of the hormonal factor(s) that cause the syndrome. Whether similar mesenchymal elements are present in tumors of epidermal and endodermal origin that are associated with oncogenic osteomalacia are unknown. However, fibrous mesenchymal elements are present in many neural tumors and metastatic prostatic carcinoma frequently have osteoblastic lesions with different amounts of fibrous tissue proliferation. Thus it is possible that oncogenic osteomalacia occurs in neoplasms of epidermal and endodermal origin when there are some of the mesenchymal elements present.

Pathophysiology

The mechanism(s) by which neoplasms cause the oncogenic osteomalacia syndrome is unknown. The general consensus is that offending tumors cause the syndrome by secreting a factor(s) which causes the renal phosphate wasting, resulting in hypophosphatemia and impair conversion of $25(OH)D_3$ to $1,25(OH)_2D_3$ resulting in low serum $1,25(OH)_2$ vitamin D_3 levels. Serum calcium levels are normal, as are levels of parathyroid hormone and parathyroid hormone-related peptide. In affected subjects resection of the tumor results in normalization of serum phosphorus levels because the TmP/GFR increases into the normal range. Also serum $1,25(OH)_2D_3$ levels normalize rapidly when the tumor is removed.

Several studies support the hypothesis that tumors cause oncogenic osteomalacia by secreting a phosphaturic factor(s). Aschinberg *et al.* (1997) induced phosphaturia in a puppy by injecting a homogenate of an epidermal nevus from a child with an oncogenic osteomalacia syndrome. However a homogenate of skin and tissue culture medium for the epidermal nevus did not cause phosphaturia in the puppy. Miyauchi *et al.* (1988) hetertotransplanted a hemiangiopericytoma from a patient with oncogenic osteomalacia into athymic nude mice. The heterotransplanted tumor increased urinary phosphate excretion in mice bearing the hemangigpericy-

toma. Nitzan *et al.* (1989) showed that a fibrosarcoma from a man with long standing oncogenic osteomalacia lowered serum phosphorus levels in athymic nude mice heterotransplanted with the tumor. The investigators grew the fibrosarcoma in tissue culture, and tested whether culture medium from the fibrosarcoma affect renal phosphate transport in a monkey proximal tubule cell culture line. In this study the culture media had no effect on phosphate transport in the cultured proximal tubule cells. Cai *et al.* (1994) cultured a sclerosing hemangioma from a patient with oncogenic osteomalacia. They showed culture medium from these tumor cells inhibited phosphate transport in cultured oppossum-kidney cells. The heat-labile factor with a mass between 8000 and 25,000 Da had some immunologic similarity to parathyroid hormone but it was neither parathyroid hormone nor parathyroid hormone-related peptide. The factor has been named "phosphatonin" and is very likely to be different from parathyroid hormone. Furthermore, phosphatonin did not influence phosphorus transport through a cyclic-AMP-dependent mechanism, did not increase calcium and phosphate mobilization from bone and did not influence bone remodeling.

Abnormal vitamin D metabolism has been recognized as a part of oncogenic osteomalacia since Drezner and Feingios (1977) reported low serum $1,25(OH)_2D_3$ levels in a patient with oncogenic osteomalacia caused by a giant cell tumor of bone. Now low $1,25(OH)_2D_3$ levels are considered an essential part of this syndrome. When serum $1,25(OH)_2D_3$ levels have been followed in patients undergo tumor resection, the low levels of the active vitamin D metabolite return to normal within 1 day. Two studies have shown that neoplasms causing oncogenic osteomalacia inhibit renal 25-hydroxyvitamin D-1α-hydroxylase activity, one in heterotransplanted athymic nude mice with prostatic carcinoma and the other in kidney cell cultures exposed to tumor extracts from an hemiangiopericytoma (Miyauchi et al., 1988; Lobaugh et al., 1984). It is unknown whether neoplasms eleaborate a single or multiple factors to inhibit phosphate reabsorption and impair 25 hydroxyvitamin D-1α-hydroxylase activity. To date, no experiments have been published to show whether these factors are caused by a single or several molecules. The observation that all patients with oncogenic osteomalacia and hypophosphatemia have inappropriately low serum $1,25(OH)_2$ vitamin D levels favors the concept of a single factor causing both defects (Kumar, 2000).

Patients with the inherited renal phosphate wasting disorder XLH have biochemical abnormalities similar to patients with oncogenic osteomalacia. Patients with XLH have hypophosphatemia, a low TmP/GFR, normal serum calcium levels, normal or elevated parathyroid hormone levels, inappropriately low serum $1,25(OH)_2$ vitamin D levels and osteomalacia. Although it would appear that the disorders may have a similar etiology, this is only partially correct.

The genetic mutation associated with XLH has been identified and the mutation involves the inactivation of an endopeptidase PHEX (phosphate regulating gene with homologies to endopeptidases located on the X chromosome) (Francis *et al.,* 1995). Although the mechanism(s) by which this mutation influences phosphate transport is unknown, several investigators have postulated that PHEX metabolizes a putative phosphate-regulating hormone called phosphatonin (Quarles and Drezner, 2001). According to this hypothesis, secondary to the inability of mutated PHEX in XLH subjects, phosphatonin, the putative phosphate regulating hormone, accumulates, interacts with the kidney and inhibits phosphate transport. At present, this hormone has not been isolated or cloned.

The inherited renal phosphate wasting disorder, autosomal dominant hypophosphate rickets has many similar biochemical characteristics to oncogenic osteomalacia and XLH including hypophosphatemia, renal phosphate wasting, inappropriately low serum $1,25(OH)_2$ vitamin D levels and osteomalacia (Econs and McEnery, 1997). The genetic mutation in this disorder is in fiborblast growth factor 23 (FGF 23) (White *et al.,* 2000). The biological actions of FGF 23 upon renal phosphate handling are unknown at present. More recently, White *et al.* (2001) have shown that FGF 23 was produced by four tumors causing oncogenic osteomalacia.

The hypothesis is that FGF 23 is phosphatontin, produced by tumors causing oncogenic osteomalcia in large amounts and unable to be metabolized by the normal endopeptidase in subjects and results in the oncogenic ostomalacia syndrome. In such subjects, tumor removal (the source of increased amounts of "phosphatontin," possibly FGS 23) causes resolution of the syndrome. In XLH, the phosphate wasting syndrome occurs because the abnormal endopeptidase PHEX cannot metabolize phosphatonin made by osteoblasts (Guo and Quarles, 1997) which results in the renal phosphate wasting disorder. Clearly, much more work will be required to provide adequate data to prove this hypothesis.

Differential Diagnosis

For many patients with oncogenic osteomalacia, making the initial diagnosis can take months to years. In the author's experience patients with bone pain, muscle weakness and hypophosphatemia have been seen for up to 3 years before the hypophosphatemia is evaluated; however, some cases have been followed up to 17 years before the diagnosis is made. When the hypophosphatemia is recognized, first it is important to establish that the low serum phosphate levels are due to a low renal phosphate reabsorption threshold. This is done by measuring the TmP/GFR (Waltan and Bijroet, 1975). If the offending neoplasm is not clinically apparent, next it is necessary to establish that the hypophosphatemia is acquired rather than having been present throughout life. Two other inherited disorders with renal phosphate wasting that can be confused with oncogenic osteomalacia include x-linked hypophosphatemic rickets/osteomalacia and autosomal dominant hypophosphatemic rickets/osteomalacia (Lyles and Drezner, 1995; Seriver *et al.,* 1977). If hypophosphatemia has been present throughout life, family members should have fasting serum phosphorus levels measured to help establish the diagnosis of XLH or ADHR. Finally, persistant hypophos-

phatemia is seen with increased secretion of parathyroid hormone and parathyroid hormone-related peptide. In patients with hyperparathyroidism, serum clacium levels are usually elevated unless there is vitamin D deficiency. Patients with elevated PTHnp levels almost always have a malignancy as well as elevated serum calcium levels.

The Fanooni syndrome represents a group of diseases, both genetic and acquired, in which hypophosphatemia occurs from a reduced TmP/GFR. This syndrome also has additional renal tubular defects causing loss of glucose, bicarbonate and amino acids. The disease, depending upon severity, may have associated osteomalacia, rickets, or short stature. Genetic diseases causing the Fanconi syndrome include: cystinosis, tyrosinemia galactosemia, Wilson's disease, and fructose intolerance (Lyles and Drezner, 1995). Acquired forms of this disease include heavy metal poisoning, hematologic malignancies, connective tissue disease and use of outdated tetracycline (Lyles and Drezner, 1995).

Another hypophosphatemic disorder is hereditary hypophosphatemic rickets with hypercalcuria (Tieder *et al.,* 1985). This rare genetic disease has hypophosphatemia due to a low TmP/GFR and hypercalcuria. In contrast to other diseases in which renal phosphate wasting occurs, serum $1,25(OH)D_3$ levels are elevated, which causes enhanced gastrointestinal absorption of calcium and hypercalcuria.

Since tumors may be small, a thorough physical examination may locate the neoplasm. Routine radiographs of the skeleton including the skull with special sinus views are helpful. Magnetic resonance imaging (MRI) is more efficient than CT scanning for identifying bone or soft-tissue mensenchymal tumors (Sundaram *et al.,* 1986, 1988). MRI scanning is also useful in planning for surgical resection. Proof of a tumor causing oncogenic osteomalacia requires resolution of biochemical abnormalities and the osteomalacia upon removal of the tumor. Since some neoplasms such as prostate carcinoma, oat cell carcinoma of the lung, and multiple myleloma may not be completely removed or eradicated, the diagnosis may be inferential. The biochemical profile and bone biopsy may suggest this diagnosis.

Therapy

The most important therapy for oncogenic osteomalacia is removal of the offending neoplasm. When this can be accomplished the syndrome remits and the patient does well. Unfortunately certain mesenchymal tumors, e.g. giant cell tumors of bone may recur or prostatic carcinoma cannot be eradicated (Miyauchi *et al.,* 1988; Harvey *et al.,* 1992; Leight *et al.,* 1993; Evens and Azzopard, 1972; McClure and Smith, 1989; Weidner *et al.,* 1985). In cases where the neoplasm can not be resected therapy with oral phosphate supplementation (1000–2000 mg daily in divided doses) and $1,25(OH)_2D_3$ (calcitriol 1.2–2.0 μg daily in divided doses) can improve the serum phosphate and $1,25(OH)_2D_3$ levels. Studies have shown that such therapy can improve bone pain and result in healing the osteomalacia on bone biopsy (Drezner and Feingios, 1977; Lobaugh *et al.,* 1984). Some investigators have shown that higher doses of oral phosphate supplements and calcitriol are necessary to raise serum phosphorus levels and heal the osteomalacia (Cheng *et al.,* 1989; Nomura *et al.,* 1982; Harvey *et al.,* 1992; Evans and Azzopard, 1972; Leicht *et al.,* 1990). Others have shown incomplete or unsatisfactory responses to this therapy (Shenker and Grenkin, 1984; Nitzan *et al.,* 1989; Scully *et al.,* 1989). Nevertheless, in a patient who cannot have their tumor completely removed, a trial of therapy with oral phosphate supplements and calcitriol should be considered since there is no other effective therapy. Such doses of medication can cause hypercalcuria, hypercalcemia, and reductions in glomerular filtration rates (Lyles and Drezner, 1995). It is necessary to follow both serum calcium and phosphorus levels as well as urinary calcium excretion and creatinine clearance. Some patients can develop secondary hyperparathyroidism, so PTH levels should also be followed (Firth *et al.,* 1985; Olefsky *et al.,* 1972).

Oral phosphate therapy is usually well tolerated, although 5–10% of treated patients develop gastrointestinal symptoms including nausea, vomiting, diarrhea, or abdominal pain. Such side effects are usually dose related, and doses required to normalize serum phosphate levels in affected patients may not be tolerable. Alternates to oral phosphate therapy are limited. The use of parenteral phosphate therapy has been reserved for life-threatening situations because of concerns over metastatic calcification, hypocalcemia, cardiac arrythmia, and electrolyte disturbances. Yeung *et al.* (2000) describe a case of oncogenic osteomalacia caused by an inoperable mesenchymal tumor in the cervical spine. The patient could not tolerate the oral phosphate supplements to restore serum phosphate levels to the normal range. The course of oncogenic osteomalacia was complicated by secondary hyperparathyroidism requiring parathyroidectomy. On three occasions, the patients was given intravenous phosphate infusions via a central venous catheter as well as oral calcitriol and calcium supplementation. These therapies contributed to improvement in biochemical and clinical parameters. The authors point out that such therapy should be used only when oral phosphate therapy is intolerable and requires meticulous monitoring (Yeung *et al.,* 2000).

In conclusion, oncogenic osteomalacia, which was once considered a rare metabolic bone disease, may be less of a rarity than previously believed. When the diagnosis suspected, an aggressive search for the offending neoplasm should be undertaken. When a tumor cannot be found, the search should be reinitiated every 3–5 years since occult growths may be discovered at a later date. Therapy for the disorder with oral phosphate supplementation and $1,25(OH)_2$ improves abnormal biochemistries but more importantly bone pain and function in patients in whom the offending neoplasm cannot be eradicated. Further studies into the pathosiciology of oncogenic ostemalacia and the heritary renal phosphate wasting disorders x-linked hypophosphatemic osteomalacia/rickets and autosomal domi-

nant hypophosphatemic rickets will provide new understanding of regulation of phosphate as well as vitamin D metabolism.

Acknowledgments

The author appreciates the aid of Sandra D. Giles in the preparation of the manuscript. Support for the study came from the VA Medical Research Service, HD30442 from NICHHD, AG11268 from NIA, 2031AH94004 from the Bureau of Health Professions, and Grant RR-30 from the Division of Research Resources, General Clinical Research Centers Program, NIH.

CHAPTER 69

Osteopetrosis

L. Lyndon Key, Jr., and William L. Ries
Department of Pediatrics, General Clinical Research Center, Medical University of South Carolina, Charleston, South Carolina 29425

Introduction

Osteopetrosis results from a reduction in bone resorption relative to bone formation, leading to an accumulation of excessive amounts of bone. The relative decrease in resorption is a consequence of inadequate osteoclastic bone resorption. This imbalance leads to a thickening of the cortical region and a decrease in the size of the medullary space in the long bones, with sclerosis of the base of the skull (Elster *et al.,* 1992a,b) and vertebral bodies. There are a number of serious consequences resulting from the excessive accumulation of bone. A reduced marrow space results in decrease in hematopoiesis even to the point of complete bone marrow failure. Extramedullary hematopoiesis occurs but is unable to compensate for the reduction in medullary blood cell production. A decrease in the caliber of the cranial nerve and vascular canals leads to nerve compression and vascular compromise. Dense, poorly vascularized bones are subject to fracture and, being vascularized, are predisposed to necrosis and infection.

An understanding of osteopetrosis in humans has been intertwined with the description and creation of a variety of animal mutations in osteoclastic function (Seifert *et al.,* 1993). While the precise genetic defect in most patients remains to be established [one exception being the deficiency in carbonic anhydrase type II (Fathallah *et al.,* 1994; Whyte, 1993a)], the animal models have contributed substantially to the understanding of osteoclastic function and dysfunction. The osteoclast biology learned from these mutants has led to a variety of treatment strategies that have been used in patients with osteopetrosis. An understanding of the genetic basis of the animal mutations has generated a list of candidate genes that may prove to be the basis for discovering the genetic defects in humans.

Clinical Description

Classically, osteopetrosis has been divided into a fatal infantile malignant form, Albers–Schönberg Disease, and a milder adult form of osteopetrosis with long-term survival (Grodum *et al.,* 1995; Key, 1987; Shapiro, 1993; Whyte, 1993b). Recently, a variety of intermediate forms have been described. Without knowledge of the genetic defect explaining the osteoclastic dysfunction, it has been difficult to delineate the mechanisms of these different forms (Table I).

Infantile Forms

A variety of presentations of osteopetrosis have been seen in infancy. In general, patients have had sporadic forms that appear to have an autosomal recessive inheritance. While the severe, malignant form predominates, milder forms and autosomal dominant inheritance patterns have also been observed in individuals diagnosed in the neonatal period (Manusov *et al.,* 1993; Whyte, 1993b). In the absence of a known genetic defect in osteoclastic function, histomorphometric and clinical parameters have been established to describe the degree of severity.

MALIGNANT

Patients with osteopetrosis presenting at birth or in early infancy are usually referred to as having the severe, malignant form. The implication is that these patients will have severe sequelae and will die during the first decade of life. This has been the justification for using treatment modalities, such as bone marrow transplantation, that carry a high risk of mortality and morbidity (Gerritsen *et al.,* 1994b; Key and Ries 1993; Schroeder *et al.,* 1992). Patients with this form are characterized by a diffusely sclerotic skeleton with little or no bone

Table I Human Osteopetrosis Classification

Form	Genetic characterization
Infantile	
Malignant	Autosomal recessive
Subgroups	
Hematological impairment	
Neurodegenerative disease	
Intermediate	Autosomal recessive or dominant
Subgroup	
Carbonic anhydrase II deficiency	Autosomal recessive
Transient	?
Adult	
Severe	Autosomal dominant
Mild (benign)	
Subtype I	?
Subtype II	Autosomal dominant

marrow space evident, even at birth (Fig. 1) (Gerritsen *et al.,* 1994a). In addition, there is evidence of a severe defect in bone resorption, leading to the presence of the "bone in bone" appearance on radiographs (Fig. 2) and in cartilaginous islands within mineralized bone on histology (Fig. 3).

However, some patients with this phenotype will not have a fatal outcome. Indeed, up to 30% of patients diagnosed with severe, malignant osteopetrosis are still alive at age 6 years, with rare patients surviving into the second or third decade (Gerritsen *et al.,* 1994a). While the quality of life is reported to be poor, up to half of the surviving patients, despite a variety of skeletal and neurologic impairments, have normal intelligence and are capable of attending school (J. Charles, pers. commun.).

A subgroup of patients have an extremely malignant form of the disease. In a group of 33 patients reported by Gerritsen *et al.,* 8 patients had hematological and visual impairment before 3 months of age (Gerritsen *et al.,* 1994a). All 8 of these patients died before the age of 12 months. Hematological impairment before 6 months of life is prognostic of a markedly reduced survival rate; however, visual impairment alone does not correlate with an early fatal outcome.

Cytological evidence of large osteoclasts with increased numbers of nuclei and a markedly increased amount of ruffled border membrane correlates with a poor prognosis for cure with bone marrow transplantation (Schroeder *et al.,* 1992; Shapiro *et al.,* 1988). While there is no exact explanation for the reduced success in cure by transplantation, the defect in bone resorption in these patients could be explained if the osteoclast itself were normal but some other aspect of the bone rendered it less resorbable. Thus, histologic and electron microscopic analysis of osteoclasts is recommended before a transplantation is undertaken.

Another form of osteopetrosis that has not responded to any therapeutic modality is associated with a neurodegenerative disease (Whyte, 1993b). In some patients, a neuronal storage disease has been suggested by cytoplasmic inclusions. In most patients, seizures, poor neurologic development, abnormalities in the cerebral cortex seen on magnetic resonance imaging, and early development of central apnea characterize this specific presentation. No therapy that has been tried in these patients (bone marrow transplantation, calcitriol, or interferon-γ) has resulted in any significant improvement of the disease. It is likely that even when the bony disease can be reversed (as has occurred using each of the modalities), the underlying neurologic disorder remains unaffected. Death usually occurs before 2 years of age.

Figure 1 The skeleton, both the long bones and the pelvis, are shown to be sclerotic in this radiograph of a 5-day-old infant with anemia and optic nerve compression. Patients with this severe presentation have a 100% chance of death before age 1 year, if untreated. Note that no intramedullary space is seen in the long bones or the pelvis.

INTERMEDIATE

The intermediate form of osteopetrosis is frequently "silent" at birth with few or no obvious clinical abnormalities (Key, 1987; Whyte, 1993b). Some cases are diagnosed in infancy, when suspected, suggesting that the defect is present at a subclinical level even from birth. Of interest, the radiographs frequently demonstrate severe manifestation of diffuse sclerotic bone in this form of the disorder, quite similar to those seen in the malignant form (Fig. 4). These patients tend to have fractures toward the end of the first decade and frequently have repetitive fractures with very minor trauma. Infections of the bone can be difficult to eradicate, especially

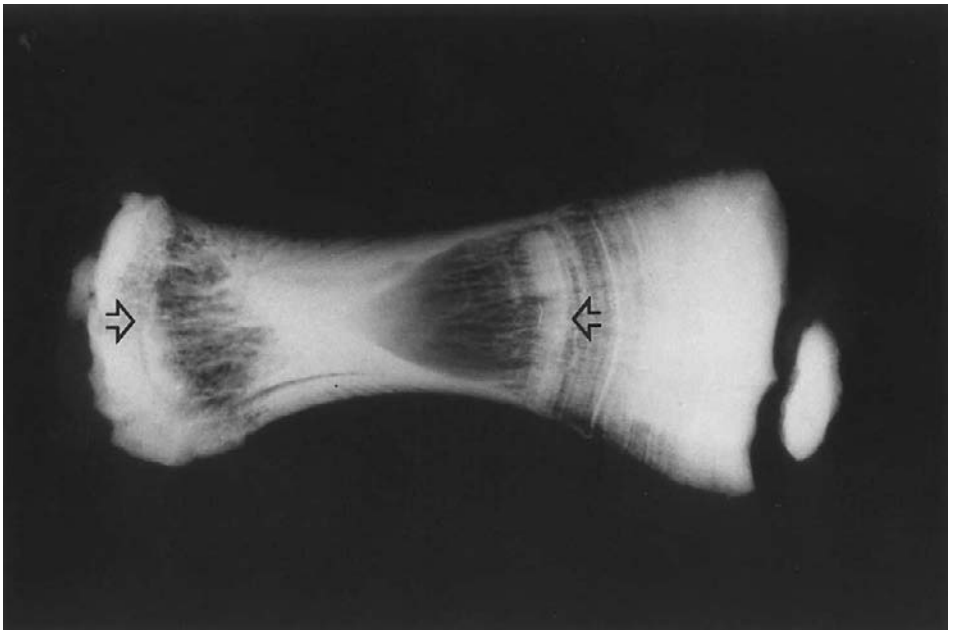

Figure 2 This radiograph shows a phalangeal bone, obtained at autopsy from a 7-year-old with malignant osteopetrosis treated with calcitriol. Note the presence of the original bony template (endobone, between the arrows) which was present at birth and never remodeled. The radiograph shows the presence of mineralized bone which has been laid down outside of this original bone/cartilage template without the underlying template having been resorbed.

if the mandible is involved. Most patients survive into adulthood. While anemia and hepatosplenomegaly are rare, at least one patient has developed anemia and thrombocytopenia so severe that he was transfusion dependent. His anemia and thrombocytopenia were eliminated by splenectomy.

A subgroup of patients with the intermediate form of osteopetrosis have a carbonic anhydrase II deficiency (Fathallah *et al.,* 1994; Whyte, 1993a). These patients have a hyperchloremic metabolic acidosis. Several different mutations have been described in the 50 cases diagnosed.

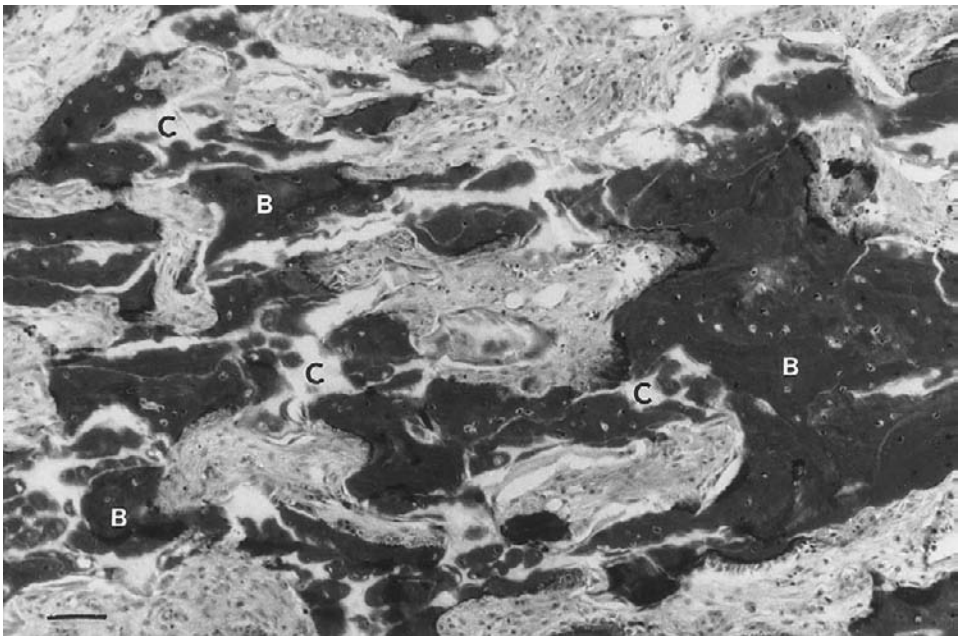

Figure 3 The pathognomonic feature of osteopetrosis at the histological level is the presence of unresorbed cartilage (denoted at "C"). Around the cartilage, a highly cellular, embryonic bone (designated as "B") has been laid down. This combination of nonresorbed cartilage and poorly formed bone is the microscopic feature which results in the macroscopic appearance seen in the "bone in bone" appearance on radiographs (see Fig. 2). The bar denotes 80

Figure 4 A radiograph of the long bones of a 6-year-old with an intermediate form of osteopetrosis shows the presence of some intramedullary space (denoted as "I"). The deformities of modeling result in bowing and thickening of the shaft and metaphyseal regions of the bone. Note a fracture, which was clinically not apparent, is present in the left tibia (arrow).

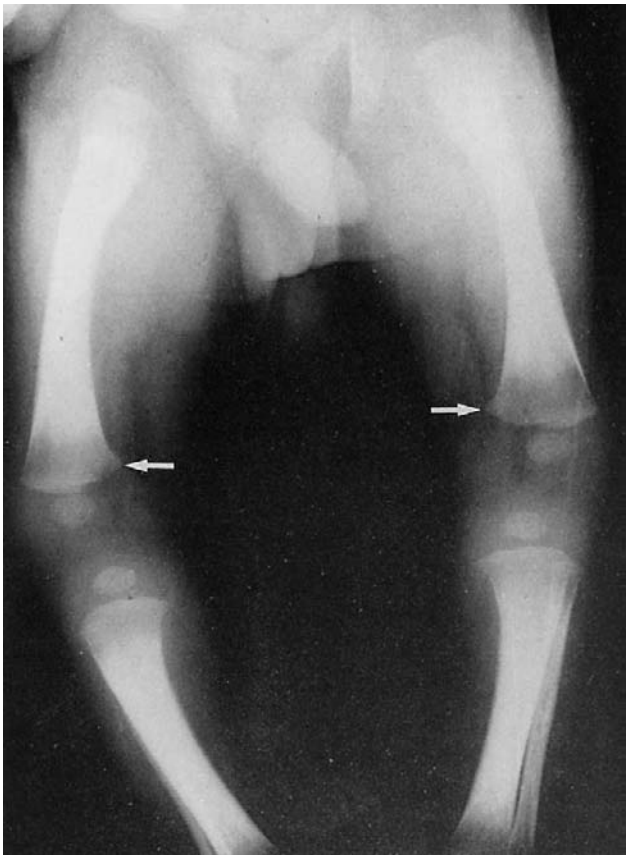

Figure 5 This radiograph of a 1 month old with craniometaphysial dysplasia demonstrates sclerotic long bones with little marrow space seen in the diaphyses. It should be noted that there is already some clearing of the bone in the distal metaphyseal region of both femurs (arrows, which had been sclerotic at birth).

Patients tend to have delayed development with a reduction in intelligence as adults, short stature, fractures, cranial nerve compression, dental malocclusion, and cerebral calcifications. Patients usually have no defects in hematological function and no increased risk of infection.

TRANSIENT

Some patients with severe radiographic abnormalities and with anemia have had severely sclerotic bone early, which resolves without specific therapy (Monaghan *et al.,* 1991; Whyte, 1993b, personal observation by Key). While long-term follow up is not available in these patients, no known sequelae resulted from the condition. The patients had no visual impairment, but did have anemia and thrombocytopenia. In one patient (personal experience), there was a history of acetazolamide administration. While osteopetrosis has not been widely associated with acetazolamide administration, the existence of osteopetrosis with naturally occurring mutations in carbonic anhydrase suggests that the therapy may be related to the osteoclastic dysfunction. In both cases, the resolution in the bone disease was apparent early (within 1 month). In addition, patients with other milder sclerosing bony dysplasias are frequently considered to have osteopetrosis in infancy. A classic case is seen in the natural history of severe craniometaphysial dysplasia where early radiographs are nearly indistinguishable from osteopetrosis (Fig. 5); however, there is no involvement of the vertebral bodies.

Adult Forms

In general patients with the adult forms of the disease have a family history suggesting an autosomal dominant inheritance pattern (Whyte, 1993b). Anemia is not a common manifestation; however, fractures and cranial nerve dysfunction are frequently observed (Bollerslev and Mosekilde, 1993; Bollerslev *et al.,* 1994). When defects have been sought for in infancy, radiographic abnormalities have been found which define the presence of the disease and portend the onset of symptoms in later life.

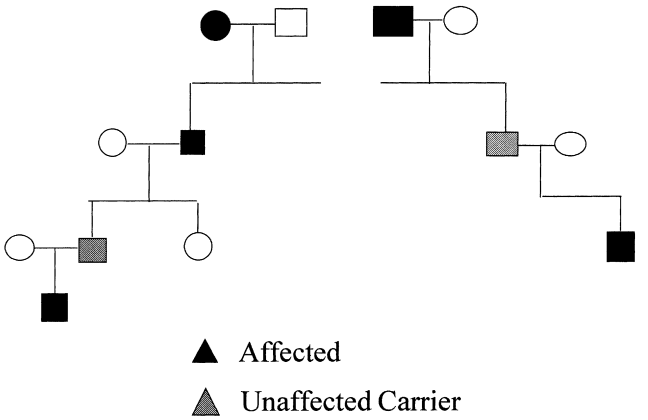

Figure 6 This is the family tree of two patients with adult forms of osteopetrosis. The presentation of these patients was severe enough (sclerosis of the long bones in one, anemia, sclerosis of the long bones, and blindness in the second) to result in an initial diagnosis of the severe malignant form.

SEVERE

We have observed two patients who presented with severe neonatal disease that had a family history suggestive of the presence of an autosomal dominant disorder. In each of these cases, the children were diagnosed with the malignant form of the disease due to anemia and cranial nerve dysfunction presenting in infancy. In one patient, there was a history of severe infections and failure to thrive. Family members in each case had survived into the fifth and sixth decade (Fig. 6). In each case, the parent transmitting the disease was unaffected.

MILD

The "benign" adult form of osteopetrosis is frequently "silent" until later in life (Bollerslev and Mosekidle, 1993; Whyte, 1993b). Two distinct subtypes have been described based upon radiographic appearance, symptoms and biochemical characteristics. Each of these subtypes have been inherited in a variety of kindreds. Each subtype has a distinct natural history, resulting in differing symptomatic presentations. Both types have universally sclerotic bones, primarily involving the axial skeleton. Little or no modeling defects are seen in the long bones. Both types have been observed in some children in the identified families. Approximately 40% of patients with the adult form of osteopetrosis are symptom-free regardless of type. Anemia is rare in either type. Bone pain is common to both types.

Type I is characterized radiographically, by massive sclerosis of the skull with increased thickness of the cranial vault. There is diffusely sclerotic bone in the spine and pelvis. Cranial nerve compression is common in type I. There are few abnormalities seen in the remodeling of bony trabeculae. Indeed, the strength of bone in type I is increased compared to normal. Thus, pathologic fractures are rarely observed.

Radiographs from patients with type II disease demonstrate massive sclerosis of the base of the skull, hypersclerotic endplates of the vertebrae resulting in the "rugger jersey" spine, and subcristal sclerotic bands diagnostic of "endobones." Bone turnover is decreased, leading to a reduction in bone tensile strength and resulting in frequent fractures. In type II, creatine phosphokinase, especially the BB isoenzyme, is increased. Histomorphometric analysis shows a defect in trabecular remodeling, resulting in bone that had not been replaced, yielding weakness.

In summary, the adult forms of osteopetrosis are usually diagnosed symptomatically in the second decade. These disorders rarely significantly alter hematopoiesis. Defects in type I disease result in cranial nerve compression, but fractures are rare. In type II disease, fractures are common, but nerve compression is rare.

Pathophysiology

Osteoclast Dysfunction

While animal models and a few patients have been found with a profoundly reduced number of osteoclasts, defective function rather than a reduction of formation appears to be the primary pathogenesis (Key and Ries, 1993). This holds true for malignant, intermediate, and benign forms. In the malignant form, there is the possibility of replacing the defective cell and curing the disease with bone marrow transplantation. However, defects in the osteoclasts' environment have also been suspected and may be the explanation for the greater-than-predicted rate of failure in bone marrow transplantation therapy in this disorder (Gerritsen *et al.,* 1994a; Key, 1987). However, to date, no patient has been definitively diagnosed with the one clear-cut stromal defect, a defect in producing macrophage colony-stimulating factor (M-CSF) seen in the *op/op* (osteopetrotic) mouse model (Key *et al.,* 1995a). One patient was reported with a decreased level of M-CSF after a failed transplantation; however, no data were available before the immunomodulation necessary for the transplantation.

A defect in white cell and osteoclastic superoxide production has been documented in the majority of patients with osteopetrosis (Key and Ries, 1993). Although the defect in superoxide generation in osteoclasts may represent a more generalized decrease in the ability of the osteoclast to resorb bone, therapy with interferon γ-1b, designed to increase superoxide production, increases white blood cell superoxide production, thereby reducing infections, and increases bone resorption, enhancing hematopoiesis and enlarging cranial nerve foramina. The result is a reduction in the need for intravenous antibiotics and transfusions and in a deceleration of cranial nerve damage. The net result is an improved survival with reduced morbidity.

GENETIC DEFECTS

The search for genetic abnormalities that result in osteopetrosis has recently identified two genetic defects that are related to the osteopetrotic condition. In the first report of a gene localization based upon linkage analysis, van Hul *et al.* reported a 8.5-cM region on chromosome 1*p*21 that is associated with the autosomal dominant adult form, type II (van Hul *et al.,* 1997). Although this region was chosen for study because of the presence of the *CSF-1* gene, a precise defect has not been identified. Indeed, a survey of 20 patients with osteopetrosis found no evidence of defects in the c-*src,* c-*fos,* c-*cbl,* and MITF (human equivalent of the mi/mi) genes (Yang *et al.,* 1998).

Two studies have identified precise mutations in a subunit of the V-type H^+-ATPase protein, OC116 (Kornak *et al.,* 2000; Frattini *et al.,* 2000). A total of 15 different genetic defects have been reported (Table II). All of these patients appear to have a classic severe osteopetrosis with severe osteosclerosis, hematologic failure secondary to reduced bone marrow space, and visual impairment in all but one patient. A history of consanguinity was a common theme for four patients.

Functionally, the defect causes the absence of the α3 subunit, OC116, of the V-type proton pump that is present along the ruffled border and responsible for acidification next to the bone surface. In the absence of this acidification, calcium cannot be removed from the surface of the bone. Of interest, a knockout animal was previously described (Li *et al.,* 1999) providing the first example of an animal model predicting a human osteopetrotic genetic defect (details of animal model below). This makes the existing animal models even more exciting as a repository of defects that may potentially explain human disease.

Animal Models

Classic

A variety of animal models for osteopetrosis have been explored. The M-CSF deficiency in the *op*/*op* mouse seems to be the most clearly related defect (Begg *et al.,* 1993; Lowe *et al.,* 1993; Marks *et al.,* 1992; Nilsson and Bertoncello, 1994; Philippart *et al.,* 1993; Wiktor-Jedrezejczak *et al.,* 1994); however, replacing the M-CSF with exogenous cytokine does not result in a complete remission (Sundquist *et al.,* 1995). Several possible explanations have been suggested. The timing of the administration may not be the most advantageous (Hofstetter *et al.,* 1995; Lee *et al.,* 1994; Sundquist *et al.,* 1995). Alternatively, there may be other related factors that must interact. One of the most plausible ideas is that in addition to circulating levels of M-CSF, there is also the need for membrane-bound M-CSF (Stanley *et al.,* 1994) on the osteoblast or embedded in the bone surface (Ohtsuki *et al.,* 1995) to be presented to the osteoclast or its precursors. A less clear-cut defect, but a demonstrated role for M-CSF therapy in improving the phenotypic abnormalities in the *tl*/*tl* (toothless) rat (Aharinejad *et al.,* 1995; Marks *et al.,* 1993), has suggested some involvement with the M-CSF production or the M-CSF receptor in the genesis of this mutant phenotype as well. To date the precise defect has not been reported. Thus, animals or humans with few macrophages and osteoclasts may be found to have a defect in M-CSF production or response.

In the mi/mi mouse (microphthalmic), there is a defect in the production of a transcription factor (Steingrímsson *et al.,* 1994). This has led to the possibility that a variety of defects, all related to the presence of a defective transcription factor,

Table II Genetic Defects in Autosomal Recessive Severe Congenital Osteopetrosis

Study	Patient	Location in DNA	Mutation	Effect	Allele
Kornak *et al.,* 2000

could exist in the osteoclast and/or in other cells as well. One suggested defect is a decrease in the c-*kit* receptor production, which is necessary for stimulation of tyrosine kinase activity with the stem-cell factor (Ebi *et al.,* 1992). Stem-cell factor and M-CSF activate similar receptor populations, c-*kit* and c-*fms,* which are quite similar in their binding regions. There are also data suggesting that possibly there is a defect in the ability of mi/mi stromal cells, failing to support osteoclastic function (Key, 1987) or possibly even inhibiting osteoclastic function *in vitro.*

Both M-CSF and/or interferon-γ have been shown to improve the defect in the mi/mi mouse (Key *et al.,* 1995a). Since these cytokines are not deficient in these animals, the studies suggest that these therapies circumvent the specific defects rather than reversing the defects directly. Similar effects of these cytokines have been observed in patients with osteopetrosis where defects are unknown and not directly related to deficiencies in cytokine production or response elements.

Knockout

Perhaps the greatest interest has been in the analysis of man-made knockout mutations, which have been found to yield an osteopetrotic phenotype. The effects of a targeted disruption of *Atp6i,* a gene encoding a subunit of the vacuolar pump in the C57BL/6J inbred mouse strain have been described (Li *et al.,* 1999). The mutant animals resulting from this mutation have extremely dense bones with cartilaginous islands, reduced marrow space (decreased by 80% in the long bones), absent tooth eruption, decreased growth, and severely deformed bones. The condition was lethal in all animals by the fifth week. These animals appear to be quite similar to the patients described with defects in the *TCIRG1* gene of the human vacuolar proton pump described by Frattini *et al.* and Kornak *et al.* (Frattini *et al.,* 2000; Kornak *et al.,* 2000) The results of this animal mutation prove that a defect in the proton pump can cause osteopetrosis, confirming the speculation that the genetic mutations in the vacuolar pump documented in humans is responsible for the associated osteopetrotic phenotype.

The most well studied of these mutants is the c-*src* knockout mutation (Boyce *et al.,* 1993; Lowe *et al.,* 1993). In this mutation, the c-*src* tyrosine kinase is defective and yields a mutant with osteoclasts lacking ruffled borders. This appears to be due to the lack of production of phosphorylated proteins necessary to allow fusion of the membrane of endosomes with the cellular membrane within the sealed attachment of the osteoclast to bone. The result is an inactive cell with none of the machinery present at the osteoclast–bone interface necessary to resorb bone. The precise mechanism is not well understood and seems to be more complex than originally thought.

In the c-*fos* knockout mutation (Jacento, 1995; Grigoriadis *et al.,* 1994; Johnson *et al.,* 1992, Wang *et al.,* 1992), there are few mature osteoclasts formed and there is a reduction in the number of osteoclasts and an increase in the number of macrophages. Thus, it appears that c-*fos* is related to the osteoclast lineage's "switch point," which determines whether the progenitor moves in the direction of the osteoclast or the macrophage (Jacento, 1995).

The knockout of PU.1 (Tondravi *et al.,* 1997), an ETS-domain transcription factor essential for the development of myeloid and B-lymphoid cells, is thought to regulate the c-*fms* receptor (receptor for CSF-1). A mutation in this gene results in a nearly complete absence of osteoclasts, resulting in severe osteopetrosis. Bone marrow transplantation with PU.1 competent stem cells rescued the animals, completely reversing the defects. No human correlate has been found. Knocking out the gene for cathepsin K generated an additional osteopetrotic mouse model (Saftig *et al.,* 1998; Gowen *et al.,* 1999). This mutant was found to have dense bones with a reduction in bone marrow space, and extramedullary hematopoiesis. While these animals shared features of osteopetrosis, it was noted that the defective bone resorption varied from bone to bone. Recently, a similar mutation has been identified in humans with pycnodysostosis, a disorder resembling osteopetrosis, but having osteoacrolysis, poor fusion of the sagittal suture, micrognathia, and a predisposition for fracture (Ho *et al.,* 1999). The osteoclastic defect appears to be an inability of the osteoclast to degrade matrix, although removal of calcium appears to be normal. Thus, it is likely that some of the knockout mutations may be genes responsible for other sclerosing bony dysplasias. It appears that mutations resulting in osteopetrosis are those that completely inactivate the osteoclastic bone resorption by either leading to a failure to generate the osteoclast itself or the failure to form the ruffled border. This suggests that there is some redundancy of function in the osteoclast's bone resorbing process such that knocking out a single enzyme system does not completely inactivate bone resorption.

At the present time, knockout mutations have been much more important in understanding osteoclastic function than in explaining the human osteopetrotic condition. However, these studies do provide a variety of candidate genes and are beginning to suggest genetic defects that will allow us to diagnose certain types of osteopetrosis.

Avian Osteopetrosis (Increased Osteoblastic Function)

Osteopetrosis has been described in the chicken and appears to result from infection with the avian leukosis virus. This sclerosing condition is characterized by an increase in bone formation by infected osteoblasts (Smith and Ivanyi, 1980) with normal osteoclastic function. Avian osteopetrosis, while similar to sclerosis seen in a variety of human diseases, has not been shown to occur in humans with one possible exception. In "transient osteopetrosis," Ozsoylu and Besim have suggested that the etiology may be bony sclerosis secondary to excessive osteoblastic function (Ozsoylu and Besim, 1992).

Therapy of Human Disease

Even with the marked advances in understanding the osteoclastic defects that could result in osteopetrosis, we are still left today with the need to treat somewhat blindly in trying to combat this disorder. Transplantation has been the mainstay of treatment; however, somewhat disappointing results and, at present, the lack of available donors have made it difficult to rely on transplantation as the sole therapy for this disease. Thus, a variety of other therapies have been attempted with some success. Because the mortality associated with failed transplantations is high, other treatment alternatives and/or stopgap measures remain important despite the inability of these therapies to completely cure the condition in most patients. These therapies may be the sole therapy of the patient or may result in a milder course of the disease while awaiting a definitive cure.

Transplantation

Despite the fact that at present transplantation is available in only ~50% of children with osteopetrosis and is

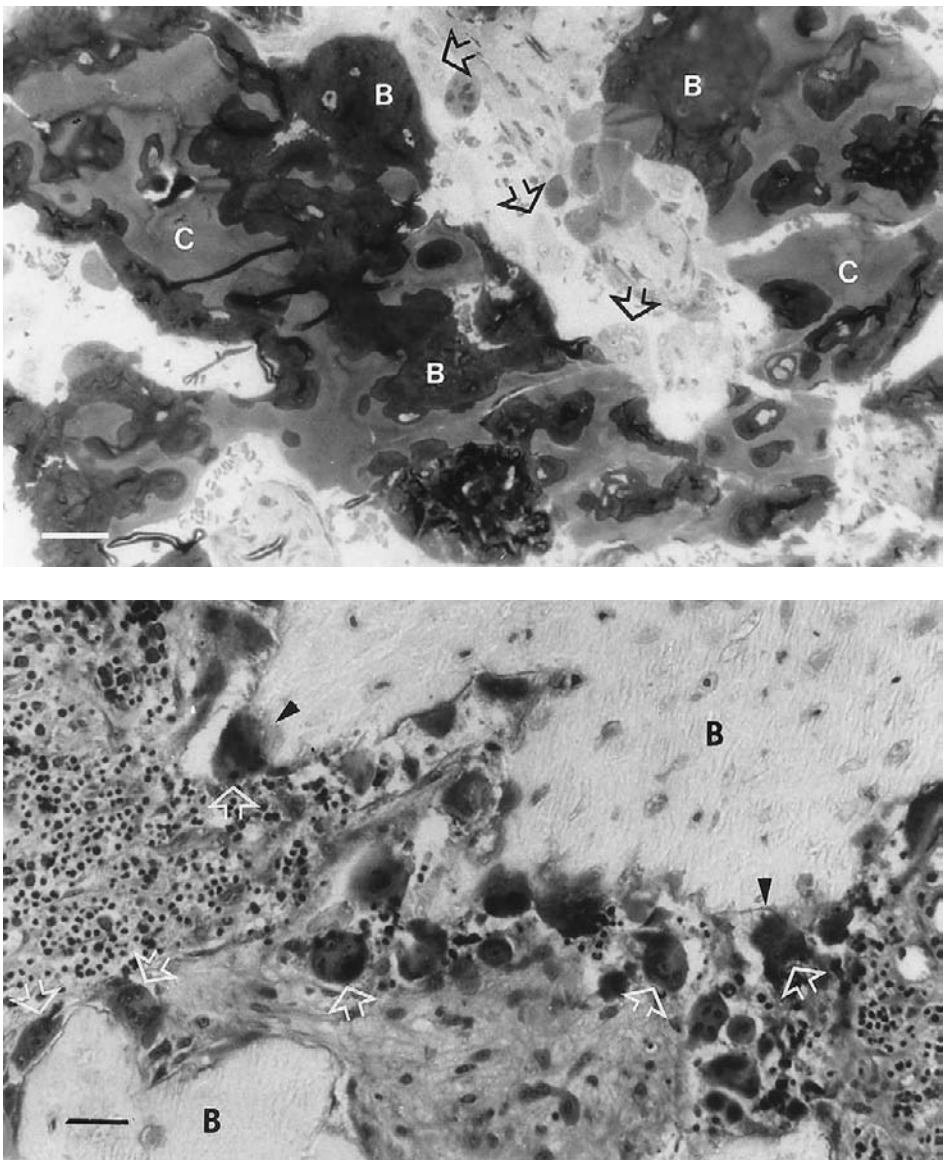

Figure 7 Bone biopsies from age 11 and 29 months in a patient with severe infantile osteopetrosis. The top panel contains a 1-μm Epon-embedded section obtained from the patient at 11 months of age, prior to therapy with interferon γ-1b and calcitriol. Coarse trabecular bone (denoted as "B") with cartilaginous streaks (denoted as "C") is evident. Lacunae are absent even though osteoclasts (arrows) adjoin the bone surface. Bone marrow cells are absent from this section. (Bottom) A 5-μm-thick methyl-methacrylate-embedded section obtained by biopsy of the same patient after 18 months of therapy. A combination of mineralized coarse trabecular bone and porous cortical bone (designated by "B") lined with numerous osteoclasts (open arrows) with brush borders and adjoining lacunae (arrowheads) is visible. Islands and streaks of cartilaginous tissue are absent. Bar = 40 μm.

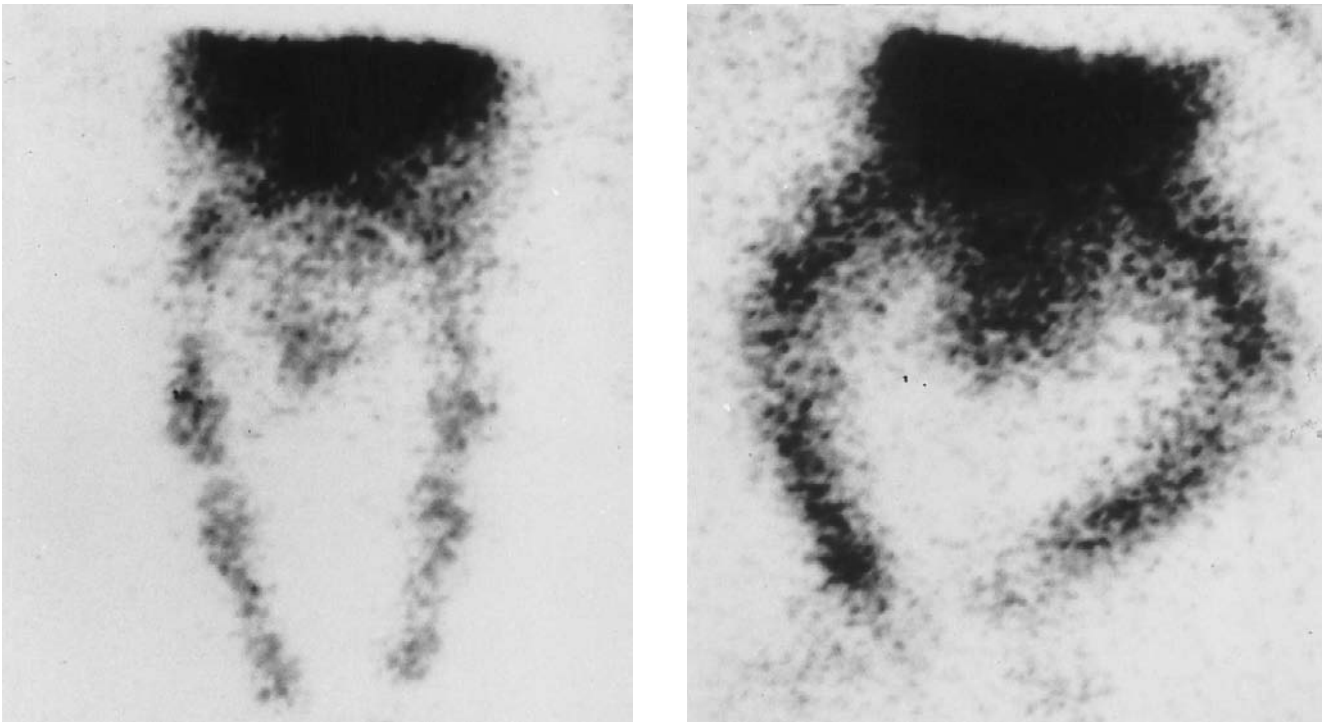

Figure 8 ^{999}Tc-labeled sulfur colloid bone marrow scans are shown from the same patient whose biopsies are shown in Fig. 7. The initial scan (left) shows abnormal uptake of label in the long bones of the lower extremities. Areas with little or no radionuclide are seen in the diaphyses with the uptake of the radionuclide being primarily concentrated to the subepiphyseal regions. (Right) After interferon gamma-1b therapy, there is an increase in the amount of radionuclide labeling and there are no longer any discreet areas with reduced uptake

successful in ~45% of patients who receive grafts; the allure of this therapy is that a successful transplantation yields a nearly complete cure (Gerritsen *et al.,* 1994b). If this cure can be obtained before there are too many physical disabilities, children with osteopetrosis tend to grow and develop normally. In transplantations where the donor graft is harvested from young siblings who have a favorable HLA match, there appears to be 70%, or slightly greater, survival. Despite the fact that not all engraftments are maintained, even the retention of a small number of donor cells seems to correct the defect significantly and stave off recurrence of symptomatic disease. However, beyond this group, the success rate is less favorable. In transplantations where the graft is obtained from HLA haplo-identical (mismatched) relatives, the engraftment and survival rates for transplants are only ~15%. Given the natural history of a survival of almost 30% for the malignant form of osteopetrosis as a whole, this is considered by most transplantation experts to be an unacceptable rate of failure. However, it should be noted that in the 15% of patients where transplantations have been successful, cures have been achieved. The great hope for the future are transplants with matched unrelated donors and possibly, cord blood stem cells (Information on cord blood transplantation in children communicated personally by M. Klemperer, St. Petersberg, FL). With the advent of DNA typing to ensure the adequacy of the matches, success rates of $\leq$80% are being achieved in most diseases. However, success rates of only ~40% have been found in osteopetrosis. The exact reason for this discrepancy is not clear at this time. The possibility that cord blood or placental transplants may improve chances for engraftments are just beginning to be explored. Nonetheless, at present, in the absence of a matched sibling donor, survival can be expected to be well below 50%.

Other Therapies

Many families have found transplantation to carry an unacceptable risk and thus, there has been a search for alternative therapies. The use of high dose calcitriol has been tried in a large number of children with some period of stabilization, and in some instances, a cure (Key and Ries, 1993; van Lie Peters *et al.,* 1993). Nonetheless, long-term cures have been achieved in 25% of patients treated.

Interferon-γ has been used as a treatment of osteopetrosis (Key *et al.,* 1995b; Kubo *et al.,* 1993). The intent of the therapy was to enhance the production of oxygen radicals by white blood cell phagocytes as a means of fighting off life-threatening infections. In addition, therapy with interferon-γ-1b along with calcitriol increases both bone remodeling and the amount of bone marrow space in patients (Fig. 7 and 8). To determine if interferon γ-1b (1.5 μg/kg/dose subcutaneously, three times per week, Actimmune, Intermune Pharmaceuticals, Inc., Palo Alto, CA) plus calcitriol (1 μg/kg/day orally) or calcitriol alone is effective in delaying the time to treatment failure, 16 patients with congenital osteopetrosis were recruited from all over the world to participate in a randomized, controlled trial. Patients were

randomized in a 2:1 ratio onto interferon γ-1b plus calcitriol or calcitriol alone, respectively. The drug was administered subcutaneously to patients three times a week. The patients receiving interferon γ-1b plus calcitriol had their first evidence of failure at a mean of 452 days compared to those on calcitriol alone, who failed at 130 days ($P = 0.016$). Only 10% of the patients treated with interferon γ-1b experienced a serious infection compared to 67% of the patients on calcitriol alone ($P < 0.0001$). In limited data, biopsies obtained from patients treated with interferon γ-1b had a 50% reduction in bone mass; while no reduction was seen in one patient treated with calcitriol alone. The size of both the optic nerve foramina and auditory canals increased in subjects treated with interferon γ-1b, but not in those treated with calcitriol only.

Summary

In summary, significant progress has been made in classifying osteopetrosis. There are at least three major categories (malignant, intermediate, benign) of the disease with a variety of subtypes. This classification allows prognostic information to be provided to the parent or patient, improving decision making concerning the appropriate therapy. The genetics of osteopetrosis have not been worked out, but the explosion of animal mutations expressing osteopetrotic phenotypes promises to lead to the identification of some, if not all, of the mutations in the near future. Finally, treatment is largely still directed toward enhancing osteoclastic function in general rather than specific defects. Bone marrow transplantation remains the only hope of complete cure. The introduction of calcitriol, M-CSF, and interferon γ-1b provides promise for the future survival and hopefully, the cure of osteopetrosis. As in the past, this very interesting family of disorders continues to lead the way in developing our understanding of osteoclastic function.

CHAPTER 70

Hypophosphatasia

Nature's Window on Alkaline Phosphatase Function in Man

Michael P. Whyte

Center for Metabolic Bone Disease and Molecular Research, Shriners Hospitals for Children, St. Louis, Missouri 63131; and Departments of Medicine, Pediatrics, and Genetics, Divisions of Bone and Mineral Diseases and Endocrinology and Metabolism, Washington University School of Medicine at Barnes-Jewish Hospital, St. Louis, Missouri 63110

Introduction

Alkaline phosphatase (ALP) was discovered in 1923 (McComb *et al.,* 1979). For most of the past eight decades, physicians have universally recognized the important clinical insight that can come from measuring ALP activity in serum. Detection and monitoring of hepatobiliary and skeletal disease are generally possible (Wolf, 1978). In fact, since the 1930s, quantitation of serum ALP activity has been routine in hospital laboratories, and this test may still be the most frequently performed enzyme assay (McComb *et al.,* 1979). Nevertheless, the physiological function of ALP, which is ubiquitous in nature, is largely unknown (Harris, 1990; McComb *et al.,* 1979; Moss, 1992; Whyte, 1994). However, as reviewed in this chapter, identification of ALP gene mutations in hypophosphatasia, a rare heritable metabolic bone disease, has confirmed in humans the hypothesis dating from its discovery that ALP functions importantly in skeletal mineralization (Whyte, 1994). The role for ALP was clarified by the observation that three phosphocompounds accumulate endogenously in hypophosphatasia. Elevated plasma levels of pyridoxal 5′-phosphate, due to alteration in vitamin B_6 metabolism, reveal that ALP acts as a cell surface enzyme (Whyte, 1994). The increased plasma and urinary concentrations of inorganic pyrophosphate, an inhibitor of hydroxyapatite crystal growth, provide a compelling explanation for the defective mineralization of bone and cartilage (Whyte, 1994). However, a great many intriguing questions remain.

Following a brief review of the history and the proposed physiological roles of ALP, an overview of hypophosphatasia is presented, and the biological insight gained from this "experiment-of-nature" is then discussed.

History and Proposed Physiological Roles of Alkaline Phosphatase

In 1923, Robert Robison (1883–1941) discovered in young rats and rabbits considerable phosphatase activity within ossifying bone and cartilage. He proposed that this enzyme functioned in skeletal mineralization by hydrolyzing some unknown phosphate ester to locally increase the concentration of inorganic phosphate (P_i) (Robison, 1923). One year later, Robison and Soames (1924) reported that this phosphatase precipitated mineral into rachitic rat bone when monophosphate esters were the only source of P_i and demonstrated its distinctly alkaline pH optimum. These studies represent the discovery of ALP (McComb *et al.,* 1979). Nevertheless, Robison never referred to this enzyme as "alkaline" phosphatase; the term was introduced by others (McComb *et al.,* 1979).

However, soon after the discovery of ALP, evidence that contradicted Robison's hypothesis emerged (McComb *et al.,*

1979). ALP was found to be abundant in tissues that normally do not calcify (e.g., liver, intestine, placenta), suggesting a more global physiological purpose. Furthermore, his theory was challenged because extracellular fluids were actually supersaturated with calcium and P_i and because he had not identified the enzyme's natural substrate(s) (Neuman and Neuman, 1957). Additional biological functions were proposed (see below).

At the end of the 1960s, electron microscopy helped to rejuvenate Robison's hypothesis when the earliest site of hydroxyapatite crystal deposition in the developing skeleton was noted by H. C. Anderson to be within novel extracellular structures called matrix vesicles (Anderson, 1969). These features were rich in ALP activity (Ali, 1986). We now know that matrix vesicles are replete with many enzymes, including inorganic pyrophosphatase (PP_i-ase) and ATPase, and may also contain phospholipids, polysaccharides, and glycolipids among numerous constituents (Anderson, 1992). During the earliest ("primary") phase of skeletal mineralization, hydroxyapatite crystals appear and grow within these structures. Soon after, the vesicles rupture and extravesicular ("secondary") mineralization occurs as crystal propagation continues (Ornoy *et al.,* 1985).

Following the discovery of matrix vesicles, *in vitro* model systems based upon inhibition of ALP with stereospecific compounds such as L-tetramisole (levamisole) demonstrated that calcification was blocked when ALP activity was inhibited (Fallon *et al.,* 1980). Nevertheless, these findings too proved controversial because subsequent controlled experiments using the noninhibitory stereoisomer sometimes also showed impaired mineralization.

Currently, the proposed biological roles for ALP in mammals are numerous (Harris, 1990; McComb *et al.,* 1979; Moss, 1992; Whyte, 1994) and include hydrolysis of phosphate esters to supply the *non*phosphate moiety, transferase action for the synthesis of phosphate esters, regulation of P_i metabolism, maintenance of steady-state levels of phosphoryl-metabolites, and action as a phosphoprotein phosphatase (Alpers *et al.,* 1990; Harris, 1990; McComb *et al.,* 1979; Moss, 1992; Muller *et al.,* 1991; Simko, 1991; Whyte, 1994). At cell membranes, it has been hypothesized that ALP conditions not only the active transport of P_i, but also the movement of calcium, fat, protein, carbohydrate, and Na^+/K^+ (Muller *et al.,* 1991; Simko, 1991). Furthermore, an interesting physical property of ALP in the placenta, binding to the Fc receptor of IgG, suggests that ALP transcytoses this immunoglobulin (Makiya *et al.,* 1992). ALP can also adhere to collagen (Wu *et al.,* 1992) (see below). In fact, sequence analyses of ALPs suggest that they may couple to other proteins, and it has been recommended that this physical property be considered when a potential physiological role of ALP is examined (e.g., phosphoprotein phosphatase action in skeletal matrix) (Tsonis *et al.,* 1988). Finally, although we now understand that ALP works primarily on cell surfaces (see below), at some stages of embryogenesis ALPs may act intracellularly (Narisawa *et al.,* 1992).

Table I Suggested Roles for ALP in Skeletal Mineralization

Locally increase Pi levels
Destruction of inhibitors of hydroxyapatite crystal growth
Transport of Pi
Ca^{2+}-binding protein (Ca^{2+} uptake by cells)
Ca^{2+}/Mg^{2+}-ATPase
Tyrosine-specific phosphoprotein phosphatase

[Reproduced with permission from M. P. Whyte: 1989. In: Peck WA (ed) Bone and Mineral Research. Vol. 6, Elsevier Science Publishers BV (Biomedical Division), Amsterdam, Vol. 6:175 – 218.]

A variety of hypotheses also explain how ALP could act specifically in skeletal mineralization (Table I) (Whyte, 1994). In 1975, nucleoside phosphate (liberated by dying cells) was proposed as the ALP substrate source of P_i necessary to fulfill Robison's theory (Majeska and Wuthier, 1975). An early and important alternative suggestion, however, offers that ALP hydrolyzes an inhibitor of calcification (Moss, 1992; Neuman and Neuman, 1957; Whyte, 1994). As will be reviewed, at least three findings favor the "inhibitor hypothesis" and implicate inorganic pyrophosphate (PP_i) (Caswell *et al.,* 1991; Whyte, 1994): high concentrations of PP_i impair the growth of hydroxyapatite crystals, ALP can function as a PP_i-ase (Moss *et al.,* 1967), and urine and plasma levels of PP_i are increased in patients with hypophosphatasia (Russell, 1965; Russell *et al.,* 1971). Alternatively, it has been suggested that ALP is a plasma membrane transporter for P_i, an extracellular Ca^{2+}-binding protein that stimulates calcium phosphate precipitation and orients mineral deposition into osteoid (deBarnard *et al.,* 1986), a Ca^{2+}/Mg^{2+}-ATPase, or a phosphoprotein phosphatase that conditions the skeletal matrix for ossification (Lau *et al.,* 1985) (Table I). In fact, as mentioned, a particular ALP structural domain could enable it to bind to types I, II, and X collagen in cartilage and bone (Tsonis *et al.,* 1988; Wu *et al.,* 1992).

Approaching nearly a century after its discovery, the most commonly used methods for assaying ALP continue to reflect ignorance of this enzyme's physiological role(s) (Harris, 1990; McComb *et al.,* 1979; Moss, 1992; Whyte, 1994). In clinical and research laboratories, ALP in diluted biological specimens is typically assayed with high concentrations (millimolar) of artificial substrates (e.g., *P*-nitrophenylphosphate) at distinctly nonphysiological alkaline pHs (e.g., pH 9.2 – 10.5) (McComb *et al.,* 1979). Such simple assays possess sensitivity but were developed primarily for clinical medicine (Wolf, 1978). In fact, for certain ALP substrates at low concentrations, although hydrolytic rates are reduced, the pH optimum is considerably less alkaline (McComb *et al.,* 1979; Moss, 1992). For years, the significance of this observation was uncertain (Harris, 1990; McComb *et al.,* 1979; Moss, 1992; Whyte, 1994).

To understand hypophosphatasia and appreciate how this disorder teaches us about the physiological role of ALP, it is first necessary to briefly review the molecular biology and biochemistry of this enzyme.

Molecular Biology and Biochemistry of Alkaline Phosphatase

ALPs (orthophosphoric-monoester phosphohydrolase, alkaline optimum, EC 3.1.3.1) are found in nearly all plant and animal species (McComb *et al.,* 1979). In humans, four ALP isoenzymes are encoded by four separate genes (Harris, 1990; Millan, 1988; Moss, 1992). Three of the isoenzymes are expressed in a tissue-specific distribution and are called intestinal, placental, and germ cell (placental-like) ALP. The fourth ALP isoenzyme is ubiquitous, but especially abundant in hepatic, skeletal, and renal tissue (liver / bone / kidney ALP) and is called tissue-*non*specific ALP (TNSALP) (Harris, 1990; Moss, 1992; Stigbrand and Fishman, 1984). The distinctive physicochemical properties (e.g., heat stability, electrophoretic mobility, etc.) among ALPs purified from liver, bone, and kidney are lost upon exposure to glycosidases (Moss and Whitaker, 1985). In fact, the TNSALPs are a family of "secondary" isoenzymes (isoforms), with the same polypeptide sequence, encoded by one gene (*TNSALP*) and differ only by posttranslational modification involving carbohydrate (Harris, 1980).

The TNSALP gene is located near the end of the short arm of chromosome 1 (1*p*36.1–*p*34); the genes for intestinal, placental, and germ-cell ALP are found near the tip of the long arm of chromosome 2 (2*q*34–*q*37) (Harris, 1990; Whyte, 2000). Unfortunately, the human gene mapping symbol for the *TNSALP* locus is *ALPL* ("ALP-liver") although the function of the liver isoform of TNSALP is unknown (*vide infra*).

The TNSALP gene is greater than 50 kb and contains 12 exons, 11 of which are translated to form the 507 amino acid nascent enzyme (Weiss *et al.,* 1988). The promoter region for *TNSALP* is located within 610 nucleotides 5′ to the major transcription start site (Kiledjian and Kadesch, 1990). TATA and Sp1 sequences may act as regulatory elements. Apparently, basal levels of *TNSALP* expression reflect inherent "housekeeping" promoter effects, whereas differential expression in various tissues may be mediated by a posttranscriptional mechanism (Kiledjian and Kadesch, 1990); the 5′ untranslated region differs between the bone and liver TNSALP isoforms (Nosjean *et al.,* 1997).

The tissue-specific ALP genes are smaller than the TNSALP gene, primarily reflecting shorter introns. Amino acid sequences deduced from the cDNAs suggest 87% positional identity between placental and intestinal ALP, but only 50 to 60% identity between TNSALP and the tissue-specific ALPs (Harris, 1990). Nevertheless, the active site of TNSALP, which is encoded by six exons and composed of 15 amino-acid residues (Zurutuza *et al.,* 1999), has a nucleotide sequence that has been conserved in ALPs found throughout nature (Henthorn and Whyte, 1991). *TNSALP* seems to represent an ancestral gene, whereas the tissue-specific ALPs likely originated from a series of gene duplications (Harris, 1990).

The ALPs are Zn^{2+}-metalloenzymes (McComb *et al.,* 1979). Catalytic activity requires a multimeric configuration of identical subunits ranging from 40 to 75 kDa. Each monomer has one active site and binds two Zn^{2+} atoms that stabilize its tertiary structure (Kim and Wycoff, 1991). The cDNA sequence of TNSALP predicts five potential N-linked glycosylation sites (Weiss *et al.,* 1988). In fact, *N*-glycosylation is necessary for enzymatic activity. *O*-glycosylation involves the bone, but not the liver, isoform of TNSALP (Nosjean *et al.,* 1997).

The ALPs are generally regarded as homodimeric in the circulation (McComb *et al.,* 1979). TNSALP, in symmetrical dimeric form, has α/β topology for each subunit with a 10-stranded β-sheet at its center (Hoylaerts and Millan, 1991). However, in tissues, ALPs are attached to cell surfaces probably as homotetramers (Fedde *et al.,* 1988).

ALP isoenzymes have broad substrate specificities and pH optima, which depend on the type and concentration of phosphocompound undergoing catalysis (McComb *et al.,* 1979). Catalytic activity requires Mg^{2+} as a cofactor (McComb *et al.,* 1979). Hydrolytic activity cleaves phosphoesters and PP_i (Xu *et al.,* 1991). The reaction involves phosphorylation–dephosphorylation of a serine residue, and dissociation of covalently linked P_i seems to be the rate-limiting step. In fact, P_i is a potent competitive inhibitor of ALP activity (McComb *et al.,* 1979). Of interest, however, P_i may also stabilize the enzyme (Farley, 1991).

Relatively little is certain about the biosynthesis of ALP in higher organisms. Analysis of the human ALP isoenzyme gene sequences indicates that the nascent polypeptides have a short signal sequence of 17 to 21 amino acid residues (Harris, 1990) and a hydrophobic domain at their carboxy-termini (Weiss *et al.,* 1988). ALPs become tethered to the plasma membrane surface, where they are bound to the polar head group of a phosphatidylinositol-glycan moiety and can be released by phosphatidylinositol-specific phospholipase (Fedde *et al.,* 1988). However, the precise interaction with phosphatidylinositol may differ among the ALP isoenzymes (Seetharam *et al.,* 1987). Intracellular degradation of ALPs can involve proteosomes (Cai *et al.,* 1998).

Actually, the ALP isoenzymes manifest broad pH optima and variable substrate specificity *in vitro* that reflect the concentration and type of phosphocompound being hydrolyzed (McComb *et al.,* 1979). ALPs can cleave PP_i or phosphoesters (Xu *et al.,* 1991). Catalysis involves phosphorylation–dephosphorylation of a serine residue. Dissociation of the covalently linked phosphate seems to be the rate-limiting step. P_i is a potent competitive inhibitor of ALP (Kim and Wyckoff, 1991; McComb *et al.,* 1979).

ALPs are coupled to cell surfaces by phosphatidylinositol (Whyte, 1994). Lipid-free enzyme comprises ALP normally found in the circulation, however, the mechanism(s) for ALP release from cell surfaces *in vivo* is unknown but

could involve a phosphatidase of the C or D type, detergent action, proteolysis, membrane fractionation, or lipolysis (Alpers *et al.,* 1990).

Clearance of circulating ALP, as for many other glycoproteins, is assumed to occur via uptake by the liver (Young *et al.,* 1984). In healthy men and women, the majority of ALP in serum reflects approximately equal amounts of the TNSALP isoforms from liver and bone (Millan *et al.,* 1980). In healthy infants and children (and particularly during the growth spurt of adolescence), serum is especially rich in the bone isoform of TNSALP (McComb *et al.,* 1979). The remaining ALP in serum is normally intestinal ALP, but this isoenzyme usually contributes just a few percent (maximum 20%) (McComb *et al.,* 1979; Mulivor *et al.,* 1985). Some individuals (with B and O blood types who are "secretors") modestly increase serum levels of intestinal ALP after ingesting a fatty meal (Langman *et al.,* 1966; McComb *et al.,* 1979). Placental ALP typically circulates only during the last trimester of pregnancy (Birkett *et al.,* 1966). Various cancers, however, put placental ALP or germ cell ("placental-like") ALP into the bloodstream (Millan, 1988). In 2001, the detailed crystal structure at 1.8Å resolution was reported for human placental ALP and deemed consistent with phosphorylated protein target (Le Due *et al.,* 2001).

Hypophosphatasia

Subnormal extracellular levels of calcium and/or P_i engender almost all types of rickets or osteomalacia. Hypophosphatasia is an instructive exception (Whyte, 1994, 2001). In the author's opinion, defended here, characterization and study of hypophosphatasia has best elucidated the physiological role of ALP. Now, as discussed below, with identification of numerous mutations in the TNSALP gene in hypophosphatasia (Weiss *et al.,* 1988; Whyte, 2000), unequivocal evidence demonstrates that TNSALP is essential for proper mineralization of our skeletons and development of our teeth (Whyte, 1994). However, the apparently undisturbed function of other organs/tissues in hypophosphatasia questions the biological significance for TNSALP elsewhere.

History

John Campbell Rathbun (1915–1972), a Canadian pediatrician, coined the term hypophosphatasia in 1948 when he reported an infant boy who developed and then died from severe rickets with epilepsy, yet whose ALP activity in serum, bone, and other tissues was paradoxically subnormal (Rathbun, 1948). About 300 patients have been described (Whyte, 2001).

Discussed later, the metabolic basis for hypophosphatasia and the physiological function of TNSALP were clarified by the discoveries in patients of elevated endogenous levels of three phosphocompounds. In 1955, increased urinary concentrations of phosphoethanolamine (PEA) provided a useful biochemical marker for the disease (Fraser *et al.,* 1955; McCance *et al.,* 1955). In 1965 and 1971, supranormal urinary and blood levels of PP_i (Russell, 1965; Russell *et al.,* 1971, respectively), suggested a mechanism for the defective mineralization of hard tissues. In 1985, high plasma concentrations of pyridoxal 5′-phosphate (PLP) indicated an ectoenzyme function for TNSALP (Whyte *et al.,* 1985).

Clinical Features

Hypophosphatasia (McKusick 146300, 171760, 241500, 241510) has been reported throughout the world and apparently affects all races. However, this condition is especially prevalent in inbred Mennonite families from Manitoba, Canada, where about 1 in 25 individuals is a carrier and 1 : 2500 newborns manifests severe disease (Greenberg *et al.,* 1993). In Toronto, Canada the incidence of severe forms was estimated by Fraser to be 1 per 100000 live births (Fraser 1957). In my experience, the disorder is particularly rare in blacks in the United States.

Despite the presence of relatively high levels of TNSALP in bone, liver, kidney, and adrenal tissue (and at least some TNSALP ubiquitously) in healthy individuals (McComb *et al.,* 1979), the impact of hypophosphatasia centers on the skeleton and dentition (Whyte, 2001). In 1953, premature loss of deciduous teeth was recognized to be a major clinical feature (Sobel *et al.,* 1953). However, the severity of expression is extraordinarily variable, ranging from death *in utero* with essentially an unmineralized skeleton, to early shedding of primary dentition only (Fraser, 1957; Whyte, 2001). In fact, some individuals with characteristic, albeit mild, biochemical abnormalities may never suffer symptoms or complications (Whyte *et al.,* 1982a).

Because the many TNSALP gene defects that cause hypophosphatasia are now rapidly being elucidated (Weiss *et al.,* 1988; Henthorn *et al.,* 1992; Mornet *et al.,* 1998; Mumm *et al.,* 1999; Whyte, 2000), a useful mutation-based nosology may emerge (Whyte, 2001). Nevertheless, the current classification of patients for prognostication, etc., remains a clinical one (Whyte, 2001). Six forms of hypophosphatasia have been identified. The age at which lesions in bone are discovered distinguish the perinatal, infantile, childhood, and adult types (Fraser, 1957; Whyte, 2001). Patients who do not have skeletal disease but develop only dental manifestations are regarded as having "odontohypophosphatasia" (Whyte, 2001). The exceedingly rare hypophosphatasia variant called "pseudohypophosphatasia" in all ways (i.e., clinical, radiographic, and biochemical) resembles infantile hypophosphatasia, except that serum ALP activity is not subnormal in the clinical laboratory (see below) (Whyte, 2001). The prognoses for these six forms of hypophosphatasia generally depend upon the degree of skeletal disease which, in turn, reflects the age at presentation. Typically, the earlier a patient manifests skeletal symptoms, the more severe the disorder (Fraser, 1957; Whyte, 2001). However, this classification scheme does not unambiguously distinguish all patients.

PERINATAL HYPOPHOSPHATASIA

This most pernicious form of hypophosphatasia is expressed *in utero* and can cause stillbirth. Profound skeletal hypomineralization results in *caput membraneceum* and limbs that are shortened and deformed during gestation and at birth. Some affected neonates survive several days or weeks, but then suffer from increasing respiratory compromise due to rachitic disease of the chest and due to lungs that are hypoplastic (Silver *et al.,* 1988). Epilepsy can occur and prove lethal *(vide infra)*. Myelophthisic anemia may be present, perhaps from encroachment on the marrow space by excessive osteoid (Terheggen and Wischermann, 1984). Rarely, there is long-term survival.

Radiographic examination of the skeleton readily distinguishes perinatal hypophosphatasia from even the most severe forms of osteogenesis imperfecta and congenital dwarfism. In fact, the X-ray appearance can be considered diagnostic. Nevertheless, there is considerable patient-to-patient variability and the radiographic findings are diverse (Shohat *et al.,* 1991). In some stillborns, the skeleton is nearly without mineralization (Fig. 1). In others, one sees marked bony undermineralization and severe rachitic changes. Occasionally, there can also be peculiar complete or partial absence of ossification of one or more vertebrae (Shohat *et al.,* 1991). In the skull, individual membranous bones may calcify only at their centers. Thus, the areas of unossified calvarium give the illusion that cranial sutures are widely separated, although they may be functionally closed. Other unusual radiographic features include bony spurs that protrude laterally from the midshafts of the ulnae and fibulae (Whyte, 1988).

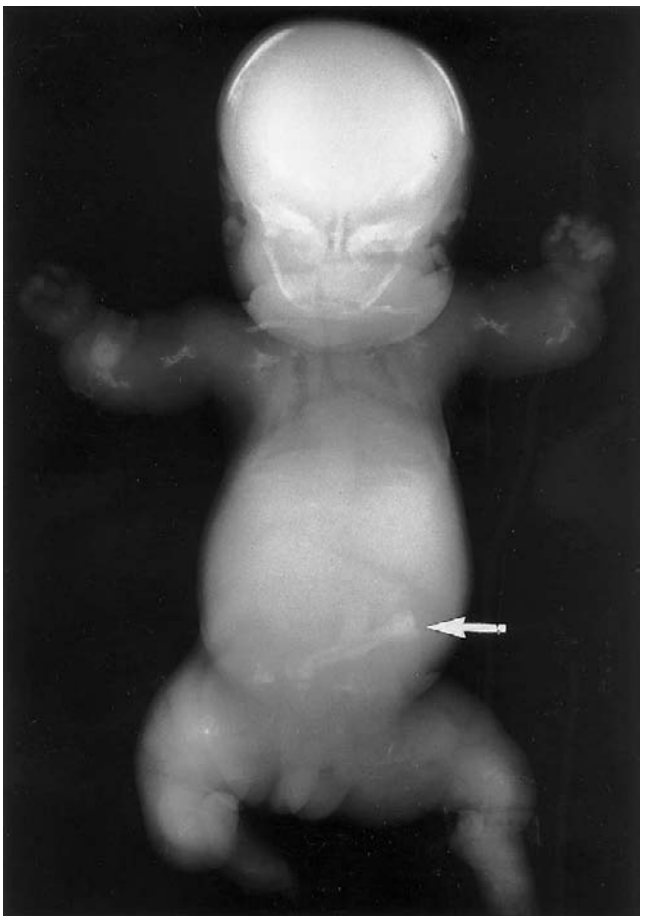

Figure 1 Perinatal hypophosphatasia. Profound skeletal hypomineralization is obvious; umbilical clip (arrow) is more dense than the pelvis. The ends of the long bones in the upper limbs show severe rachitic changes.

INFANTILE HYPOPHOSPHATASIA

This form of hypophosphatasia is the type described by Rathbun (Rathbun, 1948). It presents before the age of 6 months (Fraser, 1957; Whyte, 2001). Postnatal development often seems normal until the onset of poor feeding and inadequate weight gain and the clinical manifestations of rickets are recognized. The cranial sutures appear to be wide, but actually reflect hypomineralization of the skull and often there is a "functional" craniosynostosis. Furthermore, true premature bony fusion of these sutures can occur if the patient survives infancy. A flail chest from rib fractures, rachitic deformity, etc., often lead to pneumonia. Hypercalcemia and hypercalciuria are common and may explain nephrocalcinosis, renal compromise and episodes of recurrent vomiting (Fraser, 1957; Whyte *et al.,* 1982b).

The striking radiographic features are characteristic but generally less severe than in the perinatal form of hypophosphatasia. In some newly diagnosed patients, abrupt transition from relatively normal-appearing diaphyses to uncalcified metaphyses is of interest, suggesting that a metabolic change occurred suddenly (Fraser, 1957). Serial radiographic studies may reveal not only persistence of impaired skeletal mineralization (i.e., rickets), but gradual, generalized demineralization of osseous tissue as well (Whyte *et al.,* 1982b).

CHILDHOOD HYPOPHOSPHATASIA

This form of hypophosphatasia is especially variable in its clinical expression (Fallon *et al.,* 1984; Whyte, 2001). Premature loss of deciduous teeth (i.e., earlier than age 5 years) results from aplasia, hypoplasia, or dysplasia of dental cementum, which should connect the tooth root with the periodontal ligament (Lundgren *et al.,* 1991). The incisors are frequently shed first, but occasionally almost the entire primary dentition is exfoliated prematurely. There may be delayed walking and a characteristic waddling gait. Patients can complain of stiffness and pain and have appendicular muscle weakness (especially in the thighs) consistent with a nonprogressive myopathy (Seshia *et al.,* 1990).

Radiographs typically show characteristic focal bony defects near the ends of major long bones; i.e., "tongues" of radiolucency that project from the rachitic growth plate into the metaphysis (Fig. 2). Functional synostosis of cranial sutures occurs not uncommonly in infants and young children who are severely affected, although widely "open" fontanels appear to be present on radiographic study. This illusion results from large areas of hypomineralized calvarium. Subsequently, true premature bony fusion of cranial

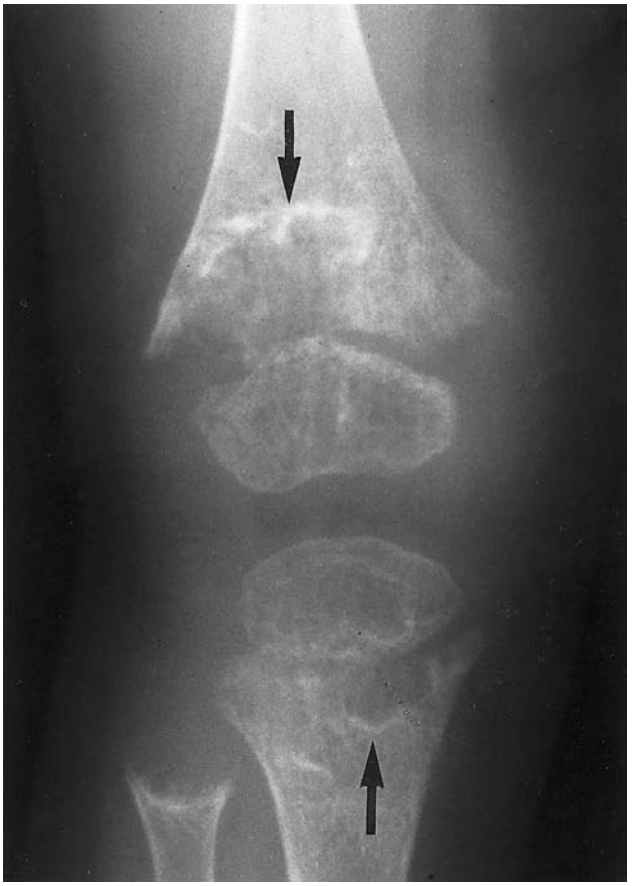

Figure 2 Childhood hypophosphatasia. Characteristic tongues of radiolucency (arrows) project from growth plates into frayed metaphyses.

sutures may also cause raised intracranial pressure. Dental radiographs sometimes show enlarged pulp chambers and root canals that characterize the "shell teeth" of rickets.

ADULT HYPOPHOSPHATASIA

This form of hypophosphatasia usually presents during middle age (Whyte, 2001; Whyte *et al.,* 1982a). Not infrequently, however, remote histories of rickets and/or premature exfoliation of deciduous teeth precede relatively good health after adolescence and during young adult life. Subsequently, osteomalacia often first manifests with painful feet due to poorly healing metatarsal stress fractures that become recurrent. With advanced disease, aching or tenderness in the thighs or hips is often explained by femoral pseudofractures that may progress to completion. Early loss or extraction of the secondary dentition is not uncommon (Whyte *et al.,* 1982a). Calcium pyrophosphate dihydrate (CPPD) crystal deposition, occasionally with overt attacks of arthritis (pseudogout), troubles some patients. Apparently, this complication stems from increased endogenous levels of PP_i (see below) (O'Duffy, 1970; Whyte *et al.,* 1982a). Affected individuals may suffer degeneration of articular cartilage and "pyrophosphate arthropathy" (Whyte *et al.,* 1982a).

In some families with hypophosphat*asemia,* calcium phosphate deposition manifests as "calcific periarthritis" with ossification of ligaments (syndesmophytes) resembling spinal hyperostosis (Forestier's disease) (Lassere and Jones, 1990).

Radiographs may also reveal osteopenia and chondrocalcinosis (Lassere and Jones, 1990; Whyte *et al.,* 1982a).

ODONTOHYPOPHOSPHATASIA

This form of hypophosphatasia is diagnosed when the only clinical abnormality is dental disease (radiographic or histologic studies reveal no evidence of rickets or osteomalacia).

PSEUDOHYPOPHOSPHATASIA

This is a particularly interesting, but especially rare, variant of hypophosphatasia. The disorder has been documented convincingly in two infants (Whyte, 2001). Clinical, radiographic, and biochemical findings of pseudohypophosphatasia recapitulate infantile hypophosphatasia, with the important exception that serum total ALP activity is consistently normal or increased (Whyte, 1994, 2001). The enzymatic defect involves a TNSALP with diminished activity toward PEA, PP_i, and PLP at physiological pH, but normal or even increased activity in the highly artificial conditions of the ALP assays used in clinical laboratories (*see below*) (Fedde *et al.,* 1990).

Laboratory Diagnosis

BIOCHEMICAL FINDINGS

Hypophosphatasia can be diagnosed confidently when the patient has a consistent clinical history, physical findings, and radiographic changes together with serum ALP activity that is clearly and reproducibly subnormal (Whyte, 2001). Even patients with odontohypophosphatasia are distinguishable from healthy individuals by their low serum ALP activity, although values do approach the lower end of carefully established, age-adjusted reference ranges (Fig. 3). Usually, the more severe the disease, the lower the age-appropriate serum ALP activity. In perinatal and infantile hypophosphatasia, hypophosphat*asemia* is detectable in umbilical cord blood at birth (Whyte, 2001).

Hypophosphat*asemia* occurs under a variety of conditions (starvation, hypothyroidism, scurvy, severe anemia, Wilson disease, celiac disease, hypomagnesemia, Zn^{2+} deficiency), from certain drugs (glucocorticoids, clofibrate, chemotherapy, intoxication levels of vitamin D, milk–alkali syndrome), and with exposure to radioactive heavy metals or massive transfusion of blood or plasma (Macfarlane *et al.,* 1992). These clinical situations, however, should be readily apparent. Of note, especially rare cases of lethal osteogenesis imperfecta (Royce *et al.,* 1988) and infants with cleidocranial dysplasia can have low levels of serum ALP activity from osteoblast dysfunction (personal observation). Finally, transient increments in serum ALP activity (probably the bone isoform of TNSALP) occur in hypophosphatasia patients after orthopedic surgery or fracture. In theory, conditions that increase serum levels of any form of ALP (e.g., pregnancy, liver disease) could mask the diagnosis. Thus, in confusing cases, documentation that serum ALP activity is low on more than one occasion during

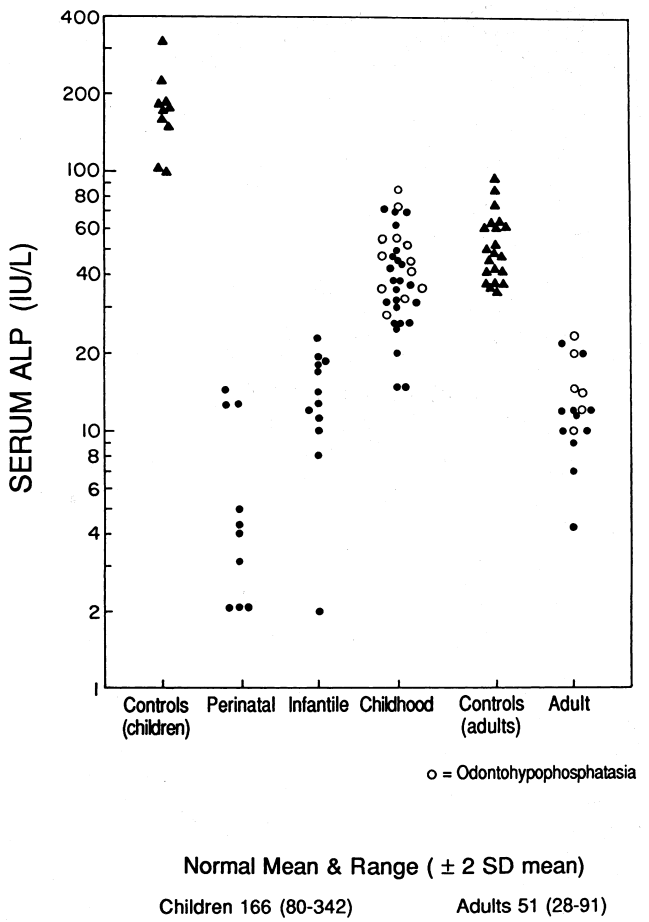

Figure 3 Serum ALP activity in hypophosphatasia. Serum ALP activity in normal children and normal adults and in 52 patients from 47 families with the various clinical forms of hypophosphatasia (note the logarithmic scale). All ALP assays performed at the Metabolic Research Unit, Shriners Hospitals for Crippled Children, St. Louis, MO. [Reproduced with permission from Whyte, M. P. Hypophosphatasia. *In* "The Metabolic and Molecular Bases of Inherited Disease" (C. R. Scriver, A. L. Beaudet, W. S. Sly, and D. Valle, eds.), 2001, 8th ed., pp. 5313–5329. McGraw-Hill, New York.]

clinical stability seems advisable. Quantitation of specific ALP isoenzymes (Mulivor *et al.,* 1985), isoforms of TNSALP (Whyte *et al.,* 1996), or leukocyte ALP (Iqbal *et al.,* 2000) may also be helpful.

Neither calcium nor P_i levels in serum are subnormal in hypophosphatasia. In fact, there may be hypercalcemia and hyperphosphatemia. Hypercalcemia and hypercalciuria occur frequently in infantile hypophosphatasia (Fraser, 1957; Shohat *et al.,* 1991; Whyte *et al.,* 1982b). The disturbed calcium homeostasis is poorly understood but appears to reflect defective uptake of mineral by a slowly growing skeleton together perhaps with progressive skeletal demineralization. In childhood hypophosphatasia, severely affected patients occasionally manifest hypercalciuria but without hypercalcemia. Serum levels of 25(OH)D and parathyroid hormone (PTH) are typically unremarkable, unless there are aberrations in serum calcium levels or renal failure (Fallon *et al.,* 1984). Several patients have had elevated serum PTH levels, but impaired renal function from hypercalcemia (causing retention of immunoreactive PTH fragments) may have explained this finding (Whyte, 1994). Low circulating levels of PTH, potentially from the feedback of hypercalcemia on the parathyroid glands, have also been reported.

Individuals with the childhood or adult forms of hypophosphatasia have serum P_i levels above the average values for controls. Indeed, 50% of these patients are distinctly *hyper*phosphat*emic.* Enhanced renal reclamation of P_i (increased TmP/GFR) is the mechanism for this poorly understood finding (Whyte and Rettinger, 1987). Conversely, especially rare patients with hypophosphat*asemia* have been reported who have *hypo*phosphat*emia* from kidney P_i wasting (Juan and Lambert, 1981).

Phosphoethanolamine Elevated urinary levels of PEA support a diagnosis of hypophosphatasia (Rasmussen, 1968), but are not pathognomonic. Licata and coworkers have shown that phosphoethanolaminuria occurs under other conditions, including several metabolic bone diseases (Licata *et al.,* 1978). For diagnosing mild cases, the clinician must recognize that urinary PEA levels are influenced by patient age and somewhat by diet, follow a circadian rhythm, and reportedly can be unremarkable in mildly affected patients. Age-adjusted normal ranges (expressed as micromoles PEA per gram of creatinine) are: <15 years, 83–222; 15–30 years, 42–146; 31–41 years, 38–155; and >45 years, 48–93 (Licata *et al.,* 1978).

Pyridoxal 5′-phosphate An increased plasma concentration of PLP is a specific and sensitive marker for hypophosphatasia (including pseudohypophosphatasia) (Coburn *et al.,* 1988; Coburn and Whyte, 1988) (Fig. 4). Commercial laboratories now perform this assay. Even patients with odontohypophosphatasia manifest this biochemical finding (Whyte *et al.,* 1985). However, vitamin supplements containing pyridoxine should not be taken for 1 week before testing. In general, the more severely affected the patient, the greater the elevation in the plasma PLP concentration. Nevertheless, there is overlap among the plasma PLP levels for the different clinical phenotypes (Fig. 4). Assay of plasma PLP levels after oral challenge with pyridoxine seems to reveal affected individuals especially well (Whyte, 1994), and this procedure can identify Canadian Mennonite carriers of severe hypophosphatasia (Chodirker *et al.,* 1990).

Inorganic Pyrophosphate Assay of urinary PP_i remains a research technique. PP_i levels are increased in most patients with hypophosphatasia, but are occasionally unremarkable in mildly affected subjects (Caswell *et al.,* 1991). Nevertheless, this biochemical parameter has been reported to be sensitive for carrier detection (Whyte, 2001).

RADIOLOGIC FINDINGS

The radiographic features have been described above for each form of hypophosphatasia.

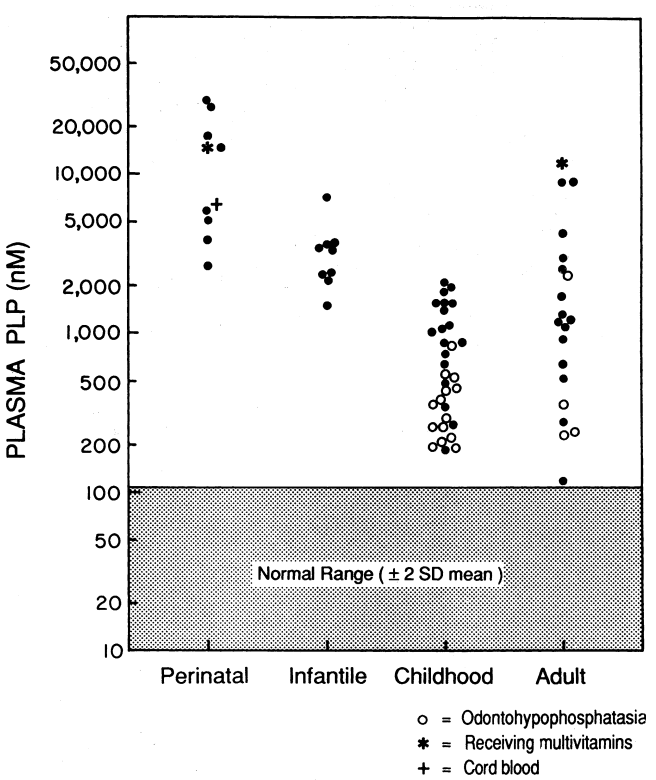

Figure 4 Plasma PLP levels in hypophosphatasia. PLP levels in plasma in various clinical forms of hypophosphatasia (hatched area is the normal range for children and adults). Note, the logarithmetic scale with some overlap between clinical forms (assays performed courtesy of Dr. Stephen P. Coburn, Fort Wayne State Developmental Center, Fort Wayne, IN). Valle, eds.), 2001, 8th ed., pp. 5313–5329. McGraw-Hill, New York.]

HISTOPATHOLOGIC FINDINGS

Histopathologic changes are limited essentially to hard tissues in hypophosphatasia. In severe cases, additional abnormalities—such as extramedullary hematopoiesis (Fallon *et al.,* 1984; Ornoy *et al.,* 1985)—may be secondary to the skeletal disease itself. The reason for pulmonary hypoplasia, however, is not clear (Silver *et al.,* 1988).

Skeleton In all but the mildest cases (i.e., odontohypophosphatasia), nondecalcified sections of bone reveal evidence of defective mineralization (Fallon *et al.,* 1984; Ornoy *et al.,* 1985). The degree of osteomalacia generally reflects the clinical severity of hypophosphatasia (Fallon *et al.,* 1984). Nevertheless, features of secondary hyperparathyroidism (present in rickets or osteomalacia associated with hypocalcemia) are generally absent (Fallon *et al.,* 1984).

In growth plates and osseous tissue, sources of the bone form of TNSALP, chondrocytes and osteoblasts, as well as matrix vesicles, are observed, but levels of TNSALP activity are subnormal (Fallon *et al.,* 1984; Ornoy *et al.,* 1985). However, the histopathologic changes cannot be distinguished from those of most other forms of rickets or osteomalacia unless ALP activity is quantitated. ALP activity in bone inversely reflects the amount of osteoid accumulation (Fallon *et al.,* 1984).

Electron microscopy of perinatal hypophosphatasia has shown normal distribution of matrix vesicles, proteoglycan granules, and collagen fibers in the extracellular space of cartilage (Ali, 1986; Fallon *et al.,* 1984), yet matrix vesicles lack ALP activity. Early reports described only isolated or tiny groups of hydroxyapatite crystals (calcospherites) frequently not associated with vesicular structures (Ali, 1986; Shohat *et al.,* 1991). More recently, Anderson and coworkers showed that matrix vesicles contain hydroxyapatite crystals that are not seen enlarging after these structures rupture (Anderson *et al.,* 1997).

Dentition Premature exfoliation of primary teeth occurs under a variety of conditions. In hypophosphatasia, a paucity of cementum due to aplasia, hypoplasia, or dysplasia (despite the presence of cells that look like cementoblasts) seems to be a major factor engendering this complication (Fig. 5) (el-Labban *et al.,* 1991; Lundgren *et al.,* 1991). If cementum is present, it may appear to be afibrillar (el-Labban *et al.,* 1991). Desiccated teeth that were shed years earlier may still be useful for examination (Fig. 5). The severity of this defect varies from tooth to tooth, but typically reflects the extent of

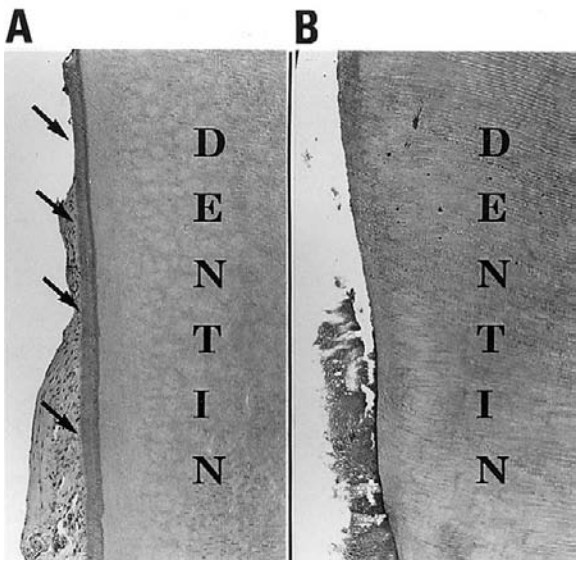

Figure 5 Dental findings in hypophosphatasia. (A) Decalcified section of part of the root of a maxillary incisor from a child with *X*-linked hypophosphatemia is essentially normal and shows primary cementum (delineated by arrows) at its surface (original magnification × 150). (B) In hypophosphatasia, cementum is absent. Original magnification × 150. [Reproduced with permission from Whyte, M. P. Hypophosphatasia. *In* "The Metabolic and Molecular Bases of Inherited Disease" (C. R. Scriver, A. L. Beaudet, W. S. Sly, and D. Valle, eds.), 2001, 8th ed., pp. 5313–5329. McGraw-Hill, New York.]

skeletal disease. Incisors are usually the most notably affected and are the first to be lost.

In addition to defects in cementum, retarded dentinogenesis seems to occur as suggested by big pulp chambers. Dentin tubules may be enlarged although reduced in number. The excessive width of predentin, increased amounts of interglobular dentin, and impaired calcification of cementum are analogous to the osteoidosis found in bone. The enamel is not impacted directly (Lundgren *et al.,* 1991). The histopathologic changes observed in the permanent teeth are similar to those in the deciduous teeth (el-Labban *et al.,* 1991), but their prognosis is better (Lepe *et al.,* 1997).

Biochemical and Genetic Defect

TNSALP DEFICIENCY

Early on, postmortem investigations of the perinatal and infantile forms of hypophosphatasia were critical for clarifying the underlying biochemical defect, but they also intimated the disorder's genetic basis. Profound deficiency of ALP activity was discovered in liver, bone, and kidney tissue, yet ALP activity was not decreased in intestine or placenta (fetal trophoblast) (Vanneuville and Leroy, 1981). This observation was consistent with amino acid sequence analyses of ALP purified from various healthy human tissues (Stigbrand and Fishman, 1984) and argued for a selective decrease in the enzymatic activity of all isoforms comprising the TNSALP family.

Postmortem studies of children or adults with hypophosphatasia have not been reported. Nevertheless, indirect findings indicated that these clinically milder forms also reflect globally diminished TNSALP activity. In such patients, TNSALP activity can be deficient in circulating granulocytes (Fallon *et al.,* 1984), bone tissue (Fallon *et al.,* 1984), and cultivated skin fibroblasts (Vanneuville and Leroy, 1981).

Exploration of the biochemical hallmark, hypophosphat*asemia,* corroborated this hypothesis and provided further insight. Hypophosphatasemia did not involve enhanced loss of TNSALP from the circulation (Gorodischer *et al.,* 1976). Purified placental ALP as well as the bone form of TNSALP (contained in plasma of patients with Paget bone disease) showed normal circulating half-lives of several days when infused intravenously into severely affected infants during attempted enzyme-replacement therapy (*vide infra*) (Whyte *et al.,* 1982b). Furthermore, coincubation experiments with mixtures of serum and coculture or heterokaryon studies with fibroblasts from severely affected patients excluded an inhibitor or absence of an activator of TNSALP (Fraser, 1957; O'Duffy, 1970; Whyte and Vrabel, 1985). Thus, the hypophosphatasemia of hypophosphatasia is due to low levels of TNSALP activity throughout the body.

In *tissues,* ALP immunoreactivity has been quantitated in liver, bone, and kidney as well as in skin fibroblasts obtained from patients with severe hypophosphatasia (Fallon *et al.,* 1989; Fedde *et al.,* 1996). The preliminary report by Fallon and coworkers, based upon a polyclonal antibody to the human liver form of TNSALP, revealed normal amounts of immunoreactive TNSALP in bone, liver, and kidney in five such individuals (Fallon *et al.,* 1989). Different investigators, using isoelectric focusing and enzyme inhibition studies, suggested that the low ALP activity in a similar patient reflected intestinal ALP (Mueller *et al.,* 1983). In fibroblasts from severely affected individuals, the ALP has somewhat different physicochemical and immunological properties compared with the enzyme from controls, but seems to be a form of TNSALP (Fedde *et al.,* 1996).

In the *circulation,* the nature of ALP in hypophosphatasia requires further study. Leukocyte ALP activity can be subnormal in any type of the disease except perhaps pseudohypophosphatasia and, therefore, likely represents TNSALP (see below) (Fallon *et al.,* 1984). Monoclonal antibody-based IRMAs for polymeric TNSALP demonstrate low levels of the bone and liver isoforms of TNSALP in sera from patients with all clinical types of hypophosphatasia except pseudohypophosphatasia, in which levels are normal (Whyte *et al.,* 1996). Upon release from plasma membranes, TNSALP in hypophosphatasia seems to be altered in such a way that immunoreactivity diminishes or clearance is accelerated (Whyte *et al.,* 1996). The observations of Fedde and coworkers indicate that the precise impact of TNSALP gene mutations (see below) on the enzyme's structure in tissues must be understood to fully appreciate the disease expression of hypophosphatasia (Fedde *et al.,* 1996).

INHERITANCE

Although it is apparent that perinatal and infantile hypophosphatasia represent autosomal recessive traits, the mode of transmission of milder forms requires investigation. Vertical propagation of mild disease seems unusual (Whyte *et al.,* 1982a). Nevertheless, multigeneration biochemical (Whyte *et al.,* 1982a) and occasionally clinical (Eastman and Bixler, 1983) abnormalities argue that less severe types of hypophosphatasia sometimes represent autosomal dominant traits. In fact, clinical studies of exceptional families are consistent with mildly affected individuals possessing a gene defect that causes severe disease in homozygotes or compound heterozygotes (Eastman and Bixler, 1982).

However, identifying carriers for hypophosphatasia using conventional biochemical testing has been difficult. The utility of quantitating several parameters, including urinary PP_i, has been discussed (Sorensen *et al.,* 1978). Pyridoxine (vitamin B_6) loading followed by assay of plasma PLP levels helps to detect Mennonite carriers in Canada (Chodirker *et al.,* 1987) (*vide infra*). Now, mutation analysis of *TNSALP* is rapidly clarifying the patterns of inheritance for hypophosphatasia. All clinical forms can be transmitted as autosomal recessive traits, but autosomal dominant inheritance of mild disease due to certain *TNSALP* mutations also occurs (Henthorn, *et al.,* 1996; Whyte, 2000) (*vide infra*).

GENE DEFECTS

In 1988, proof that hypophosphatasia can involve the TNSALP (candidate) gene came with the discovery by Weiss and coworkers of a homozygous *TNSALP* missense mutation in a consanguineous patient with perinatal hypophosphatasia (Weiss *et al.,* 1988). Site-directed mutagenesis and transfection analysis confirmed that the single base transition compromised the enzyme's catalytic activity, perhaps by altering metal ligand binding to an important arginine residue at the catalytic pocket (Weiss *et al.,* 1988).

In 1992, Henthorn and colleagues reported eight additional missense mutations in four unrelated patients with perinatal or infantile hypophosphatasia (Henthorn *et al.,* 1992). Allele-specific oligonucleotide screening disclosed 23 individuals, among 50 unrelated patients manifesting all clinical forms of hypophosphatasia, with one of these base changes (the other TNSALP allele remained uncharacterized). Two siblings with typical childhood hypophosphatasia and one unrelated elderly woman with classic adult hypophosphatasia proved to be compound heterozygotes for a novel combination of two of these molecular defects. This observation confirmed that some cases of nonlethal hypophosphatasia reflect autosomal recessive inheritance and the childhood and adult forms can, as predicted, be the same entity (Weinstein and Whyte, 1981; Henthorn *et al.,* 1992).

In 1993, Greenberg and coworkers discovered that homozygosity for a 10th TNSALP missense mutation accounts for the high incidence of severe hypophosphatasia in Canadian Mennonites, presumably reflecting a "founder effect" (Greenberg, *et al.,* 1993).

Now, all clinical forms of hypophosphatasia (except pseudohypophosphatasia) have been shown to involve mutations in *TNSALP* that compromise the enzyme's structure (Whyte, 2000). Other gene defects have not been encountered. However, a genetic nosology for hypophosphatasia must currently consider 79 specific *TNSALP* mutations (Mornet *et al.,* 1998) and in the future this classification scheme will likely involve many more (Mumm, *et al.,* 1999), thereby creating significant challenges for phenotype/genotype correlation. Perhaps information from heterozygous carriers of hypophosphatasia concerning the quantitative impact of individual *TNSALP* defects *in vivo* will prove helpful in predicting disease severity (Whyte, 2000). A web site now records *TNSALP* mutations (http://www.sesep.uvsq.fr/Database.html).

TNSALP STRUCTURAL DEFECTS

Many of the 79 different mutations identified to date in hypophosphatasia (Taillander *et al.,* 2001) alter an amino acid residue that is conserved in mammalian TNSALPs (Henthorn and Whyte, 1992; Mornet *et al.,* 1998; Whyte, 2000). In fact, several of the changes are conserved in bacteria (Henthorn *et al.,* 1992).

Revelation of the three-dimensional structure of *Escherichia coli* ALP by X-ray crystallography (Kim and Wyckoff, 1991) has underpinned further progress in our understanding of the biochemical basis for hypophosphatasia (Henthorn *et al.,* 1992; Kim and Wyckoff, 1991). Missense mutations in *TNSALP* can be examined for their impact on dimeric TNSALP [Chemscape Chime version 1.02 by MDL Information Systems, Inc. (San Leandro, CA) at *http://www.mdli.com* and RasWin Molecular Graphics, Windows version 2.6 by Roger Sayle, Glaxo-Wellcome Research and Development (Stevenage, Hertfordshire, UK) at *http://www.umass.edu/microbio/rasmol/index.html*]. Some alterations in *TNSALP* appear to disturb the enzyme's catalytic pocket or structurally important metal ligand binding sites; others could affect dimer formation (Mornet *et al.* 1998). Nevertheless, how all *TNSALP* mutations identified to date are deleterious is far from understood (Whyte, 2000). In fact, site-directed mutagenesis with the Ala^{161}–Thr substitution, first discovered to cause hypophosphatasia (Weiss *et al.,* 1988), does not compromise catalytic activity of *E. coli* ALP (Chaidaroglou and Kantrowitz, 1993). It seems that some mutations alter intracellular movement of TNSALP (Mornet *et al.,* 1998; Shibata *et al.,* 1998; Fukushi *et al.,* 1998).

Treatment

MEDICAL

There is no established medical regimen for hypophosphatasia, although several therapies have been studied (Fraser *et al.,* 1955; Whyte *et al.,* 1982, 1986a). Some patients with infantile hypophosphatasia manifest progressive skeletal demineralization (Whyte *et al.,* 1982b); others show spontaneous improvement (Whyte *et al.,* 1986a).

Hypercalcemia in infantile hypophosphatasia can be treated by restriction of dietary calcium and/or glucocorticoid therapy (Whyte *et al.,* 1982b). However, progressive skeletal demineralization may follow (Whyte *et al.,* 1982b, 1986a). Consequently, subcutaneous injections of salmon calcitonin could be helpful (Barcia *et al.,* 1997).

Hypothetically, treatment with drugs that would stimulate TNSALP biosynthesis or enhance its activity in the skeleton might be beneficial for hypophosphatasia. Administration of cortisone to a few patients with severe disease reportedly was associated with periods of normalization of serum ALP activity and radiographic improvement (Fraser and Laidlaw, 1956), but this has not been a consistent finding (Fraser, 1957). Brief treatment with Mg^{2+}, Zn^{2+}, or an active fragment of PTH to stimulate ALP activity has been unsuccessful. Hypophosphat*asemia* seems to be quite refractory in hypophosphatasia. The author is aware of serum ALP activity remaining subnormal in one patient despite viral hepatitis and in two patients suffering end-stage kidney disease, perhaps with renal osteodystrophy.

Enzyme replacement therapy for hypophosphatasia has been attempted by intravenous infusion of several types of ALP. Generally, the results have been disappointing. In 1972, serum from a patient with Paget bone disease, given by Macpherson and colleagues to an affected infant, was associated with radiographic improvement (Macpherson *et al.,* 1972). However, subsequent trials of this treatment

showed no significant clinical or radiographic benefit for four patients with infantile hypophosphatasia (Whyte *et al.,* 1984). In 1982, intravenous infusions weekly of fresh plasma from healthy subjects was followed by clinical and radiographic advances in one child (Albeggiani and Cataldo, 1982). Furthermore, plasma from several healthy individuals that had been pooled and then administered intravenously was followed by correction of hypophospha*tasemia* and marked temporary clinical, radiographic, and histologic improvement in a boy with the infantile form (Whyte *et al.,* 1986a). However, subsequent trials of combined plasma infusions did not produce this response (Whyte *et al.,* 1988). In follow-up of a brief report in 1989 which suggested that intravenous administration of ALP purified from liver improved the histologic appearance of bone and decreased urinary PEA levels in an infant with hypophosphatasia (Weninger *et al.,* 1989), a vigorous trial was conducted with intravenous infusions of purified placental ALP. Elevated concentrations of PLP in plasma and increased PEA and PP_i levels in urine were found to normalize during the third trimester of pregnancy in women who are hypophospha*tasemic* carriers for hypophosphatasia (Whyte *et al.,* 1995). Accordingly, placental ALP seems to recognize the same substrates as TNSALP; the presence of placental ALP in the circulation, or more likely *in situ,* could reflect a form of "endogenous" enzyme replacement therapy. Nevertheless, when purified placental ALP was infused intravenously into a severely affected infant in repeated doses that caused *hyper*phosphatasemia, there were only modest decrements of plasma PLP and urinary PEA concentrations, no change in urinary PP_i levels, and no clinical or radiographic improvement (Whyte *et al.,* 1992).

These discouraging cumulative observations from attempted ALP replacement therapy may reflect the fact the *tissue* levels of ALP are normally greater than those achieved in the circulation by such treatments. Alternatively, the findings are consistent with a requirement for ALP *in situ* in the skeleton (and/or perhaps bound to a lipid bilayer; e.g., placenta) for physiologic activity (Whyte *et al.,* 1995). In this regard, extreme skeletal disease occurs in perinatal hypophosphatasia despite abundant circulating placental ALP in the mother; here the *in utero* environment is clearly not protective (Whyte, 2001).

There is now 4-year follow-up of one patient with infantile hypophosphatasia which indicates that marrow cell transplantation, especially a stromal cell boost, can treat potentially lethal disease, perhaps by engendering sufficient numbers of TNSALP-replete osteoblasts (Whyte *et al.,* 1998).

Because patients with hypophosphatasia are often hyperphosphatemic, I speculate that dietary P_i restriction and/or P_i binding may be therapeutic by diminishing competitive inhibition of TNSALP by P_i (Coburn *et al.,* 1999) and by inducing TNSALP gene expression (Goseki-Sone *et al.,* 1999).

SUPPORTIVE

Symptoms from CPPD crystal deposition or perhaps periarticular calcium phosphate precipitation ("calcific periarthritis") may respond to nonsteroidal anti-inflammatory agents.

Prognosis

Perinatal hypophosphatasia is almost always a fatal condition. With intensive support, life may be extended for a short time. Rarely, there is long-term survival. Infantile hypophosphatasia has a less certain outcome. Often, there is clinical and radiographic deterioration. Approximately 50% of these patients die from the pneumonia and respiratory compromise that follows worsening skeletal involvement in the chest (Fraser, 1957). The prognosis, however, seems to improve after infancy. Sometimes, there is remarkable spontaneous improvement following a diagnosis of infantile hypophosphatasia. In fact, a preliminary report from Canada (Ish-Shalom *et al.,* 1986) suggests that, in their patient population, the stature of adult survivors of infantile hypophosphatasia may be normal (the author, however, is aware of significant exceptions in the United States) (Whyte, 2001). Childhood hypophosphatasia may also spontaneously improve, but usually after adolescence. Unfortunately, recurrence of symptoms in adulthood is possible, if not likely (Fraser, 1957; Weinstein and Whyte, 1981). Adult hypophosphatasia causes lingering and recurrent orthopedic difficulties following the onset of skeletal symptomatology (Whyte *et al.,* 1982a). Worsening osteomalacia, associated with osteopenia and fractures, can occur in affected women at menopause, but was not prevented by estrogen replacement therapy in two patients (personal observation).

Prenatal Diagnosis

The perinatal form of hypophosphatasia has been diagnosed reliably *in utero.* During the first trimester, chorionic villus samples from 15 pregnancies were assessed using a monoclonal antibody that captures TNSALP for assay of its catalytic activity (Brock and Barron, 1991). During the second trimester, perinatal hypophosphatasia has been diagnosed by ultrasonography (van Dongen *et al.,* 1990), radiographic study, and assay of ALP activity in amniotic fluid cells by an experienced laboratory (Kousseff and Mulivor, 1981). Combined use of these techniques, with preference for serial fetal ultrasonography, was deemed best before DNA-based studies became possible (Henthorn and Whyte, 1995). Indeed, we now know that mild forms of hypophosphatasia can cause *in utero* bowing of the lower extremities detected by ultrasound, suggestive of a potentially lethal form of skeletal dysplasia. Postnatally, the deformity corrects spontaneously and the phenotype is childhood hypophosphatasia (Moore *et al.,* 1999; Pauli *et al.,* 1999).

Currently, *TNSALP* mutation detection is proving especially reliable (Henthorn and Whyte, 1995), including for the infantile form. However, the great number and some variety of specific defects in *TNSALP* complicates the search.

Physiological Role of ALP Explored in Hypophosphatasia

Demonstration by Weiss and colleagues in 1988 that a missense mutation within the TNSALP gene can inactivate this ALP isoenzyme and that homozygosity for the defect causes severe hypophosphatasia (Weiss *et al.,* 1988) provided proof that Robert Robison (Robison, 1923; Robison and Soames, 1924) was correct; i.e., ALP functions importantly in mineralization of the skeleton (Whyte, 1994). Elucidation of the dental manifestations of hypophosphatasia showed that this is also true for dentition. Description of many *TNSALP* structural mutations in all forms of hypophosphatasia (Henthorn *et al.,* 1992; Greenberg *et al.,* 1993; Mornet *et al.,* 1998; Zurutuza, *et al.,* 1999; Whyte, 2000) confirms these physiological roles for TNSALP in man.

Subsequently, *in vitro* models showed that transfection of ALP cDNA conferred both catalysis against P_i esters and mineralization in a calcification system (Farley *et al.,* 1994) (Yoon *et al.,* 1989). In fact, there has been skepticism that this type of experiment accurately reflects biomineralization, because increases in P_i concentration in metastable solutions are expected to precipitate calcium phosphate.

Furthermore, in 1995, Waymire and coworkers described a *tnsalp* "knockout" mouse (Waymire *et al.,* 1995). This murine model manifests a disturbance in vitamin B_6 metabolism that causes lethal seizures. With pyridoxine treatment, the epilepsy is ameliorated and the mice survive long enough to develop skeletal and dental disease. In 1999, Fedde and coworkers demonstrated that this murine model and the *tnsalp* knockout mouse developed by Narisawa and colleagues (Narisawa *et al.,* 1997) recapitulate the infantile form of hypophosphatasia remarkably well (Fedde *et al.,* 1999).

Several specific roles for TNSALP in skeletal formation have been proposed (Table I). Investigation of hypophosphatasia is a "window of opportunity" to explore each function in man. The *tnsalp* knockout mouse compliments and can expand these patient studies. Recently, the mineralization defect was reproduced with osteoblasts in culture lacking TNSALP (Wennberg *et al.,* 2000). The disturbance does not seem to be related to the aberration in vitamin B_6 metabolism (Narisawa *et. al,* 2001).

Electron microscopy of skeletal tissue from severely affected patients indicates that deficient TNSALP activity causes a fundamental disturbance in biomineralization at the very earliest sites of calcification. In 1985, Ornoy and coworkers reported that the process of "primary mineralization" is deranged. Hydroxyapatite crystals were found near, but not within, patient matrix vesicles (Ornoy *et al.,* 1985). However, in 1997, Anderson and colleagues discovered that secondary (extravesicular), not primary, mineralization is deranged (Anderson *et al.,* 1997). There appeared to be a failure of hydroxyapatite crystal growth after matrix vesicles ruptured.

The defects in the dentin and the cementum of teeth seem to be analogous to those in the skeleton (Lundgren *et al.,* 1991). A prominent role for TNSALP during two critical phases of dental biomineralization, initiation, and completion was proposed recently (Hotton *et al.,* 1999).

Although the liver, kidneys, and adrenal glands are normally rich in TNSALP activity (McComb *et al.,* 1979), they are not dysfunctional in hypophosphatasia (*see below*). It has been suggested that TNSALP deficiency might disturb the biosynthesis of phospholipids causing atelectasis, however, the respiratory problems of patients likely reflect rib cage deformities, hypoplastic lungs, etc. (Silver *et al.,* 1988). Accordingly, it may be that TNSALP is critically important in humans only for mineralization of hard tissues (Whyte, 1994). Why patients with severe hypophosphatasia experience idiopathic seizures is not clear, but this complication has not responded to vitamin B_6 treatment. Conversely, the observation of epilepsy in the murine model is significant, because low levels of γ-aminobutyric acid occur in the central nervous system (Waymire *et al.,* 1995) and pyridoxine supplementation is helpful (Fedde *et al.,* 1999).

As reviewed below, discovery that PEA, PLP, and PP_i accumulate endogenously in hypophosphatasia (and are inferred therefore to be natural substrates for TNSALP) has helped elucidate the physiological role of TNSALP in humans.

Phosphoethanolamine

The reports in 1955 by McCance and colleagues (McCance *et al.,* 1955) and Fraser and coworkers (Fraser *et al.,* 1955) that PEA levels are elevated in urine and plasma in hypophosphatasia provided both a useful biochemical marker for this disorder and the first evidence from this inborn error of metabolism for a natural substrate for TNSALP. In 1968, detailed evaluation by Rasmussen of the renal handling of PEA showed that this phosphocompound is excreted when plasma levels are scarcely detectable; i.e., essentially no renal threshold exists for PEA excretion (Rasmussen, 1968).

Although the metabolic origin of PEA is uncertain, it is thought not to be a derivative of phosphatidylethanolamine, i.e., from plasma membrane phospholipid breakdown. The principal source of circulating PEA has been reported to be the liver, which metabolizes PEA to ammonia, acetaldehyde, and P_i in a reaction catalyzed by O-phosphorylethanolamine phospholyase (Gron, 1978). Indeed, in one family with adult hypophosphatasia, urinary levels of PEA correlated inversely with the circulating activity of the liver (but not the bone) isoform of TNSALP (Millan *et al.,* 1980). PEA is now known to be a constituent of the phosphatidylinositol–glycan linkage apparatus (Low and Zilversmit, 1980). Hence, the source of circulating and urinary PEA could be the degradation of this tether for a variety of cell-surface (ecto-) proteins (*vide infra*).

Pyridoxal 5′-Phosphate

Discovery in 1985 that plasma levels of PLP are elevated in hypophosphatasia helped to clarify the physiological role of TNSALP (Whyte *et al.,* 1985). As reviewed in Fig. 6, the

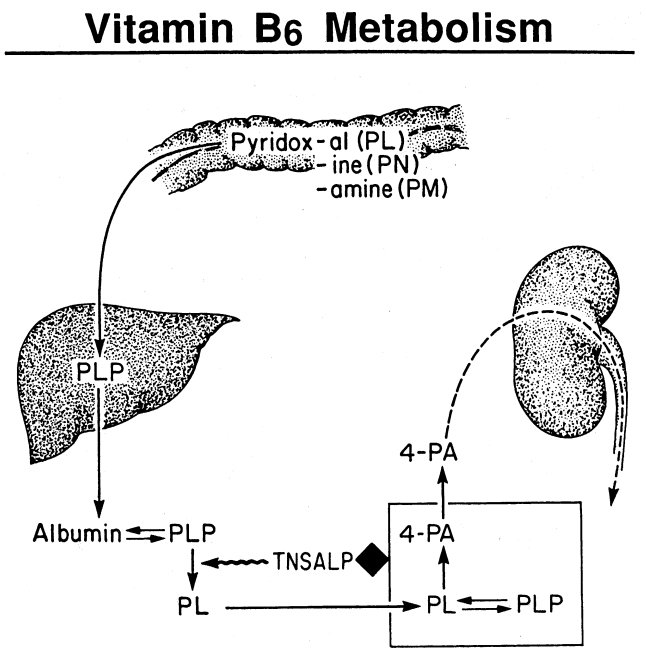

Figure 6 Role of TNSALP in vitamin B_6 metabolism. The various vitameric forms of vitamin B_6 in the diet are absorbed into the hepatic portal circulation (phosphorylated forms are first dephosphorylated in the gut). In the liver, they are converted to PLP, which is secreted bound to albumin into the plasma. Before entering tissues, plasma PLP must be dephosphorylated to PL which can traverse membranes. 4-Pyridoxic acid (4-PA), the major degradation product of vitamin B_6, is excreted in the urine. High plasma levels of PLP in hypophosphatasia, yet normal plasma concentrations of PL, are consistent with an ectoenzyme role for TNSALP in the extracellular dephosphorylatin of PLP to PL. [Reproduced with permission from Whyte, M. P. Hypophosphatasia. *In* "The Metabolic and Molecular Bases of Inherited Disease" (C. R. Scriver, A. L. Beaudet, W. S. Sly, and D. Valle, eds.), 2001, 8th ed., pp. 5313–5329. McGraw-Hill, New York.]

dietary forms of vitamin B_6 (pyridoxine, pyridoxal, and pyridoxamine and their phosphorylated derivatives) are converted to PLP in the liver (Dolphin *et al.,* 1986). Organ ablation studies indicate that the liver is the principal source of plasma PLP in mammals. PLP is released from hepatocytes into the circulation where $>95\%$ is coupled to albumin (Dolphin *et al.,* 1986). Some additional PLP in plasma is bound to various enzymes; only a small amount of PLP circulates freely.

Similar to many phosphorylated compounds, PLP cannot cross plasma membranes, but first must be dephosphorylated to pyridoxal (PL) before it can enter tissues. Inside cells, PL is rephosphorylated to PLP or converted to pyridoxamine 5′-phosphate. These phosphocompounds act intracellularly as cofactors for a considerable variety of enzymatic reactions. Ultimately, vitamin B_6 is degraded to a 4-pyridoxic acid, primarily in the liver, and is then excreted into the urine (Dolphin *et al.,* 1986; Coburn *et al.,* 2001).

In disorders characterized by elevations in circulating bone and liver TNSALP activity, plasma PLP concentrations are decreased (Anderson *et al.,* 1980). The diminished plasma PLP levels have been attributed to vitamin B_6 deficiency. However, the discovery of elevated plasma levels of PLP in hypophosphatasia explains the reciprocal relationship between PLP concentrations and TNSALP activity. Importantly, hypophosphatasia indicates that such changes may not be physiologically significant because TNSALP acts on extracellular, not intracellular, dephosphorylation of PLP. Cell membranes are impermeable to PLP. The elevated plasma level of PLP in hypophosphatasia does not seem to reflect enhanced PLP synthesis, but failure of PLP hydrolysis outside cells (Whyte *et al.,* 1985). Accordingly, TNSALP (known to be associated with plasma membranes) seems to function as an ectoenzyme (Fedde *et al.,* 1988). Consonant with this conclusion is the observation that patients with hypophosphatasia typically do not have symptoms of vitamin B_6 excess. Peripheral neuropathy, a complication of vitamin B_6 toxicity (Dolphin *et al.,* 1986), is not a feature of this disorder (*see below*). Similarly in hypophosphatasia, there does not seem to be deficiency of vitamin B_6. Stomatitis, dermatitis, peripheral neuritis, anemia, or depression—clinical hallmarks of vitamin B_6 deficiency (Dolphin *et al.,* 1986)—are not characteristics. Furthermore, a variety of biochemical findings indicate that intracellular levels of vitamin B_6 are normal in hypophosphatasia. First, urinary concentrations of 4-pyridoxic acid were unremarkable in all of four patients examined with the childhood form of the disease (Whyte *et al.,* 1988). Second, children with hypophosphatasia respond normally to L-tryptophan loading—a test for vitamin B_6 deficiency (Whyte and Coburn, unpublished observation). Third, in homogenates of TNSALP-deficient fibroblasts obtained from patients with infantile hypophosphatasia, the levels of PLP and the total amount of the various other forms of vitamin B_6 are the same as in controls (Whyte *et al.,* 1986b). Finally, tissues obtained at necropsy from three perinatal cases of hypophosphatasia (plasma PLP concentrations 50- to 900-fold elevated) contained essentially normal levels of PLP, PL, and total vitameric B_6 (Whyte *et al.,* 1988).

Because TNSALP seems to condition dephosphorylation of PLP to PL extracellularly, plasma levels of PL could be low in hypophosphatasia. However, patients with hypophosphatasia usually have normal or somewhat supranormal plasma PL levels (Whyte *et al.,* 1985). Whether extracellular levels of PL are intrinsically normal, or there is sufficient extracellular dephosphorylation of excess PLP to PL to account for the normal vitamin B_6 status, is uncertain.

Of note, vitamin B_6 deficiency has been associated with renal stone disease and epilepsy. Nephrocalcinosis in infants with hypophosphatasia is likely due to hypercalciuria. However, the possibility of altered oxalate metabolism (a consequence of vitamin B_6 deficiency) has not been studied (Dolphin *et al.,* 1986). The epilepsy of severely affected patients may be related to cranial deformity, hemorrhage, periodic apnea, etc. Of interest, however, PEA seemed to cause seizures when given intravenously to a severely affected infant during a study of PEA metabolism (Takahashi *et al.,* 1984). In two patients with perinatal hypophosphatasia and epilepsy, both of whom had plasma PL levels below assay sensitivity, administration of vitamin B_6 as pyridoxine did

not correct the seizure disorder (personal observation). The *tnsalp* knockout mouse model for hypophosphatasia, however, manifests seizures that respond to pyridoxine administration (Waymire *et al.,* 1995; Fedde *et al.,* 1999).

The clinical and biochemical observations concerning vitamin B_6 metabolism in hypophosphatasia indicate an ectoenzyme role for TNSALP (Whyte *et al.,* 1985). Characterization of liver ALP as a plasma membrane-bound glycoprotein, covalently linked to the polar head group of phosphatidylinositol–glycan anchors, is consistent with this hypothesis (Low and Saltiel, 1988). In fact, Fedde and coworkers used cultivated human osteosarcoma cells (Fedde *et al.,* 1988) and dermal fibroblasts from patients with infantile hypophosphatasia (Fedde *et al.,* 1990) exposed to PLP and PEA in the medium to demonstrate that TNSALP is primarily plasma membrane-associated with ectotopography (see below).

Inorganic Pyrophosphate

The discoveries of Russell and colleagues in 1965 and 1971 that PP_i levels are increased in patient urine (Russell, 1965) and plasma (Russell *et al.,* 1971) constitute a tenable explanation for the disordered calcium metabolism and defective skeletal mineralization in hypophosphatasia (Caswell *et al.,* 1991). At low concentrations, PP_i can enhance calcium and P_i precipitation from solution to form amorphous calcium phosphate yet PP_i can prevent transformation of such precipitate to hydroxyapatite crystals. Additionally, absorption of PP_i to hydroxyapatite crystals will impair their growth and dissolution (Caswell *et al.,* 1991).

Caswell and coworkers, using cultivated TNSALP-deficient fibroblasts from perinatal and infantile patients, demonstrated that nucleoside triphosphate pyrophosphatase (NTP-PP_i-ase) activity is unremarkable in hypophosphatasia. Generation of PP_i extracellularly from ATP by these cells is normal (Caswell *et al.,* 1986). Consequently, NTP-PP_i-ase seems to be different from TNSALP. This conclusion is supported by recent studies of osteoblasts from the *tnsalp* knockout mouse (Johnson *et al.,* 2000). Conversely, the clearance of $^{32}PP_i$ administered into the circulation of two adults with hypophosphatasia was markedly delayed, supporting the hypothesis that endogenous accumulation of PP_i reflects defective degradation of PP_i (Caswell *et al.,* 1991).

Consonant with the *in vitro* effects of PP_i, several disturbances of mineralization are observed in hypophosphatasia that probably reflect local concentrations of PP_i together with other factors. Low concentrations of PP_i cause precipitation of amorphous calcium phosphate and may explain the associated calcific periarthritis (Lassere and Jones, 1990). Furthermore, ALP has been shown to dissolve CPPD crystals *in vitro* (Xu *et al.,* 1991). This PP_i-ase activity seems to be unrelated to its capacity to hydrolyze phosphoesters. Thus, CPPD crystal deposition leading to chondrocalcinosis, pseudogout, and pyrophosphate arthropathy would be explained by failure of TNSALP not only to destroy PP_i but to hydrolyze CPPD crystals as well. High concentrations of PP_i inhibit hydroxyapatite crystal formation and growth; rickets or osteomalacia would be the cardinal clinical feature. As discussed, electron microscopy of bone shows aberrations in secondary mineralization of skeletal tissue surrounding matrix vesicles (Anderson *et al.,* 1997).

Circulating TNSALP

Several observations suggest that ALP in the circulation is physiologically inactive (Whyte *et al.,* 1982b). Among the most compelling evidence is the observation that infants with hypophosphatasia who received intravenous infusions of plasma from patients with Paget bone disease, or who were given purified placental ALP (engendering elevated serum ALP levels), demonstrated no clinical or radiographic improvement. In fact, such therapy failed to normalize urinary PEA or PP_i levels or plasma PLP concentrations (Whyte *et al.,* 1982b). Hence, deficiency of TNSALP activity intrinsic to the skeleton seems to account for the rickets and osteomalacia of hypophosphatasia. In fact, in studies reminiscent of Robison's work, Fraser and Yendt reported in 1955 that rachitic rat cartilage would calcify in serum obtained from an infant with hypophosphatasia, yet slices of the patient's costochondral junction would not mineralize in synthetic calcifying medium or in the pooled serum from healthy children (Fraser and Yendt, 1955). Although this observation appears to support an *in situ* role for TNSALP, such models have been criticized as merely reflecting P_i liberation followed by mineral precipitation (Khouja *et al.,* 1990). Experience with marrow cell transplantation for one patient with infantile hypophosphatasia, who had clinical and radiographic improvement despite unaltered biochemical abnormalities, suggests that even small increases in ALP activity within the skeleton can improve mineralization in hypophosphatasia (Whyte *et al.,* 1998). In fact, transfection studies indicate that small differences in ALP activity reflecting various *TNSALP* mutations can account for lethal versus nonlethal hypophosphatasia (Mornet *et al.,* 1998).

Hypophosphatasia Fibroblast Studies

Much of our insight concerning the physiologic role of TNSALP has come from investigation of *patients* with hypophosphatasia. Although dermal fibroblasts are not rich in ALP activity (Fedde *et al.,* 1990; Whyte and Vrabel, 1985; Whyte *et al.,* 1986b), these cells express some TNSALP-like activity which peaks at confluence in culture (Whyte and Vrabel, 1987). Hypophosphatasia fibroblasts in monolayer obtained from severely affected patients are profoundly deficient ($< 5\%$ control) in ALP activity (Whyte *et al.,* 1983). What ALP activity is present seems to be a form of TNSALP (Whyte *et al.,* 1987).

Preliminary studies using patient fibroblasts indicate that phospholipid composition and rates of $^{32}P_i$ accumulation are normal (Tsutsumi *et al.,* 1986; Whyte and Vrabel, 1983). In 1990, Fedde and colleagues demonstrated that TNSALP is present primarily at the surface of these cells (Fedde *et al.,* 1990). The ectophosphatase activity hydrolyzes extracellular PEA and PLP (Fedde *et al.,* 1990). Although some reports suggest that ALP conditions cell growth and differentiation by influencing the phosphorylation of nucleotide pools, hypophosphatasia fibroblasts proliferate at normal rates (Whyte *et al.,* 1983). Furthermore, TNSALP does not seem to be a phosphoprotein phosphatase at plasma membranes (Fedde *et al.,* 1993).

Hypophosphatasia as a Model for TNSALP Function

Observations from hypophosphatasia indicate how TNSALP might act physiologically in man (Fig. 7): (1) Increased endogenous levels of PEA, PP_i, and PLP indicate that TNSALP is catalytically active toward a variety of substrates with fairly variable chemical structure and can act not only as a phosphomonoester phosphohydrolase but also as an inorganic pyrophosphatase (Fig. 7). (2) Because in healthy individuals the putative natural substrates for TNSALP (PEA, PP_i, and PLP) occur in extracellular fluid at nanomolar or micromolar concentrations, TNSALP must act at levels of these compounds that are much lower than the millimolar concentrations of artificial substrates used in routine clinical assays. (3) Clearly, TNSALP must function at physiologic pH. Accordingly, the term "alkaline phosphatase" is a misnomer. (4) Clinical and biochemical investigations of vitamin B_6 metabolism, supported by cell culture studies, reveal that TNSALP acts primarily as an ectoenzyme. Extracellular accumulation of PEA, PP_i, and PLP is a consequence of deficient ecto-TNSALP activity. Increments of membrane-impermeable PLP in plasma, but not in tissues, explains the absence of vitamin B_6 deficiency or toxicity. (5) The origin of plasma PLP appears to be the liver. The source of PEA is unclear, but excesses might reflect incomplete degradation of the phosphatidylinositol–glycan moiety that anchors proteins to cells surfaces. PP_i is formed extracellularly by a separate enzyme, NTP-PP_i-ase. (6) Calcium *phosphate* crystal deposition causes calcific periarthritis and calcium *pyrophosphate* dihydrate crystal formation results in chondrocalcinosis, pseudogout, and/or pyrophosphate arthropathy. Calcific periarthritis reflects the regional effect of PP_i at low concentrations to stimulate amorphous calcium phosphate formation. Rickets and osteomalacia reflect the effect of high extracellular concentrations of PP_i to inhibit hydroxyapatite crystal formation and growth at sites of mineralization. (7) Failure of enzyme replacement therapy by intravenous infusion of various forms of ALP indicates that TNSALP is physiologically active in tissues, but not in the circulation.

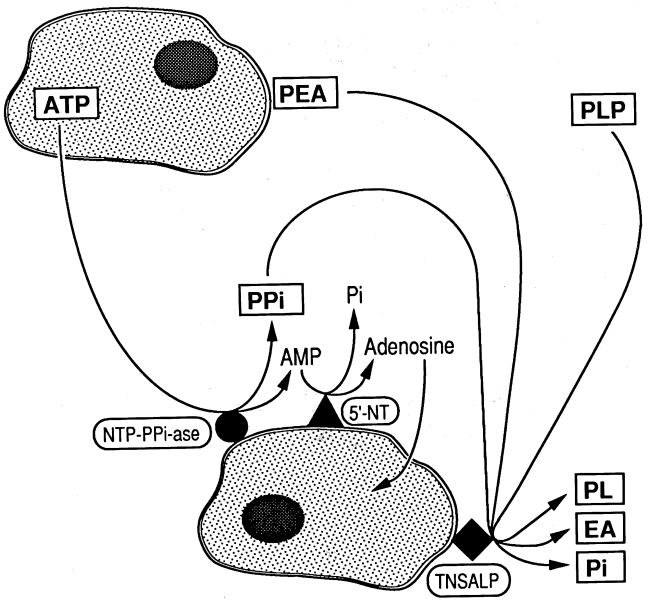

Figure 7 Metabolic basis for hypophosphatasia (hypothesis). Extracellular generation of PPi, presumably by the action of nucleoside triphosphate pyrophosphatase (NTP-PP_i-ase), is normal in hypophosphatasia, but extracellular degradation of PEA, PP_i, and PLP is diminished because of deficient ecto-TNSALP activity. Accumulation of PP_i extracellularly accounts for the CPPD precipitation and associated calcium phosphate crystal deposition. The inhibitory effect of PP_i on hydroxyapatite crystal growth accounts for the rickets/osteomalacia. [Reproduced with permission from Whyte, M. P. Hypophosphatasia. *In* "The Metabolic and Molecular Bases of Inherited Disease" (C. R. Scriver, A. L. Beaudet, W. S. Sly, and D. Valle, eds.), 2001, 8th ed., pp. 5313–5329. McGraw-Hill, New York.]

Conclusions

Hypophosphatasia is a rare but remarkably instructive inborn error of metabolism that establishes a critical role for ALP in mineralization of the skeleton and formation of the dentition in humans. Subnormal serum ALP activity (hypophosphat*asemia*), the biochemical hallmark, reflects a generalized deficiency of activity of the tissue-*nonspecific* ("liver / bone / kidney") ALP isoenzyme (TNSALP). Activities of the three tissue-specific ALP isoenzymes in humans—intestinal, placental, and germ cell (placental-like) ALP—are not diminished.

Hypophosphatasia is characterized clinically by defective skeletal mineralization that manifests as rickets in infants and children and osteomalacia in adults. Clinical expressivity is, however, extremely variable. Stillbirth can occur from *in utero* onset in the perinatal form, which is apparent in newborns and is associated with the most severe skeletal hypomineralization and deformity as well as epilepsy in some patients. The infantile form presents as through a developmental disorder by age 6 months. It can cause craniosynostosis and nephrocalcinosis from hypercalcemia and hypercalciuria and is often fatal due to worsening rachitic disease. Premature loss of deciduous teeth, rickets, and muscle weakness are the cardinal clinical features of childhood hypophosphatasia. Adult hypophosphatasia typically results in

recurrent metatarsal stress fractures and pseudofractures in long bones of the lower limbs and occasionally manifests with arthritis from CPPD crystal deposition and rarely with calcific periarthritis from precipitation of calcium phosphate. Odontohypophosphatasia refers to especially mild disease with dental but no skeletal manifestations. Pseudohypophosphatasia is an extremely rare variant that resembles infantile hypophosphatasia except that serum ALP activity is normal in routine clinical assays.

Perinatal and infantile hypophosphatasia are transmitted as autosomal recessive traits and can be due to homozygosity or compound heterozygosity for a great number of different mutations in *TNSALP* that affect the structure of the encoded enzyme. Most are missense mutations. Individuals with even the mildest forms of hypophosphatasia can also be compound heterozygotes for *TNSALP* defects. In some kindreds, however, mild disease is transmitted as an autosomal dominant trait.

There is no established medical treatment for hypophosphatasia. Enzyme replacement therapy by intravenous infusion of ALP from various tissues has generally been disappointing, suggesting that circulating TNSALP is physiologically inactive. Marrow cell transplantation has been followed by considerable clinical and radiographic improvement, without biochemical changes, in one severely affected infant.

Prenatal diagnosis of *perinatal* hypophosphatasia has been successful. During the second trimester of pregnancy, assay of ALP activity in amniotic fluid cells, as well as fetal ultrasonography or radiography have proven helpful. During the first trimester, chorionic villus samples have been used for quantitation of TNSALP activity. Now, molecular studies of *TNSALP* are available, but must deal with a considerable number of different *TNSALP* mutations.

Three phosphocompounds [phosphoethanolamine (PEA), inorganic pyrophosphate (PP_i), and pyridoxal 5′-phosphate (PLP)] accumulate endogenously in hypophosphatasia and are inferred to be natural substrates for TNSALP. Preliminary studies using ^{31}P-NMR spectroscopy indicate that there are at least several more, but their identities have not yet been characterized. A variety of evidence shows that PLP, a cofactor form of vitamin B_6, collects extracellularly; intracellular levels of PLP are normal. This observation explains the absence of symptoms of deficiency or toxicity of vitamin B_6 and indicates that TNSALP functions as an ectoenzyme. Extracellular accumulation of PP_i, which at low concentrations promotes calcium phosphate deposition yet at high concentrations acts as an inhibitor of hydroxyapatite crystal growth, seems to explain the associated calcific periarthritis as well as the CPPD crystal deposition and defective mineralization of bones and teeth.

Acknowledgments

I am grateful to the staff of the Center for Metabolic Bone Disease and Molecular Research, Shriners Hospitals for Children, St. Louis, Missouri, for making this chapter possible. My colleague, Steven Mumm, Ph.D., is making important contributions to our understanding of the molecular basis of hypophosphatasia. Becky Whitener, CPS, provided expert secretarial help. This work was supported by Grant 8580 from the Shriners Hospitals for Children and The Clark and Mildred Cox Inherited Metabolic Bone Disease Research Fund.

CHAPTER 71

Paget's Disease of Bone

Frederick R. Singer
John Wayne Cancer Institute, Saint John's Health Center, Santa Monica, California 90404

G. David Roodman
Department of Medicine, Division of Hematology, University of Texas Health Science Center, and Audie Murphy Memorial Veterans Hospital, San Antonio, Texas 78284

The Patient

Paget's disease is a common disorder of the skeleton that is local in nature and extremely variable in its clinical manifestations (Singer and Krane, 1998). The majority of patients are without symptoms. When symptoms are present, skeletal deformity and pain are most common. Deformities are usually most apparent in the skull, face, and lower extremities. Pain is of several origins. Localized bone pain is surprisingly uncommon, but joint pain (hips and knees) is seen not infrequently due to degenerative arthritis. Pain of neural or spinal origin is unusual but the most severe.

A variety of complications may first bring the patient to medical attention. The complications depend both on the affected skeletal sites and the overall extent of the disease (six bones are commonly involved). Patients with Paget's disease in the skull often develop a hearing deficit if the temporal bone is affected. Massive enlargement of the cranium is associated with basilar impression and neurological impairment. Vertebral involvement may produce compression fractures, spinal stenosis, neurological impairment, and degenerative arthritis. Paget's disease in the pelvis and femurs commonly is associated with degenerative arthritis of the hips. Involvement of the femur and tibia may lead to pathological fractures of these long bones. Nonunion of a femoral fracture is relatively common. Degenerative arthritis in the knees is also a common feature when lower extremity long bones are extensively involved by Paget's disease. The most serious complication is the development of a sarcoma that fortunately occurs in only $<1\%$ of patients. It always arises in a pagetic lesion and not in unaffected bone. Systemic complications of Paget's disease generally occur with more extensive disease. Hypercalcemia, preceded by hypercalcuria, usually is noted with total bed rest and is related to the accelerated bone resorption induced by immobilization. Increased cardiac output, and less commonly, congestive heart failure, are a consequence of the great vascularity of bones affected by Paget's disease. Hyperuricemia has been observed in males with extensive disease and may reflect increased purine turnover.

Recent evidence suggests that Paget's disease occurs much more commonly in families than was previously reported. An extensive investigation of the relatives of 35 patients with Paget's disease in Madrid revealed that 40% of the patients had at least one first-degree relative with the disease (Morales-Piga *et al.,* 1995). All studies of familial Paget's disease suggest an autosomal dominant inheritance. There is considerable evidence for a predisposition gene on the long arm of chromosome 18 (Cody *et al.,* 1997; Haslam *et al.,* 1998). There is also evidence for genetic heterogeneity in that a majority of families with Paget's disease do not show linkage of the disease to markers on chromosome 18 (Hocking *et al.,* 2000). As yet, no predisposition gene has been identified in familial Paget's disease, but families with a rare variant of Paget's disease (Osterberg *et al.,* 1988) exhibit mutations in the gene coding receptor activator of nuclear factor-κ B (RANK) (Hughes *et al.,* 2000). This gene is located on 18*q* in the same region as the predisposition gene for Paget's disease, but mutations in the RANK gene have not been reported in patients with familial or sporadic Paget's disease.

Radiology and Nuclear Medicine

The diagnosis of Paget's disease is primarily accomplished by roentgenographic evaluation of the skeleton. Over the years it has become clear that the disease evolves through several stages as observed by serial roentgenograms.

The initial stage of the disease is represented by a localized area of reduced bone density often referred to as an osteolytic lesion. This is most readily detected in the skull where it is found as a discrete round or oval lesion in the frontal or occipital bones. It is called *osteoporosis circumscripta.* Paget's disease in the long bones almost always begins in the subchondral region of either epiphysis (uncommonly both may be affected simultaneously). The osteolytic process has then been seen to advance proximally or distally at ~1 cm/year in the untreated patient. The advancing front usually has a V-shaped or arrowhead appearance.

In the most advanced stage of Paget's disease, the areas of previous osteolytic dominance now are characterized by a chaotic sclerotic appearance, a phase that is called osteoblastic or osteosclerotic. In long bones the osteolytic phase is commonly seen preceding the osteosclerotic region when much of the bone has been affected by the disease. Another feature of this phase is considerable thickening of the sclerotic bone, which can reach monumental proportions in the skull. Osteolytic activity of a secondary nature often can be observed as clefts in the thickened bone. It is likely that the evolution of the disease into its most severe form occurs over much of the life span of the patient. Two other features of the disease have been noted through serial roentgenographic observations. Although the disease can slowly course through an entire bone, it does not cross a joint space to affect an adjacent bone. Also it is extremely rare for new lesions of Paget's disease to be detected at any site in the skeleton after the diagnosis and extent of the disease has been determined initially.

Bone scans are the most sensitive means of detecting pagetic lesions. Radiolabeled bisphosphonates accumulate in regions where blood flow and bone formation are increased and can outline early lesions that are not detectable on roentgenograms. Radioactive gallium can also define areas of Paget's disease activity because of uptake of gallium by osteoclasts.

Histopathology

Beginning with the observations of Schmorl in 1932, it has become appreciated that the osteoclast is the dominant cell in the pathogenesis of Paget's disease. Osteoclasts are increased in number in the Haversian canals of the cortex in the absence of other abnormalities and are in great number at the leading edge of the osteolytic front. The osteoclasts in Paget's disease may be far greater in size than osteoclasts in normal bone and contain as many as 100 nuclei in a cross section as compared with two or three nuclei in a normal osteoclast. Osteoclasts of Paget's disease have a characteristic ultrastructural abnormality (Gherardi *et al.,* 1980; Howatson and Fornasier, 1982; Mills and Singer, 1976; Rebel *et al.,* 1974). This consists of microfilaments, sometimes grouped in a paracrystalline array, located in the nucleus and sometimes in the cytoplasm of osteoclasts (Fig. 1). These microfilaments are not seen in nonpagetic bone or bone marrow cells. These inclusions closely

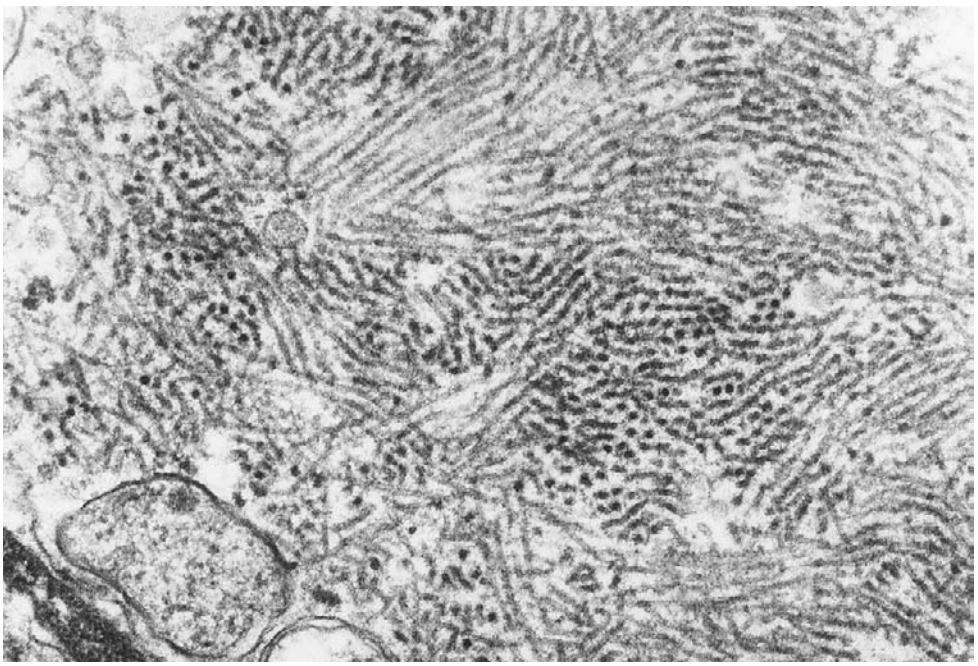

Figure 1 Electron micrograph of a nuclear inclusion in an osteoclast of a patient with Paget's disease. The microfilaments are seen both in longitudinal array and in paracrystalline array in cross section. Provided by Dr. Barbara G. Mills.

resemble nucleocapsids of viruses of the Paramyxoviridae family, a group of RNA viruses responsible for some of the most common childhood diseases. Despite the finding of these inclusions in the vast majority of patients studied, the budding off of an infectious virus from the osteoclasts has rarely been observed (Abe *et al.,* 1995).

Osteoblasts are another prominent feature of the cellular pathology of Paget's disease. Large numbers of osteoblasts are often found near areas of resorbed bone and may even be prominent in a lesion that appears purely osteolytic by X-ray. The osteoblasts are usually prism-shaped or polyhedral and contain abundant rough endoplasmic reticulum, mitochondria, and a well-developed Golgi zone. These signs of cellular activity are consistent with the increased bone formation in active lesions established by the use of double labeling with tetracycline.

In addition to the increased numbers of osteoclasts and osteoblasts, the marrow of pagetic lesions tends to be grossly abnormal. The normal hematopoietic elements are usually absent and replaced by mononuclear cells of indeterminate origin intermixed with highly vascular connective tissue.

The bone matrix in Paget's disease is highly abnormal in structure and arises as a consequence of disordered bone resorption and formation. The matrix consists of a "mosaic" of irregularly shaped pieces of lamellar bone with an erratic pattern of cement lines. The matrix is interspersed with numerous foci of woven bone, which, in adults, is ordinarily found associated with fracture healing.

Biochemistry

The biochemical findings in Paget's disease help to provide an integrated assessment of the cellular events occurring throughout the skeleton of affected patients.

Historically, the earliest index of bone matrix resorption was measurement of urinary hydroxyproline excretion while ingesting a low-gelatin diet. This index is well correlated with the extent of the disease despite the fact that hydroxyproline is a prominent component of extraskeletal connective tissue as well as skeletal collagen. Measurement of collagen cross-link degradation products in urine provides more specific measurements of skeletal matrix. Urinary *N*-telopeptide, pyridinoline, and deoxypyridinoline have all been reported to be more specific indices of skeletal matrix resorption and are not influenced by dietary gelatin (Alvarez *et al.,* 1995; *Garnero et al.,* 1994).

Serum tartrate-resistant acid phosphatase, presumably released by osteoclasts, appears to be another index of bone resorption in Paget's disease but is not routinely available (Kraenzlin *et al.,* 1990).

Osteoblast activity can be assessed by measurement in the serum of total alkaline phosphatase activity, bone-specific alkaline phosphatase activity, osteocalcin concentration, and type 1 carboxy-terminal procollagen peptide concentration. The most useful of these serum markers are the total alkaline phosphatase and bone-specific alkaline phosphatase (Alvarez *et al.,* 1995; Garnero and Delmas, 1993). For reasons that are not understood, serum osteocalcin is a poor index of disease activity; similarly, the type I carboxy-terminal procollagen assay is insensitive to increases in bone turnover and does not change reproducibly as the disease is suppressed by medical therapy.

Therapy

Salmon calcitonin by injection and etidronate disodium by the oral route are both effective medications for Paget's disease. They have been in use for ~20 years. They generally suppress biochemical parameters of the disease by 50%. Intravenous pamidronate disodium, oral alendronate, and risedronate sodium are more recent, more potent bisphosphonates that can reduce bone turnover to normal in the majority of patients with Paget's disease (Singer and Krane, 1998).

Surgery is sometimes used in Paget's disease in patients with associated degenerative arthritis of the hip (total hip replacement) and of the knee (high tibial osteotomy). Orthopedic and/or neurosurgical procedures may occasionally be necessary after fractures and when skull or vertebral complications are present.

Evidence for the Presence of Paramyxoviruses in Paget's Disease

In early studies, Mills and colleagues attempted to rescue an infectious virus from cells cultured from surgical specimens of Paget's disease (Mills and Singer, unpublished observations; Mills *et al.,* 1979). After trypsinization or after growing cells from explants of pagetic bones, cells were cultivated for months and then cocultivated with cell lines used to isolate Paramyxoviridae viruses. These studies failed to demonstrate an infectious virus in pagetic bone. Perhaps this is not surprising since little anatomic evidence of an infectious virus has been found in any specimen of Paget's disease, and the mononuclear cells cultured from surgical specimens rarely were found to exhibit nuclear inclusions. Mills and colleagues (1985) also attempted to develop an animal model of Paget's disease by injecting crushed bone extracts or lysates from cells cultured from pagetic bone into the tibiae of athymic nude mice. Nothing resembling Paget's disease was induced in the mouse bone, although one cell line did produce an osteosarcoma-like lesion reproducibly.

Despite the failure to find an infectious (mature) virus in specimens of Paget's disease, abundant evidence has been generated using immunohistological and molecular biological techniques that indicate the presence of viral antigens and mRNA in Paget's disease. Initially Rebel and colleagues (1980a) used a variety of antisera directed against measles virus to demonstrate measles antigen in the osteoclasts of 20 patients with Paget's disease, but not in one patient with fluorosis and another with a healing fracture. Positive results

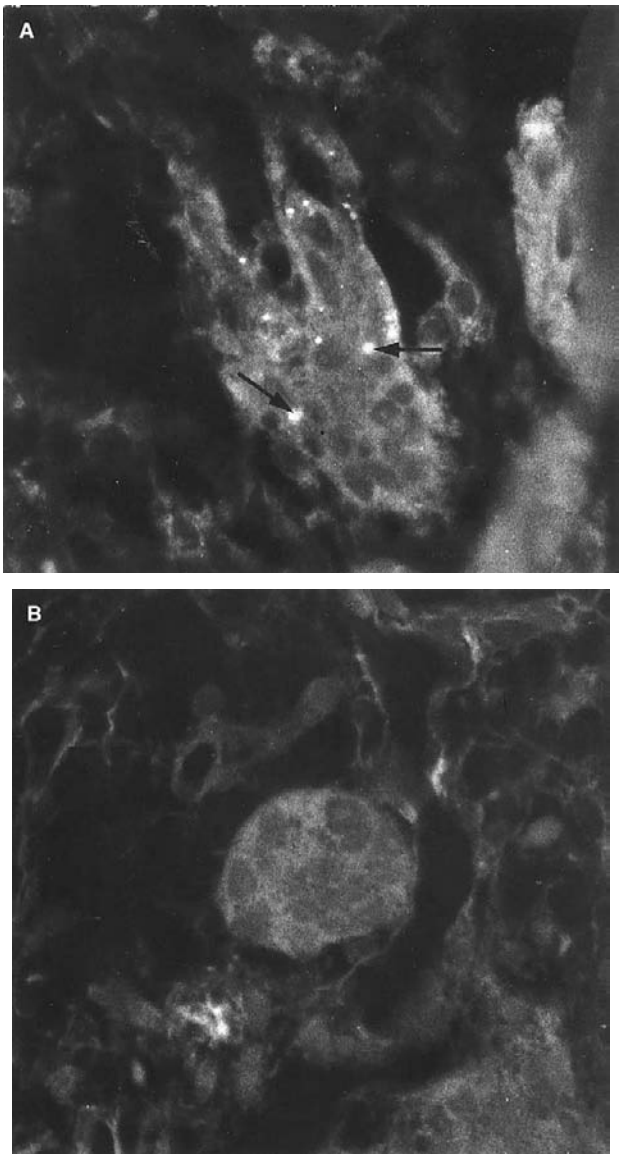

Figure 2 (A) A section of decalcified pagetic bone incubated with rabbit anti-LEC serum followed by goal antiserum coupled to fluorescein isothiocyanate. The LEC strain of measles virus was isolated from a patient with SSPE. The osteoclast shows a strong positive punctate (arrows) fluorescent reaction. (B) A section of decalcified pagetic bone was treated as in (A) except nonimmune rabbit serum was used instead of anti-LEC serum. There is no fluorescent reaction. Reproduced with permission from Rebel *et al.,* 1980b.

were obtained with both indirect immunofluorescence (Fig. 2) and immunoperoxidase techniques (Rebel *et al.,* 1980b). Mills and colleagues (1980, 1981) initially reported that cell cultures from pagetic bone, as well as bone sections from 12 patients, were positive when stained with an antiserum against respiratory syncytial virus but not with antisera against measles virus, parainfluenza viruses, influenza A and B, rubella, mumps, and herpes simplex. Subsequently, Mills and colleagues (1984) did observe that measles virus nucleocapsid protein antigens were present in the osteoclasts and/or cultured bone cells of most patients with Paget's disease. Of particular interest was their finding that in serial sections of pagetic bone, both measles virus and respiratory syncytial virus nucleocapsid antigens were demonstrable in the same osteoclasts. This observation could not be explained by cross-reactivity of the measles virus monoclonal antibodies used in this study with respiratory syncytial virus antigens and vice versa. In other immunohistological studies, Basle and colleagues (1985) demonstrated not only measles virus antigens in 6 of 6 specimens of Paget's disease but also simian virus 5 in 6 of 6 and parainfluenza 3 in 3 of 6. No reactivity with respiratory syncytial virus, mumps virus, influenza virus, or adenovirus type 5 antibodies was found in this study. Subsequently, Basle did find a positive response with a monoclonal antibody against respiratory syncytial virus provided by Mills (pers. commun.). He also noted the presence of measles virus and respiratory syncytial virus antigens in the same osteoclasts on serial sections of pagetic bone. Recently Mills and colleagues (1994) have studied immunohistological staining of long-term cultures of marrow from patients with Paget's disease and from normal subjects with respect to viral antigens. In 12 of 12 patients, measles virus and/or respiratory syncytial virus nucleocapsid antigens were found in 40–50% of the mononuclear cells and/or multinucleated cells in culture. In the control subjects, $< 5\%$ of cells were positive. Reddy and colleagues (1995) found measles virus transcripts in peripheral blood mononuclear cells in 4 of 5 patients and 0 of 10 normal subjects.

In the past 15 years, the techniques of molecular biology have increasingly been applied to the issue of the identity of the osteoclast inclusions of Paget's disease. In the first study, Basle and colleagues (1986) used *in situ* hybridization with a cloned measles virus cDNA probe specific for the nucleocapsid protein to search for measles virus RNA sequences in the bone of five patients. These sequences were detected in 80–90% of the osteoclasts in these specimens. Surprisingly, 30–40% of the mononuclear cells in these bone specimens also had detectable mRNA sequences of measles virus nucleocapsid protein. Evidence of the measles virus was found in osteoblasts, osteocytes, fibroblasts, lymphocytes, and monocytes. Negative results were obtained in three subjects who had fluorosis, fracture healing, and hyperparathyroidism, respectively.

Because an epidemiological study in England indicated that patients with Paget's disease were more likely to have had a pet dog in the past (O'Driscoll and Anderson, 1985), Gordon and colleagues (1991) used *in situ* hybridization to examine the possibility that canine distemper virus might be involved in Paget's disease. Canine distemper virus is a paramyxovirus with considerable structural homology to measles virus. Bone biopsies from 27 patients and 6 patients with other bone disorders (primary hyperparathyroidism, prostatic carcinoma, osteoporosis, osteomalacia, and fracture healing) were studied. Sense and antisense RNA probes to the nucleocapsid and fusion genes of the canine distemper virus were used as well as RNA probes to mRNA sequences of measles virus nucleocapsid protein. There was no demonstrable cross-reactivity of these probes with the heterologous

virus under the experimental conditions used by the investigators. Eleven of 25 patients showed hybridization with the antisense but not the sense canine distemper virus fusion protein probe. Ten of 26 patients also showed hybridization with the antisense but not the sense probe for canine distemper virus nucleocapsid protein. The canine distemper virus probes produced hybridization in 80% of multinucleated osteoclasts, 60% of osteoblasts, and in osteocytes as well as marrow mononuclear cells (monocytes, lymphocytes). No significant hybridization was found with the measles virus probe, and none of the control specimens reacted with any of the above probes. In a subsequent study, Gordon and colleagues (1992) obtained pagetic bone for RNA extraction, reverse transcribed the RNA, and specifically amplified for canine distemper virus and measles virus sequences using the polymerase chain reaction (PCR) technique. They found that 8 of 13 patients had canine distemper virus nucleic acid sequences, and 1 of 10 patients had measles virus nucleic acid sequences in the bone specimens. One patient had both. Dideoxy sequencing of the canine distemper virus PCR products revealed 2% base pair (bp) changes in a 187-bp fragment from within position 1231–1464 of the nucleocapsid gene as compared with the Onderstpoort strain of canine distemper virus. Further support of the hypothesis that canine distemper virus could be involved in the pathogenesis of Paget's disease was sought by examining the bones of dogs with distemper infections (Mee *et al.,* 1992). In 2 of 4 dogs studied, *in situ* hybridization of metaphyseal specimens revealed strong signals with sense and antisense probes for the nucleocapsid and phosphoprotein genes. The osteoclasts were strongly positive but osteoblasts, osteocytes, and bone marrow cells were also positive. Mee and colleagues (1993) also have found canine distemper virus transcripts in the bone cells of dogs with metaphyseal osteopathy. This is an acute disorder affecting young rapidly growing dogs whose signs include fever, anorexia, and painful swollen metaphyses. The histology does not resemble Paget's disease. Although the presence of canine distemper virus transcripts in dogs with distemper or metaphyseal osteopathy does not relate directly to Paget's disease, it does indicate that a paramyxovirus can infect mammalian bone cells. This has also been demonstrated *in vitro* by incubating canine distemper virus with canine bone marrow (Mee *et al.,* 1995).

Additional evidence of paramyxovirus nucleocapsid transcripts in Paget's disease has come from the studies of Reddy and colleagues. They studied bone marrow mononuclear cells obtained from aspirations of the iliac crests of 6 patients with radiologically demonstrable Paget's disease and from the aspirations of 10 normal subjects (Reddy *et al.,* 1995). Using the reverse transcriptase–PCR techniques, they observed that 5/6 patients had measles virus nucleocapsid transcripts, whereas none of the 10 normal subjects had detectable transcripts. Dideoxy sequencing of the PCR fragments revealed several mutations within the position 1360–1371 bp of the nucleocapsid gene as compared with the Edmonston strain of measles virus. These mutations are in the same region as the mutations reported in the canine distemper virus nucleocapsid gene. Since granulocyte macrophage colony-forming units (CFU-GM), the most likely osteoclast precursors, circulate in the peripheral blood, Reddy and colleagues (1996) examined peripheral blood samples for the presence of measles virus nucleocapsid transcripts by reverse transcriptase-PCR in Paget's disease and control subjects. In 9 of 13 patients, measles virus transcripts were detected. They were localized to peripheral blood monocytes (whose precursor is CFU-GM) by *in situ* hybridization. Studies were negative in 10 control subjects.

Three studies from the United Kingdom and one United States study have produced negative results with respect to detection of Paramyxoviridae mRNA in Paget's disease. In one study, RNA extracts of 10 bone specimens failed to exhibit measles virus, canine distemper virus, respiratory syncytial virus, or parainfluenza 3 virus transcripts after reverse transcriptase-PCR evaluation (Ralston *et al.,* 1991). In a second study, both bone cells cultured from pagetic explants and bone biopsies were studied similarly by reverse transcriptase-PCR techniques for the presence of measles virus and canine distemper virus transcripts (Birch *et al.,* 1994). Completely negative results were obtained. A second United Kingdom study using the same primers also failed to find measles virus or canine distemper virus transcripts in long-term bone marrow cultures from lesions of Paget's disease (Ooi *et al.,* 2000). In the United States study, Nuovo and colleagues (1992) also could not detect measles virus-specific cDNA in pagetic specimens using PCR and *in situ* hybridization in combination. The explanation for the disparate results may reflect the techniques used by these investigators. They did not use secondary PCR to try to demonstrate the presence of paramyxovirus nucleocapsid mRNA and may have used inappropriate primers. Measles virus transcripts in Paget's patients are in extremely low abundance, so that secondary PCR and very stringent PCR conditions and primers are required to demonstrate viral mRNAs.

Several studies have addressed the levels of circulating antibodies against various paramyxoviruses in patients with Paget's disease. Antibody titers have not been found to be greater in Paget's disease than in control subjects (Basle *et al.,* 1983; Gordon *et al.,* 1993: Pringle *et al.,* 1985).

Cellular and Molecular Biology of Paget's Disease

The development of *in vitro* techniques for the study of the ontogeny of human osteoclasts has made it possible to gain new insights into the pathogenesis of Paget's disease. Kukita and colleagues (1990) first established long-term cultures of marrow from involved bones from patients with Paget's disease and noted that the multinucleated cells that formed shared many of the characteristics of pagetic osteoclasts. As compared with osteoclast-like cells formed in normal marrow cultures, the pagetic osteoclast-like cells formed more rapidly and in much greater numbers (10- to 100-fold greater), had increased numbers of nuclei and had higher levels of tartrate-resistant acid phosphatase. Examination of these cells by electron microscopy did reveal many features

of osteoclasts found in pagetic bone biopsies, but the characteristic nuclear and cytoplasmic inclusions were not observed. As previously mentioned, the antigens of measles virus and respiratory syncytial virus nucleocapsids were detectable in these cells (Mills *et al.,* 1994); apparently the nucleocapsid structures do not form in this *in vitro* setting.

Because the increased numbers of osteoclasts in pagetic lesions are of obvious importance in the pathogenesis of the disease, it seemed logical to examine osteoclast precursors in the marrow aspirates to determine if they were abnormal or whether other cells in the marrow microenvironment were participants in the pathology. Demulder and colleagues (1993) examined CFU-GM in cultures of unfractionated marrow mononuclear cells and found that CFU-GM colony formation was significantly increased compared with that of normal cells. Using an antibody that recognizes the CD34 antigen present on most hematopoietic precursors, they also isolated enriched hematopoietic precursors and found similar numbers of osteoclast precursors in pagetic and normal marrow aspirations. Subsequent coculture experiments with highly purified hematopoietic precursors ($CD34^+$ cells) and nonhematopoietic marrow accessory cells ($CD34^-$ cells) demonstrated that the growth of pagetic precursors was significantly enhanced by both normal and pagetic $CD34^-$ cells. CFU-GM colony formation was also significantly increased when normal $CD34^+$ cells were cocultured with pagetic, but not normal, $CD34^-$ cells. CFU-GM colony-derived cells from pagetic patients also formed osteoclast-like multinucleated cells with 1,25-dihydroxyvitamin D_3 ($1,25\text{-}(OH)_2D_3$), concentrations 1/10th of that required for normal multinucleated cell formation. Thus, these experiments suggest that osteoclast precursors are abnormal in Paget's disease and that other cells in the pagetic marrow microenvironment may stimulate the growth and differentiation of these abnormal precursors (Fig. 3). Recently, Menaa and coworkers (2000a) have extended the original studies of Demulder *et al.* (1993) to further understand the enhanced sensitivity of osteoclast precursors from patients with Paget's disease to the marrow microenvironment and the enhanced osteoclastogenic potential of the marrow microenvironment from Paget's patients. Menaa and coworkers (2000a) showed that pagetic osteoclast precursors are hyperresponsive to RANK ligand, a recently described member of the tumor necrosis factor (TNF) gene family, which is absolutely required for osteoclast formation. The increased sensitivity to RANK ligand was due to the additive effects of interleukin-6 produced by the pagetic marrow and RANK ligand on osteoclast formation. Furthermore, Menaa and coworkers showed that marrow stromal cells from patients with Paget's disease expressed higher levels of RANK ligand than normal marrow stromal cells. Thus, in pagetic lesions the osteoclast precursors are hyperresponsive to RANK ligand, and increased amounts of RANK ligand are expressed in the marrow microenvironment, further enhancing the osteoclastogenic potential of the pagetic lesion. In areas of bone not affected by Paget's disease, enhanced expression of RANK ligand was not detected.

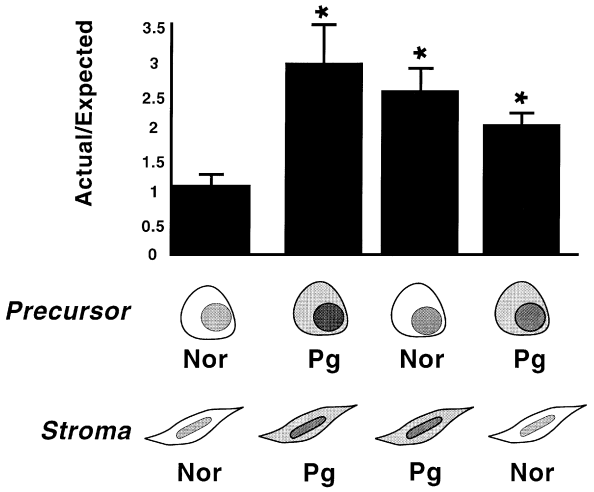

Figure 3 Summary of coculture studies using highly purified osteoclast precursors from normal and pagetic patients and stromal cells from normal and pagetic patients. Coculture of pagetic osteoclast precursors with normal or pagetic stromal cells produces a significantly increased number of CFU-GM-derived colonies over the expected number. When highly purified normal osteoclast precursors are cocultured with normal stromal cells, the expected number of CFU-GM-derived colonies are formed. In contrast, when normal osteoclast precursors are cocultured with pagetic marrow stromal cells, increased CFU-GM-derived colonies are formed. These data suggest that pagetic marrow stromal cells can increase the growth of both normal and pagetic osteoclast precursors and that the pagetic stromal cells can enhance the growth of normal osteoclast precursors above expected levels. The results are presented as the ratio of actual over the expected number of CFU-GM colonies formed. The asterisk denotes a significant difference from the normal cell combination. Adapted from Demulder *et al.,* 1993.

As noted above, a strong candidate for a significant autocrine/paracrine factor involved in the increased osteoclast formation in Paget's disease is interleukin-6. Roodman and colleagues (1992) found that conditioned media from long-term pagetic marrow cultures increased multinucleated cell formation in normal marrow cultures, and antibodies to interleukin-6 blocked the stimulatory activity. Antibodies to interleukin-1, GM-CSF, and TNF-α had no effect on the stimulatory activity. *In situ* hybridization studies demonstrated that the multinucleated cells in the pagetic marrow cultures were actively transcribing interleukin-6 mRNA. In addition, bone marrow plasma samples obtained from sites of Paget's disease had increased levels of interleukin-6 in 9 of 10 patients as compared with samples from normal subjects. Peripheral plasma also had elevated interleukin-6 levels in 17 of 27 patients. In another study, basal plasma interleukin-6 activity was increased in 19 of 22 patients (Schweitzer *et al.,* 1995). The concept that interleukin-6 may be an important autocrine/paracrine factor in Paget's disease is also supported by the studies of Hoyland and colleagues (1994), who used *in situ* hybridization to localize the expression of interleukin-6, interleukin-6 receptor, and interleukin-6 transcription factor in the bone of patients with Paget's disease in comparison with those with osteoarthritis. The osteoblasts in both disorders expressed all three mRNAs, but in Paget's disease interleukin-6 and its receptor mRNA showed higher levels of expression. In the

osteoclasts of both disorders, the receptor and transcription factor were expressed, but only in Paget's disease was interleukin-6 mRNA expressed in osteoclasts. Hoyland and Sharpe (1994) also examined the expression of c-*fos* protooncogene in the bone of 6 patients with Paget's disease by *in situ* hybridization. c-*fos* has been found to be important in the regulation of osteoclasts and was markedly upregulated in pagetic osteoclasts and, to a lesser extent, in the osteoblasts. It is possible that this is a consequence of interleukin-6 action (Korholz *et al.,* 1992).

Ralston and colleagues (1994) also studied cytokine and growth factor expression in bone explants of Paget's disease and in control subjects (postmenopausal women with and without osteoporosis and young bone graft patients) and could not find differences between pagetic and nonpagetic bone. Interleukin-6 mRNA was not detected in 40% of the pagetic specimens from severely affected individuals. There is no obvious explanation for their nonconfirmatory data.

Another abnormality of pagetic osteoclast precursors is that they are hyperresponsive to 1,25-$(OH)_2D_3$. Osteoclast precursors form osteoclasts *in vitro* with concentrations of 1,25-$(OH)_2D_3$ that are 1–2 logs less than that required to induce osteoclast formation by normal osteoclast precursors (Kukita *et al.,* 1990). Menaa and coworkers (2000b) have shown that this increased sensitivity to 1,25-$(OH)_2D_3$ is not due to increased numbers of vitamin D receptors in pagetic osteoclast precursors or to mutations in the vitamin D receptor. Recently, Kurihara and colleagues (2000a) have used a GST–vitamin D receptor fusion protein to further examine the increased sensitivity of pagetic osteoclast precursors to 1,25-$(OH)_2D_3$. These workers found that TAFII-20, a component of the TFIID transcription complex, was increased in osteoclast precursors from patients with Paget's disease compared to normals. This increase in expression of TAFII-20 did not require treatment of the cells with 1,25-$(OH)_2D_3$. These data suggest that pagetic osteoclast precursors express higher levels of TAFII-20 or have increased levels of a coactivator which can bind to TAFII-20 and the vitamin D receptor in the presence of lower concentrations of 1,25-$(OH)_2D_3$ to initiate transcription of VDR responsive genes.

The Etiology of Paget's Disease

As has been reviewed, Paget's disease is a focal disorder that often occurs in multiple family members. In most affected individuals, it progresses slowly over many years without extending to new sites of involvement. The underlying pathophysiology appears to reflect a localized increase in the numbers of osteoclasts followed by a secondary increase in osteoblastic activity. The osteoclasts have striking characteristics by both light and electron microscopy. In Paget's disease the osteoclasts may be far greater in size than osteoclasts in normal individuals or in patients with diseases in which osteoclasts are activated such as primary hyperparathyroidism. A correlate of this observation is the increased number of nuclei noted in the pagetic osteoclast. The nuclei and cytoplasm harbor microfilamentous inclusions that are structurally identical to the nucleocapsids of viruses of the Paramyxoviridae family. However, the structure of a mature Paramyxoviridae virus has rarely been reported in bone biopsy or cell culture specimens. Immunohistological and molecular techniques have indicated the presence of Paramyxoviridae proteins and mRNA in patients with Paget's disease. Recently, Kurihara and coworkers (2000b) have tried to determine the pathophysiologic role of the measles virus nucleocapsid gene in abnormal osteoclast activity in Paget's disease. These workers transfected normal human osteoclast precursors with the measles virus nucleocapsid gene or the matrix gene. They showed that cells transfected with the nucleocapsid gene but not the matrix gene formed osteoclasts that had many of the features of pagetic osteoclasts. The multinucleated cells that formed in these cultures were markedly increased in number and size, had increased numbers of nuclei per osteoclast, had increased bone-resorbing capacity, and were hyperresponsive to 1,25-$(OH)_2D_3$. All these are features of pagetic osteoclasts. Furthermore, these osteoclasts produced increased amounts of interleukin-6 compared to normal osteoclasts formed in marrow cultures. Similarly, Reddy and coworkers (1999b, 2000a) have produced transgenic mice in which the measles virus receptor, CD46, is targeted to cells in the osteoclast lineage. These workers have shown that bone marrow cells from these animals, when infected with measles virus, form osteoclasts which have the features of pagetic osteoclasts. Taken together, these recent studies support a pathophysiologic role for paramyxovirus in the abnormal osteoclast in Paget's disease and implicate the nucleocapsid gene as a potential mediator of these effects. Finally, interleukin-6 has been implicated as a potential important mediator of osteoclast function in Paget's disease. Based on this information, it seems reasonable to propose the hypothesis that Paget's disease represents a slow virus infection of bone.

Slow (or persistent) viral infections of the nervous system have been studied since the mid-1960s when Bjorn Sigurdsson, an Icelandic veterinary virologist, identified several viral disorders in sheep which exhibited a prolonged incubation period before the occurrence of symptoms. In man, the best studied disorder of this type is subacute sclerosing panencephalitis (SSPE). A small percentage of children experience an often fatal neurological syndrome ~5 years after a classical measles infection (ter Meulen *et al.,* 1983). It proved quite difficult to rescue an infectious virus from brain specimens from patients with SSPE although nucleocapsid-like structures similar to those in Paget's disease were abundant. Persistent infection of human glioma cell lines with measles virus has been shown to result in the induction of interleukin-6 (Schneider-Schaulies *et al.,* 1993). This observation may be relevant to Paget's disease. Examination of measles virus genes from a brain specimen of an SSPE patient revealed that nearly 2% of the nucleotides were mutated during persistence and that 35% of these mutations resulted in amino acid changes (Cattaneo *et al.,* 1988). This also appears analogous to findings in Paget's disease.

The existence of persistent viral infections of the nervous system provides a model for pursuing a similar pathogenesis of Paget's disease. An acute viral infection with one of several paramyxoviruses could result in the establishment of a persistent viral infection in one or more bone and/or bone marrow cells, particularly in genetically susceptible individuals. This could trigger the initial osteoclastic stimulus with interleukin-6 as an important intermediary. Subsequently, the normal osteoblastic response to bone resorption may become overzealous in response to the continuing pathologic osteoclastic activity.

Many issues need to be resolved before the viral hypothesis of Paget's disease can be accepted. The characteristic osteoclast nuclear and cytoplasmic inclusions of Paget's disease have also been noted in some patients with giant cell tumors of bone (Schajowicz *et al.,* 1985), pycnodysostosis (Beneton *et al.,* 1987), osteopetrosis (Mills *et al.,* 1988), and primary oxalosis (Bianco *et al.,* 1992). Does this mean that the inclusions are merely incidental findings in all these disorders or in the appropriate genetic setting does a persistent viral infection trigger the pathology?

It is of considerable importance to determine the complete sequences of the Paramyxoviridae proteins and genes found in the pagetic specimens. This would clarify whether there were two viruses in many lesions, whether gene recombination occurs, or whether mutations over time account for the finding of measles and respiratory syncytial virus antigens in the same osteoclasts.

In the past there has been no evidence that canine distemper virus is responsible for any human disorder. The finding of antibodies to canine distemper virus in the circulation of patients with Paget's disease and in control subjects is consistent with this possibility. These antibody titers did not correlate with antibodies to measles virus in these individuals (Gordon *et al.,* 1993).

Of particular interest is what accounts for the focal nature of Paget's disease when circulating mononuclear cells can be demonstrated to contain measles virus transcripts? Based on the studies of Menaa *et al.* (2000a), it seems that changes in the marrow microenvironment are critical for maintenance of the localized lesions. It remains for future studies to fully define the cytokines produced by the bone cells and marrow stroma which interact to produce the florid advancing pathology of a pagetic lesion.

Clearly, it will require many more investigations into the mechanism of the proliferation of osteoclasts in Paget's disease before the etiology of this common skeletal problem will be understood fully.

CHAPTER 72

Genetic Determinants of Bone Mass and Osteoporotic Fracture

Stuart H. Ralston

Department of Medicine and Therapeutics, University of Aberdeen Medical School, Aberdeen AB25 2ZD, Scotland

Introduction

Osteoporosis is a common disease characterized by low bone mass, microarchitectural deterioration of bone tissue, and an increased risk of fracture. Bone mineral density (BMD) is an important risk factor for osteoporotic fracture and osteoporosis is defined to exist when BMD values fall more than 2.5 standard deviations below the young adult mean. Whilst 50% of all women will have osteoporosis by the age of 80 according to this definition, only a small proportion of these individuals will suffer a fragility fracture. This is because fall-related factors such as advancing age, muscle weakness, impaired vision, and cognitive impairment contribute to fracture risk (Dargent-Molina *et al.,* 1996), as well as other determinants of bone fragility such as bone quality, bone turnover, and femoral neck geometry (Faulkner *et al.,* 1993; Garnero *et al.,* 1996a; Bauer *et al.,* 1997). Over the past 5 years, increasing interest has focused on the role that genetic factors play in regulating BMD and other determinants of osteoporotic fracture risk. In this chapter, I will describe the strategies which have been used to identify and quantitate genetic influences on bone mass and other phenotypes relevant to the pathogenesis of osteoporotic fracture and discuss the candidate loci and genes that have been implicated in regulation of these processes.

Identifying and Quantitating Genetic Effects on Osteoporosis

Genetic contributions to diseases and continuous traits can be identified and quantitated by studies of twins and families (Martin *et al.,* 1997). Twin studies provide the classical method of dissecting out the relative importance of genes and environment to disease etiology by comparing the similarity of monozygotic (MZ) and dizygotic (DZ) twins. While MZ twins and DZ twins generally share similar environments, they differ genetically in the sense that MZ twins share 100% of their genes in common whereas DZ twins share only 50% of their genes in common. Assuming that a disease has a genetic component, it is expected to occur significantly more frequently in MZ as compared with DZ twins. The same is true for genetically determined quantitative traits such as BMD which are more closely correlated in MZ than DZ twin pairs (Fig. 1). Genetic influences on diseases and quantitative traits can also be assessed by studying the resemblance between other relatives such as parent–offspring pairs or sibling pairs. For qualitative traits (such as presence of absence of an event like fracture) familial resemblance is usually expressed in terms of a relative risk (denoted λ), which is derived from the proportion of relatives affected with a disease as compared with the population prevalance of the disease. The higher the λ value, the greater the genetic contibution to the disease. For quantitative traits, resemblance between relatives is usually expressed in terms of "heritability," which is defined as the ratio of genetic variance to total variance of the trait. Two types of heritability are recognized. Heritability in the narrow sense (h^2) is usually derived by comparing resemblance between parents and offspring and reflects the component of genetic variance which is directly transmissible from one generation to the next (this component of genetic variance is also called "additive genetic variance"). In practice, h^2 values are derived from the regression coefficient (slope) of mid-parent values (i.e., mean of father and mother) against offspring values (either one child or mean

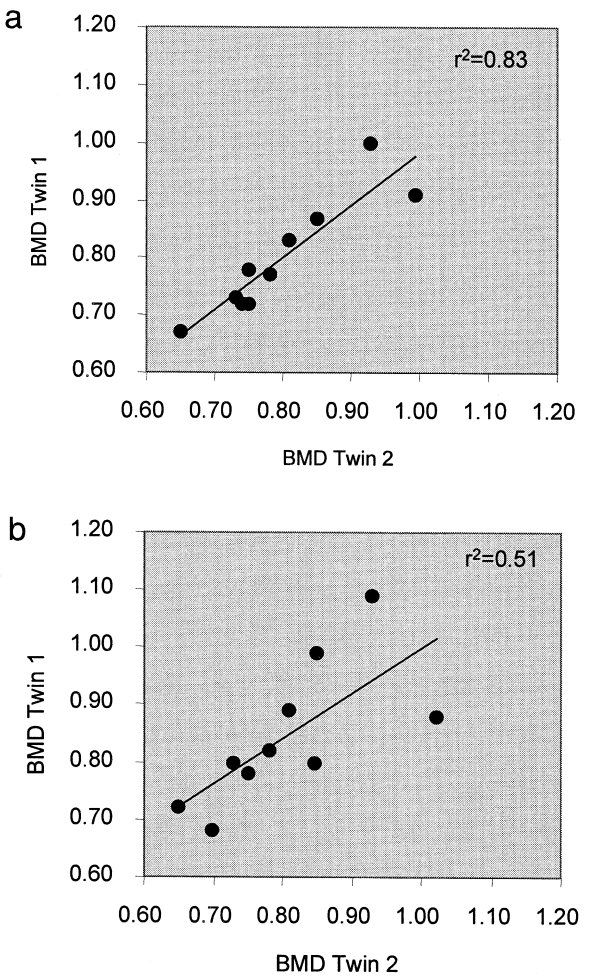

Figure 1 Analysis of heritability of quantitative traits in twins. Comparing values for quantitative traits such as BMD in MZ and DZ twin pairs can help define the role of genetic influences on the trait. In the example shown, the closer correlation between BMD values in the MZ twin pairs (a) as compared with the DZ (b) is consistent with a role for genetic factors in regulating BMD.

Evidence for a Genetic Contribution to BMD and Osteoporotic Fracture

Studies in twins and families have indicated that genetic factors play an important role in the regulation of BMD, other markers of fracture risk, and osteoporotic fracture itself. It has been estimated from twin studies, for example, that between 50 and 85% of the variance in BMD is genetically determined depending on the site examined (Smith *et al.,* 1973; Pocock *et al.,* 1987; Christian *et al.,* 1989; Slemenda *et al.,* 1991; Flicker *et al.,* 1995). Family studies have also shown evidence of strong genetic effects on BMD, with heritability estimates ranging from about 40 to 85% (Krall and Dawson-Hughes, 1993; Gueguen *et al.,* 1995). The data are more conflicting with regard to the influence of genetic factors on age-related bone loss; in one study of wrist BMD in elderly male twins, no evidence for a genetic effect on bone loss was found (Christian *et al.,* 1989), whereas in another study of younger female twins strong genetic effects on axial bone loss were observed (Kelly *et al.,* 1993). Recent interest has focused on the relationship between genetic factors and the clinically important outcome of osteoporotic fracture. A twin study in Finland (Kannus *et al.,* 1999) showed slightly higher rates of concordance for fracture in MZ as compared with DZ twins but the differences were not significant overall, leading the authors to conclude that environmental factors may be more important in the pathogenesis of fracture. A recent family based study demonstrated clear evidence for a genetic contribution to the pathogenesis of wrist fracture, however, with relative risks of 1.31 for women with a maternal history of wrist fracture and 1.88 for a woman whose sister had suffered a wrist fracture (Deng *et al.,* 2000). This study also showed that BMD values were reduced in women with Colles' fracture, suggesting that the genetic contribution to fracture was mediated in part, by differences in BMD. There is evidence from twin studies and population-based studies that family

of all children). Heritability in the broad sense (H_2) on the other hand, is usually derived by comparing resemblance between siblings. This reflects the component of variance derived from genes inherited from the parents (i.e., additive variance), *plus* the variance which occurs as the result of gene–gene interactions, *plus* the variance that results from common environment. In practice, heritability in the broad sense (H_2) estimates are derived from twice the correlation coefficient (r value) between siblings in a regression analysis. If values for heritability in the broad sense are higher than values for heritability in the narrow sense, it implies that gene-gene interactions and/or shared environment contribute substantially to the resemblance between siblings. Common environment is, however, very difficult to separate out from genetic components using family and sib-pair designs, leading to erroneous estimates of heritability.

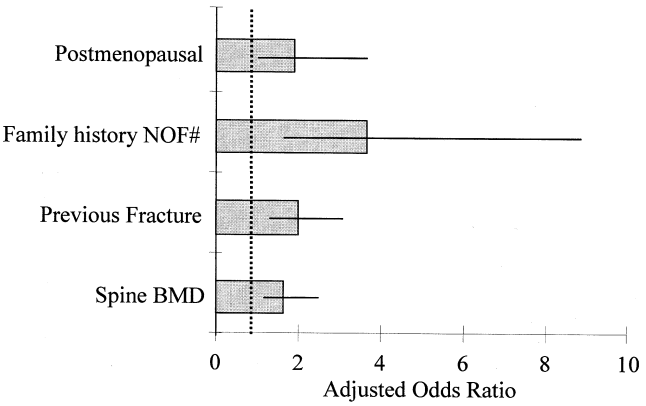

Figure 2 Family history of fracture predicts osteoporotic fracture independent of BMD. Comparison of relative risk for fracture (± 95% confidence intervals) in perimenopausal women according to menopausal status, history of previous fracture, family history of hip fracture (adjusted for BMD), and a 1 SD reduction in spine BMD. Data from Torgerson *et al.* (1996).

resemblance in BMD is not the only factor of importance in determining fracture risk, however. Twin studies have shown that determinants of osteoporotic fracture which are independent of BMD such as femoral neck geometry (Arden *et al.,* 1996; Flicker *et al.,* 1996); ultrasound properties of bone (Arden *et al.,* 1996) and biochemical markers of bone turnover (Garnero *et al.,* 1996b) also have a strong heritable component. Population-based studies support the potential importance of these and other variables in determining fracture risk in showing that family history of fracture is a significant risk factor for fracture by mechanisms that are partly independent of bone density (Cummings *et al.,* 1995; Torgerson *et al.,* 1996; Keen *et al.,* 1999a) (Fig. 2). In conclusion, there is evidence for a strong genetic contribution to the pathogenesis of osteoporotic fracture by genes which regulate several predisposing phenotypes including BMD, bone turnover, skeletal geometry, and bone quality.

Patterns of Inheritance for Regulation of Bone Mass

Several different genes each with modest effects, are thought to combine with environmental factors to regulate BMD and other determinants of fracture risk in most normal individuals (Gueguen *et al.,* 1995). In some cases, however, the influence of a single gene can predominate. Syndromes of low BMD and osteoporosis which are inherited in a Mendelian manner include osteogenesis imperfecta, due to mutations in the collagen genes (Rowe, 1991), osteoporosis–pseudoglioma syndrome (Gong *et al.,* 1998), and severe osteoporosis associated with inactivating mutations in the aromatase (Morishima *et al.,* 1995) and estrogen receptor alpha genes (Smith *et al.,* 1994). Increased BMD can also occur as the result of mutations in a single gene. The classic example of this is osteopetrosis, which is characterized by disordered osteoclast function and greatly increased BMD. A syndrome of unusually high BMD distinct from osteopetrosis has also been described which is inherited in an autosomal dominant manner (Johnson *et al.,* 1997). In all of the above examples, the consequences of the gene mutation on bone cell function are so profound as to overwhelm the effects of the many other genes which contribute to regulation of bone mass. Even in such extreme cases, it is sometimes possible to identify polygenic effects on disease severity. The best examples of this are in osteogenesis imperfecta, where disease severity can vary markedly within and between families who have identical mutations in the collagen genes, presumably due to the influence of other genes on bone mass and bone fragility (Willing *et al.,* 1990).

Strategies for Identifying Osteoporosis Genes

The approaches used to identify the genes responsible for diseases with a genetic component have been recently reviewed by Ott and Hoh (2000) and these are discussed in more detail below.

Linkage Analysis

The classical approach for gene discovery is linkage analysis which involves identifying a model of inheritance for the disease and looking for evidence of segregation of the disease within a family according to that model (for example, autosomal dominant or autosomal recessive). The results of linkage studies are reported by calculating the lodscore, which is defined as the logarithm of the odds that the disease locus and marker locus are linked (no recombination between loci) rather than unlinked (50% recombination between loci). Because lodscores are a function of the recombination fraction (θ), they are calculated over a range of recombination values and the maximum value (Zmax) is estimated. By convention, linkage is considered significant when the lodscore exceeds about +3.3, whereas linkage is considered suggestive when the lodscore exceeds +1.9. Conversely, linkage can be excluded by the finding of a lodscore below −2.0. Linkage studies are usually carried on a genome-wide basis, with a panel of markers approximately 10 cM apart, but they may also be conducted in relation to a specific locus or gene. Linkage analysis has been used widely in human genetic mapping and has been successful in identifying disease genes in hundreds of monogenic traits. It is less suitable for the study of complex diseases such as osteoporosis or complex traits such as BMD, where multigeneration families are more difficult to come by and the mode of disease inheritance is generally unclear.

Allele-Sharing Studies

Allele-sharing studies test the hypothesis that sibling pairs who are both affected by a disease inherit the same alleles in certain regions of the genome more often than would be expected by chance. As in the case of classical linkage analysis, these studies are generally performed by studying a panel of polymorphic markers on a genome-wide basis, but may also be performed by studying markers within specific candidate genes or candidate loci. Allele-sharing studies can also be used in the analysis of quantitative traits such as BMD. By calculating the difference between sib-pairs for the trait under study and relating this to the number of alleles shared identical by descent at a specific marker, it is possible to assess if there is evidence of linkage between that marker and the quantitative trait (Fig. 3). As in the case of classical linkage studies, statistical significance in sib-pair linkage studies is usually measured in terms of lodscore units. It should be noted, however, that the threshold values for significant linkage using sib-pair methods are between +0.5 and +1.3 lodscore units higher than with classical linkage methods, depending on which statistical program is used to analyze the data (Nyholt, 2000). Advantages of the allele-sharing approach include the fact that it does not require collection of large families and that it does not depend on knowing the mode of disease inheritance. A disadvantage of

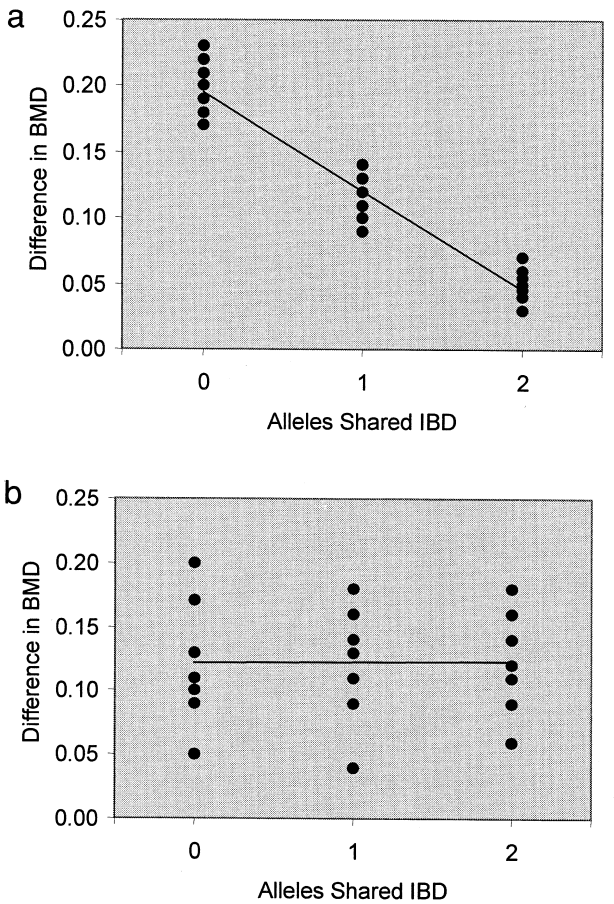

Figure 3 Assessing linkage between a genetic marker and quantitative trait in sib-pairs. Linkage studies of quantitative traits in sib-pairs are based on assessing whether the difference between sib pairs is related to number of alleles shared identical by descent with a series of polymorphic markers. (a) Clear evidence of linkage as reflected by the close concordance between BMD values in sib-pairs who share both alleles identical by descent (IBD) and marked discordance of BMD values in sib-pairs who share no alleles IBD. (b) There is no evidence of linkage since the difference in BMD values between sib-pairs is unrelated to alleles shared IBD.

the approach is that it requires large numbers of sib pairs to gain adequate statistical power for the detection of genes which have modest effects on disease susceptibility.

Association Studies

Association studies compare the frequency with which polymorphisms in or around a candidate gene of interest are present in a group of patients with a disease as compared with a group of controls. Association studies may also be used to study quantitative traits such as BMD by comparing the mean values of the trait in different genotype groups. Recent interest has focused on the possibility that association studies may also be used to search for novel loci on a chromosome-wide or genome-wide basis using the technique of linkage disequilibrium mapping (Collins *et al.,* 1999). Linkage disequilibrium (LD) refers to the phenomenon whereby genomic regions which are physically close to one another on the same chromosome tend to segregate together from one generation to the next. Linkage disequlibirum mapping exploits this fact in testing the hypothesis that unrelated individuals who have the same disease will also share in common those regions of the genome which predispose to that disease. Successful LD mapping depends on analyzing a dense set of markers, spaced no further apart than the average distance of LD in the population under study. It has been estimated on the basis of experimental data that LD extends on average about 300 kb (Collins *et al.,* 1999), but this varies depending on the chromosomal region and population under study (LD tends to extend further in isolated, genetically homogeneous populations).

Association studies have been successful in identifying a role for the HLA region in the pathogenesis of autoimmune diseases and the role of the ApoE gene in sporadic Alzheimer's disease. A potential pitfall with association studies is that they can give spurious results due to population stratification, particularly when the sample sizes are small and when insufficient care has been paid to matching cases and controls. These problems have probably been overestimated in the past and can be partly circumvented by careful study design with statistical correction for possible confounding factors. It should be noted, however, that positive associations between candidate gene polymorphisms and disease can occur as the result of two mechanisms; the first is that the polymorphism actually causes or contributes to the disease. In this case one would expect to find a similar association in all populations which carry the polymorphism. The second possibility is that the polymorphism is in linkage disequilibrium with the actual cause, which may be another polymorphism or mutation in the same gene, or in a gene nearby. Defining a causative role for any individual polymorphism and a complex disease is difficult. Approaches which may be employed include haplotype analysis, which involves genotyping several polymorphisms at the candidate locus in an attempt to identify those that are most strongly associated with the disease. Once these polymorphisms have been identified, functional studies are required to define the biological effects of putative disease-causing polymorphisms on protein function and/or gene transcription *in vitro* and *in vivo.*

The transmission disequilibrium test (TDT) if often used to confirm the results obtained from population based association studies (Spielman *et al.,* 1993). This examines the hypothesis that a polymorphism or allele contributes to disease by analyzing the frequency with which affected individuals inherit the allele from a heterozygous parent. If the given allele contributes to disease, then the probability that an affected person has inherited the allele from a heterozygous parent should vary from the expected mendelian ratio of 50:50 (Fig. 4). Because the transmitted allele acts as the "case" and the nontransmitted allele acts as the "control," the TDT is unaffected by confounding due to population stratification. These advantages of the TDT are offset by the fact that it is applicable only to the study of diseases where parental samples are available. This is a limiting factor in

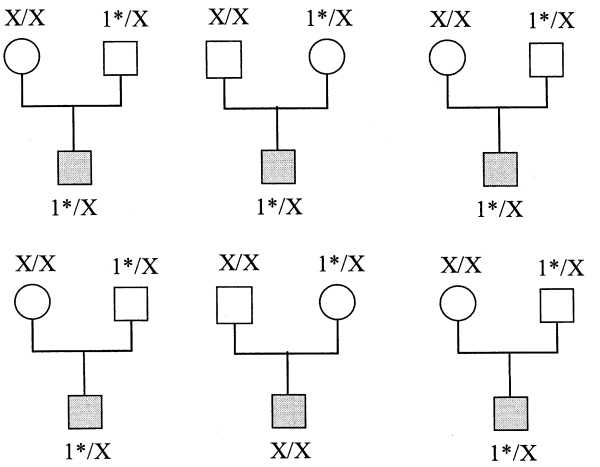

Figure 4 The transmission disequilibrium test. The transmission disequilibrium test is based on assessing if an allele suspected to increase the risk of disease (here designated 1*) is transmitted to affected children from heterozygous parents more frequently than would be expected by chance (i.e., more than 50% of the time). In the example shown the 1* allele is transmitted 5/6 possible times, whereas the expected value would be 3/6. Nonrisk alleles are represented by "X".

the study of late-onset diseases such as osteoporosis where fracture might be the phenotypic measure of interest.

Animal Studies

Studies in experimental animals provide an additional method of identifying the genes responsible for human disease, based on the assumption that key regulatory genes will be shared across species. These approaches are discussed in more detail in Chapter 96.

Linkage and Allele Sharing Studies

Relatively few classical linkage studies have been performed in the osteoporosis field. An exception is the study by Johnson *et al.* (1997), who described a large family in which unusually high bone mass (BMD *Z* score +3.0 or greater) was inherited in a simple autosomal-dominant fashion through several generations. A genome-wide search in this family resulted in the identification of a candidate locus for the syndrome on chromosome 11q12–q13 and excluded the rest of the genome. This locus is of interest since it harbors the gene responsible for the osteoporosis pseudoglioma syndrome (OPS), an autosomal recessive disease, characterized by ocular abnormalities and juvenile osteoporosis (Gong *et al.,* 1998) and with autosomal recessive osteopetrosis—a disease characterized by increased BMD and defective osteoclast function (Heaney *et al.,* 1998). Recently mutations of the TCIRG1 gene, encoding a subunit of the vacuolar proton pump have been identified as causing many cases of 11q-12–q13-linked autosomal recessive osteopetrosis in humans (Frattini *et al.,* 2000). Mutations of the murine homolog appear also to be responsible for autosomal recessive osteopetrosis in oc/oc mice (Scimeca *et al.,* 2000). This raises the possibility that TCIRG1 is the gene responsible for other disorders of BMD that have been mapped to 11q12–q13. It is currently unclear whether OPS and/or the high bone mass syndrome are also caused by mutations in TCIRG1, however, or whether other genes are responsible.

In contrast to the paucity of classical linkage studies, several sib-pair-based linkage studies have been conducted to try and identify loci involved in the regulation of bone mass (Table 1). Devoto *et al.* (Devoto *et al.,* 1998) conducted a genome search in a series of affected sibling pairs recruited from several families with history of osteoporosis. These studies identified loci on chromosomes 1p36, 2p23–p24, and 4q32–34 where the data were suggestive of linkage to spine or hip BMD (lodscores between +2.5 and +3.5). Several other loci with lodscores between +1.5 and +2.5 were also identified, including a broad region of chromosome 11q, which was seemingly distinct from the 11q12–q13 locus identified by Johnson *et al.* (1997). Further studies by the same group subsequently confirmed evidence of linkage to the 1p36 locus in a second set of sib-pairs (Spotila *et al.,* 1998). Nui and colleagues conducted a genome-wide search for loci that regulated forearm BMD in 153 healthy sib-pairs, drawn from a Chinese population (Nui *et al.,* 1999). In this study, evidence suggestive of linkage to BMD was found on chromosome 2p23–p24 (lodscore +2.15) and chromosome

Table I Candidate Loci for Regulation of BMD Identified by Genome Searches

Author	Type of study	Locus	Peak lodscore	Phenotype
Devoto *et al.,* 1998	Sib-pair	1p36	3.51	Hip BMD
		2p23	2.29	
		4q33	2.95	
Nui *et al.,* 1999	Sib-pair	2p21	2.15	Wrist BMD
		13q24	1.67	
Koller *et al.,* 2000	Sib-pair	1q21–q23	3.86	Spine BMD
		5q33–q35	2.23	Hip BMD
		6p11–p12	2.13	Hip BMD
Johnson *et al.,* 1997	Family	11q12–q13	5.74	Spine BMD
Koller *et al.,* 1999	Sib-pair	11q12–q13	3.50	Hip BMD

13*q*34 (lodscore 1.67). Prompted by the observation that high bone mass, OPS, and osteopetrosis all mapped to chromosome 11*q*12–*q*13, Koller and coworkers evaluate this region for evidence of linkage to spine and hip BMD in a study of 835 healthy Caucasian and African-American sib-pairs (Koller *et al.,* 1999). These studies showed evidence of linkage to the region of interest with a peak lodscore of +3.51 for spine BMD. Although positive lodscores were observed in both ethnic groups, the effect was greater among Caucasian women. Koller subsequently conducted a whole genome search in an expanded sample of sib-pairs derived from the same population (Koller *et al.,* 2000). The highest multipoint lodscore attained in this sample was +3.86 at chromosome 1*q*21–*q*23 in relation to lumbar spine BMD. Other lodscores suggestive of linkage were observed on chromosome 5*q*33–*q*35 (lodscore of +2.23 with femoral neck BMD) and chromosome 6*p*11–*p*12 (lodscore of +2.13 with lumbar spine BMD). Interestingly, while the 11*q*12–*q*13 region continued to show evidence of linkage in the whole genome scan, the results were much weaker than in Koller's candidate locus linkage study (Koller *et al.,* 1999). Duncan and colleagues conducted a sib-pair linkage study in 115 probands and 499 of their relatives using polymorphic markers in the vicinity of 23 candidate genes which have implicated in the regulation of bone mass (Duncan *et al.,* 2000). The highest lodscore was observed at the PTH receptor 1 locus in chromosome 3*p* (lodscores = +2.7–3.5, depending on the method of analysis) but positive lodscores (above +1.7–1.8) were also observed at the vitamin D receptor (VDR) locus, the collagen type I alpha 1 (COLIA1) locus, and the epidermal growth factor locus.

Candidate Gene Studies

These have been widely used in studying the genetic basis of osteoporosis, focusing on candidate genes such as cytokines and growth factors, which regulate bone turnover; those that encode components of bone matrix; and those that encode receptors for calciotropic hormones. Individual candidate genes that have been implicated in the regulation of bone mass or osteoporotic fractures are discussed in more detail below.

Vitamin D Receptor

The active metabolites of vitamin D play an important role in regulating bone cell function and maintenance of serum calcium homeostasis by binding to the vitamin D receptor and regulating the expression of a number of response genes. Polymorphisms affecting both the 3′ and 5′ regions of the VDR gene have been studied in relation to BMD and other phenotypes relevant to the pathogenesis of osteoporosis. The first study of VDR genotypes in relation to calcium metabolism were those of Morrison who found an association between polymorphisms affecting the 3′ region of the gene and circulating osteocalcin levels (Morrison *et al.,* 1992). In a subsequent study, the same group reported a significant association between a *BsmI* polymorphisms in intron 8 of VDR and BMD in a twin study and a population based study, but this association was later found to be much weaker than originally reported due to genotyping errors (Morrison *et al.,* 1997). A large number of studies have now been carried out looking at the association between BMD and other aspects of calcium metabolism in relation to *BsmI* and other polymorphisms at the VDR locus. Several studies have supported the original findings whereas others have found no significant association and still others reported an inverse associations to those originally reported (Houston *et al.,* 1996; Uitterlinden *et al.,* 1996). Gong and colleagues recently reviewed the results of 75 articles and abstracts published between 1994 and 1998 which related BMD and associated skeletal phenotypes to VDR polymorphisms. The main conclusions to emerge from this study were that there was a highly significant association between VDR polymorphisms and BMD overall and that positive results were significantly more common in studies that included premenopausal rather than postmenopausal women (Gong *et al.,* 1999). From this the authors concluded that the body of evidence strongly supported an association between VDR alleles and BMD but that the association may have been missed in some studies because of small sample size and other confounding factors. There is evidence to suggest that the relationship between VDR genotype and BMD may be modified by environmental factors such as calcium intake (Ferrari *et al.,* 1995; Krall *et al.,* 1995) and vitamin D intake (Graafmans *et al.,* 1997). In keeping with this view, intestinal calcium absorption has been associated with the *BsmI* VDR polymorphism in some studies (Dawson-Hughes *et al.,* 1995; Gennari *et al.,* 1997). The mechanism by which this occurs is unclear and no association has been found between genotype and mucosal VDR density (Barger-Lux *et al.,* 1995). Four studies have looked at the association between VDR *BsmI* alleles and fracture. In one, a positive association was found but this was significant only in a subgroup of older women age 75 years and above (Feskanich *et al.,* 1998). Three other studies found no association with osteoporotic fracture (Looney *et al.,* 1995; Houston *et al.,* 1996; Ensrud *et al.,* 1999). Studies which have sought to define functional associations of the 3′ VDR polymorphisms have yielded mixed results. Reporter gene constructs prepared from the 3′ region of the VDR gene in different individuals have shown evidence of haplotype-specific differences in gene transcription, raising the possibility that polymorphisms in this region may be involved in regulating affect RNA stability (Morrison *et al.,* 1994). In support of this view, cell lines which were heterozygous for the *TaqI* polymorphism showed differences in allele-specific transcription of the VDR gene (Verbeek *et al.,* 1997). In this study, however, transcripts from the "t" allele were 30% more abundant than those from the "T" which is the opposite from the result expected on the basis of Morrison's results (Morrison *et al.,* 1994). Other *in vitro* studies have shown no differences in allele-specific transcription, mRNA stability, or ligand binding in relation to the *BsmI* polymor-

phism (Mocharla *et al.,* 1997; Gross *et al.,* 1998a; Durrin *et al.,* 1999). Another common polymorphism has been described in exon 2 of the VDR gene, which is a T → C transition, recognized by the *FokI* restriction enzyme (Arai *et al.,* 1997; Gross *et al.,* 1998b). This transition introduces an alternative translational start codon that results in a shorter isoform of the VDR gene. The *FokI* polymorphism has been associated with BMD in some studies (Gross *et al.,* 1997; Arai *et al.,* 1997; Harris *et al.,* 1997) but not in others (Eccleshall *et al.,* 1998; Sowers *et al.,* 1999; Langdahl *et al.,* 2000a). The *FokI* polymorphism has been associated with osteoporotic fractures in Italian women (Gennari *et al.,* 1999), but no association was found in Danish women (Langdahl *et al.,* 2000a). Functional studies of the *FokI* polymorphism have yielded mixed results. A positive association with intestinal calcium absorption was reported in one study (Ames *et al.,* 1999), but two other studies yielded negative results (Zmuda *et al.,* 1999; Cauley *et al.,* 1999a). Studies *in vitro* have shown that different VDR *FokI* alleles differ in their ability to drive reporter gene expression (Arai *et al.,* 1997; Jurutka *et al.,* 2000) and the polymorphic variant lacking three amino acids ("F") has also been found to interact with human basal transcription factor IIB more efficiently than the longer isoform ("f"). Finally, peripheral blood mononuclear cells (PBMC) from "FF" individuals were also been found to be more sensitive to the growth inhibitory effects of calcitriol than PBMC from "Ff" and "ff" individuals (Colin *et al.,* 2000). Contrasting with these results, however, Gross and colleagues found no evidence of functional differences between *FokI* alleles in terms of ligand binding, DNA binding, or transactivation activity (Gross *et al.,* 1998b). In summary, the studies which have been performed to date indicate that allelic variation at the VDR gene locus may have a role to play in the genetic regulation of bone mass. These effects appear to be modified by dietary calcium and vitamin D intake and in some studies have been associated with differences in intestinal calcium absorption. The association between genotype and BMD is weak, however, and no clear association with fracture has emerged. There is some evidence to suggest that different VDR isoforms encoded by the *FokI* variants differ in terms of receptor function although associations between this polymorphism, BMD, and fracture have been inconsistent.

Type I Collagen

Type I collagen is a major structural protein of bone, and the genes encoding this protein (COLIA1 and COLIA2) are strong candidates for the genetic regulation of bone mass. In support of this view, mutations affecting these genes are estimated to be responsible for up to 90% of cases of osteogenesis imperfecta, a hereditary disease characterized by premature osteoporosis and bone fragility (Rowe, 1991). Polymorphisms affecting the coding regions of the collagen type I genes are rare and do not appear to be associated with osteoporosis (Spotila *et al.,* 1994). This led Grant and colleagues to look for evidence of an association between polymorphisms affecting the transcriptional control regions of the COLIA1 gene and osteoporosis (Grant *et al.,* 1996). In these studies, Grant described a G → T polymorphism affecting a binding site for the transcription factor Sp1 in the first intron of COLIA1, which was more prevalent in osteoporotic patients then in controls (Grant *et al.,* 1996). Positive associations between the COLIA1 Sp1 polymorphism and bone mass or osteoporotic fractures were subsequently reported in many other studies (Uitterlinden *et al.,* 1998; Garnero *et al.,* 1998; Langdahl *et al.,* 1998; Roux *et al.,* 1998; Alvarez *et al.,* 1999; McGuigan *et al.,* 2000; Weichetova *et al.,* 2000) (Fig. 5). Several investigators have found that the association between COLIA1 alleles and fracture persists after correction for BMD and/or is stronger than expected on the basis of allele-specific differences in bone mass (Grant *et al.,* 1996; Uitterlinden *et al.,* 1998; Langdahl *et al.,* 1998; Keen *et al.,* 1999b). This has led to speculation that the polymorphism may principally act as a marker for increased bone fragility rather than reduced BMD. Some investigators have found no association between the COLIA1 Sp1 polymorphism and BMD or fracture although these studies have been small, with limited statistical power (Liden *et al.,* 1998; Hustmyer *et al.,* 1999). The relationship between COLIA1 alleles and bone loss has been studied by two groups, following on from the study of Uitterlinden who found that genotype-related differences in BMD increased with age (Uitterlinden *et al.,* 1998). In the study of Harris and colleagues, the COLIA1 "ss" genotype was strongly associated with increased bone loss over a 5-year period in 243 elderly men and women

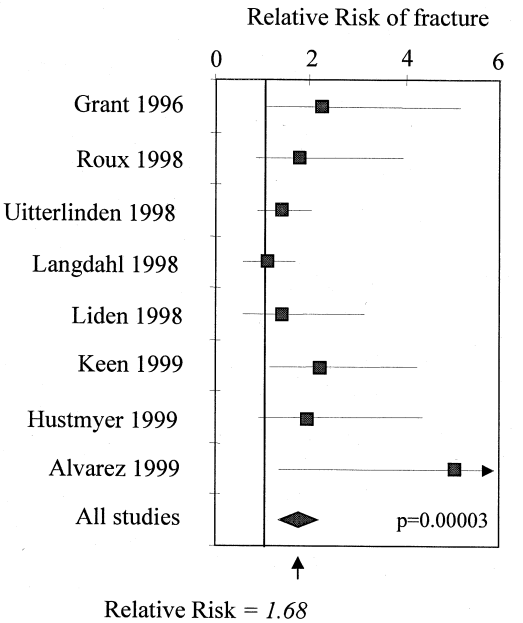

Figure 5 Metaanalysis of COLIA1 polymorphisms and osteoporotic fracture. The odds ratio (± 95% CI) for osteoporotic fracture in relation to carriage of the COLIA1 "s" allele is shown for individual studies performed between 1996 and 1999 and for all studies combined. Overall there was a highly significant 1.68-fold increased risk of fracture in patients who carry the "s" allele when compared to that seen with "SS" homozygotes.

(Harris *et al.,* 2000). In the study of Heegard, however, no association was found between COLIA1 alleles and bone loss in a cohort of 133 women followed over 18 years (Heegaard *et al.,* 2000). The COLIA1 Sp1 polymorphism has been studied in relation to BMD in children but the results have been contradictory; in one study COLIA1 alleles were strongly related to volumetric BMD measured by QCT in Mexican-American girls (Sainz *et al.,* 1999), whereas no association was found in another study of Caucasian girls (Tao *et al.,* 1999). Quite marked ethnic differences have been reported in population prevalence of the COLIA1 "s" allele, which is relatively common in Caucasian populations, but is rare in Africans and Asians (Beavan *et al.,* 1998; Nakajima *et al.,* 1999). This has been suggested as a possible mechanism by which ethnic difference in fracture risk may be determined. The mechanism by which the Sp1 polymorphism predisposes to osteoporosis remains to be fully defined but preliminary data has shown evidence of allele-specific differences in binding of the Sp1 protein to the polymorphic recognition site, differences in allele-specific transcription, differences in collagen protein production, and differences in bone strength in samples derived from patients of different genotype (Mann *et al.,* 2001).

In summary, there is fairly convincing evidence to suggest that the COLIA1 Sp1 polymorphism acts as a marker for osteoporotic fracture. There is also evidence for weak association with BMD, which becomes more marked with increasing age, suggesting that COLIA1 alleles may be associated with age-related bone loss rather than peak bone mass.

Estrogen Receptor Genes

Estrogen, by interacting with its receptors in bone and other tissues plays an important role in regulating skeletal growth and maintenance of bone mass. Knockout mice for ERα and ERβ have reduced BMD compared to that seen in wild-type controls (Korach, 1994; Windahl *et al.,* 1999) and osteoporosis has also been observed in a man with an inactivating mutation of the ERα gene (Smith *et al.,* 1994). These data indicate that the ER genes are strong candidates for genetic regulation of bone mass. Sano *et al.* (1995) reported a positive association between a TA repeat polymorphism in the ERα gene promoter and bone mass in a small study of Japanese subjects. Similar results were reported by groups in the United States and Italy (Sowers *et al.,* 1999; Becherini *et al.,* 2000). Other investigators have reported positive associations between haplotypes defined by *PvuII* and/or *XbaI* polymorphisms in the first intron of the ERα gene and bone mass (Kobayashi *et al.,* 1996; Mizunuma *et al.,* 1997; Ongphiphadhanakul *et al.,* 1998; Sowers *et al.,* 1999) as well as age at menopause (Weel *et al.,* 1999). Other studies in Korean (Han *et al.,* 1997), Belgian (Vandevyer *et al.,* 1999), and Italian (Gennari *et al.,* 1998) women have found no association between *PvuII* polymorphisms and bone mass, however. Polymorphisms of ERα have also been studied in relation to postmenopausal bone loss. In a longitudinal study of Finnish women, early postmenopausal bone loss was associated with the ERα *PvuII* polymorphism (Salmen *et al.,* 2000), whereas a similar study by Willing showed no such association (Willing *et al.,* 1998). No association studies have been performed in which ERα polymorphisms have been related to osteoporotic fractures.

The molecular mechanism by which ERα polymorphisms influence bone mass are as yet unclear. The *PvuII* and *XbaI* polymorphisms lie in an apparently nonfunctional area of the gene but are in linkage disequilibrium with the TA polymorphism in the ERα promoter (Becherini *et al.,* 2000). It is conceivable that the TA repeat could influence gene transcription, but this has not yet been studied. In summary, ERα polymorphisms seem to be associated with BMD in some populations, although the mechanisms by which they do so remain unclear. The ERβ gene has been little researched as a candidate for osteoporosis, apart from one study which showed an association between a microsatellite marker close to the ERβ gene and BMD (Ogawa *et al.,* 2000).

Transforming Growth Factor Beta

Transforming growth factor beta (TGFβ) is a pleiotropic regulatory protein with diverse effects on cell growth and differentiation. Current evidence suggests that TGFβ plays an important role in bone metabolism, where it is thought to act as a coupling factor between resorption and formation and in keeping with this hypothesis, mutations have been described in the signal peptide region of the TGFβ molecule, which is responsible for Camaruti–Engelmann disease, a rare disorder characterized by bone pain and osteosclerosis affecting the diaphysis of long bones (Kinoshita *et al.,* 2000; Janssens *et al.,* 2000). In view of the above, the TGFβ genes represent important candidates for the regulation of bone mass and bone turnover. A rare C-deletion polymorphism in intron 4 of TGFβ-1 has been associated with low BMD, increased bone turnover, and osteoporotic fracture in one study from Denmark (Langdahl *et al.,* 1997), and very similar results were recently reported in another study from Italy (Bertoldo *et al.,* 2000). Although this polymorphism is close to the splice junction, it does not affect the splice acceptor site and the functional effects on TGFβ function (if any) are unknown. Another polymorphism of the TGFβ-1 coding region has been described which causes a Leucine–Proline substitution in the signal peptide region of TGFβ at amino acid 10. The C allele has been associated with high BMD and a reduced frequency of osteoporotic fractures in two Japanese populations (Yamada *et al.,* 1998), with BMD in Japanese adolescents (Yamada *et al.,* 1999), and with reduced rates of bone loss and improved response to treatment with alphacalcidol, an active metabolite of vitamin D (Yamada *et al.,* 2000). This polymorphism is associated with raised circulating levels of TGFβ, suggesting that it may influence protein secretion or stability. Two promoter polymorphisms of TGFβ have also

been described which are also associated with circulating TGFβ levels (Grainger *et al.,* 1999), but the relationship with BMD has not yet been reported.

Interleukin-1 Gene Cluster

Cytokines such as interleukin-1 have important effects on bone cells *in vitro* and have been implicated in the pathogenesis of postmenopausal bone loss. These genes are therefore important candidates for the genetic regulation of bone mass. The interleukin-1 gene cluster on chromosome 2 contains the genes for interleukin 1 (IL-1) alpha and beta genes as well as the gene for the interleukin-1 receptor antagonist (IL-1RA). Polymorphisms of these genes have been widely studied in relation to inflammatory disorders and some alleles have been identified which are associated with production of IL-1 or IL-1RA *in vitro.* This has prompted studies of the IL-1 gene cluster polymorphisms in relation to BMD. Keen and colleagues studied the relationship between BMD and bone loss in 108 postmenopausal women who were genotyped for an 86-base-pair repeat polymorphism in the second intron of the IL-1RA gene. No difference in BMD was observed between genotypes, but the A1/A1 genotype was found to be associated with increased bone loss at the spine. In another study, Langdahl found evidence of an association between IL-1RA polymorphisms and BMD was well as an association with osteoporotic fracture (Langdahl *et al.,* 2000b). The results of this study were in partial agreement with those reported by Keen (Keen *et al.,* 1998) in that the A1/A1 and A1/A3 genotypes were associated with reduced BMD. In contrast, no association was found between IL-1β polymorphisms and BMD. The mechanisms by which these polymorphism associate with BMD remain to be determined. Leukocytes from individuals with the A1/A1 and A1/A3 genotypes have been shown to produce less IL-1RA *in vitro* than the other genotype groups which would be consistent with increased bone loss, but plasma IL-1RA levels have paradoxically found to be higher in those who carry the A1/A1 genotype. These studies are of interest but further work will be required to clarify the relationship between IL-1RA alleles, BMD, and fracture and to identify the mechanisms responsible for the effects that have been observed.

Interleukin-6

Interleukin-6 is another potential candidate gene for the regulation of BMD, in view of its suggested role as a mediator of osteoclast activity and postmenopausal induced bone loss. Murray looked for evidence of an association between association between BMD and osteoporotic fracture in relation to an AT-rich minisatellite repeat in the 3′ flanking region of the IL-6 gene. In this study a positive association was found with lumbar spine BMD but no association was found with osteoporotic fracture (Murray *et al.,* 1997). In a further study a polymorphic AC-rich minisatellite close to the IL-6 gene was also reported to be associated with wrist BMD in Japanese women (Tsukamoto *et al.,* 1998). The most comprehensive study of IL-6 polymorphisms in relation to BMD is that of Takacs, however, who conducted a large-scale linkage and association study of the IL-6 gene in over 800 Caucasian and African-American sib pairs found no evidence to suggest that IL-6 alleles were related to BMD (Takacs *et al.,* 2000). These results do not support an important role for IL-6 in the genetic regulation of BMD.

Apolipoprotein E

The human Apolipoprotein E gene is polymorphic, with three common alleles (ε2, ε3, ε4) coding for three isoforms (E2, E3, E4) which differ from each other by a single amino acid and their binding affinity for the four ApoE receptors. ApoE has been suggested as a candidate for regulation of BMD because it is involved in the transport of vitamin K, which is a necessary cofactor for the hydroxylation of osteocalcin—an osteoblast-specific protein. Shiraki and colleagues reported that BMD values were significantly reduced in Japanese women who carried the ApoE4 allele (Shiraki *et al.,* 1997). While Salamone *et al.* (2000) found that the ApoE4 genotype was associated with accelerated postmenopausal bone loss in women from the United States, Heikkinen *et al.* (2000) found no association between ApoE and BMD or bone loss over a 5-year period in a study of 464 Finnish women. This study was complicated by the fact that half were randomized to HRT and half to calcium and vitamin D supplements, however. In a further study of American Caucasian women Cauley and colleagues (1999b) found a positive association between the ApoE4 allele and hip fracture that was independent of BMD.

In summary, the data assembled so far suggest that ApoE is a promising candidate gene for further study. More work will be required to assess the significance of the association between ApoE and bone phenotypes, however, and to investigate mechanisms by which it affects the skeleton.

Calcitonin Receptor

Calcitonin is a physiological inhibitor of osteoclast function, and its receptor is highly expressed on osteoclasts. A coding polymorphism causing a Proline–Leucine substitution at codon 436 of the calcitonin receptor gene has been described and the relationship between this polymorphism and BMD has been studied in French and Italian populations. Masi *et al.* (1998) reported that individuals homozygous for the Leucine substitution had reduced bone mass when compared with heterozygotes and Proline homozygotes. Taboulet and colleagues (Taboulet *et al.,* 1998) also reported an association between BMD and this polymorphism, but found that heterozygotes had higher BMD and a reduced risk of fracture

when compared with homozygotes. The effects of this polymorphism on calcitonin receptor function has not yet been studied and the absence of an allele–dose effect in the Taboulet study is difficult to explain.

Other Candidate Genes

Several other polymorphisms in candidate genes have been associated with bone mass, ultrasound properties of bone or bone dimensions in isolated studies and these are summarized in Table II. The results of these studies should be regarded as provisional until repeated and confirmed by other investigators.

Gene–Gene Interactions

As stated previously, genetic regulation of bone mass and other determinants of fracture risk appears to be under polygenic control. In view of this several investigators have studied the relationship between combinations of candidate gene polymorphisms and BMD. Willing and colleagues (Willing *et al.,* 1998) looked at the interaction between VDR and ERα polymorphisms in predicting BMD in a series of 171 postmenopausal women and found that individuals with combination of ERα *PvuII* "PP" and VDR "bb" genotypes had very high average BMD values at all skeletal sites examined. Another study by Gennari *et al.* (1998) in a population of postmenopausal Italian women, showed that the combination of VDR and ERα genotypes identified subgroups of individuals with very high and very low BMD. Vandevyer *et al.* (1999), however, found no significant interaction between VDR and ERα genotypes in predicting BMD in Belgian postmenopausal women.

Caution must be exercised in interpreting the results of studies that show an apparent interaction between two genetic polymorphisms in predicting BMD. The studies that have been performed so far have been of limited size with the result that subgroups of patients with different combinations of genotypes have been extremely small. For example, in Willing's study, the high BMD "PP/bb" subgroup consisted of only 11 individuals. Similarly, in Gennari's study, the high BMD "AABBtt-PPXX" subgroup consisted of 9 individuals, compared with 14 individuals for the low BMD "aabbTT-ppxx" subgroup. This raises the possibility of type II (false positive) statistical errors and indicates the need for large sample sizes when assessing gene–gene interactions

Pharmacogenetics and Osteoporosis

Pharmacogenetics is the study of how genetic factors influence the response to drug treatment. This is a subject of increasing interest in clinical medicine since it raises the prospect of being able to predict individual responses to drug treatment on the basis of genetic profiling (Roses, 2000). Several investigators have now looked at associations between candidate gene polymorphisms and the response of BMD to anti-osteoporotic treatments.

Table II Candidate Gene Studies in Osteoporosis

Candidate gene	Function	Type of polymorphism	Association	No. and type of subjects studied	Ethnic group (study)
Androgen receptor	Hormone receptor	Polyglutamine repeat, exon 1	BMD	261 Postmenopausal women	Caucasian (Sowers *et al.,* 1999)
PTH	Regulates calcium homeostasis	Intronic silent	Total body BMD; Bone dimensions	383 Postmenopausal women 91 Healthy women	Japanese (Hosoi *et al.,* 1999) Caucasian (Gong *et al.,* 2000)
PPAR gamma	Regulates adipocyte differentiation	Coding silent H446H	BMD	404 Postmenopausal women	Japanese (Ogawa *et al.,* 1999)
AHSG	Matrix component	Coding transitions T230M and T238S	Heel ultrasound, BMD, height	222 Postmenopausal women	Caucasian (Zmuda *et al.,* 1998, Dickson *et al.,* 1994)
Osteocalcin	Osteoblast product	Promoter polymorphism	BMD	160 Postmenopausal women	Japanese (Dohi *et al.,* 1998)
BMP-4	Osteoblast growth factor	Coding transition V147A	BMD (negative)	154 Postmenopausal women	Italian (Semprini *et al.,* 2000)
Matrix Gla protein	Matrix component	CA repeat	Wrist BMD	460 Postmenopausal women	(Tsukamoto *et al.,* 2000a)
MTHFR	Regulates folate metabolism;	Coding transition A222V	Spine BMD Total body BMD	307 Postmenopausal women	Japanese (Miyao *et al.,* 2000)
TNFR2	Receptor for TNF	Polymorphisms in 3′ UTR:	Spine BMD	34 Men / 125 women	Caucasian; Ashkenasi Jews (Spotila *et al.,* 2000)
CASR	Extracellular calcium receptor	CA repeat	Wrist BMD	247 Women	Japanese (Tsukamoto *et al.,* 2000b)

Calcium and Vitamin D

There is fairly convincing evidence that the VDR *BsmI* polymorphism predicts response of BMD to calcium supplementation. Ferrari and colleagues (Ferrari *et al.,* 1995) were the first to show a link between dietary calcium intake and VDR polymorphisms when they reported an association between bone loss at the lumbar spine in elderly individuals who were heterozygous for the *BsmI* polymorphism. Subsequently Krall and colleagues (Krall *et al.,* 1995) studied the relationship between VDR alleles and bone loss in 229 women who had participated in a controlled trial of calcium supplements in the prevention of postmenopausal bone loss. The calcium supplemented group showed no relationship between VDR genotype and bone loss, whereas in the placebo group, bone loss was significantly greater in the BB group when compared with the other genotype groups. Graafmans *et al.* (1997) studied the response to vitamin D supplementation in a series of 81 postmenopausal Dutch women who had taken part in a placebo-controlled trial of vitamin D supplementation on BMD and fracture incidence. These workers observed that the 2-year change of BMD values in the vitamin D group relative to the placebo group was significantly higher in the "BB" and "Bb" genotypes when compared with the "bb" genotype group. This study is of interest in relation to another study by the same group which showed that the "bb" genotype also had low BMD in a population-based study. Yamada and colleagues (2000) studied the relationship between response of BMD to 1α-hydroxyvitamin D in relation to a signal peptide polymorphism of the TGFβ1 gene. This study comprised 363 postmenopausal women who were treated with 1α-hydroxyvitamin D ($n = 117$); hormone replacement therapy (HRT) ($n = 116$), or who were untreated ($n = 130$). Individuals with the high BMD associated "CC" genotype responded significantly better to vitamin D treatment than the other genotype groups. The same trend was observed in the HRT group but the differences were not significant.

HRT Response

Some information is available on the relationship between candidate gene polymorphisms and response to HRT. Ongphiphadhanakul and colleagues (2000) studied the relationship between ERα polymorphisms and 1-year response to HRT treatment in 124 postmenopausal Thai women. Individuals with the "pp" genotype at the ERα *PvuII* site were found to respond less well to HRT (+2.3% increase in BMD) than the other genotype groups (+6–7% increase in BMD). In a similar but larger study of 248 Korean women, however, Han and colleagues (1999) found no association between *XbaI* or *PvuII* polymorphisms and 1-year response of BMD to HRT. Salmen *et al.* (2000) similarly found no association between ERα genotype and response to HRT in a study of 145 Finnish women. Taken together, these data do not support the view that ERα polymorphisms consistently predict response to HRT. Other candidate genes have been also studied in relation to HRT response. They include TGFβ1 (discussed above) and ApoE, which was analyzed by Heikkinen and colleagues (2000) in a study of 232 women who were treated with HRT and followed up after a 5-year period. No association was observed in this study between ApoE genotype and HRT responsiveness.

Response to Bisphosphonates

This is an area of great clinical relevance but is one that has been little studied. Marc and colleagues (Marc *et al.,* 1999) looked at the relationship between VDR genotype and response to Etidronate therapy in a small series of 24 postmenopausal women undergoing treatment with etidronate. The mean change in BMD over a 2-year period was significantly greater in the BB vs bb group with intermediate values in the heterozygotes. In another study, Qureshi *et al.* (1997) looked at the association between COLIA1 genotype and the response to etidronate treatment in a series of 48 early postmenopausal women who took part in a randomized controlled trial of etidronate in the prevention of postmenopausal bone loss. While no difference was observed in response of spine BMD to etidronate treatment, those with the "s" allele responded significantly less well at the femoral neck when compared with "SS" homozygotes. These preliminary data are of interest in raising the possibility that genetic markers can be used to predict therapeutic response to bisphosphonates, but further work in larger groups of patients will be required to confirm and extend these observations.

Implications for Clinical Practice

Studies on the genetic basis of osteoporosis have important implications for clinical practice. Mapping and identification of genes that regulate BMD offers the prospect of identifying novel molecules that can serve as targets for drug design in the search for new treatments for bone diseases. In addition, genetic markers that are associated with BMD or osteoporotic fracture could be used in the identification of patients at risk of fracture. The most promising candidate genes identified so far in this respect are COLIA1, TGFβ, and ApoE, although it is likely that information from genetic profiling using these and other markers would be combined with other risk factors such as low BMD to identify individuals at risk of fracture. The utility of this approach has recently been demonstrated for the COLIA1 polymorphism which has been found to enhance fracture prediction when combined with BMD measurements in two studies (McGuigan *et al.,* 1998; Weichetova *et al.,* 2000). Another benefit may be in identifying individuals who respond best to anti-osteoporotic treatments. This has already been demonstrated for some polymorphisms in relation to calcium and vitamin D treatment and further

work is certain to be performed in this area to identify genetic markers of response to other drug treatments as well as to identify markers for the development of adverse effects (Roses, 2000).

Introduction

Osteoporosis is a reduction in bone mass and a change in microarchitecture, which increases the susceptibility to fractures. The bone loss is brought about by an imbalance between bone resorption and bone formation, coupled processes that occur continuously throughout the skeleton to carry out its functions. Osteoclastic bone resorption releases calcium, phosphate, and other ions from bone for homeostasis and initiates the structural remodeling, which adapts skeletal architecture to mechanical loads. Bone resorption can also alter the bone marrow space in response to hemopoietic needs (Shinar and Rodan, 1993). As a consequence, the balance between bone resorption and bone formation can be influenced by many factors, which could therefore cause or contribute to osteoporosis. The key to understanding the pathogenesis of osteoporosis is the elucidation of factors that govern osteoclastic bone resorption, osteoblastic bone formation, and the link between the two. Characterization of these processes in the adult should help treat and manage this multifactorial disease. State-of-the-art knowledge of these subjects is covered in several chapters in this volume. Here we shall attempt in summary form to bring this information together in the context of osteoporosis.

Peak Bone Mass vs Rate of Bone Loss

Among the parameters that can be measured today, bone mass, as estimated by bone densitometry, is still the best predictor of osteoporotic fractures (Black *et al.,* 1992; Cummings *et al.,* 1995b; Melton *et al.,* 1993; Wasnich and Miller, 2000; Melton *et al.,* 1998; see also Chapter 74). The amount of bone in all individuals increases during growth, reaches peak in the 20s, starts decreasing in the late 30s, and exhibits an accelerated loss in women during the first 5–10 years after menopause (Melton, 1995), followed by a slower steady decrease thereafter. The latter phase is also seen in men after the age of 40. The amount of bone at a given age, and therefore the risk of osteoporotic fractures, will depend on the peak bone mass of that individual and the rate of bone loss until that age. Bone loss is determined by the balance between the rate of bone resorption and bone formation. The determinants of peak bone mass are primarily genetic (Cooper, 1999; see also Chapter 72), as shown by twin studies (Pocock *et al.,* 1987; Slemenda *et al.,* 1991), with the potential contribution of calcium intake, diet, and exercise during childhood and puberty (Nieves *et al.,* 1995). Family history and the geographic distribution of the incidence of osteoporosis in Europe further point to the importance of genetic background and dietary habits in the pathophysiology of this disease (Johnell *et al.,* 1995, Kanis *et al.,* 1999).

From a therapeutic/medical perspective, the pathogenesis of bone loss is probably most important since the majority of patients are seen many years after reaching peak bone mass. Twin studies (Pocock *et al.,* 1987) suggest that the rate of bone loss is less strongly influenced by genetics than peak bone mass.

It is apparent that multiple genes are responsible for the susceptibility to osteoporosis. Polymorphism in the genes of type I collagen, interleukin-1 (IL-1), and the receptors for estrogen, vitamin D, and IGF1 have been implicated in the pathogenesis of osteoporosis, among others, however, further studies are needed to validate these observations (Cooper, 1999). A couple of "high-bone-density" genes have been fully or partially identified by positional cloning

(Balemans *et al.,* 2001; Brunkow *et al.,* 2001; Johnson *et al.,* 1997; Koller *et al.,* 1998), but their relationship to bone density in the population at large remains to be established.

Most conditions that lead to osteoporosis, including estrogen deficiency, hyperparathyroidism, and hyperthyroidism, are associated with increased osteoclastic bone resorption. Multiple genes are likely to determine the level of these and other resorption stimuli, excessive response to such stimuli, and/or inappropriate "coupling" between resorption and formation. The possibilities are many. Although bone formation increases along with resorption, that increase is often insufficient to maintain bone balance. It should be kept in mind that it takes 3–4 months for osteoblastic bone formation to replace the bone resorbed by osteoclasts in 2–3 weeks (Eriksen, 1986). It is therefore possible that the defect is not in the "coupling," the molecular basis of which requires further study, but in the physiological ability of the bone formation process to keep up with the increased level of resorption. Higher turnover would thus lead to greater bone loss, as it usually does. Following is an analysis of the possible control points in resorption, coupling, and formation and how they might be affected by the etiological factors of osteoporosis.

Bone Resorption

Bone resorption is determined by the number of sites at which resorption occurs (estimated histomorphometrically by activation frequency), by the rate of osteoclast recruitment, and by the intensity and duration of osteoclast activity. These processes are discussed in detail elsewhere in this volume. To briefly summarize, starting with resorption sites, their distribution is probably not random and seems to be related to mechanical function, since the absence of strain (force divided by cross-sectional area), produced for example either by bed rest, lack of gravity, paralysis, or casting of a limb, increases bone resorption in the affected bone(s). Lack of mechanical strain could thus contribute to bone loss.

Extent resorption is influenced by factors that govern osteoclast number and activity. Osteoclasts are derived from hemopoietic precursors, probably granulocyte-macrophage colony-forming units (CFU-GM), branching off the monocyte macrophage lineage and suppression of the macrophage phenotype(Roodman, 1995; Lean *et al.,* 2000). Studies in mice have demonstrated the obligatory requirement of receptor-activating NF-κB (RANK) ligand (RANKL) a tumor necrosis factor (TNF)-related cytokine and its receptor RANK (receptor activating NF-κB) for osteoclast formation and activity (see Chapter 7). RANK-ligand activity is tightly modulated by its soluble neutralizing receptor osteoprotegerin (OPG), the lack of which produces in mice osteopenia, and the excess osteopetrosis (Bucay *et al.,* 1998; Simonet *et al.,* 1997). These factors became obvious candidates for the pathogenesis of osteoporosis, but no change in their abundance in the circulation has been observed in osteoporotic patients so far. On the other hand, agents that stimulate bone resorption *in vivo* and increase osteoclast formation from bone marrow cultures *in vitro* were shown to modulate RANK/RANKL/OPG production and signal transduction in culture (Chapter 7). Many of these agents have previously been implicated in the pathogenesis of osteoporosis including parathyroid hormone (Silverberg *et al.,* 1996), prostaglandin E (PGE) (Kawaguchi *et al.,* 1995), interleukin-1 (Kitazawa *et al.,* 1994), TNF-α (Kitazawa *et al.,* 1994), and, under certain conditions, IL-6 (Jilka *et al.,* 1995). Estrogen administered *in vivo* was shown to suppress *ex vivo* in human macrophages the production of IL-1 (Kitazawa *et al.,* 1994), TNF-α (Kitazawa *et al.,* 1994 Chapter 36), and prostaglandin E_2 (PGE2) (Kawaguchi *et al.,* 1995) and in murine bone marrow stromal cells, IL-6 (Jilka *et al.,* 1995). Estrogen was also shown in experimental systems to modulate RANK abundance and signaling as well as the production of M-CSF (monocyte-macrophage colony-stimulating factor), essential for osteoclastogenesis (see Chapter 36). In estrogen deficiency, hyperparathyroidism, and hyperthyroidism- associated bone loss, there is clear histological and biochemical evidence for increased osteoclastic bone resorption (Delmas, 1993; Parisien *et al.,* 1990) and increased osteoclast recruitment, which could be explained by effects of these agents on osteoclast differentiation from precursor cell. The histological appearance of osteoclast clusters and analogy with the function of monocytes and leukocytes raises the possibility that osteoclasts themselves may release osteoclast recruiting factors during bone resorption.

The next aspect deals with the extent of osteoclast activity once started. Trabecular perforation is a characteristic histological feature of cancellous bone in postmenopausal osteoporosis (Parfitt *et al.,* 1983). It has therefore been suggested that the intensity or duration of osteoclast activity may be increased. However, direct measurement of the depth of bone resorption lacunae, albeit imprecise (Compston and Croucher, 1991), failed to detect estrogen effects on this parameter (Steiniche *et al.,* 1989). It is therefore possible that trabecular perforation reflects the cumulative effect of resorption over time rather than the result of osteoclast activity in a single cycle of remodeling. Trabecular perforation is not a pronounced feature of bone loss in hyperthyroidism, for example, where it was reported that the trabeculae are thinner, but their number is not decreased. The data base for these observations is limited, moreover, they are all based on analysis of the iliac crest, which was shown to have different rates of cancellous bone turnover than vertebrae, and the cancellous bone volume of the two bones was also found to differ, possibly due to differences in mechanical function.

The stimuli responsible for stopping osteoclast activity during remodeling are not known. *In vitro* an osteoclast does not resorb a specific site for more than a couple of hours (Kanehisa and Heersche, 1988) and, when it moves away, it leaves behind nonmineralized, undigested matrix. Mineralized matrix seems to be a requirement for effective osteoclast activity (Chambers *et al.,* 1984). In addition to the systemic hormone calcitonin, local humoral factors, shown

experimentally to inhibit osteoclast formation or activity, include transforming growth factor (TGF)-β (Hattersley and Chambers, 1991), IL-4 interferon-γ. (Lacey *et al.,* 1995), prostaglandin E (Chambers and Ali, 1983) and IL-18, via GM-CSF (granulocyte-macrophage colony-stimulating factor) ((Horwood *et al.,* 1998). There is no conclusive evidence showing that these factors stop osteoclast activity during bone remodeling. It has also been suggested that mechanical strain in the matrix may inhibit osteoclast activity (Hillam and Skerry, 1995); mechanical strain increases prostaglandin production in bone cells (Somjen *et al.,* 1980), but there is no evidence that it plays a role in this case.

Recent evidence suggests that in postmenopausal osteoporosis the rate of bone resorption, reflected in biochemical markers, participates in the susceptibility to fractures not only by determining bone loss, but by increasing bone fragility directly (see Chapter 74), via effects on bone structure. Increased resorption could weaken trabeculae and cortical bone, due to indentations and incomplete mineralization at multiple remodeling sites.

To summarize this section, in most osteoporoses there is increased bone resorption, resulting from the combined effects of increased osteoclast "tonus" caused by sex steroid deficiency, with the potential contribution of secondary hyperparathyroidism due to inadequate calcium intake and vitamin D deficiency, all superimposed on reduced mechanical loads. Quantitatively, osteoclast recruitment, i.e., osteoclast number, which is strongly influenced by sex steroids, seems to be the rate-limiting factor.

Coupling Bone Resorption to Formation

The next point relevant to the pathophysiology of osteoporosis is the coupling of formation to resorption. Histologically, bone formation follows resorption. Calcium kinetics as well as biochemical markers have shown that the two change usually in tandem in the same direction. This led to the postulate that the two processes are mechanistically coupled and to the search of "coupling" factors. It is of interest that many molecular factors that stimulate bone resorption can also stimulate, apparently independently, bone formation. These include prostaglandin E (Jee *et al.,* 1995), parathyroid hormone (Dempster *et al.,* 1993), and possibly others, such as IL-1 (Boyce *et al.,* 1989) and TGF-β (Centrella *et al.,* 1994). Stimulation of bone resorption and formation by these agents would be one form of coupling. Unequal effects of these factors on resorption and formation, respectively, could bring about the inadequate coupling seen in osteoporosis (Martin and Rodan, 2001). It has been reported, for example, that estrogen increases skeletal resistance to parathyroid hormone-induced resorption (Cosman *et al.,* 1994).

Another proposed coupling mechanism is the release of bone- forming growth factors from the matrix during resorption, for example, IGF (Mohan and Baylink, 1991) or TGF-β (Oreffo *et al.,* 1989). Since estrogen may stimulate production of these factors by osteoblasts (Centrella *et al.,* 1994; Schmid and Ernst, 1992), their abundance in bone would decrease in estrogen deficiency.

A third interesting hypothesis proposed by Frost states (paraphrased) that since bone structure and mass are regulated by mechanical load, the set point of that feedback is altered by estrogen deficiency (Frost, 1987). For example, in the absence of estrogen, a hypothetical sensor would perceive the mechanical load to be lower and reduce bone mass accordingly. This idea can be further developed to consider mechanical forces themselves as a coupling factor (Rodan, 1991, 1996) since they stimulate bone formation and may inhibit resorption. The feedback loop would be local at the site of bone remodeling and would work as follows. Bone resorption, initiated, for example, by a decrease in mechanical strain or a need for calcium mobilization, would proceed until dissipation of that stimulus. A thinner trabecula subjected to the prevailing force would experience a higher strain. Bone formation would follow and continue as long as osteoblasts perceive locally increased strain. Such a feedback loop would explain the resorption of mechanically nonfunctional cancellous bone and the well-known adaptation of trabecular architecture to the lines of mechanical force. This is consistent with the observation that in perforated trabeculae, which do not carry load, bone resorption seems to be more extensive and is not followed by formation and the fact that in vertebrae the vertical trabeculae, which play a primary role in weight-bearing, are most conserved during bone loss (Mosekilde, 1990). The adaptation of bone architecture to mechanical loads could not be explained in any other way. In essence, this is biomechanical coupling of bone resorption to formation, since resorption inevitably would increase the degree of mechanical strain in the tissue and formation would take place to relieve that strain. The most likely receptors for mechanical strain, at this time, are the integrins (Hynes, 1992) through which cells bind to the extracellular matrix, where the strain is produced (Rodan, 1991).

Why does this coupling fail in estrogen deficiency? It is possible, as suggested by Frost, that the response of osteoblasts to strain is diminished, possibly via effects on integrin signaling. Another simple reason may be that, in the face of excessive bone resorption, the increase in bone formation cannot keep pace. As mentioned, it takes 3–4 months to replace bone resorbed in 2–3 weeks. Once resorption is abated by estrogen, bisphosphonates, or calcitonin, the remaining trabeculae can increase in size until they optimize their load-bearing capacity. This could take longer than one remodeling cycle, which may explain the continuous increase in bone density observed with bone resorption inhibitors well beyond the 4 months required for the filling of the "remodeling space" (Tonino *et al.,* 2000).

Bone Formation

The next arm in the remodeling cycle to be considered in the pathophysiology of osteoporosis is bone formation. A reduction in bone formation could lead to inadequate bone

replacement during remodeling and to gradual bone loss. This would be consistent with reduced "wall thickness," the amount of bone formed in a remodeling cycle (Compston and Croucher, 1991; Kimmel *et al.,* 1990), and reduced cancellous bone formation (Parfitt *et al.,* 1995), reported in some osteoporotic patients by histomorphometry of the iliac crest. However, using biochemical markers which measure bone turnover in the whole skeleton, several studies have shown on the average a significant increase in bone turnover (resorption and formation) in patients with postmenopausal osteoporosis, regardless of age (Delmas, 1993; and Chapter 74). It is possible that reductions in bone formation observed in iliac crest biopsies, the only accessible site in patients, are not representative of the skeleton as a whole. Nonetheless there is probably a population of patients, possibly among the very old ones, in which decreased bone formation plays a role in their osteoporosis, for example in growth hormone and/or IGF-1 deficiency (Langlois *et al.,* 1998; Kurland *et al.,* 1998). Both growth hormone and IGF-1 injected in humans were shown to increase the level of biochemical markers for bone formation as well as for bone resorption, although the total "bone balance" estimated by bone mineral density did not improve (Marcus, 2000). Our knowledge of the physiological control of bone formation during bone remodeling is more limited than that of bone resorption, which limits the understanding of "coupling" and effective use of bone-forming agents in therapy.

Following this general discussion of pathophysiological mechanisms, focused on the failure of bone remodeling to maintain adequate bone mass, we shall now briefly discuss each of the known etiological factors. This discussion is meant to complement related chapters in this volume.

Local Factors in Osteoporosis

There are many reasons for exploring the roles of local regulators of bone resorption and formation in the pathogenesis of osteoporosis. However, most of the evidence is either based on animal models or indirect data in humans. Direct evidence for an alteration in local factors in osteoporotic patients remains an exciting, but not yet realized, research goal. Among the reasons for exploring local factors are that it has been difficult to demonstrate consistent, relevant differences in the levels of systemic hormones in osteoporotic patients compared with appropriate controls (Lips *et al.,* 1987; Silverberg *et al.,* 1989; Tiegs *et al.,* 1985) and many osteoporotic patients have site-specific changes related to their particular fracture syndrome (Cummings *et al.,* 1995a). This exploration has been reinforced by the discovery of many local factors that influence bone metabolism. These are discussed in detail elsewhere in this volume. This chapter will summarize results that point to their possible pathogenetic role in osteoporosis. The problem has been difficult, not only because there are so many local factors, but also because these factors have complex effects on bone cells, probably related to multiple receptor and signal transduction systems. Moreover, these factors can be produced by nonbone cells adjacent to the skeleton, including hematopoietic and vascular elements.

Estrogen and Local Factors

Osteoporotic women and men are usually estrogen deficient. While estrogen may affect systemic hormones and play a direct role in the activity of differentiated bone cells, there is also evidence that estrogen can affect the production or activity of local factors, including cytokines, prostaglandins, and growth factors. There are many local factors that respond to estrogen, and these factors can modulate each other, so that decreasing or increasing a single factor may not give an accurate picture of its physiologic or pathologic role. Data from animal models and cell and tissue cultures suggest that estrogen deficiency increases and estrogen replacement decreases the activity of IL-1, TNF-α, and IL-6, as well as prostaglandins (Kawaguchi *et al.,* 1995; Kimble *et al.,* 1995; Manolagas and Jilka, 1995). Estrogen can increase TGF-β, leading to osteoclast apoptosis (Hughes and Boyce, 1997), and increase osteoprotegerin which would block both formation and activity of osteoclasts (Hofbauer *et al.,* 1999).

Cytokines and Osteoporosis

The cytokines that affect bone metabolism can be classified in three groups. IL-1 and TNF-α are potent stimulators of bone resorption *in vivo* and *in vitro.* IL-4, IL-13, and interferon-γ (INF-γ) can inhibit bone resorption. IL-6, IL-11, and related cytokines that interact with a receptor system involving the protein GP-130 probably act as stimulators of an early stage of osteoclast formation, thus enhancing bone resorptive responses to other agonists. All of these factors can influence prostaglandin production (see below).

IL-1 and TNF-α probably play a central role in mediating bone loss in the ovariectomized rat (Kimble *et al.,* 1995). Bone loss can be prevented in this model, not only by estrogen, but by a combination of IL-1 receptor antagonist and TNF binding protein. The role of TNF-α is further supported by the finding that bone loss after ovariectomy is blunted in a transgenic animal model in which the TGF binding protein is overexpressed (Ammann *et al.,* 1995). However, bone loss after ovariectomy is also blocked in transgenic mice which lack the IL-1 activating receptor (Lorenzo *et al.,* 1998).

These cytokines may come from marrow hematopoietic cells rather than bone cells. Marrow supernatants from ovariectomized animals stimulate prostaglandin production and bone resorption, and this effect can be blunted by adding the IL-1 receptor antagonist to the supernatants (Kawaguchi *et al.,* 1995). In humans, peripheral macrophages or marrow cells of estrogen-deficient women have been reported to produce more IL-1, TNF-α, and IL-6 (Pacifici *et al.,* 1991a;

Abrahamson *et al.,* 2000; Kassem *et al.,* 1996; Bismar *et al.,* 1995). However, these results are variable and not been confirmed in all studies (Hogasen *et al.,* 1995, McKane *et al.,* 1994, Kassem *et al.,* 1996). Nevertheless, there does appear to be increased bone resorbing activity produced by cultured monocytes of postmenopausal women, compared to premenopausal women (Cohen-Solal *et al.,* 1998).

IL-4 and IL-13 can inhibit bone resorption, in part by decreasing prostaglandin production (Kawaguchi *et al.,* 1996, Miyaura *et al.,* 1995; Nakano *et al.,* 1995). However, IL-4 has also been shown to enhance macrophage colony-stimulating factor production in marrow cells, which could have a positive effect on osteoclastogenesis (Lacey *et al.,* 1994). IL-4 overexpression in transgenic mice produces a picture of osteoporosis with low turnover and decreased osteoblastic function (Lewis *et al.,* 1993). The mechanism is not known and may depend on effects of IL-4 early in development.

A role for IL-6 is supported by two lines of evidence (Manolagas and Jilka, 1995). (1) IL-6 can enhance osteoclastogenesis when added with its soluble receptor. Some of this effect may also be due to stimulation of prostaglandin synthesis (Tai *et al.,* 1997). (2) IL-6 production is regulated by systemic hormones. Its hepatic production is increased by parathyroid hormone (PTH) (Mitnick *et al.,* 2000). An initial study suggested that the bone loss induced by ovariectomy did not occur in animals in which the IL-6 gene had been knocked out, but subsequent analysis of later generations of this line did not confirm this point. IL-6 antibodies can diminish osteoclastogenesis in cell cultures but do not prevent bone loss in ovariectomized animals and do not block the stimulation of prostaglandin production by marrow supernatants (Kawaguchi *et al.,* 1995, Kimble *et al.,* 1995). Circulating IL-6 levels decrease with age in humans, but no difference has been found between osteoporotic patients and age-matched controls (McKane *et al.,* 1994). However, marrow cells from estrogen-deficient humans produce more IL-6 (Bismar *et al.,* 1995). Other cytokines may be involved. IL-11 can enhance osteoclast production (Manolagas and Jilka, 1995), and LIF has biphasic effects on bone resorption (Lorenzo, 1991). Overexpression of LIF also results in osteoporosis in animals (Metcalf and Gearing, 1989).

Macrophage colony-stimulatory factor (M-CSF or CSF-1) is important in osteoclast formation and acts through a pathway involving the c-*fos* gene (Grigoriadis *et al.,* 1994). Animals with deficiency of M-CSF or a knockout of c-*fos* have osteopetrosis. However, overexpression of c-*fos* does not cause osteoporosis, but does result in increased bone and cartilage tumor formation.

Prostaglandins, Leukotrienes, and Nitric Oxide in Osteoporosis

Prostaglandins (PGs), leukotrienes (LTs), and nitric oxide (NO) can be produced by bone cells and adjacent hematopoietic and vascular cells and have potent effects on bone resorption and formation (Gallwitz *et al.,* 1993, Kawaguchi *et al.,* 1995, Ralston *et al.,* 1995). Their production is increased in a number of inflammatory models. These factors may interact with each other. For example, the response of the bone cells to fluid shear stress involves an increase in both NO and PG production, and both can be blocked by blocking NO synthesis (Klein-Nulend *et al.,* 1998). The increase in PG production is attributed to induction of COX-2. Impact loading increases both PG and NO production (Pitsillides *et al.,* 1995; Burger and Klein-Nulend, 1999). LTs can stimulate bone resorption by both prostaglandin-dependent and -independent mechanisms and may activate osteoclasts directly, in contrast to PGs, which increase osteoclastogenesis but have a direct inhibitory effect on the activity of isolated osteoclasts (Flynn *et al.,* 1999).

PGs may mediate some of the resorptive effects of cytokines. PGs have biphasic effects on both formation and resorption of bone. Exogenous PGs and circulating PGs produced by malignant tumors can increase both resorption and formation of bone in humans. There are data supporting a role for endogenous PGs in the bone loss associated with immobilization and ovariectomy in animals, and inhibitors of PG synthesis may decrease bone resorption, although their multiple effects on other organs limits their use (Bell *et al.,* 1994). This problem may be overcome by the use of COX-2 selective inhibitors (Raisz, 2001). On the other hand, the anabolic response to impact loading could be blocked by COX-2 inhibitors (Chow and Chamber, 1994).

Growth Factors and Osteoporosis

Both the IGF and TGF-α families are expressed abundantly in bone. It seems likely that a loss of the activity of these factors could be important in the impairment of bone-formation responses that is characteristic of osteoporosis (Boonen *et al.,* 1999). Studies of these factors are complicated by the presence of multiple binding proteins for IGFs and by the complex activation pathways of TGFβ. There is conflicting evidence concerning the levels of IGFs and their binding proteins (IGFBPs) in osteoporosis. Local production of IGFs and activation by changes in binding protein could play an important role. For example, IGFBP-5 may be a factor that binds and decreases the activity of IGF in bone (Nicolas *et al.,* 1995) as well as a direct stimulation of growth. PTH and PGE_2 can cause the release of IGFBP-5, and this, together with the ability of these hormones to increase IGF-1 production, may be responsible for some of their anabolic effect (Hakeda *et al.,* 1996). Decreased levels of TGF-β, but not IGFs, have been reported in ovariectomized rats (Finkelman *et al.,* 1992). Other growth factors such as fibroblast growth factor (FGF) and platelet-derived growth factor (PDGF) could be involved, but these have not yet been studied either in animal models or in human disease.

Systemic Factors in the Pathophysiology of Osteoporosis

In addition to local factors that are ultimately and mechanistically of pivotal importance in the cellular pathophysiology of osteoporosis, systemic regulators of mineral metabolism are believed to play an important role. Clearly, a reduction in circulating concentrations of estrogens is the single most important reason why postmenopausal women are at greater risk for bone loss than premenopausal women (Lindsay, 1995). More recent obseervations from the Study of Osteoporotic Fractures have established further that the low "residual" estrogen levels in postmenopausal women not taking estrogens are determinants in bone mineral density and in fracture risk (Ettinger *et al.,* 1998; Cummings *et al.,* 1998). The importance of estrogen sufficiency in men also has elegantly been elucidated in two male models of estrogen deficiency involving the estrogen receptor (Smith *et al.,* 1994) and the aromatase enzyme that converts androgens to estrogens (Morishima *et al.,* 1995; Carani *et al.,* 1997; Bilezikian *et al.,* 1998; Grumbach and Auchus, 1999). Animal knockout experiments of the alpha-estrogen receptor and of the aromatase gene provide further support for the key role of estrogens in male development (Lubahn *et al.,* 1993; Couse and Korach, 1999; Windahl *et al.,* 1999; Oz *et al.,* 2000).

The importance of estrogen in male skeletal health is amplified further in epidemiological studies correlating declining estrogen levels, but not declining testosterone levels, in age-related bone loss in men (Khosla *et al.,* 2001). Falahati-Nini *et al.* (2000) have shown recently that when men are rendered temporarily but acutely hypogonadal, estrogen is the prime regulator of the subsequent increase in markers of bone resorption.

The importance of androgens in establishing and maintaining bone mass is also well recognized (Orwell, 1996, 1998). In addition to the sex steroids, glucocorticosteroids are key systemic factors in bone metabolism. We recognize the glucocorticosteroids not so much for any major role they may play in normal mineral homeostasis but rather for their devastating impact on bone metabolism when present in excess (Reid, 1999). In Cushing's disease or when glucocorticosteroids are used therapeutically, bone loss is a major complication. Excessive thyroid hormone may also have a deleterious effect on bone metabolism (Stern and Lakatos, 1999). Elsewhere in this book, these points are considered in depth. This section deals primarily with evidence that casts a potential role for the calciotropic hormones in the pathophysiology of osteoporosis.

Vitamin D

1,25-Dihydroxyvitamin D, the active metabolite of vitamin D, enhances the absorption of calcium from the gastrointestinal tract, helps to regulate calcium handling in the kidney, serves to maintain normal bone remodeling, and is an important regulator of parathyroid hormone (Clemens and O'Riordan, 1995). Any abnormality in vitamin D formation, metabolism, or action could lead, therefore, to profound changes in calcium balance and result in bone loss. Many studies report a fall in the circulating concentration of 1,25-dihydroxyvitamin D with advancing age (Eastell *et al.,* 1991; Epstein *et al.,* 1986; Tsai *et al.,* 1984; Fujisawa *et al.,* 1998). More consistently, levels of the substrate for 1,25-dihydroxyvitamin D, namely 25-hydroxyvitamin D, fall as a function of age (Blumsohn and Eastell, 1995). Reduced concentrations of these vitamin D metabolites are thus considered to be one reason why vitamin D deficiency is implicated in age-associated reductions in bone mass.

Inadequate sources of vitamin D from either diet or sunlight are the most obvious possibilities for reduced levels of vitamin D in older individuals. In the skin, ultraviolet B, at 290–315 nm, converts 7-dehydrocholesterol to previtamin D (Clemens and O'Riordan, 1995) 7-Dehydrocholesterol levels in the skin fall by ~50% between 20 and 80 years of age (MacLaughlin and Holick, 1985). The process by which skin produces previtamin D is also a function of sunlight itself. In northern latitudes, sunlight may contribute very little to vitamin D stores during the long winter months (Bouillon *et al.,* 1987; Hodkinson *et al.,* 1973; Webb *et al.,* 1988, 1990). Even in Maine and Massachusetts, no synthesis of previtamin D occurs in the skin during the late fall and winter (Rosen *et al.,* 1994; Webb *et al.,* 1988). Other factors such as avoidance of sunlight and the use of highly protective UV-blocking creams may contribute to the diminishing importance of sunlight as a source of vitamin D.

The other source of vitamin D, the diet, is also a factor contributing to the potential for inadequate stores with age. Among adult Americans, vitamin D intake is rather marginal, 75–150 IU daily, well below the recommended daily allowance of 400–600 IU (Consensus Development Conference, 1994). In addition, mechanisms associated with absorption of vitamin D from the gastrointestinal tract begin to decline with age (Barragry *et al.,* 1978).

Subclinical vitamin D deficiency has been shown in some groups of osteoporotic American women (Villareal *et al.,* 1991). A number of studies indicate subclinical vitamin D deficiency among home-bound subjects or those living in extended care facilities (Chapuy *et al.,* 1992; Gloth *et al.,* 1995; Komar *et al.,* 1993).

Adequate vitamin D depends not only upon sufficient sources and absorption but also upon normal metabolism of the parent vitamin. Alteration of hepatic or renal hydroxylation of vitamin D or 25-hydroxyvitamin D, respectively, can lead to deficiency (Rao, 1993; Siegel and Bilezikian, 1995). The kidney becomes a pivotal organ in this discussion because it is the source of the active metabolite, 1,25-dihydroxyvitamin D. Factors that help to regulate the renal formation of 1,25-dihydroxyvitamin D are parathyroid hormone, phosphorus, calcium, and 1,25-dihydroxyvitamin D itself. A decline in the ability of the kidney to form 1,25-dihydroxyvitamin D develops with age (Gallagher, 1990).

Older individuals respond to the stimulating effects of parathyroid hormone on 1,25-dihydroxyvitamin D production less well than young, normal individuals (Riggs *et al.,* 1981; Tsai *et al.,* 1984). Despite attempts to demonstrate a specific defect in renal hydroxylating capacity in osteoporosis (Slovik *et al.,* 1981; Tsai *et al.,* 1984), most studies have equated the defect with declining renal function *per se* (Halloran *et al.,* 1990, 1996)

Other hypotheses related to the role of vitamin D in the pathogenesis of osteoporosis focus on reduced sensitivity of the small intestine to 1,25-dihydroxyvitamin D. Intestinal resistance to 1,25-dihydroxyvitamin D is a proposed primary alteration (Eastell *et al.,* 1991; Pattanaungkul *et al.,* 2000) due to an acquired alteration in binding of 1,25-dihydroxyvitamin D to its receptors in the small intestine (Francis *et al.,* 1984), or to an age-related reduction in intestinal vitamin D receptor concentration (Ebeling *et al.,* 1992; Gennari *et al.,* 1990; Horst *et al.,* 1990).

Finally, controversial observations implicating genetic polymorphisms of the vitamin D receptor point to possible underlying genetic bases for osteoporosis (Eisman, 1995; Peacock, 1995). Such genetic alterations could have as a functional counterpart altered physiological action of vitamin D on calcium absorption (Dawson-Hughes *et al.,* 1995). This subject, reviewed elsewhere, does not provide the kind of certainty that one requires to establish the vitamin D receptor in mechanisms associated with the pathophysiology of osteoporosis (Grant and Ralston, 1997; Cooper, 1999; Nguyen and Eisman, 2000).

The potential role of vitamin D in the pathophysiology of osteoporosis should be distinguished from overt vitamin D deficiency that is associated with the clinical syndromes of rickets (children) or osteomalacia (adults). This discussion highlights, instead, the concept that subclinical vitamin D inadequacy occurring by any of the mechanisms described above leads to suboptimal peak bone mass or to impaired maintainance of calcium balance. The clinical endpoint, osteoporosis, is not believed to be different from any other presentation of age-related osteoporosis. Thomas *et al.* have shown that subclinical vitamin D deficiency as defined by levels of 25-hydroxyvitamin D below 15 ng/ml occurs rather commonly among free-living subjects in Boston, Massachusetts, during both the winter and the summer months (Thomas *et al.,* 1998).

Parathyroid Function

Parathyroid hormone is a central regulator of calcium homeostasis by virtue of its actions to remodel bone, to reclaim filtered calcium in the kidney, and to facilitate absorption of calcium from the gastrointestinal tract via its action to stimulate the renal production of 1,25-dihydroxyvitamin D (Goltzman and Hendy, 1995). Normal bone remodeling depends upon normal dynamics and actions of parathyroid hormone. One could postulate that excessive or deficient parathyroid hormone could account for bone loss associated with aging. Indeed, two central, but opposing, hypotheses state that either too much or too little parathyroid hormone contributes to age-related bone loss (Bilezikian and Silverberg, 2000; Silverberg and Bilezikian, 2001). These two concepts will be exlored in this section.

There is now general agreement that parathyroid hormone concentrations increase with age. Immunoradiometric (IRMA) and immunochemiluminometric (ICMA) assays, which selectively measure circulating intact parathyroid hormone, have helped to demonstrate that the increase in parathyroid hormone is not due to declining renal function alone (Nussbaum and Potts, 1994). Earlier radioimmunoassays that measured circulating, inactive fragments typically showed increases that could have been due to reduced renal clearance of these fragments by the aging kidney. It is now clear, however, that there is a clear increase in biologically active levels of parathyroid hormone as a regular function of aging, independent of any change in renal function. The increase in parathyroid hormone may be associated with a similar rise in bone turnover as assessed both by bone markers (Duda *et al.,* 1988; Eastell *et al.,* 1988) and by histomorphometric indices of bone metabolism (Vedi *et al.,* 1982).

A key hypothesis implicating parathyroid hormone in the development of osteoporosis relates either to the increase in parathyroid hormone concentrations with age or to enhanced sensitivity at target organs (Kotowicz *et al.,* 1990; Riggs and Melton, 1983). If sensitivity to parathyroid hormone is enhanced in the postmenopausal state, for example, normal circulating concentrations of parathyroid hormone could be deleterious in older individuals. Enhanced sensitivity to parathyroid hormone has been invoked as an explanation for why, in the first decade after the menopause, primary hyperparathyroidism seems to be commonly revealed. However, there are no prospective data showing that in these women, primary hyperparathyroidism existed in a subclinical form before the menopause. Nevertheless, it is generally accepted that when postmenopausal patients with primary hyperparathyroidism are given estrogen, calcium levels decline without any change in the circulating concentration of parathyroid hormone (Marcus *et al.,* 1984; Selby and Peacock, 1986). These observations argue for an inhibitory effect of estrogen on parathyroid hormone action in bone and for enhanced sensitivity to the skeletal effects of parathyroid hormone when women become estrogen deficient. Such a mechanism could be operative in postmenopausal women without primary hyperparathyroidism. Some reports have attempted to show that for each picomole per liter rise in parathyroid hormone, osteoporotic women have a specific and quantitatively higher level of bone turnover and bone loss (Kotowicz *et al.,* 1990). However, enhanced sensitivity to parathyroid hormone has not been universally demonstrated (Ebeling *et al.,* 1992a; Tsai *et al.,* 1989).

The nuances of parathyroid hormone dynamics calls attention to the circadian rhythm of parathyroid hormone secretion. Daily parathyroid hormone secretion follows a biphasic profile with peaks at 1800 and 0200 hr (Calvo

et al., 1991; Markowitz *et al.,* 1988; Tohme *et al.,* 1995). Presumably, the larger nocturnal peak is secondary to mild hypocalcemia induced by nighttime fasting. In older osteoporotic women, whose baseline level of parathyroid hormone was elevated, it was shown that the normal diurnal pattern of parathyroid hormone secretion was not altered but rather that the nocturnal secretion of bone resorption markers was increased. Although Ledger *et al.* (1995) implicated parathyroid hormone as causative in the nocturnal increase in bone markers, other explanations, independent of parathyroid hormone, are equally plausible. Nevertheless, McKane *et al.* (1996) have shown that the age-related increase in parathyroid hormone can be controlled by increasing dietary calcium, albeit to rather high levels, ~2.5 g daily, and that concomitant reductions in elevated urinary markers of bone resorption are seen.

One avenue for investigation of a definitive role for parathyroid hormone in the pathogenesis of osteoporosis has focused upon a possible genetic basis. This possibility has been much less intensively studied than that for the vitamin D receptor but the results are similarly inconclusive. Suggestive, but by no means definitive, data have been provided, linking the parathyroid hormone type 1 receptor to osteoporosis (Duncan *et al.,* 1999). Another recent study found a polymorphism in the parathyroid hormone gene to be a marker for low bone mineral density in a group of postmenopausal Japanese women (Miayo *et al.,* 1999).

In the discussion of parathyroid hormone as a possible causative factor in the pathogenesis of osteoporosis, its interactions with estrogen are of particular interest. Clearly, there is functional interaction between parathyroid hormone and estrogens, best illustrated in the menopausal woman who becomes estrogen deficient. At this time, primary hyperparathyroidism often surfaces as a clinical disorder (Silverberg and Bilezikian, 2000).

In addition, use of estrogen in postmenopausal women with primary hyperparathyroidism is associated with a reduction in serum calcium levels (Marcus *et al.,* 1984a; Selby and Peacock, 1986). The reasonable postulate follows that estrogen is somehow an antagonist to the actions of parathyroid hormone. The logic follows that in the context of estrogen deficiency (i.e., the menopause), the "deleterious" actions of parathyroid hormone are no longer opposed.

Gallagher has shown that estrogen treatment increases calcium absorption with a concomitant increase in parathyroid hormone levels (Gallagher *et al.,* 1980). If this increase in parathyroid hormone is a response to a small decrease in serum calcium levels—assuming a direct effect of estrogen of gastrointestinal calcium absorption (see later)—one would expect to see an increase in PTH levels, but the results have not been consistent (Stock *et al.,* 1985; Marshall *et al.,* 1984; Boucher *et al.,* 1989). Several studies have proposed in fact that estrogen deficiency alters the set point for parathyroid hormone secretion in normal women (Boucher *et al.,* 1989), and that in osteoporotic women, blunted parathyroid gland sensitivity to circulating calcium is also seen (Cosman *et al.,* 1991). In addition, estrogen therapy in postmenopausal women leads to reduced bone resorption, but not bone formation, in response to parathyroid hormone (Cosman, 1993).

The concept of parathyroid hormone as a pathophysiological culprit in postmenopausal osteoporosis has been stated even more boldly by Riggs *et al.* (1998), who have proposed a "unitary model for involutional osteoporosis." In this hypothesis, Riggs *et al.* advance the idea that not only is parathyroid hormone involved in the early postmenopausal mechanisms of estrogen deficiency—a relative suppression—but that increases in parathyroid hormone are important later in the setting of age-related bone loss. They have proposed that in the second, age-related phase of bone loss, the actions of estrogen deficiency are no longer primarily at skeletal sites but rather at the gastrointestinal and renal systems. These extraskeletal actions of estrogen deficiency lead to increased urinary calcium excretion and reduced calcium absorption. The resulting secondary increase in parathyroid hormone then is responsible for the ensuing bone loss that continues as part of the aging process. The hypothesis could be strenghtened by more direct experimental observations that estrogens indeed do have important nonskeletal effects at these sites in the way the hypothesis envisions.

The hypothesis also is problematical from a chronological point of view. The actions of estrogens are seen in two time frames, the early one being a skeletal action and the later one being directed at nonskeletal sites. It is not clear how the actions of estrogen deficiency would affect these tissues differentially in time. Other confounding elements to the hypothesis are covered by Bilezikian (1998).

An important alternative hypothesis is that the age-related increase in parathyroid hormone is adaptive, protecting against bone loss, and that in osteoporosis, heightened parathyroid glandular responsiveness is required to maintain bone mass. In this context, reduced responsiveness of the parathyroid glands is viewed as contributing to the development of osteoporosis.

Altered responsiveness to parathyroid hormone could be due to changes in circadian rhythmicity of parathyroid hormone secretion. In contrast to the studies of Ledger *et al.* (1995) showing normal circadian rhythm of parathyroid hormone, Eastell *et al.* (1992) reported that women exhibited a blunted parathyroid hormone peak compared with men, and subsequently, a less dramatic decline in nighttime urinary calcium excretion. Nighttime urinary calcium excretion declined in men by 34% whereas in women, it decreased by only 17%. Postmenopausal osteoporotic women showed a further blunting of their nocturnal parathyroid hormone peak, with no change in fractional excretion of calcium at night (Eastell *et al.,* 1992). Such inefficient renal calcium conservation could contribute to the osteoporotic process by excessive nocturnal urinary calcium excretion.

In addition to a possible blunted circadian rhythm of parathyroid hormone associated with osteoporosis, Prank *et al.* (1995) have shown that pulsatile secretory dynamics of parathyroid hormone in osteoporotic women are abnormal.

Pulsatile parathyroid hormone secretion is normally superimposed upon the diurnal rhythmicity of the hormone, a phenomenon typical of many hormones besides parathyroid hormone, such as growth hormone, ACTH, and cortisol. Prank and colleagues postulated that such abnormalities in pulsatility could contribute to osteoporosis. The reduction in pulsatility could also be a physiological explanation for why intermittent parathyroid hormone is a promising therapy to restore bone mass in osteoporosis (Dempster *et al.,* 1993; Slovik *et al.,* 1986). The demonstration that intermittent administration of parathyroid hormone in low dosage is anabolic for osteoporotic bone further underscores the strength of the hypothesis implicating relative parathyroid hormone deficiency in osteoporosis while also illustrating the complexity of parathyroid hormone actions on bone. (Lindsay *et al.,* 1997; Kurland *et al.,* 2000; Neer *et al.,* 2000; Roe *et al.,* 1999).

Further evidence for abnormalities in parathyroid hormone secretory dynamics in osteoporosis comes from the work of Silverberg and colleagues (1989), who studied parathyroid hormone glandular responsiveness in osteoporosis. After a hypocalcemic stimulus, osteoporotic women demonstrated a much less exuberant increase in parathyroid hormone than their age-matched nonosteoporotic counterparts. It is of further interest that the normal older women exhibited a much greater response to the same hypocalcemic stimulus than younger subjects (Silverberg *et al.,* 1986), arguing for a physiological need for greater parathyroid hormone responsiveness with aging. The greater parathyroid hormone response was required to maintain 1,25-dihydroxyvitamin D levels in the older, nonosteoporotic subjects. It is not clear whether this age-related increase in parathyroid hormone responsiveness with aging reflects an altered set point for calcium or not (Cosman *et al.,* 1991; Ledger *et al.,* 1994).

The evidence thus seems to suggest that parathyroid hormone has the potential to be both catabolic and anabolic on the skeleton. This point is well illustrated further in primary hyperparathyroidism in which the anabolic potential for cancellous sites (vertebral spine) and the catabolic potential for cortical sites (distal radius) are often seen in the same patient (Silverberg *et al.,* 1989, 1994). How parathyroid glandular responsiveness and parathyroid hormone *per se* are important in the pathogenesis of osteoporosis remain to be clearly elucidated.

Calcitonin

Calcitonin, a natural product of C-cells in the thyroid gland, has intrinsic antiresorptive properties on bone (Becker *et al.,* 1995). Despite this property and several clinical examples of its antiresorptive efficacy in Paget's disease of bone and in hypercalcemia of malignancy, it has been difficult to establish a physiological role for calcitonin in normal calcium metabolism. Nor surprisingly, therefore, attempts to link deficiencies in calcitonin to osteoporosis have been disappointing (Blumsohn and Eastell, 1995).

Basal calcitonin concentrations, metabolic clearance, and production rates are all unchanged in osteoporosis (Reginster *et al.,* 1992). Calcitonin levels do not appear to decline with age (Body and Heath, 1983; Tiegs *et al.,* 1986). Moreover, in the menopause, calcitonin kinetics to provocation do not appear to be consistently altered (Pansini *et al.,* 1988; Stevenson, 1982). It would seem at this point that calcitonin is not an important systemic factor in the development of osteoporosis.

Summary

This chapter has reviewed underlying hypotheses to account for the pathophysiology of osteoporosis and the potential roles of local and systemic factors in its development. In chapters found elsewhere in this volume, many of these concepts are developed more fully in the context of what is currently known about the processes and mechanisms underlying the biological, biochemical, and molecular characteristics of the skeleton.

CHAPTER 74

Evaluation of Risk for Osteoporosis Fractures

Patrick Garnero and Pierre D. Delmas
Inserm Research Unit 403, Hôpital E. Herriot, and Synarc, Lyon 69003, France

Introduction

Osteoporosis is a systemic disease characterized by a low bone mass and microarchitectural deterioration of bone tissue, with a consequent increase in skeletal fragility and susceptibility to fracture (Anonymous, 1993). This definition implies that the diagnosis can and probably should be performed before any fragility fracture has occurred, which is a real challenge for the clinician. The level of bone mass can be assessed with adequate accuracy by measuring bone mineral density (BMD) using dual X-ray absorptiometry (DXA). However, this measurement does not capture all risk factors for fracture. Bone fragility also depends on the architecture and remodeling of bone, i.e., the quality of bone that cannot be readily assessed. It has been suggested that this component of bone strength may be assessed by ultrasonic measurements of bone and by measuring bone turnover using specific serum and urinary markers of bone formation and resorption. In addition the risk of fracture is also influenced by the propensity to fall and the ability to adapt to such falls, and these extraskeletal risk factors for fracture can be evaluated with simple questionnaires and clinical tests. In this paper we will briefly review the diagnostic values of clinical risk factors, bone mass assessment by DXA and ultrasound, and biochemical markers, and we will discuss the potential utility of combining these various tests for predicting fracture risk.

Clinical Risk Factors for Fractures

Clinical risk factors for osteoporosis can be used in two different ways: (1) to identify those women who are more likely to have osteoporosis and therefore who should have a BMD measurement; (2) to improve the fracture risk prediction in women who have already had a BMD measurement. Several clinical risk factors are associated with a low BMD, but none is powerful enough to predict BMD level in individuals (Aloia *et al.,* 1985; Liel *et al.,* 1988; Eiders *et al.,* 1989; Kleerekoper *et al.,* 1989; Stevenson *et al.,* 1989; Slemenda *et al.,* 1990; Pouilles *et al.,* 1991; Ooms *et al.,* 1993; Dawson-Hughes *et al.,* 1993; Kanis *et al.,* 1997). Some diseases such as anorexia nervosa, intestinal malabsorption, chronic renal failure, severe hyperthyroidism, Cushing's syndrome, and prolonged immobilization are often associated with osteoporosis, but their prevalence in the general population is low, and they have limited value for screening purposes. Conversely, some risk factors such as low calcium and high caffeine intake and alcohol and tobacco use have a high prevalence but a poor predictive value. Thus, models based on the combination of clinical risk factors evaluated by extensive questionnaires have failed to predict bone mass with sufficient accuracy to be useful in the management of the individual patient as they have poor sensitivity and specificity (Kleerekoper *et al.,* 1989; Slemenda *et al.,* 1990; Pouilles *et al.,* 1991).

We looked at the predictive value of clinical risk factors for osteoporosis in a cohort of 666 healthy postmenopausal women belonging to the OFELY cohort who completed an extensive questionnaire on fracture and medical history, diet, and exercise habits. We found that seven variables were independent predictors of femoral neck BMD, i.e., age, years since menopause, weight, history of fragility fracture after age 45, estrogen and corticosteroid therapy, and some rare diseases associated with osteoporosis. These were used to compute a score ranging from 0 to 19, and we found that a score of 4 had a sensitivity of 93% and a specificity of 61%

for detecting osteoporosis defined by a femoral neck BMD *T* score of $\leqslant -2.5$ (Albrand *et al.,* 1998).

More recently, in a population of 6958 elderly women age 75 years and over who participated in the EPIDOS study, it was found that the most predictive factors for very low BMD defined as a *T* score of $\leqslant -3.5$ were low body weight, history of fracture after the age of 50 years, slow gait, balance impairment, low grip strength, and dependence for instrumental activities of daily living. Using a score based on these risk factors has a sensitivity of 80% at the median cutoff (Dargent-Molina *et al.,* 2000). Weight was the strongest determinant of very low BMD and has about the same sensitivity as the complete score. If these findings can be confirmed in other larger cohorts, such simple rapid questionnaires might be useful for detecting those asymptomatic postmenopausal women who would benefit from a BMD measurement.

Clinical risk factors can also be used to improve the prediction of fracture risk in women who already had a bone mass measurement. In elderly women, several clinical features have been shown in prospective cohort studies to be associated with the risk of hip fracture even after adjustment for the level of hip BMD (reviewed in Eddy *et al.,* 1998). Ninety percent of hip fractures in elderly people result from a fall, and factors that influence the risk of falling and/or the protective response during a fall are likely to influence the risk of hip fracture (Grisso *et al.,* 1991). In a large prospective study of 9516 white American women, 65 years of age or older, Cummings *et al.* (1995) identified several fall-related risk factors that predicted hip fracture, including the use of long-acting benzodiazepines and anticonvulsant drugs, low physical activity, the inability to rise from a chair without using one's arms, visual impairment, and some indices of poor health status. Neuromuscular impairment increases the risk of falling but also influences the speed of adaptation, the coordination and the protective response during a fall. In a cohort of 7575 French women age 75 years of older, the risk of subsequent hip fracture was significantly increased, even after adjustment for femoral hip BMD, in women with a slow gait speed, with difficulties in doing a tandem (heel-to-toe) walk—i.e., with neuromuscular impairment—and in women with a visual acuity $<2/10$ (Dargent-Molina *et al.,* 1996). The incidence of hip fractures among women classified at high risk based on both a high fall-risk status and low BMD was found to be 29 per 1000 woman-years, compared with 11 per 1000 in women at risk on the basis of either a high fall-risk status or a low BMD, and with 5.4 per 1000 woman-years in those at low risk on the basis of both criteria (Dargent-Molina *et al.,* 1996).

Even with this combined approach, about one-third of women with hip fracture had not been identified as being at high risk, indicating that other factors are important in the pathogenesis of hip fracture. A maternal history of hip fracture doubles the risk of hip fracture even after adjustment for femoral neck BMD (Cummings *et al.,* 1995), stressing the importance of heredity in determining the geometry and structural properties of bones. One such factor is the length of the femoral neck, which has been shown in prospective studies to be associated with hip fractures, especially of the femoral neck (Faulkner *et al.,* 1993). A history of wrist and vertebral fractures, but also of any fracture, increases the risk of hip fracture after adjustment for BMD.

Although these clinical risk factors can easily be assessed with a rapid questionnaire and physical examination, they are probably of limited value in younger women. A personal history of fractures is still predictive, but their prevalence is much lower in women younger than 65 years of age. Fall-related factors have not been tested but are likely to be poor discriminants in younger and healthier women. On the basis of data generated in the Study of Osteoporotic Fractures, the National Osteoporosis Foundation of the USA recommended four clinical risk factors that are likely to provide information about the risk of osteoporotic fractures independently of the level of BMD: maternal history of hip fracture, personal history of fragility fracture after 45 years of age, smoking, and low body weight (<57 kg) (Eddy *et al.,* 1998).

Bone Mineral Density and Ultrasound Measurements

Several cross-sectional studies have shown that bone mass—measured by a variety of techniques including single and dual photon absorptiometry, DXA, quantitative computed tomography, radiography absorptiometry, and radiogrammetry of the metacarpal—is significantly lower in osteoporotic patients than in controls. The strength of the association has been confirmed by several prospective studies showing that each decrease of 1 standard deviation of BMD measured by DXA is associated with an age-adjusted 50–150% increase in the risk of osteoporotic fractures in postmenopausal women (Marshall *et al.,* 1996; Kanis and Gluer, 2000). The risk prediction has been found across various age ranges (but is weaker after 80 years of age), in ambulatory and long-term care residents (Broe *et al.,* 2000), and in studies with short- and long-term (up to 15 years) follow-up and is stronger when BMD is measured at the site of the future fracture. Measurements of BMD with an adequate technique at the spine, hip, forearm, or heel or total-body BMD/BMC have similar value in predicting the risk of all osteoporotic fractures. If the main concern is to detect the risk of hip fracture, measurement of hip BMD is preferable. Prediction of intertrochanteric fractures is improved by measuring the trochanteric area; prediction of femoral neck fractures is increased by measuring the femoral neck and further enhanced when measurement is limited to the upper half of the femoral neck (Schott *et al.,* 1998; Duboeuf *et al.,* 1997). The WHO definition of osteoporosis and low bone mass provides adequate cutoffs for identifying women at high risk of hip fracture, as shown in Fig. 1, from the EPIDOS study (Schott *et al.,* 1998).

Bone quantitative ultrasonography (QUS) is a promising recent technique for the diagnosis of osteoporosis (reviewed

Figure 1 Hip fracture incidence per 1000 women-years assessed prospectively over 2 years of follow-up according to baseline level of femoral neck BMD in 7598 healthy women 75 years of age and older. The EPIDOS study. Adapted from Schott *et al.* (1998).

in Jergas and Schmidt, 1999; Bauer, 1999). Provided that revised diagnostic criteria are used for QUS (Frost *et al.,* 2000) which, however, may be device specific, it has recently been shown that a similar proportion of postmenopausal women are identified as osteopenic as with spine or hip BMD (Frost *et al.,* 2001). Low calcaneal broadband ultrasound attenuation and speed of sound predict the risk of hip fracture in elderly institutionalized (Porter *et al.,* 1990) and healthy (Hans *et al.,* 1996; Bauer *et al.,* 1997) women with a power similar to BMD. More recently in a small prospective study of younger postmenopausal women, ultrasound transmission velocity measured at the distal radius and patella was predictive of all nonspine fractures, with a higher prediction of wrist fractures by distal forearm ultrasound and hip and ankle fractures by patella ultrasound (Gnudi *et al.,* 2000). It has been suggested that QUS may give information not only about BMD but also about the architecture and elasticity of bone, and that a combination of DXA and calcaneal QUS may be useful for identifying women at very high risk of fracture (Porter *et al.,* 1990; Hans *et al.,* 1996; Bauer *et al.,* 1997; Gnudi *et al.,* 2000). QUS is an attractive technique as it is relatively cheap, does not involve ionizing radiation, and is portable and is therefore suitable for screening strategies. There are, however, some unresolved issues: the accuracy, long-term stability and precision of the technique are unknown, and it is yet unclear whether the prospective data obtained with QUS of the calcaneus can be extrapolated to other sites (tibia, phalanges, patella) measured with devices that may have quite distinct technical features. Prediction of fractures others than hip remains to be further evaluated in large prospective studies. In addition, the various devices have not been cross-calibrated. Once these different issues are resolved, QUS may play an important role in the assessment of fracture risk.

Assessment of Fracture Risk by Biochemical Markers

Hormones

Because the trauma associated with hip fracture produces acute changes in hemodynamics and in a variety of hormones, hormonal measurements performed after fracture are difficult to interpret. Only data from prospective studies in which blood and urine sampling was performed prior to the fracture will be reviewed. Although vitamin D deficiency and age-related secondary hyperparathyroidism have been suggested to play a role in the skeletal fragility of elderly women, measurements of serum 25-hydroxyvitamin D (25-OHD), 1,25-dihydroxyvitamin D (1,25-(OH)2D), and serum parathyroid hormone (PTH) appear to have limited value in healthy women for the prediction of fracture. In the EPIDOS cohort, serum PTH and 25-OHD were not predictive of hip fracture risk (Garnero *et al.,* 1996b). These findings were confirmed in the Study of Osteoporotic Fractures (SOF) in women over 65 years of age showing no predictive value of serum PTH and 25 OHD for either hip or vertebral fractures (Cummings *et al.,* 1998). In the same study women in the lowest quintile for serum 1,25-(OH)2 D (<23 pg/ml) had a 2-fold increase in the risk of hip (but not of vertebral) fracture that was no longer significant after adjustment for

calcaneal BMD (Cummings *et al.,* 1998). In a younger population of healthy postmenopausal women from 50 to 89 years of age (OFELY study, mean age 64 years), we recently found no significant association between serum levels of 25 OH D and the risk fractures (40% vertebral, 60% nonspine fractures), whereas women in the highest quartile of PTH had a 1.8-fold increased risk (Garnero *et al.,* 2000a).

Estrogen deficiency is believed to be one of the few major determinants of postmenopausal bone loss and skeletal fragility. However, circulating 17β-estradiol levels explain only a small proportion of interindividual variability of BMD and bone loss (Slemenda *et al.,* 1996) and most of cross-sectional studies have failed so far to show different serum 17β-estradiol values in fracture cases and in controls. In a recent study, Cummings *et al.* (1998) showed that women 65 years of age and older with undetectable serum estradiol (<5 pg/ml) had a 2.5-fold increase in the risk of subsequent hip and vertebral fractures as compared with women with detectable serum estradiol, an association that remained significant after adjustment for age, weight, serum estrone, sex-hormone-binding globulin (SHBG) and calcaneal BMD. Such a finding was, however, not confirmed in another large prospective study (EPIDOS) in women 75 years of age and older in whom women with low estradiol levels were not at increased risk of hip fracture (Chapurlat *et al.,* 2000). In contrast, we found that elderly women with serum levels in the highest quartile were moderately protected from fracture with a relative risk of 0.66 compared to the other women. However, this protective effect disappeared after adjustment by body weight, suggesting that the association between increased estradiol levels and decreased hip fracture risk is mainly mediated by body weight. The reasons of the discrepancies between the SOF and EPIDOS studies on serum estradiol data are unclear and could be due to differences in body weight (higher in the SOF study), but more probably to difference in age which was on average 8 years lower in the SOF study. It seems indeed reasonable to believe that the role of residual secretion of steroids is more likely to play a role in younger postmenopausal women. This hypothesis is supported by results obtained in the OFELY cohort comprising younger postmenopausal women. In that population, serum estradiol levels in the lowest quartile (<11 pg/ml) had a relative risk of all osteoporotic fractures of 2.2 compared to the other women (Table I), an association that remained significant after adjustment for age and body weight (Garnero *et al.,* 2000a). In the same study we also found that decreased levels of dehydroepiandrosterone sulfate (DHEAs)—which can be metabolized to both active androgens and 17β-estradiol—were also associated with increased fracture risk independently of body weight and estradiol levels (Garnero *et al.,* 2000a). Thus, all together, these recent data suggest that the influence of the residual secretion of estrogen on the risk of fracture may decrease with advancing age. The increased risk associated with low estradiol levels in younger postmenopausal women does not seem to be mediated by increased bone resorption as in the OFELY study markers of bone resorption were predictive of fracture risk independently of serum estradiol levels (Garnero *et al.,* 2000a). A potential mechanism could be that low estradiol levels are associated with increased osteocyte death (Tomkinson *et al.,* 1997), a common finding in elderly women with hip fracture (Dunstan *et al.,* 1990). SHBG binds 17β-estradiol and thereby decreases its bioavailability. In the three above-described studies a high serum SHBG was moderately—and not consistently across all fracture types—associated with an increased risk of osteoporotic fractures (Cummings *et al.,* 1998; Garnero *et al.,* 2000a; Chapurlat *et al.,* 2000). In the SOF study women with both undetectable serum 17β-estradiol and a high SHBG had a marked increase in hip and vertebral fractures with relative risks of 6.9 and 7.9, respectively (Cummings *et al.,* 1998).

Table I Serum Hormone Levels and the Risk of Osteoporotic Fracture In Postmenopausal Women: The OFELY Study

Hormones at baseline	Cutoff of high risk	Relative risk (95% Cl)
Estradiol	Lowest quartile	2.2 (1.2–4.0)
	each 10 pg/ml decrease	1.5 (0.95–2.2)
DHEA sulfate	Lowest quartile	2.1 (1.2–3.8)
Sex-hormone binding globulin	Each additional 1 μg/dl	1.5 (1.1–2.1)
	Highest quartile	1.6 (0.9–2.9)
Estrone	Lowest quartile	1.5 (0.8–2.8)
Testosterone	Lowest quartile	1.4 (0.7–2.8)
PTH	Highest quartile	1.8 (1.01–3.4)
25 (OH) vitamin D	Lowest quartile	1.2 (0.6–2.2)

Note. Osteoporotic fractures (20 vertebral and 35 peripheral) were recorded during an average 5-year follow-up in 435 healthy postmenopausal women (mean age 64 years). Adapted from Garnero *et al.* (2000a).

Biochemical Markers of Bone Turnover and the Rate of Bone Loss

Several cross-sectional studies indicate that bone turnover increases rapidly after the menopause and this increase in both bone formation and bone resorption is sustained long after the menopause, up to 40 years (Garnero *et al.,* 1996a). BMD measured at various skeletal sites correlated negatively with bone turnover assessed by various markers in postmenopausal women. We have shown that the correlation between bone markers and BMD becomes much stronger with advancing age, so that in women more than 30 years after the menopause bone turnover accounts for 40 to 50% of the variance of bone mineral density of the whole skeleton (Garnero *et al.,* 1996a). These cross-sectional data suggest that a sustained increase of bone turnover in postmenopausal women induces a faster bone loss and therefore an increased risk of osteoporosis.

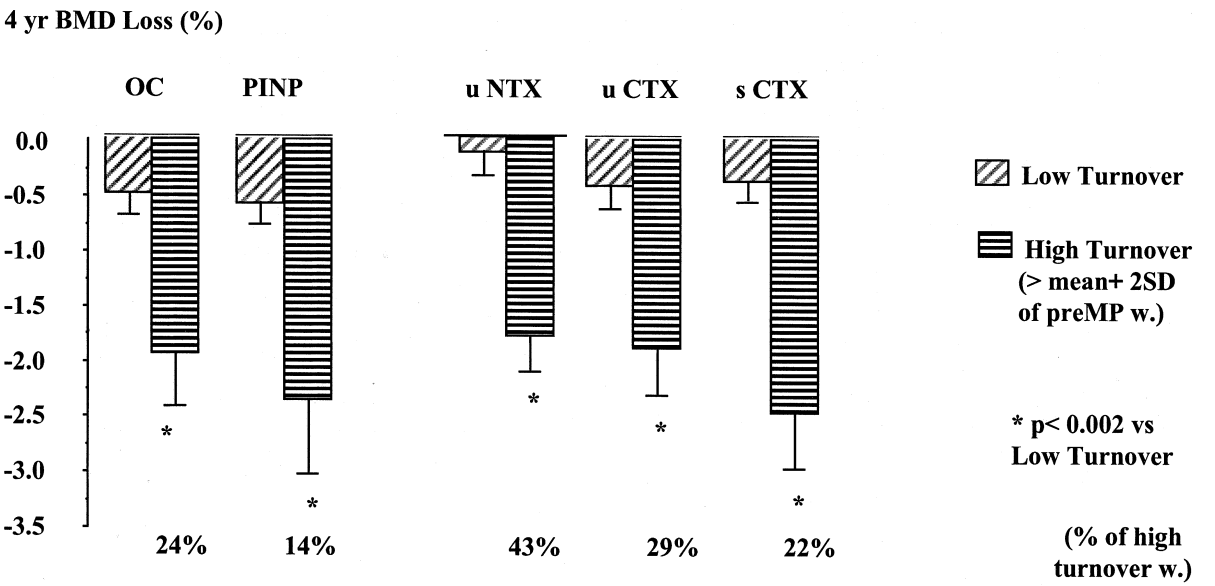

Figure 2 Rate of bone loss in postmenopausal women with high and low bone turnover. Bone loss at the forearm was evaluated by measuring BMD by DXA on four occasions over a 4-year period in 305 postmenopausal women (mean age, 64 years). For each bone marker each women was classified as a low or high bone turnover using as a cutoff the mean value + 2 SDs of 134 premenopausal women. The figure shows the percentage of bone loss from baseline during the 4-year study period in low and high bone turnover groups. Women whose baseline marker values indicated high bone remodeling lost bone two to six times faster over the next 4 years than those whose marker values were normal. Adapted from Garnero *et al.* (1999).

Longitudinal studies, which are necessary to avoid potential confounding factors, suffer, however, from methodological issues: indeed, when bone loss is assessed by annual measurement of BMD at the spine, hip, or radius over 2–4 years, the amount of bone loss is of the same order of magnitude as the precision error of repeated measurements in a single individual, i.e., 3–4%. This technical limitation precludes a valid assessment of the relationship between the rate of bone turnover and the subsequent rate of bone loss in individual postmenopausal women, and probably explains some of the conflicting results that have been published and recently extensively reviewed (Stepan, 2000). Indeed, the association between baseline levels of bone markers and rate of bone loss is more consistent and stronger when bone loss is measured at a very precise site such as radius than when measured at the spine and hip (Stepan, 2000). When the precision error on the rate of bone loss is reduced by performing nine measurements over 24 months, the correlation coefficient between bone markers and bone loss tends to improve from about −0.3 to −0.8 (Johansen *et al.,* 1988). Recently in a cohort of 305 postmenopausal women ages 50–88 years (mean 64 years) who had annual radius BMD measurements over 4 years, we have investigated the predictive value of baseline values of bone turnover markers (Garnero *et al.,* 1999). Serum and urinary C-terminal cross-linking telopeptide of type I collagen (CTX) and urinary N-terminal cross-linking telopeptide of type I collagen (NTX) for bone resorption, and serum osteocalcin and procollagen type I N propeptide (PINP) for bone formation, were found to be highly correlated with the rate of bone loss. In addition, in women within 5 years of menopause who had the highest rate of bone loss, correction of the observed correlation coefficients by errors on bone loss and bone marker measurements resulted in a marked increase in the predictive value of bone markers (Table II). Women with baseline values of bone turnover above the premenopausal range had a rate of bone loss four- to sixfold higher than women with a low turnover (Fig. 2). Ultimately, the weight of evidence will come from long-term studies. A retrospective study (Ross and Knowlton, 1998) performed over 13 years in women (mean age at baseline, 62 years) in whom calcaneal BMD loss was assessed by eight measurements, showed that 1 standard deviation increase in new specific bone markers such as osteocalcin, bone-specific alkaline phosphatase, and free pyridinoline cross-links was associated with a twofold increased risk of rapid bone loss defined as the upper tertile of rate of loss. There is currently only one prospective longitudinal long-term study in which the assessment of bone turnover with nonspecific markers (serum alkaline phosphatase, fasting urinary calcium, and hydroxyproline) at the time of menopause was correlated with the spontaneous rate of bone loss over the next 12 years. This study showed that early postmenopausal women classified as fast losers based on these markers had lost 50% more bone 12 years later than those diagnosed as slow losers (Hansen *et al.,* 1991).

In summary, with the current performance of bone marker and bone loss measurements, it appears that a single measurement of biochemical markers of bone turnover cannot predict the absolute rate of bone loss in an individual

Table II Correlation between Baseline Levels of Biochemical Markers of Bone Turnover and the Forearm Bone Loss over 4 Years in 51 Women within 5 Years of Menopause: The OFELY Study

Marker of bone turnover	Observed *r* value	*R* value after correction for error of the estimation on individual		
		Error on bone loss	Error on bone marker	Error on rate of bone loss and bone marker
Osteocalcin	−0.53	−0.72	−0.68	−0.91
PINP	−0.40	−0.54	−0.48	−0.66
U-NTX	−0.39	−0.53	−0.56	−0.76
U-CTX	−0.40	−0.55	−0.59	−0.81
S-CTX	−0.47	−0.64	−0.58	−0.79

Note. The error on the rate of bone loss was estimated from the mean and standard errors of the estimate for individual regression analyses of BMD against time. The error on the bone turnover marker levels was estimated from published intraindividual coefficients of variation for each marker. Correction of the observed correlation coefficients by errors on bone loss, bone markers, and both parameters were based on the formula proposed by Hassager *et al.* (1991). Adapted from Garnero *et al.* (1999).

woman. However, clearly increased levels of bone markers in postmenopausal women can be regarded as a risk factor for rapid bone loss in the subsequent years.

Markers of Bone Turnover and Fracture Risk

Several retrospective studies have compared bone marker levels in patients with osteoporotic fractures and in controls. However, bone turnover can change after a fracture because of immobilization, because of callus formation and/or because of the frequent regional activation of bone turnover (Ingle *et al.,* 1999a,b). To overcome these limitations, relationships between bone turnover markers and fracture have been investigated when samples were taken within a few hours after the hip fracture or several years after when the primary remodeling period of high activity has passed (reviewed in Garnero, 2000). Although most of these retrospective studies suggested that bone resorption is increased and bone formation is decreased in fracture cases compared to age-matched controls (Akesson *et al.,* 1993, 1995), we cannot exclude that a proportion of these changes of bone turnover may be the result of acute changes in body fluid and hormone levels related to the trauma. Thus, it seems difficult from retrospective studies to determine whether differences in bone turnover levels are related to the underlying rate of bone turnover leading to fracture, or to changes of bone turnover occurring after the fracture.

Relating baseline bone turnover levels with the subsequent risk of osteoporotic fractures is the valid methodology to assess their clinical utility. The previously mentioned study (Hansen *et al.,* 1991) was extended to a 15-year follow-up of 182 women during which 23 women experienced a peripheral fracture and 25 had one or more spinal fractures (Riis *et al.,* 1996). The fracture group had a significantly lower BMD than the group without fracture and a higher initial 3-year rate of bone loss after the menopause. Interestingly, bone mass and the rate of bone loss predisposed to fracture to the same extent, with odds ratios of about 2. Women with both initial low bone mass and an increased rate of bone loss had a threefold increase in the risk of fracture compared with the whole population. This study suggests that initial peak bone mass and postmenopausal rate of bone loss are both important determinants of osteoporosis.

More recently prospective studies have looked at the relationships between levels of biochemical markers of bone formation and bone resorption and the risk of fractures (reviewed in Garnero, 2000). For bone formation markers, conflicting results have been obtained. In the large multicentric cohort of elderly women in France (EPIDOS), no significant relationships were found between levels of serum osteocalcin and bone alkaline phosphatase and the risk of hip fracture occuring during a 2-year follow-up (Garnero *et al.,* 1996b). More recently in two prospective studies performed in younger healthy postmenopausal women [OFELY and Hawai Osteoporosis Study (HOS)], a significant positive association between increased levels of bone alkaline phosphatase and the risk of vertebral and nonvertebral fracture was observed (Garnero *et al.,* 2000a; Ross *et al.,* 2000). The different findings between these studies may be related to the type of fracture but more probably to the duration of follow-up which was of 22 months in the EPIDOS study and of 5 years in the OFELY study. As discussed above, high levels of bone formation markers are associated with a greater bone loss (Garnero *et al.,* 1999). Thus, if the increased risk of fracture is mediated partly through a more rapid bone loss (Hansen *et al.,* 1991), a follow-up of several years may be necessary to detect the association.

In contrast to bone formation markers, very consistent data on the relationship between increased levels of bone resorption markers and fracture risk have been reported in four large prospective studies (Rotterdam, EPIDOS, OFELY, and HOS). Indeed, levels of bone resorption assessed by urinary or serum CTX or urinary free deoxypyridinoline above the premenopausal range were consistently associated with about a twofold higher risk of hip, vertebral, and nonhip and

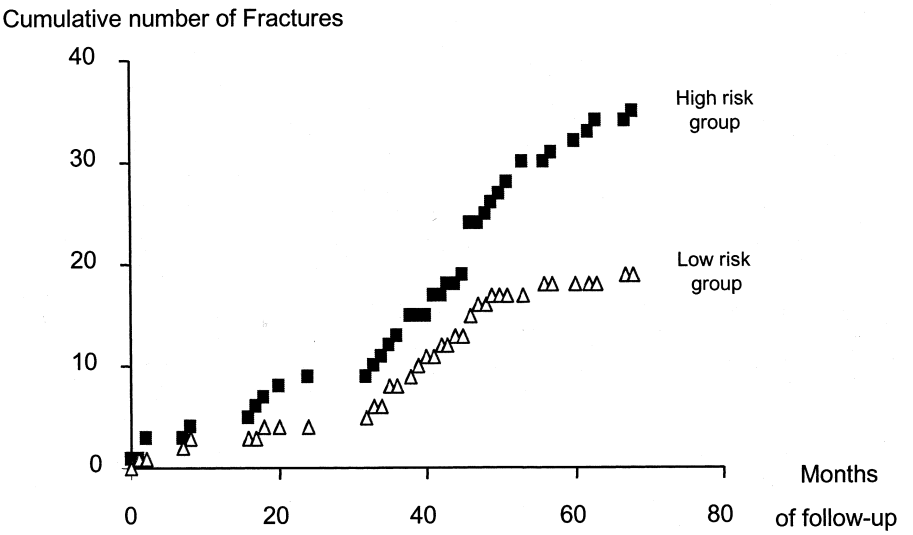

Figure 3 Cumulative number of fractures according to time of follow-up in postmenopausal women with baseline levels of urinary CTX in the highest quartile (high-risk group) and in women with levels in the three lowest quartile (low-risk group). The OFELY study. The number of incident fractures is higher in those women with baseline levels of urinary CTX in the highest quartile compared to women with levels in the three lowest quartiles, irrespective of time of follow-up. For the design of the OFELY study please refer to legend to Table I. Adapted from Garnero *et al.* (2000a).

nonvertebral fractures (Garnero *et al.,* 1996b, 2000a; Ross *et al.,* 2000; van Daele *et al.,* 1996) (Fig. 3). Serum CTX should be measured on fasting morning samples to reduce the variability of the measurement. The odds ratio was not modified after adjusting for potential confounding factors such as mobility status and were only marginally decreased after adjusting for BMD measured by DXA. Thus, the combination of BMD and bone turnover measurement allows the identification of a subgroup of elderly women at much higher risk of hip fracture than those identified by each test alone (Table III). Increased bone resorption was associated with increased fracture risk only for values above the upper limit of the premenopausal range, indicating that bone resorption becomes deleterious for bone strength only when it exceeds a normal physiological threshold, which appears to be the upper range of premenopausal women. These data also suggest that increased resorption could lead to increased skeletal fragility through two independent mechanisms. First, a prolonged increase of bone turnover will lead after several years to a lower BMD, which is a major determinant of reduced bone strength. Second, increased bone resorption above the upper limit of the normal range may induce microarchitectural deterioration of bone tissue such as perforation of trabeculae, a major component of bone strength.

Table III Combination of Bone Mineral Density (BMD) by DXA and Bone Resorption Markers to Predict the Risk of Fractures in Postmenopausal Women: The OFELY Study

	Odds ratio	Probability of fracture (%) (for 5 years)
All women		12.6
Low femoral neck BMD (T score <-2.5)	2.8 (1.4–5.5)	39
High S-CTX (T score $>+2$)	2.1 (1.2–3.8)	25
High urinary free DPD (T score $>+2$)	1.8 (1.0–3.4)	24
Low BMD + high S-CTX	3.8 (1.9–7.3)	54
Low BMD + high free DPD	2.1 (0.7–6.1)	45

Note. S-CTX, serum C-terminal crosslinking telopeptide of type I collagen; Free DPD, free deoxypyridinoline.

For the design of the OFELY study, please refer to legend of Table I. Adapted from Garnero *et al.* (2000a).

Modifications of type I collagen structure, the major organic component of bone tissue, is likely to be involved in decreased bone strength and increased susceptibility of fracture associated with osteoporosis. Indeed, several biochemical studies performed on bone specimens taken from patients with osteoporosis have shown abnormalities in posttranslational modifications of type I collagen molecules. These, which result from enzymatic processes, include an overhydroxylation of lysine residues, an overglycosylation of hydroxylysine, and a reduction in the concentration of nonreduced cross-links that can be associated with reduced bone strength (Bailey *et al.,* 1992; Kowitz *et al.,* 1997; Oxlund *et al.,* 1996). More recently new age-related nonenzymatic posttranslational modifications of type I collagen, so-called racemization and isomerization, have been demonstrated to occur in bone tissue and more specifically involve the aspartic acid residue in position 19

of the C-telopeptide of the alpha 1 chain (Fledelius *et al.,* 1997; Cloos and Fledelius, 2000) (see Chapters 12 and 90). The degree of isomerization and racemization of type I collagen can be detected *in vivo* by the urinary excretion of the different isoforms of CTX: α L CTX, which reflects newly synthesized collagen and three age-related isoforms, the isomerized isoform, β L CTX, the racemized form, α D CTX, and the isomerized and racemized form, β D CTX. In patients with Paget's disease of bone there is a larger increase of urinary α L CTX compared to β L CTX, resulting in a ratio, αL/βL, that was threefold higher than in controls (Garnero *et al.,* 1997). These data suggest that type I collagen within the abnormal woven pagetic bone, which is characterized by decreased strength, is associated with a decreased isomerization as indicated by a higher urinary αL/βL ratio, an hypothesis that was actually confirmed by immunohistochemistry analysis of pagetic bone tissue (Garnero *et al.,* 1997). More recently in the OFELY cohort, we found that the CTX ratios αL/βL and αL/αD were also increased in the 69 women who sustained incident fractures during an average 7-year follow-up compared to the 366 women of the same cohort who did not fracture (Garnero *et al.,* 2000b). In addition, an increased urinary ratio between native and age-related forms of type I collagen CTX was associated with increased fracture risk independently of the level of BMD of the hip and of bone resorption rate with an odds ratio of 2.0 (1.2–3.5). Thus, if confirmed in other prospective studies, a decreased degree of type I collagen isomerization/racemization as reflected by increased urinary αL/βL and αL/αD ratio, respectively, could be associated with alterations in the structure, maturation, or orientation of collagen fibers which may result in reduced bone strength.

Osteocalcin contains three residues of γ-carboxyglutamic acid (GLA), a vitamin K-dependent amino acid. It was postulated that impaired γ-carboxylation of osteocalcin could be an index of both vitamin D and vitamin K deficiency in elderly populations. In two prospective studies performed in a cohort of elderly institutionalized women followed for 3 years (Szulc *et al.,* 1993, 1996) and in a population of healthy elderly women (EPIDOS study) (Vergnaud *et al.,* 1997), levels of serum undercarboxylated osteocalcin over the premenopausal range, but not total osteocalcin, was associated with a two to threefold increase in the risk of hip fracture. More recently in a population of healthy home-dwelling women and men age 70 years and older, the ratio between carboxylated on total osteocalcin — an indirect index of undercarboxylated osteocalcin — was strongly associated with increased fracture risk, with highest predictive value in individuals older than 80 years (Luukinen *et al.,* 2000). Like markers of bone resorption, the prediction of undercarboxylated osteocalcin was still significant after adjusting for hip BMD, and those women with both a low bone mass and high undercarboxylated osteocalcin had a fivefold increased risk in hip fracture compared with the general population (Vergnaud *et al.,* 1997).

Combined Assessment of Fracture Risk

Cummings *et al.* (1995) looked at the value of combining a variety of clinical risk factors obtained by questionnaire and physical examination with BMD of the calcaneus to predict the risk of hip fracture in women over 65 years of age. The incidence of hip fracture ranged from 1.1 per 1000 woman-years among women with no more than two risk factors and calcaneal BMD in the upper tertile, to 27 per 1000 woman-years among those with five or more risk factors and BMD in the lowest tertile.

In the OFELY prospective cohort we have shown that combination of the strongest single clinical risk factor (history of fracture after the age of 45 years), with a low hip BMD and high levels of bone resorption assessed by urinary CTX improve the predictive value of a single test with relative risk of fracture increasing from 1.8–2.8 to 5.8 (Fig. 4) (Garnero *et al.,* 2000a). Similarly in a nested case–control analysis of the EPIDOS study, we have compared the ability of history of fracture after the age of 45 years, hip BMD, heel broadband ultrasound attenuation and urinary CTX to predict the risk of hip fracture and we investigated whether a combination of these parameters could improve the predictive value (Garnero *et al.,* 1998). The outcome of these combinations depends on whether the goal is to improve the sensitivity, or the specificity and therefore depends on the treatment strategy. If the strategy is to increase the sensitivity, i.e., to detect as many at risk patients as possible and to avoid false negatives, combining different tests is no more effective than lowering the diagnostic threshold of a single test. Conversely, combining two tests with adequate cutoffs is useful for increasing the specificity without decreasing the sensitivity obtained with a single test — a strategy to target a subset of high-risk patients. For example, the combination of urinary CTX with either hip BMD or heel BUA increases the specificity by 10% with a sensitivity similar to hip BMD or heel BUA alone. Such a combined diagnostic approach might be more cost-effective than BMD measurement alone, as it results in a lower number of patients to be treated to avoid one hip fracture. If DXA or ultrasound is not available, we found that the combination of a high bone resorption marker and a positive history of any type of fracture gave a predictive value similar to that obtained with BMD or heel BUA alone (Garnero *et al.,* 1998).

Conclusion

Osteoporosis can be identified early during the course of the disease before the occurrence of major fragility fractures such as vertebral and hip fractures using diagnostic tests with appropriate prognostic value. With the emergence of effective — but rather expensive — treatments, it is essential to detect those women at higher risk of fracture. Because the pathogenesis of fragility fractures is multifactorial, involving not only the level of BMD but also bone architecture, bone

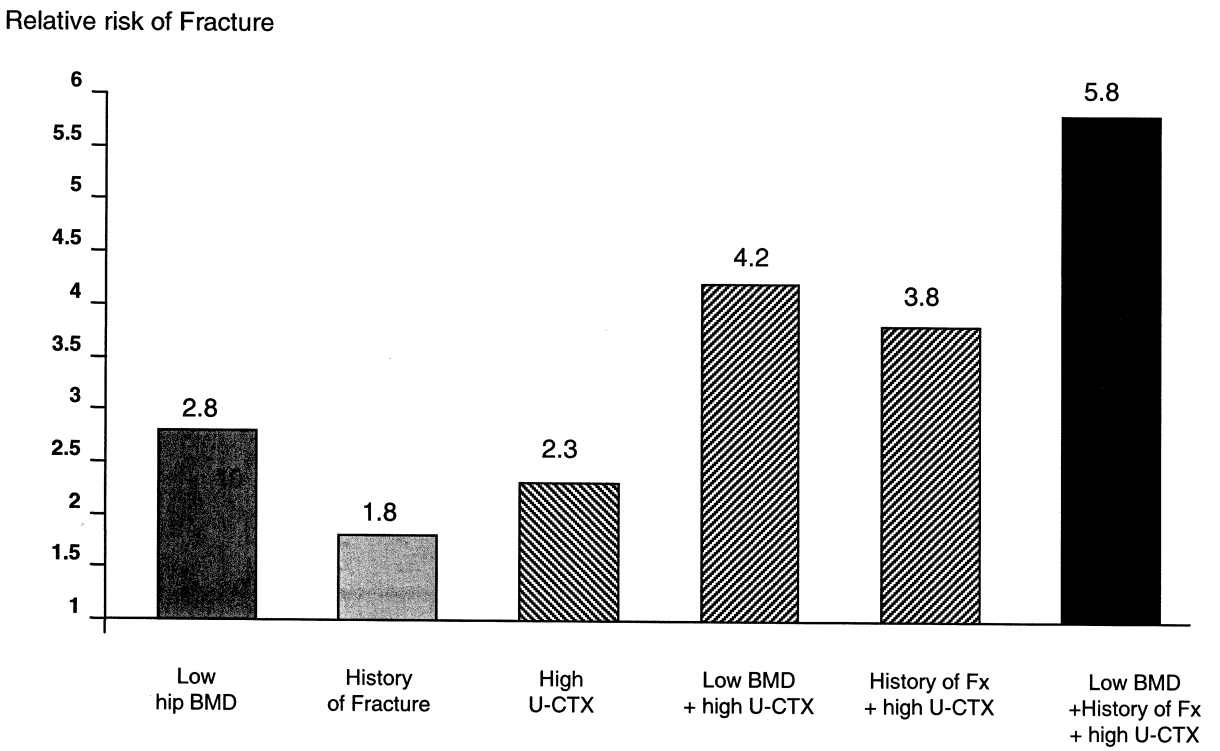

Figure 4 Combination of clinical risk factors, bone mass, and bone turnover measurements to identify women with the highest risk of fracture. Low hip BMD was defined as values at 2.5 SD or below the mean of young adults. High urinary CTX corresponds to values in the highest quartile. Relative risks are adjusted for age and physical activity. For the design of the OFELY study please refer to legend to Table I. Adapted from Garnero *et al.* (2000a).

turnover and fall-related factors, a global diagnostic approach is probably desirable. There is some evidence that such an integrated strategy using major clinical risk factors (e.g., history of fractures, low body weight), measurement of BMD by DXA or heel ultrasound and measurement of bone resorption by urinary or serum biochemical markers could be useful for detecting high-risk patients. These combinations of diagnostic tests should be validated in other prospective studies and operational thresholds should be developed and adapted to treatment strategies.

Parathyroid Hormone

A. B. Hodsman,[*] D. A. Hanley,[†] P. H. Watson,[*] and L. J. Fraher[*]

[*]Department of Medicine and the Lawson Health Research Institute, St. Joseph's Health Centre, and the University of Western Ontario, London, Ontario, Canada N6A 4V2; and [†]Division of Endocrinology and Metabolism, Faculty of Medicine, University of Calgary, Calgary, Alberta, Canada

Introduction

In all but the most recent textbooks of physiology, parathyroid hormone (PTH) is thought to increase serum calcium, partly by increasing the rate of bone remodeling. PTH is thought of as a bone-resorbing hormone. Although bone resorption is a prominent histological event seen in bone sections obtained from patients suffering from pathological secretion of PTH, osteoclasts do not present PTH receptors, and the enhanced bone resorption accompanying pathological PTH secretion appears to require the presence of osteoblasts (McSheehy and Chambers, 1986; Parfitt; 1976). Patients with primary hyperparathyroidism may be at increased risk for ongoing bone loss and fractures, together with evidence for increased bone turnover (Christiansen *et al.,* 1999; Grey *et al.,* 1994; Khosla *et al.,* Parisien *et al.,* 1995; Silverberg *et al.,* 1999).

The anabolic properties of exogenously injected PTH (bovine parathyroid gland extracts) were first reported in a series of serendipitous findings dating back to 1931 (Pehue *et al.,* 1931; Selye, 1932), in both human and animal situations. Some 45 years later Reeve and colleagues, citing circumstantial evidence in both clinical hyperparathyroid states and animal data, used a synthetic human PTH(1–34) amino terminal fragment to treat a small group of elderly individuals with osteoporosis. (Reeve *et al.,* 1976, 1980). They reported a dramatic histological improvement in bone turnover and structural trabecular growth.

Solid-state synthesis of peptides is expensive. However, the small number of clinical trials evaluating the potential of exogenous PTH therapy to treat osteoporosis, consistently demonstrated a beneficial anabolic effect. (Bradbeer *et al.,* 1992; Finkelstein *et al.,* 1994; Hesch *et al.,* 1989; Hesp *et al.,* 1981; Hodsman and Fraher, 1990; Hodsman *et al.,* 1991, 1993, 1997; Lindsay *et al.,* 1997; Neer *et al.,* 1987, 1991; Reeve *et al.,* 1981, 1987, 1990, 1991, 1993; Slovik *et al.,* 1981, 1986; Sone *et al.,* 1995). Commercial development of PTH awaited the technologic advances needed for inexpensive large-scale manufacture of peptides by fermentation. Indeed, the first report of a commercial dose-finding 12-month controlled clinical trial evaluating the efficacy of hPTH(1–84) on bone mineral density (BMD) against placebo is available only in abstract format (Lindsay *et al.,* 1998).

Advantages of Anabolic Agents for Reversal of Osteoporosis

There are strong epidemiologic associations between BMD measurements at either central (lumbar spine) or appendicular sites (femoral neck, distal radius, os calcis) and the current or future risk for osteoporotic fractures (Cummings, *et al.,* 1993; Marshall *et al.,* 1996; Ross *et al.,* 1991). There is approximately a twofold increase in the risk of fracture for every 1.0 standard deviation below average age- and sex-adjusted BMD, increasing dramatically if there is a preexisting fragility fracture in an individual with a low BMD (Marshall *et al.,* 1996; Ross *et al.,* 1991). Relatively small BMD increments reported in published placebo-controlled clinical trials, translates into an incident fracture reduction of approximately 50% within 1–4 years of therapy. The evidence for this is best illustrated in the randomized controlled clinical trials of the bisphosphonates (Black *et al.,* 1996; Cummings *et al.,* 1993; Harris *et al.,* 1999; Liberman *et al.,* 1995; McClung *et al.,* 2001; Reginster *et al.,* 2000).

There are currently two therapeutic strategies to treat osteoporosis. These strategies are illustrated in Fig. 1. For the purposes of this figure a fracture threshold has been indicated, but the gradient of risk is continuous (as it is for many biological variables such as blood pressure and cholesterol in ischemic vascular disease). The most important role for an anabolic agent in bone would be the rapid induction of new bone formation in the skeleton to reduce the risk of fragility fractures. It is against this background that the role of PTH therapy is discussed.

Anti-resorptive Agents

This approach relies upon the inhibition of osteoclastic activity during the bone mineralization unit (BMU) remodeling activity, allowing osteoblastic function to continue unimpeded. For example, the randomized, placebo-controlled clinical trials (RCT) of the bisphosphonates, alendronate and risedronate, have defined the benefits of this strategy, resulting in an increased BMD and significant reductions in incident fracture risk (Black *et al.,* 1996; Cummings *et al.,* 1993; Harris *et al.,* 1999; Liberman *et al.,* 1995; McClung *et al.,* 2001; Reginster *et al.,* 2000). Evidence from observational cohort studies suggests that estrogen also reduces osteoporosis-related fractures by up to 50% (Eiken *et al.,* 1996; Kiel *et al.,* 1987; Lofkin *et al.,* 1992; Maxim *et al.,* 1995; Naessen *et al.,* 1990), however, only one short-term RCT supports this observation (Lufkin *et al.,* 1992).

The large-scale RCT with raloxifene (a selective estrogen receptor modulator) demonstrated comparable anti-fracture efficacy for vertebral (but not for peripheral) fractures, after a gain in vertebral BMD of $<3\%$ over 36 months (Ettinger *et al.,* 1999). Another anti-resorption agent, calcitonin, was shown to reduce incident vertebral fractures without any significant increment in BMD (Chestnut *et al.,* 2000). These RCT's of anti-resorptive therapy have called into question that increments in BMD automatically translate into a reduced fracture risk. Nonetheless, overall gains in BMD at an axial measurement site following bisphosphonate therapy (typically 4–8% at the lumbar spine over 3 years) may reduce incident fractures by approximately 40–50%. Detailed reports of anti-resorptive therapies are reviewed in other chapters.

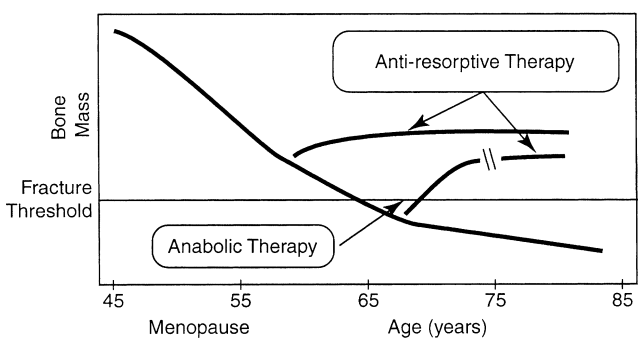

Figure 1 Depicts the relative efficacy of different strategies to maintain bone mass. (Top) Anti-resorptive strategy. Various agents (e.g., estrogens, bisphosphonates, calcitonin) will arrest ongoing age-related and postmenopausal bone loss. Reductions in bone resorption and turnover are observed, and gains in skeletal bone mass may occur due to the reduced bone resorption and perhaps to a reversal of the remodeling deficit. (Bottom) Anabolic therapy. Agents such as PTH and sodium fluoride directly stimulate osteoblastic activity to increase bone mass, despite concurrent increases in bone turnover (i.e., there is an increase in both bone formation and resorption). The rapid increase in bone mass should accelerate the reduction in future fracture risk more effectively than the use of an anti-resorptive agent alone.

Anabolic Agents

There are two principal agents which have been shown to stimulate osteoblast function within bone: sodium fluoride and analogs of PTH. Sodium fluoride and its slow-release formulations are discussed elsewhere in this publication. The landmark publication of Riggs *et al.* (1982) suggested that plain sodium fluoride significantly reduced vertebral fracture rates. A subsequent placebo-controlled trial demonstrated a rapid and linear gain in lumbar spine BMD of 9% per year over 4 years (Kleerekoper *et al.,* 1991). However, this result provided no evidence for a reduction in incident fractures (Kleerekoper *et al.,* 1991). Since the fluoride dose in this trial might have been toxic and adversely affected the matrix quality of newly formed bone, the lower dose, slow-release fluoride formulation studied by Pak *et al.* (1995) may be of interest. In this randomized trial, fluoride-treated patients gained BMD in the lumbar spine of 4% per year and experienced a 64% reduction in incident vertebral fractures.

By whatever outcome measure used, PTH analogs have been shown to be anabolic, resulting in comparable gains in bone mass by comparison with fluoride. These gains are considerably more rapid than those seen with anti-resorptive agents. However, fluoride therapy has not supported the dictate that gains in BMD translate into lower fracture rates. Since there are as yet few controlled trials reporting incident fractures in patients treated with PTH analogs, it is necessary to evaluate the potential mechanisms by which PTH has seemingly paradoxical anabolic effects, focusing on the preclinical data in osteopenic animal models, as well as the available clinical evidence.

Potential Mechanisms of Anabolic Action

The physiological action of PTH is to maintain the ambient concentration of ionized calcium in blood by: (a) influencing calcium reabsorption from the glomerular filtrate of kidney tubule cells and; (b) indirectly by enhancing calcium absorption from the gut through increased activity of renal vitamin D-1-hydroxylase, which produces $1\alpha,25(OH)_2D_3$ (Bilezikian *et al.,* 1994; Brabant *et al.,* 1992). PTH also initi-

ates a series of events which result in release of skeletal calcium by osteoclasts.

In 1931, Pehue *et al.* described the case history of an 8-year-old Parisian child who had succumbed to anemia due to the obliteration of his marrow space by bone; he was subsequently discovered to have had hypertrophic parathyroids (Pehue *et al.,* 1931). Subsequently Selye suggested that, in contrast to the findings in primary hyperparathyroidism, PTH could have a potent anabolic effect (Selye, 1932). Selye was able to mimic this clinical situation in 30-day-old albino male rats with daily injections of 5 IU of Lilly parathyroid extract for 30 days. These low doses of parathyroid extract resulted in the production of osteopetrotic bone with no sign of osteoclastic bone resorption. Numerous investigators have since confirmed the anabolic action of PTH (used as either the 1–84 holohormone or various amino-terminal analogs) when administered as multiple intermittent doses and have coined this effect "the PTH paradox" (Morley *et al.,* 1997).

The amino-terminal third of the PTH molecule appears to contain most of the biological activity of bone. Both the intact PTH(1–84) and the synthetic amino terminal 1–34 PTH peptide act through signaling pathways in target cells. In osteoblasts, the type 1 PTH/PTH-related protein (PTHrP) receptor is coupled to both the adenylate cyclase-activating G protein (Gs) and the phospholipase C-activating (Gq) protein. PTH requires the first two amino acids and some part of the amino acid 25–34 region to activate Gs, but only the 28–32 portion to activate Gq (Whitfield *et al.,* 1998). PTH fragments such as (1-desamino) hPTH (1–34), hPTH (8–84), or hPTH (28–48), which stimulate membrane bound protein kinase C (PKC), but not adenylate cyclase in isolated osteoblasts, do not stimulate bone formation in the oophorectomized rat model of osteoporosis. However, hPTH (1–31) amide, which stimulates the adenylate cyclase pathway as effectively as hPTH (1–34) or hPTH (1–84), but yet does not activate the PKC pathway, is capable of stimulating the growth of both trabecular and cortical bone in the same animal model (Rixon *et al.,* 1994; Whitfield *et al.,* 1996). Administration of analogs or activators of cAMP mimic many of the effects of PTH on osteoblasts in culture, thus strongly suggesting that the bone anabolic properties of PTH are associated with activation of the cAMP–protein kinase A pathway.

The exact cellular mechanisms and principal mediators of PTH action on osteoblasts have not been fully elucidated, but likely results from a combination of growth factor actions available in the immediate bone marrow environment, as well as the recruitment of new preosteoblasts from marrow stromal cells. There is strong evidence that PTH stimulates both the insulin-like growth factor (IGF) and transforming growth factor-β (TGF-β) systems in osteoblasts (Dempster *et al.,* 1993; Johansson and Rosen, 1998). The insulin-like growth factor regulatory system is composed of two growth factors (IGF-I and IGF-II), two receptors, six binding proteins which regulate IGF bioavailability, and IGF-binding protein (IG-FBP)-specific proteases. After PTH binding to the osteoblast PTH receptor and the generation of cAMP, these cells produce more IGF-II, IGFBPs -1, -4, and -5, and the IGFBP-3 and -5 proteases (Johansson and Rosen, 1998). PTH also directly stimulates the synthesis of TGF-β by mature osteoblasts (Canalis, 1996). IGF-I, IGF-II, and TGF-β secreted by osteoblasts can be bound to the collagen matrix of bone where they reside as a sort of growth factor bank. When PTH induces osteoclastic bone resorption during the bone remodeling cycle, growth factors are released into the immediate environment where they can act on resident osteoblasts (Canalis, 1996). The anabolic effect of PTH also results in the appearance of multistacked active osteoblasts (whose origin is uncertain) at sites of bone formation. They may be osteoprogenitor cells from marrow precursors, PTH responsive postmitotic cells which have been recruited to the site by chemotaxis, or bone lining cells which have been induced to re-enter proliferative cycles and pile up (Dobnig and Turner, 1995; Watson *et al.,* 1995).

Recent observations suggest that the receptor for PTH, the type 1 PTHR, may be targeted to the nucleus of receptive cells (Watson *et al.,* 2000a,b). In epithelial-derived cells of rat liver, kidney, uterus, ovary, and small intestine there exists a proportion of cells with PTHR immunoreactivity in the nucleus, an observation borne out by cell fractionation and Western and/or ligand blot analysis (Watson *et al.,* 2000a). A potential nuclear localization signal (NLS) has been identified in the cytoplasmic tail of the PTHR that is conserved across species (Watson *et al.,* 2000a). The PTHR is the first member of the G protein-coupled receptor family identified to have nuclear translocation activity (Burysek and Houstek, 1996; Jans and Hassan, 1998; Radulescu, 1995). It is well-documented that receptors of other growth factor (Jans and Hassan, 1998; Radulescu, 1995) cytokine families (Burysek and Houstek, 1996; Jans and Hassan, 1998) (e.g., the insulin and fibroblast growth factor 1 α receptor) translocate to the nucleus where they (or their cognate ligand) have a direct influence on nuclear function. The physiological implication of this data is, as yet, unclear but there is obviously the potential for the PTHR to have a direct effect on nuclear function independent of its nominal signaling pathways. In studies of bone cells in culture, the localization of the PTHR to the nucleus coincided with the onset of mitosis, perhaps suggesting a role for the nuclear PTHR in PTH anabolism via cell proliferation (Watson *et al.,* 2000b). Clearly, the anabolic effect of PTH is not through a simple mechanism but most likely involves a coordinated effort from all of its signalling abilities.

Animal Models of PTH Effects on Bone Metabolism

Detailed investigation of the anabolic action of PTH requires a suitable animal model. The ovariectomized (OVX) mature rat rapidly develops osteopenia which is characterized by a significant decrease in both cancellous bone mineral and bone mass, and a marked increase in osteoblast and osteoclast activity typical of increased bone turnover (Frost and Jee,

1992; Hock *et al.,* 1988; Hori *et al.,* 1988; Liu and Kalu, 1990; Liu *et al.,* 1991; Wronski *et al.,* 1989, 1991). The OVX rat has been widely accepted as a model for human postmenopausal osteoporosis since it closely parallels the early, rapid phase of bone loss characteristic of postmenopausal humans (reviewed in Kalu, 1991; Liu *et al.,* 1991). The osteopenia of OVX rats shares many characteristics in common with the bone manifestations of perimenopausal bone loss including increases in both bone resorption and activation frequency, with a relative deficiency in bone formation leading to a negative modeling balance (Frost and Jee, 1992; Kimmel *et al.,* 1993; Liu and Kalu, 1990; Liu *et al.,* 1991; Wronski *et al.,* 1989).

The OVX rat has been extensively used as a model for the *in vivo* anabolic action of intermittent treatment with PTH (Hori *et al.,* 1988; Jerome, 1994; Kimmel *et al.,* 1993; Liu and Kalu, 1990; Shen *et al.,* 1992; Tada *et al.,* 1990; Wronski *et al.,* 1993). Studies by the Kalu laboratory (Liu and Kalu, 1990) have shown that hPTH 1–34 treatment of mature, OVX rats prevents the 50% reduction in trabecular bone volume following OVX, and enhances bone volume to a level threefold that of sham-operated controls. PTH also reverses preexisting bone loss induced by OVX. (Kimmel *et al.,* 1993; Liu *et al.,* 1991; Shen *et al.,* 1992; Tada *et al.,* 1990; Wronski *et al.,* 1993). Dempster and colleagues have shown that the increase in bone formation rate after intermittent therapy with PTH is primarily due to an increase in both total mineralization surface and the mineral apposition rate which occurs in the first week after the initiation of treatment (Meng *et al.,* 1996). Measurement of BMD in PTH-treated rats has also shown positive increments in femur (Mosekilde *et al.,* 1994), vertebrae (Mosekilde *et al.,* 1994; Wronski; *et al.,* 1988), and tibia (Gunness-Hey and Hock, 1989; McMurtry *et al.,* 1992; Mosekilde *et al.,* 1994), confirming the histological data. All of these studies show a PTH-induced increase in bone formation chiefly by the induction of osteoblast function. Thus, intermittent PTH therapy increases osteoblastic bone formation via increased activation frequency, resulting in positive bone balance (Wronski *et al.,* 1993).

Another important consideration is the quality of the bone produced by PTH therapy. Data from the rat have shown that PTH works primarily by increasing trabecular thickness, not number (Kimmel *et al.,* 1993; Lane *et al.,* 1995; Li *et al.,* 1995; Shen *et al.,* 1993). Assessment of trabecular connectivity demonstrates that PTH produces well-connected trabecular bone of normal three-dimensional architecture when used in combination with estrogen as an anti-resorptive agent (Shen *et al.,* 1993, 1995; Tada *et al.,* 1990), but not when used on its own (Shen *et al.,* 1993). One last point to bear in mind is the biomechanical strength of PTH-induced bone, since nothing is gained if the newly formed bone does not provide the strength and support to protect against fractures. Numerous studies of load-to-failure rates in vertebral bodies, femoral shafts and femoral necks have shown that bone from PTH-treated OVX rats consistently performs better than that from sham-operated controls (Li *et al.,* 1995; Meng *et al.,* 1996; Mosekilde *et al.,* 1994, 1995; Shen *et al.,* 1995; Sogaard *et al.,* 1994). This pattern held true even in a primarily cortical bone site (femoral shaft) (Meng *et al.,* 1996) and correlated well with observations of increased tabecular thickness and bone mineral density (Li *et al.,* 1995; Meng *et al.,* 1996).

Much effort has been applied to the problem of either augmenting the bone formation induced by PTH therapy or maintaining the gains of bone following cessation of PTH therapy with an anti-resorptive agent. The bisphosphonates are the anti-resorptives of choice for a variety of reasons, but most notably because of their efficacy in achieving gains in bone mineral density in osteoporotic patients. Risedronate has been carefully evaluated to determine if concurrent therapy is additive to the anabolic effect of PTH in the osteopenic rat model. These studies have shown that combination therapy with risedronate and PTH provides no further advantage over PTH alone in the mature ovariectomized rat when vertebral bone mass and strength (Mosekilde *et al.,* 1994), and femoral neck strength (Sogaard *et al.,* 1994) are assessed. Similar results were obtained with aged ovariectomized rats after evaluation of the first lumbar vertebra and proximal tibia by histomorphometry. (Qi *et al.,* 1995). There has been some concern that PTH therapy may adversely affect cortical bone width and strength but studies with PTH alone or risedronate cotherapy show no effects of PTH on cortical bone in the ovariectomized rat and no advantage to risedronate cotherapy (Baumann and Wronski, 1995; Mosekilde *et al.,* 1995; Wronski and Yen, 1994).

However, studies with other bisphosphonates suggest that these compounds can blunt the anabolic effect of PTH on bone formation rates in cancellous bone of the ovariectomized rat. This has been found for pamidronate (Cheng *et al.,* 1995), tiludronate (Delmas *et al.,* 1995), and YM-175 (Mashiba *et al.,* 1997). Thus, *concurrent* therapy of bisphosphonates and PTH does not appear to confer therapeutic advantages. On the other hand, *maintenance* of bone mass following cessation of PTH therapy might be successfully achieved by bisphosphonates (Ritlmaster *et al.,* 2000).

Clinical Studies

There are approximately 32 published papers and numerous recent abstracts describing the outcomes of therapy with PTH (Bradbeer *et al.,* 1992; Finkelstein and Arnold, 1999; Finkelstein *et al.,* 1994, 1998a,b; Fujita *et al.,* 1999a,b; Gallagher, 1999; Hesch *et al.,* 1989b; Hesp *et al.,* 1981; Hodsman and Fraher, 1990; Hodsman *et al.,* 1991, 1993, 1997, 2000; Kurland *et al.,* 2000; Lane *et al.,* 1998a,b, 2000; Lindsay *et al.,* 1997, 1998; Neer *et al.,* 1987, 1993, 2001; Plotkin *et al.,* 1998; Reeve *et al.,* 1981, 1987, 1993, 1994, 1990, 1976a,b, 1980; Rittmaster *et al.,* 2000a,b; Roe *et al.,* 1999; Slovik *et al.,* 1981, 1986; Sone *et al.,* 1995). Treatment protocols have been very heterogeneous, over periods of 6 to 36

months. Most subjects have been women, over 60 years of age with a diagnosis of osteoporosis, but more recently there have been studies involving younger women with acute estrogen deficiency (Finkelstein and Arnold, 1999; Finkelstein *et al.,* 1998b, 1994), men with osteoporosis (Korland *et al.,* 2000) and glucocorticoid-induced osteopenia (Finkelstein and Arnold, 1999; Finkelstein *et al.,* 1998b; Lane *et al.,* 1998b, 2000). Only recently have the studies involved a randomized design in which acceptable control subjects did not receive PTH (Finkelstein and Arnold, 1999; Finkelstein *et al.,* 1998b, 1994; Fujita *et al.,* 1999b; Gallagher, 1999; Kurland *et al.,* 2000; Lane *et al.,* 1998b, 2000; Lindsay *et al.,* 1998; Neer *et al.,* 1999; Ross *et al.,* 1990). Many studies have included concomitant therapy with the specific intention of minimizing the resorptive properties of PTH; "cotherapy" with estrogen has been widely used (Bradbeer *et al.,* 1992; Lane *et al.,* 1998b, 2000; Lindsay *et al.,* 1997; Reeve *et al.,* 1990, 1991, 1993), but other studies have included calcitonin (Hesch *et al.,* 1989b; Hodsman and Fraher, 1990; Hodsman *et al.,* 1991, 1993, 1997, 2000) and calcitriol (Neer *et al.,* 1987, 1991; Reeve *et al.,* 1987; Slovik *et al.,* 1986).

There are many unknown issues raised by the use of PTH peptides as a prospective treatment for osteoporosis, although the evidence to date highlights only the potential benefits. We will discuss these clinical issues under the headings by which regulatory agencies currently examine data for the treatment of osteoporosis.

Fractures

While fracture risk reduction is the gold standard of efficacy for all osteoporosis treatments, there is at present limited information regarding the efficacy of PTH in this regard. Two of the recently published trials mention fracture rates as secondary outcomes (Hodsman *et al.,* 1997; Lindsay *et al.,* 1997), but neither study included true control groups for comparison. Hodsman *et al.* (1997) reported a vertebral fracture incidence of 4.5/100 patient years in a group of elderly patients with preexisting vertebral fractures and receiving eight 28-day cycles of hPTH(1–34) over 2 years (Hodsman *et al.,* 1997), Lindsay *et al.* (1997) reported an incidence of 2.5/100 patient years in a comparable group of patients receiving daily hPTH(1–34) injections over 3 years. Since both studies enrolled high-risk female patients with an average of >2 preexisting vertebral fractures, an average age of over 60 years, and comparable BMD measurements, they document fracture incidences in a high-risk population. A reasonable historical comparison can be made with the placebo (calcium supplemented) arm of the Fracture Intervention Trials, in which new vertebral fracture incidence rates were documented at 10/100 patient years in a cohort of women with only one prevalent osteoporosis-related vertebral fracture who were followed for 3 years (Black *et al.,* 1997).

The anti-fracture efficacy of PTH(1–34) has recently been reported in a placebo-controlled RCT, designed to evaluate the anti-fracture efficacy of this analog in post-menopausal women with prevalent vertebral fractures. (Neer *et al.,* 2001). At present this is the only Phase III trial specifically designed to address the anti-fracture efficacy of PTH. The significant trial outcomes for reduced incident vertebral and nonvertebral fracture rates together with BMD measurements can be compared to placebo-treated patients and are shown in Fig. 2 through 4. In this study, PTH(1–34) treatment in daily doses of 20–40 μg/day over 21 months resulted in a significant reduction in incident vertebral fractures by over 65% (Fig. 2, RR 0.43, CI 0.20–0.52). Even nonvertebral fractures were significantly reduced by up to 45% (Fig. 3), despite the relatively short duration of the trial. Thus it seems likely that PTH therapy has the potential to reduce incident fractures not only in the spine, but also at other sites. Although this is only the first trial of a PTH analog with sufficient power to evaluate fracture prevention, the findings contrast with trials of fluoride therapy, in which it has been difficult to detect non-vertebral fracture benefits, despite large increments in BMD. An evaluation of the absolute fracture reductions reported by Neer *et al.* (2001) after only 21 months of therapy with PTH(1–34) reveals a number needed to treat (NNT) estimate of only 10 and 27 women needing treatment to prevent one vertebral or one nonvertebral fracture, respectively. Recognizing differences in subject recruitment and duration of therapy, this compares favorably with the post hoc analysis of the Fracture Intervention Trials with alendronate reported by Ensrud *et al.* (1997); in women selected for alendronate therapy who are at comparable risk (prevalent vertebral fractures and femoral neck *T* score of <1.6), the NNT calculations to prevent one new vertebral fracture or any new clinical fracture were 16 and 26, respectively, albeit these estimates require up to 60 months of treatment.

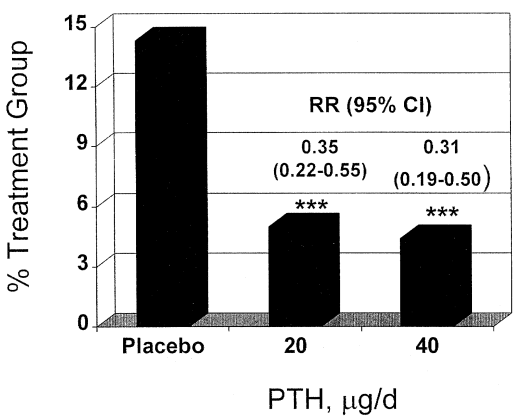

Figure 2 Reduction in vertebral fracture rates during a randomized controlled clinical trial of median duration 21 months. Compared with placebo ($n = 544$), both doses of PTH(1–34) (20 μg/day, $n = 541$; and 40 μg/day, $n = 552$) significantly reduced the risk of one or more vertebral fractures ($^{***}P < 0.001$). Adapted from Neer *at al.* (2001).

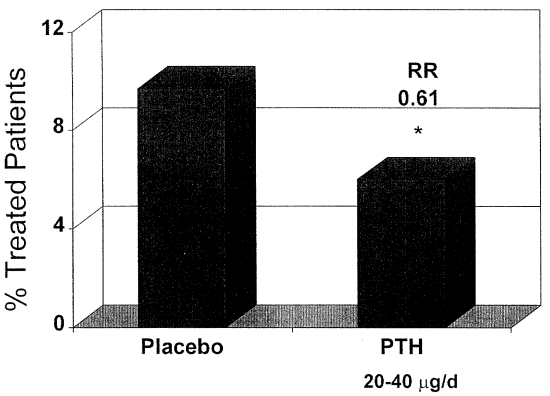

Figure 3 Reductions in all nonvertebral fractures during treatment with PTH(1–34) over 21 months. Adapted from Neer *et al.* (2001). Compared to placebo, new fractures were similarly reduced at both doses of PTH ($^{*}P < 0.04$ to < 0.02).

Bone Mass Measurements

Of all osteoporosis therapies in current use or in late stages of clinical development, PTH has shown the greatest effect on bone mass. Although trials of fluoride may have shown comparable or even greater gains in lumbar spine bone density, major concerns about the quality of new bone stimulated by this treatment remain to be settled. (Riggs *et al.,* 1990). Table I selectively summarizes the results of available studies of PTH therapy in which bone mass was measured. The data provided in the table are the percentage increase over baseline or placebo for the highest dose of PTH analog used in the trial. The method of measurement of bone mass or density (BMD) has varied among these studies and includes both dual-energy X-ray absorptiometry (DEXA) and quantitative computed tomography (QCT) for axial sites, as well as peripheral areal measurements of the forearm. Since these BMD measurements are not entirely comparable, only key points are summarized in this section.

Lumbar Spine

PTH causes a significant increase in BMD in the lumbar spine which exceeds that reported for all other available therapies except sodium fluoride. The studies of PTH as a monotherapy are of relatively short duration (2 years or less) so it is impossible to determine whether this increase is dose- and duration-dependent or if it reaches a plateau in a manner similar to those of antiresorptive therapies (Riggs and Melton, 1992). There are two RCTs of PTH monotherapy: a Phase II study of recombinant hPTH 1–84 (Lindsay *et al.,* 1998) and a Phase III study of recombinant hPTH 1–34 (Neer *et al.,* 2001).

In the first study, daily subcutaneous injections of 50, 75, and 100 μg of hPTH 1–84, were given to women with BMD criteria for osteoporosis (Kanis *et al.,* 1994), in a randomized placebo-controlled 1-year clinical trial sponsored by Allelix Biopharmaceuticals (Mississauga, ON, Canada) (Lindsay *et al.,* 1998). A dose-dependent increase in lumbar spine BMD measured by dual-energy X-ray absorptiometry (DEXA) was seen over the baseline measurement, reaching 6.9% in the 100 μg/d group (Lindsay *et al.,* 1998). Changes in bone mineral content were even greater, reflecting an apparent increase in the area of the vertebral bodies examined by DEXA. However, the total body bone mineral density (TBBM) decreased significantly compared to placebo over the 1 year of treatment by 0.9%. This finding raises the issue that PTH acts to increase trabecular bone mass at the expense of the cortical bone envelope. Alternatively, it seems likely that PTH causes acceleration of cortical remodeling, resulting in an enlarged expansion of the remodeling space. Increments in cortical bone mass would be expected to occur later, as the anabolic action of PTH gradually leads to a net remodeling gain over time. Within this study, the subsequent treatment of approximately one-third of the study cohort with an anti-resorptive agent, alendronate, for a second 12-month interval supports the latter alternative explanation (see below) (Rittmaster *et al.,* 2000b).

The Phase III RCT of PTH(1–34) in the treatment of osteoporosis (sponsored by Eli Lilly, Indianapolis, IN) was reported by Neer *et al.,* (2001). Subjects were recruited with prevalent vertebral fractures due to osteoporosis (Neer *et al.,* 2001). Subjects received daily subcutaneous injections of placebo or 20 or 40 μg of hPTH (1–34). The sponsor terminated this trial after an average of 21 months of therapy, because of a long-term toxicity study in Fisher rats in which a significant incidence of osteosarcoma was found during life-long treatment of these animals with very high doses of PTH(1–34) (Neer *et al.,* 2001). Nevertheless, dramatic effects on BMD and fracture incidence were observed in this clinical trial. In the spine, the increase in BMD was 9.7 and 13.7% in the groups receiving 20 and 40 μg, as opposed to an insignificant increment of 1.1% in the placebo group (Fig. 4). TBBM increased in the PTH-treated groups (Neer *et al.,* 2001) in contrast to the shorter 1-year study of hPTH(1–84) (Lindsay *et al.,* 1998), which reinforces the possibility that the initial loss of BMD reflects the opening of a remodeling space.

The general conclusion from all studies of lumbar spine BMD is that a progressive increase occurs for the duration of therapy (Table I). When PTH is stopped, two studies have shown a continuing gain in bone mass that may reflect the filling in of the increased remodeling space (Finkelstein and Arnold, 1999; Lane *et al.,* 2000). On the other hand, cessation of PTH therapy might be expected to result in reestablishment of the pretreatment pattern of bone losses. One year follow-up of patients in the study by Lindsay *et al.* (1997) suggests that this loss may be attenuated by the continuation of hormone-replacement therapy (HRT). However, a 4% annual loss in lumbar spine BMD was seen during the year after PTH therapy had been discontinued, in spite of continued HRT in another clinical trial combining PTH and HRT (reported by Roe *et al.,* 2000).

Table I Selected Publications Outlining Changes in Bone Mineral Density Measurements during and/or Following PTH Therapy

Note. TBBM, total body bone mineral (usually excludes skull). Data are significantly different from controls unless stated (ns).

[**] Control group had a significant loss of BMD (i.e., PTH prevented loss).

[a]Superscript by author indicates published data from the same study cohort.

[b]Analog is hPTH(1–34) unless otherwise stated.

[c]BMD measurement made by DEXA or similar areal method unless stated for QCT. (quantitative computed tomography).

Hip

There are differences in the BMD responses to PTH among different regions of the skeleton. One of the major concerns about "anabolic agents" is that the increase in spinal (largely trabecular) bone mass may be at the expense of cortical bone, in particular, at important fracture regions such as hip and forearm. Some studies with sodium fluoride have shown dramatic increases in the spine but loss, or no improvement, at cortical bone sites. If PTH causes a marked increase in cortical bone remodeling, one might expect a decline in BMD in cortical sites during the early stage of PTH therapy, with a later increase if the net effect of PTH is increased bone formation. In reviewing the results of the clinical studies which included BMD measurements at the hip (Table I), a net positive effect of PTH is seen.

Several studies showed no change or a decline in femoral neck or total hip BMD within the first year of treatment (Finkelstein *et al.,* 1998a; Lane *et al.,* 1998a), and this is particularly clear in the 1-year study of hPTH(1–84) (Lindsay *et al.,* 1998), in which there was no change in hip BMD.

The few studies, which have gone beyond 12 months of therapy, have shown a gain in hip BMD (Hodsman *et al.,* 1997; Kurland *et al.,* 2000; Lindsay *et al.,* 1997; Neer *et al.,* 2001; Roe *et al.,* 1999). In the Phase III trial of hPTH(1–34) reported by Neer *et al.* (2001), there were significant BMD gains seen in the hip after just under 2 years of therapy. In the total hip BMD measurements, the placebo group lost 1.6% while gains of 2.6% (20 μg dose) and 3.6% (40 μg dose) were seen in the PTH-treated groups (Fig. 4). Similar dose-dependent improvements in trochanter, femoral neck, and intertrochanteric regions were observed, and the 5.1% increase in femoral neck is greater than that reported for any anti-resorptive therapy after 2 years.

Again, these observations can be explained by postulating the activation of an increased number of bone remodeling units, resulting in an increased remodeling space within the skeleton. During the early stages of PTH therapy, this may cause a decline in BMD in some areas, but as the enlarged remodeling space begins to be filled, increased hip BMD appears as the net result.

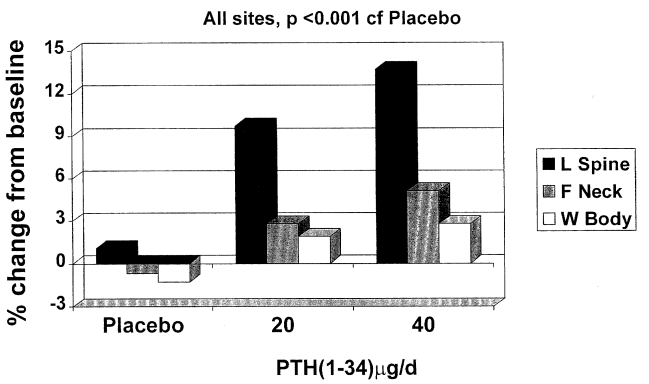

Figure 4 Changes in BMD measurements over 21 months during a randomized placebo-controlled clinical trial of PTH(1–34). Adapted from Neer *et al.* (2001).

Forearm

The earlier studies of PTH have shown inconsistent results in the forearm. In reviewing studies in which PTH was not being used in combination with estrogen, three small studies showed no change (Hesch *et al.,* 1989b; Neer *et al.,* 1987; Reeve *et al.,* 1987), and three showed significant decline (Hodsman *et al.,* 1991; Neer *et al.,* 1997, 2001). One study, using a PTHrP analog (semparatide acetate) reported by Gallagher (1999) also showed a decrease in forearm BMD. The best assessment of hPTH 1–34 effects on BMD of the forearm probably comes from the Phase III trial reported by Neer *et al.,* which averaged 21 months of therapy. It showed a significant, though modest 2–3% decline in BMD of the forearm. This may be a concern, but the decline was not progressive in the second year of the study (Neer *et al.,* 2001).

Total Body Bone Mineral

In the 1-year Phase II randomized placebo-controlled trial of hPTH 1–84, there was a significant decline in TBBM content as assessed by DEXA (Lindsay *et al.,* 1998). In the subjects receiving 75 and 100 μg PTH(1–84), there was a slight but significant decline (0.3 and 0.9%, respectively) in TBBM, reflecting loss in the arms and legs. This loss was thought to represent a generalized increase in cortical bone turnover and would be expected to be transient. Longer term studies with PTH(1–34) have demonstrated small increases in TBBM as shown in Table I and Fig. 4 (Lindsay *et al.,* 1997; Neer *et al.,* 2001).

PTH in Combination with Other Treatments

During the past 20 years, PTH therapy has been used in a heterogeneous fashion: as a single agent, with or without nutritional calcium and vitamin D supplements (Fujita *et al.,* 1999a; Hesp *et al.,* 1981; Kurland *et al.,* 2000; Neer *et al.,* 2001; Reeve *et al.,* 1980a,b, 1981, 1976a,b), with estrogen or androgen as a concurrent anti-resorptive agent (Bradbeer *et al.,* 1992; Lane *et al.,* 1998a; Lindsay *et al.,* 1995, 1997; Reeve *et al.,* 1990, 1991; Roe *et al.,* 1999), with bisphosphonates (Rittmaster *et al.,* 2000b), with calcitriol (Neer *et al.,* 1987, 1991, 1993; Reeve *et al.,* 1987; Slovik *et al.,* 1986); in several cyclical protocols with or without calcitonin (Hesch *et al.,* 1989b; Hodsman and Fraher, 1990; Hodsman *et al.,* 1991, 1993, 1997; Reeve *et al.,* 1987).

Despite the heterogeneity of these protocols, the overall effect of PTH in combination with other therapies has been remarkably consistent: an increase in trabecular bone (as measured by BMD or histomorphometry), with somewhat

smaller changes in bone mass in the appendicular skeleton. Most reported studies had small samples of treated subjects and thus a low power to dissect the interactions of concurrent therapies. Only a minority of studies have evaluated the effects of PTH in a truly randomized trial design in which control subjects received only nutritional supplements of calcium and vitamin D (Fujita *et al.,* 1999a; Gallagher, 1999; Kurland *et al.,* 2000; Lindsay *et al.,* 1998; Neer *et al.,* 2001; Sone *et al.,* 1995). However, some guarded conclusions can be made.

Estrogen

The concurrent use of anti-resorptive agents, specifically estrogen is attractive. If estrogen can selectively blunt the resorptive action of PTH on bone without deleterious inhibition of its anabolic effects, this combination would be ideal. The experimental literature is confusing. Cosman *et al.* infused PTH over 20 hr (approximately 800 units to each of 17 estrogen-treated and 15 estrogen-deficient postmenopausal women with osteoporosis) (Cosman *et al.,* 1993). The estrogen-deficient women had a significantly higher excretion of bone resorption markers (urinary OH–proline and deoxypyridinoline) suggesting a protective effect of estrogen on resorption. However, in a similar experiment Tsai *et al.* (1989) infused 400 units/day for 3 days to three groups of subjects, premenopausal, and postmenopausal women with and without osteoporosis. They found no differences in serum calcium or urinary OH-Pro excretion and concluded that estrogen did not have such a protective effect. Using an alternative approach of calcium deprivation to induce endogenous 2° hyperparathyroidism, the same group reached similar conclusions (Ebeling *et al.,* 1992). Marcus *et al.* (1992) gave acute (20 min.) infusions of graded doses of PTH to 15 postmenopausal women before and after starting estrogen replacement, and no differences were found in serum $1,25(OH)_2D$ increments or urinary cAMP excretion as a result of estrogen therapy. They concluded that the renal–endocrine axis was not affected by estrogen deficiency. The flaw in these arguments is the fact that clinical responses to PTH infusion favor bone catabolism, while intermittent injections favor anabolism (Hodsman *et al.,* 1993).

In the study by Reeve *et al.* (1991), daily PTH injections and concurrent estrogen therapy were combined in nine women. By comparison with historical controls (women treated with PTH alone) (Reeve *et al.,* 1980b), calcium balance studies were significantly improved; cotreatment with estrogen actually led to a 12% decrease in urinary calcium (Reeve *et al.,* 1991), rather than the 14% increase seen historically (Reeve *et al.,* 1980b). To date there are no controlled factorial studies to test the estrogen effect independently of PTH.

However, many clinical studies of PTH therapy have incorporated concurrent therapy with estrogen, or estrogen/-progesterone therapy (HRT; see Table 1). The intent of these combinations has been to limit the ongoing bone resorption induced by PTH. In this context Lindsay *et al.* (1997) reported a progressive total 3-year net gain over baseline lumbar spine BMD of 13%. In a study of glucocorticoid-treated women, who were all on stable HRT, Lane *et al.* (1998a) reported similar increments of 11% in the spine (35% by QCT) over 1 year. In a more recent RCT, employing the same dose of PTH(1–34) (40 μg daily), in postmenopausal women receiving HRT, Roe *et al.* reported average gains of BMD in the lumbar spine of 29% over 2 years (79% increments at this site as measured by QCT) (Roe *et al.,* 1999, 2000). It is difficult to reconcile the dramatic differences in BMD increments on the one hand between the two studies reported by Lindsay *et al.* (1997) and Lane *et al.* (1998a) and on the other hand by Roe *et al.* (1999, 2000), despite the reported dose of PTH being similar for all three studies. Possibly the absolute BMD of patients reported by Roe *et al.* who were approximately 8 years older was much lower than in the other studies, leading to a much higher relative gain. Alternatively the specific activity of the preparation used by Roe *et al.* may have been much higher, leading to a larger functional dose.

Bisphosphonates

No clinical studies combining bisphosphonates with PTH have been reported to date. As discussed in section 4, the data for bisphosphonate interactions with PTH in animal models are also unclear, with contradictory evidence that the *concurrent* use of bisphosphonates may blunt the anabolic agents of PTH. This is an important issue. Given the increase in skeletal bone remodeling induced by an activation drug such as PTH (at the BMU level), it is likely that the remodelling space within all skeletal bone envelopes will be enlarged as a transient state (Parfitt, 1980). The enlarged remodeling space could be exploited by anti-resorptive drugs as *maintenance* therapy after discontinuing PTH. This hypothesis has been tested in only one published study.

Approximately one-third of the randomized Phase II cohort of patients treated with PTH (1–84) for 1 year (Lindsay *et al.,* 1998) were subsequently treated with open-label alendronate, 10 mg daily. As reported by Rittmaster *et al.* (2000), there was a further rapid increment in BMD at all sites, such that the aggregate gain over 2 years in BMD at the highest dose of PTH (1–84) was 14.1% at the spine, 4.5% at the femoral neck, and 3.3% for the whole body. Since there had been significant negative changes in whole body BMD during the 12 months of PTH treatment, the subsequent rapid reduction of bone turnover induced by alendronate was consistent with closing down the skeletal remodeling pace.

Calcitriol

The studies by Neer and co-workers combined concurrent calcitriol with daily PTH injection therapy (Neer *et al.,* 1987, 1991; Slovik *et al.,* 1981, 1986). This strategy was

adopted because the earlier dietary calcium balance studies of Reeve and co-workers demonstrated minimal adaptations of dietary calcium absorption despite obvious histomorphometric restoration of trabecular bone and increased urinary Ca excretion. Since exogenous PTH does increase serum $1,25(OH)_2D$ levels in the short term (Hodsman and Fraher, 1990; Lindsay *et al.,* 1993) and is associated with increased fractional ^{45}Ca absorption, the need for the addition of calcitriol therapy remains unproven. The changes in lumbar BMD reported by Neer and co-workers are comparable to other studies but theirs was the first group to report significant losses of BMD at the radius in a controlled clinical trial (15 patients on calcium, 15 patients on PTH + calcitriol 0.25 μg/day, over 2 years) (Neer *et al.,* 1991). The control group lost 1.7% and the experimental group lost 5.7% in radial BMD—all in the first year of treatment. The greater and abrupt loss of appendicular bone mass in the experimental group might indicate a permanent loss to cortical bone but an alternative explanation includes the possibility of an effect consistent with increased intracortical modeling.

Cyclical Therapy with PTH and Calcitonin

Cyclical therapy with PTH and an antiresorptive agent, calcitonin, is of interest insofar as it might provide insights as to how the hormone might ultimately be given in the most economical fashion. The concept for the cyclical use of PTH should be distinguished from its direct anabolic effects on the skeleton. Since PTH also activates bone remodeling, cyclical protocols have attempted to exploit the ADFR hypothesis (A, activate remodeling; D, depress resorption in the activated bone modelling units; F, a treatment-free period of bone formation; R, repeat the treatment cycle). In fact, none of the cyclical protocols can be considered as true ADFR protocols and should be regarded as hybrid anabolic protocols.

Hesch and Hodsman have combined cyclical PTH(1–34) and 1–38 with concomitant or sequential cycles of calcitonin (Hesch *et al.,* 1989b; Hodsman and Fraher, 1990; Hodsman *et al.,* 1991, 1993, 1997, 2000). There is little evidence that the anti-resorptive action of calcitonin provides any additional clinical benefit. Short cycles of PTH (400–500 units/day, approximately 40 μg) for less than 14 days provide little evidence of skeletal activation of bone turnover or anabolism (Hodsman and Fraher, 1990; Hodsman *et al.,* 1991; Reeve *et al.,* 1987), although biochemical responses are detectable within this time frame. However, 28-day cycles of high-dose PTH (800 units, or 65 μg daily) appear to provide a strong stimulus for activation of bone turnover (Hodsman *et al.,* 1993) and anabolic effects on bone mass (Hodsman *et al.,* 1993, 1997). The reported changes in lumbar spine BMD, with small increments in femoral neck BMD with 28-day cycles of high-dose PTH may provide an alternative approach to harnessing the anabolic effects of PTH, but there are no controlled trials comparing cycles of PTH therapy with daily injections.

Use of PTH in Conditions Other Than Postmenopausal Osteoporosis

As noted previously, PTH has been used successfully to improve BMD in estrogen-treated women with glucocorticoid-induced osteoporosis (Lane *et al.,* 1998a). Of note in that study, BMD continued to increase at the spine and hip measurement site during the 12 months of observation following 12 months of PTH therapy, suggesting that treatment with continued HRT as an anti-resorptive therapy effected similar reductions in bone turnover to those seen previously with alendronate (Table I) (Lane *et al.,* 2000).

PTH(1–34) has also been shown to prevent the large and rapid loss of bone mass following "medical oophorectomy" induced by the gonadotrophin antagonist, nafarelin (Finkelstein *et al.,* 1994). Following cessation of nafarelin and PTH therapy, bone mass continued to increase during 1 year of follow-up, such that in the subjects previously treated with PTH, BMD in the spine was actually higher than it had been at baseline 2 years earlier (Table I).

Finally, PTH appears to have equivalent anabolic effects in men with osteoporosis (Kurland *et al.,* 2000; Slovik *et al.,* 1986), although the numbers of men so far studied are very small (see Table 1).

Histology

As described in earlier sections, changes in bone histology can be detected in animal experiments very early on in the course of PTH therapy. Similar changes have been recorded in clinical studies (Hodsman *et al.,* 1993).

After only 28 days of hPTH (1–34) injections, Hodsman *et al.* (1993) reported that changes in both formation and resorption surfaces were increased 2 to 5 times those measured in a control panel of osteoporotic bone biopsies. Since tetracycline bone markers were given on days 14 and 28, the increased bone formation surfaces were likely the result of osteoid formation on quiescent bone surfaces, since there had not been sufficient time for a *de novo* resorption/reversal cycle to be completed. Dynamic histomorphometric measurements confirmed greatly increased bone formation rates and a two- to threefold increase in the activation frequency of bone remodeling. There was no evidence for impaired mineralization as measured by mineral apposition rates and trabecular architecture was apparently normal (Hodsman *et al.,* 1993). This study involved 28 day cycles of PTH(1–34) injections which were repeated at three-monthly intervals. After 2 years, repeated biopsies demonstrated that bone resorption and formation surfaces remained two- to threefold higher than untreated controls, with comparable increases in activation frequency of bone remodeling (Hodsman *et al.,* 2000). The mean wall thickness of completed trabecular osteons was significantly increased after 2 years of cyclical PTH therapy, suggesting that therapy resulted in a sustained positive remodeling balance. Over 2 years, the cortical thickness in these

iliac crest biopsies remained significantly higher than in controls, with no change in cortical porosity (Hodsman *et al.,* 2000). Although the trial was small ($n = 29$), this study provides histological support for the positive benefits of PTH on trabecular bone without detriment to the cortical bone envelope (Hodsman *et al.,* 2000).

Reeve and co-workers have reported changes in bone histomorphometry after 6 to 12 months of daily PTH therapy (Bradbeer *et al.,* 1992; Reeve *et al.,* 1980b, 1987, 1991, 1993). Using each patient as an internal control, significant increases in trabecular area, trabecular width, and mean trabecular osteon wall thickness of between 5 and 25% over baseline measurements were documented (Bradbeer *et al.,* 1992; Reeve *et al.,* 1991). Although the earlier study by Reeve *et al.,* demonstrated increased trabecular osteoid surfaces (from 23.3 to 35.2%) and resorption surfaces (from 3.9 to 6.2%) (Reeve *et al.,* 1980b), their later study demonstrated that if anything, these same parameters tended to decrease with time (Reeve *et al.,* 1993). Although little kinetic data (based on *in vivo* tetracycline labels) are available from Reeve and co-workers, the available evidence suggests that long-term PTH therapy (i.e., of more than 6 to 12 months duration) favors a positive osteon remodeling balance, and normal bone architecture, but that the dramatic short-term histological evidence for increased bone turnover is not sustained over time.

Biochemical Markers of Bone Metabolism

Biochemical markers of bone turnover provide noninvasive indicators of the balance between bone resorption and bone turnover (Delmas *et al.,* 1991; Garnero *et al.,* 1994; Riis *et al.,* 1995). Because PTH is regarded as a hormone with potent bone-resorbing properties, leading to concomitant increases in urinary calcium excretion, other markers of bone resorption are of great importance. In this section, discussion of biochemical markers of bone resorption will be restricted to urinary hydroxy-proline (OH-Pro), deoxypryidinoline (DPD), and the collagen cross-linked N-telopeptides (NTx). Markers of bone formation will focus on bone-specific alkaline phosphatase (BSAP) and/or osteocalcin. However, a complete interpretation of the data is founded by heterogeneous study designs and duration of therapy.

Reeve *et al.* (1980b) reported a 26% increase in OH-Pro excretion in patients treated with daily PTH, but either no change or a 100% fall in urinary OH-Pro in a small group of 12 patients who were treated with estrogen or androgen as concurrent anti-resorptive therapy (Reeve *et al.,* 1987, 1991). When using a dose of PTH (800 units/day), Hodsman *et al.* reported a 53% increase in urine OH-Pro after 1 month of treatment with no significant changes in urine DPD excretion (Hodsman *et al.,* 1993). However, other investigators have variously reported increments in either urinary OH-Pro, DPD, or NTx excretion that are much higher (150–350% over baseline) (Finkelstein *et al.,* 1998a; Kurland *et al.,* 2000; Lane *et al.,* 2000; Lindsay *et al.,* 1997; Sone *et al.,* 1995). These markers of bone resorption all tend to be maximal within the first 6–12 months of PTH treatment and fall back toward baseline values over longer periods of continuing therapy.

Increments in both BSAP and osteocalcin are consistently seen and vary between approximately 115 and 250% (Finkelstein *et al.,* 1998a; Fujita *et al.,* 1999a; Hodsman *et al.,* 1997; Kurland *et al.,* 2000; Lane *et al.,* 2000; Lindsay *et al.,* 1997). These increments in biomarkers of bone formation precede evidence of bone resorption, but again are maximal within 6 to 12 months and fall toward baseline values in the longer studies.

In summary, the reported measurements of biochemical markers for bone resorption and formation support the rapid onset of skeletal activation and bone turnover in response to PTH as reported histologically by Hodsman *et al.* (1993, 2000). Increments in bone formation markers are consistent and of considerable magnitude, in keeping with direct osteoblastic stimulation and bone anabolism (Hodsman *et al.,* 1997; Lindsay *et al.,* 1997). Increments in bone resorption markers are less consistent, but still of considerable magnitude. Since declines in biochemical markers of bone turnover after 2–3 years of therapy appear to be consistent, these markers may substantiate the premise that skeletal resistance to the anabolic effects of PTH peptides might occur during the first three years of therapy.

Calcium Balance Studies

Prior to 1980, there were few methods to document changes in bone mass in response to any agent. Bone biopsies yield important information, but the measured parameters are not precise (typical CV $\pm$ 20%) (Chavassieux *et al.,* 1985). Therefore, early studies relied on classical dietary calcium balance studies and radio-isotopic techniques of assessing skeletal calcium accretion to determine the extent to which new therapies for osteoporosis improved skeletal bone mass. The methodology of the reports discussed below is not easy to follow, but the cited references provide a source for such documentation. Moreover, the reader should appreciate that the cited clinical protocols vary widely with respect to dose of PTH, duration of therapy and concurrent medication. Given these limitations, the results indicate enough consistency to describe the results in general terms.

In the initial report by Reeve *et al.,* (1976a), four patients treated with PTH (500 units/day), demonstrated an improved dietary calcium balance averaging 7.3 mmol/day. Net diet absorption of ^{47}Ca averaged 3.4 mmol/day. Measured accretion of ^{47}Ca by the skeleton averaged 6.3 mmol/day. These data seemed to confirm that the observed improvements in bone histology were indeed due to an anabolic effect of the injected hPTH(1–34). A subsequent report on the short-term changes (less than 1 month) measured in the same subjects defined dose dependent effects, with calcium

balance improving over doses of 500 to 1000 units hPTH (1–34)/day, but deteriorating at doses of 1500 units/day (Reeve *et al.,* 1976b). In a small group of four patients treated with 450–750 units hPTH(1–34) over 1 month reported by Slovik *et al.,* a similar dose dependency was observed, with positive dietary calcium balance (2.2 mmol/day) seen only at the lower doses of PTH (Slovik *et al.,* 1981).

In summary, kinetic calcium data demonstrate trends toward positive dietary calcium balances during a variety of therapeutic PTH protocols. These techniques have not been as sensitive to changes in bone mass as dual-energy absorptiometric measurements, but they comprise the only existing evidence that prolonged PTH treatment does not result in consistent total body calcium depletion. However, two reports suggest that higher doses of PTH (>1000 units/day) may be deleterious to total body calcium balance (Reeve *et al.,* 1976b; Slovik *et al.,* 1981).

Effects on Serum and Urinary Calcium

The biological effects of PTH when given by continuous intravenous infusion, intravenous bolus or subcutaneous injection are not the same. For example, continuous infusion of hPTH(1–34) caused marked bone resorption in the rat (Tam *et al.,* 1981). When infused into osteoporotic subjects, Hodsman *et al.* reported that a given dose of hPTH(1–34) caused significantly larger increments in total serum calcium over 24 hr than the same dose given by a single subcutaneous injection (Hodsman *et al.,* 1993). The PTH infusion led to a significant fall in biochemical markers of bone formation, suggesting, if anything, that continuous intravenous infusion of PTH is anti-anabolic (Hodsman *et al.,* 1993). Similar findings in osteoporotic subjects were reported by Cosman *et al.* (1993), albeit that concurrent estrogen therapy might have mitigated the catabolic effects of PTH infusion.

Increments in serum calcium following subcutaneous PTH injection are delayed and do not peak until 4–8 hr postdosing (Hodsman *et al.,* 1993; Lindsay *et al.,* 1993), but they are generally within the normal physiological range. Since the clearance of injected PTH is so rapid, no obvious safety concern has arisen after over 20 years of PTH therapy. However, persistent hypercalcemia may occur during daily PTH injections. In the only published RCT evaluating PTH(1–34) against placebo, serum calcium measurements 24 hr after daily injections of PTH in a dose of 20 μg/day (approximately 250 units) were mildly elevated (<11.5 mg/dl) in about 10% of patients, and not sustained in a third of these women (Neer *et al.,* 2001). Dose reduction because of sustained hypercalcemia within the dose ranges chosen in most published trials is seldom necessary, and cessation of nutritional calcium supplementation is often sufficient to manage increments in serum calcium above the normal physiological range. Short-term increments in serum $1,25(OH)_2D_3$ have been reported after subcutaneous hPTH(1–34) (Fujita *et al.,* 1999a; Hodsman and Fraher, 1990; Lindsay *et al.,* 1993), together with increased fractional absorption of dietary calcium (Hodsman and Fraher, 1990) and hypercalciuria (Hodsman *et al.,* 1993; Lindsay *et al.,* 1993). However, of the three studies reporting long-term biochemical changes in response to hPTH(1–34) injections, sustained increments in serum $1,25(OH)_2D_3$, and hypercalciuria were not of clinical importance (Hodsman *et al.,* 1997; Lindsay *et al.,* 1997; Neer *et al.,* 2001).

Pharmacokinetics of PTH Administration

Since most therapeutic protocols have reported the response of the skeleton to daily subcutaneous injections, this section focuses on the pharmacodynamic responses to PTH when given by this route.

In a small study involving four healthy young subjects, Kent *et al.* (1995) reported that after subcutaneous administration of 1250 units hPTH(1–34) (100 μg, 20 nmol) the time to reach maximum plasma concentration T_{max} was approximately 15 min, with immunoreactive PTH concentrations decaying to baseline after 180–240 min. Two additional reports, in estrogen-treated postmenopausal osteoporotic subjects and in both young and untreated postmenopausal subjects (Fraher *et al.,* 1993; Lindsay *et al.,* 1993), provided very similar data, i.e., peak immunoreactive increments in serum hPTH(1–34) levels at 20–30 min postinjection, increasing 10- to 15-fold over baseline (depending upon injected dose), and decaying within a $T_{\frac{1}{2}}$ of about 75 min (Fig. 5).

The only detailed pharmacodynamic study published for other PTH peptides is a dose-finding single subcutaneous injection report on hPTH(1–84). Schwietert *et al.* (1997) reported minimal changes in total serum calcium in response to single injections of up to 5 μg hPTH(1–84)/kg (approximately 0.5 nmol/kg). However, with this peptide, absorption appeared to be associated with a double peak in C_{max} with an

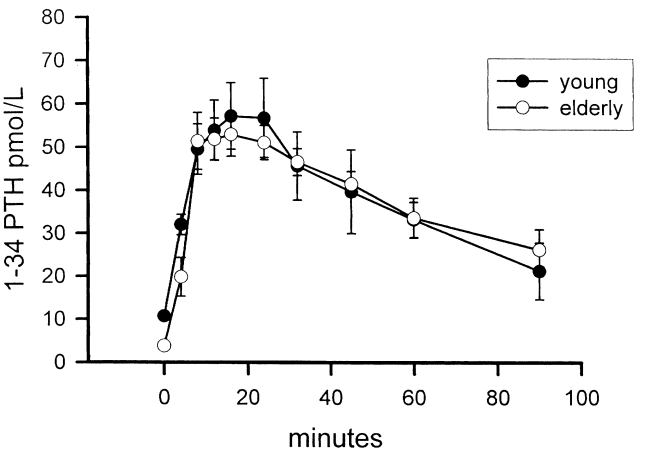

Figure 5 Pharmacokinetics of PTH(1–34) given by subcutaneous injection. Serum concentrations of hPTH(1–34) after subcutaneous injection of 800 IU PTH peptide in 10 young adults ages 25 ± 9 (SD) years and 9 elderly women with osteoporosis, ages 67 ± 11 years. Adapted from Fraher *et al.* (1993).

early peak occurring <20 min postinjection and a second peak appearing $1\frac{1}{2}-2$ hr later. This pharmacokinetic profile occurred at all doses of hPTH(1–84) and appears to be different from that observed after hPTH(1–34) dosing.

It is therefore quite possible that different PTH peptides have different biological properties on bone metabolism together with different safety profiles.

Immunological Responses to Exogenous PTH

Of the available reports in which antibody formation was deliberately sought, 67 of 1168 patients apparently developed anti-hPTH(1–34) antibodies in low titers. (Hesch *et al.,* 1989b; Hodsman *et al.,* 1997; Neer *et al.,* 2001; Reeve *et al.,* 1976a, 1987, 1991) Four patients discontinued hPTH(1–34) therapy because of generalized urticarial reactions or local irritation at the injection site (Reeve *et al.,* 1976a, 1980b). Although the 6% incidence of anti-PTH(1–34) antibodies may seem high, it is likely that the earlier reports reflect impurities in the hPTH(1–34) formulations that were used; native hPTH(1–34) is a naturally occurring peptide and should not be immunogenic. Whether the newer PTH analogs possess this drawback awaits further clinical testing.

Other Analogs and Delivery Systems

The principal analog used in the reported clinical literature was the presumed bioactive amino-terminal fragment of PTH, namely hPTH(1–34). Several have used hPTH(1–38) because it might be more potent than hPTH(1–34) (Hesch *et al.,* 1984, 1989a,b; Hodsman and Fraher, 1990; Hodsman *et al.,* 1991), but there is no compelling reason to accept this. The natural hPTH(1–84) holohormone is currently under development for clinical trials and appears to be anabolically equipotent to PTH(1–34). Other analogs include hPTH-(1–31) amide and its lactam. These analogs stimulate adenyl cyclase with equivalent potency to the holohormone PTH-(1–84), but seem to have no effect on the phospholipase C messenger system; in animal models of anabolic bone formation they are equipotent to PTH(1–34) (Whitfield *et al.,* 1997). There is a single report of continuous intravenous infusion of PTH(1–31) amide in young human subjects (Fraher *et al.,* 1999). When compared to an equimolar dose of infused PTH(1–34), comparable urinary and plasma cyclic AMP responses were seen, but the PTH(1–31) amide resulted in no increase of serum and urinary calcium or in urinary NTx. This suggests that analogs can be designed with more selective potency for bone formation over bone resorption. Other PTH analogs, published in abstract, appear to be potent anabolic agents in animal experiments (Henry *et al.,* 1996; Yee *et al.,* 1996a,b). So far only the PTHrP(1–34) analog, semparatide, has been evaluated in a small Phase II randomized clinical trial. (Gallagher, 1999). Over 6 months, significant dose-dependent increments in BMD measurements of the lumbar spine and total hip were seen, with slight reductions of the radius and TBBM (Table I). Half of the study cohort received a second 6-month period of alendronate treatment and experienced a further acceleration of BMD gain at all sites, similar to that reported by Rittmaster *et al.* (2000). So far this study has been reported only in abstract form, making it difficult to compare safety and efficacy to PTH(1–34).

While all PTH peptides are currently under clinical development using the subcutaneous injection route, alternative delivery systems include:

(a) automated injection or transcutaneous delivery
(b) intranasal delivery
(c) transpulmonary delivery of aerosolised peptide (Deftos *et al.,* 1996).

Alternative delivery systems are in the early stages of clinical evaluation. Intranasal delivery devices have been demonstrated for both PTH and calcitonin peptides, using lyophilized, microparticulate delivery systems (Deftos *et al.,* 1996; Nomura *et al.,* 1996). Transpulmonary systems have been developed in which aerosol delivery to the bronchoalveolar tree leads to 30 to 40% bioavailability of PTH peptide compared with that seen through intravenous routes of administration, with profiles of peptide absorption that are very similar to those delivered by subcutaneous injection (Patton *et al.,* 1994). While noninjectable routes of PTH peptide delivery are still in the realm of experimental medicine, there is no reason to believe that this compliance barrier cannot be crossed in the near future. In the short term, research using injectable PTH peptides has not been a significant barrier to patient compliance.

Adverse Effects during PTH Therapy

Over 2800 patients have received PTH in the published literature, but most studies have been small (fewer than 50 participants) and of short duration. In only four studies were there more than 100 subjects receiving active PTH peptide (Fujita *et al.,* 1999a; Gallagher, 1999; Lindsay *et al.,* 1998; Neer *et al.,* 1999), representing close to 2250 patient years. No serious adverse reactions have surfaced beyond the obvious need to monitor serum and urine calcium concentrations, the majority of which can be handled by appropriate dose reductions during the initial weeks of treatment (Neer *et al.,* 2001). Nausea, headache, dizziness, arthralgia, and leg cramps following injection occur in 5–15% of women, in a dose-dependent fashion, but are likely to be rare in doses chosen for commercial applications (Finkelstein *et al.,* 1994; Neer *et al.,* 2001). Hodsman *et al.* (1997) have raised an issue about the long-term safety of PTH on renal function. In this report, 39 patients were treated with cyclical high dose PTH (800 units per day for four 28-day cycles/year over 2 years). This patient group experienced a significant 10% increase in serum creatinine (albeit within the normal range of age-related serum creatinine). Thus, PTH-induced hypercalciuria might conceivably affect renal function.

The study of PTH(1–34) reported by Neer *et al.* (2001) was terminated prematurely after the consistent dose-dependent appearance of osteosarcomas in a concurrent study in Fischer 344 rats undergoing a standard carcinogenicity bioassay. In that study, animals were treated with near-lifetime daily injections of PTH(1–34), and developed osteosarcoma after 18 months of dosing, by which time osteosclerosis and extramedullary hematopoesis had occurred. PTH did not increase the incidence of nonskeletal tumours, and osteosarcoma has not been reported in other species after similar dosing protocols (Neer *et al.,* 2001). The mitogenic potential of PTH peptides (as given therapeutically for osteoporosis) has not surfaced as an issue in published clinical trials, and since the study reported by Neer *et al.* is the largest trial to date, it is encouraging that the incidence of all neoplasms in the treated patients was actually lower than that observed in the placebo arm (Neer *et al.,* 2001). To date osteosarcoma has not been reported after therapeutic treatment with a PTH peptide in human subjects. In the 2 naturally occurring clinical conditions in which long-term increments in circulating PTH are well documented (primary and secondary hyperparathyroidism associated with chronic renal failure) there is no reported incidence of osteosarcoma (Kaplan *et al.,* 1971; Koppler and Massry, 1988; Maissonneure *et al.,* 1999; Vamvakas *et al.,* 1998). Although the mitogenic potential for PTH analogs has not been confirmed outside of a single laboratory experiment, PTH does appear to act as a growth factor within skeletal tissue and its receptor is widely distributed in other tissues. Therefore the oncogenic potential of these peptides should not be dismissed.

Conclusion

To date, the 25-year clinical experience of PTH therapy indicates that this is an important anabolic agent with the potential to reverse osteoporosis. Very few safety concerns have been raised over treatment periods of 2–3 years. The introduction of PTH peptides/analogs holds promise for a new class of agents which might reduce fractures in osteoporotic individuals. However, there are several outstanding questions raised by the published literature; the order in which we have listed them in no way reflects their order of importance.

(1) The safety prolife of PTH peptides remains to be established. Although ongoing long-term placebo-controlled trials will establish this, a small minority of patients develop sustained hypercalcemia and hypercalciuria, and there is at least one report of declining renal function over time (Hodsman *et al.,* 1997).

(2) While PTH holds the promise of rapid increments in skeletal bone mass in osteoporotic subjects, anti-fracture efficacy has been clearly demonstrated in one completed Phase III clinical trial (Neer *et al.,* 2001). Nonetheless, are the anabolic benefits to the skeleton restricted to the trabecular envelope? Do patients lose cortical bone as suggested by the radial bone mass data reported by Neer *et al.* (1991)? This important question is crucial but other data regarding the radius, total body calcium balance (Lindsay *et al.,* 1997; Neer *et al.,* 2001), and total body bone mineral density (Lindsay *et al.,* 1997) suggest that the effect of PTH treatment is most potent at trabecular sites but not detrimental to cortical bone.

(3) Given that PTH therapy induces rapid gains in bone mass (assessed by BMD measurement), can these gains be translated into sustainable bone mass. Animal data suggest that concomitant or sequential bisphosphonate therapy either blunts the skeletal response to PTH or blunts subsequent therapy with the peptide (Cheng *et al.,* 1995; Delmas *et al.,* 1995; Mashiba *et al.,* 1995), although this is not an invariable finding (Mosekilde *et al.,* 1995). To date, clinical studies suggest that concurrent estrogen therapy and daily PTH injections result in significant increments in total body BMD as well as increments at axial sites (Lindsay *et al.,* 1997). Sequential therapy with alendronate following 1 year of therapy with daily hPTH(1–84) injections resulted in marked gains in both axial and appendicular bone mass (Rittmaster *et al.,* 1998). This approach may suggest a role for anti-resorptive therapy as a sequential regimen in the overall management of osteoporosis, rather than concomitant therapy.

(4) Is concurrent medication necessary during PTH therapy? Most studies have utilized a variety of agents (including calcium, vitamin D or calcitriol, calcitonin, and estrogen). While the published data employing such strategies are not convincing, factorially designed clinical trials have not been done.

(5) Will cycles of PTH injections prove to be as effective as continued daily dosing? This question has a significant impact on cost and compliance.

(6) Does the skeleton develop resistance to continued PTH therapy? If so, will interval rechallenge be effective? Perhaps most importantly, will PTH therapy be as effective in patients previously treated with bisphosphonates but who have had less than adequate responses to this class of therapeutic agents?

(7) Will analogs of PTH be better anabolic agents than hPTH(1–34) or hPTH(1–84)?

CHAPTER 76

Calcium

Robert P. Heaney
Creighton University, Omaha, Nebraska 68178

Background

Calcium in the Environment in Which Life Arose

Calcium is the fifth most abundant element in the biosphere, after iron, silicon, oxygen, and aluminum. Unlike silicon and aluminum, whose compounds are quite insoluble, calcium salts exhibit an intermediate solubility that both permits them to be present in solution in the waters in which life evolved and to support development of various hard, solid organs for use by evolving life forms. Calcium is dissolved in seawater, for example, at concentrations up to 10 mM, ~10 times that which is found in the extracellular fluid of mammals. Even fresh water, if it is to support an abundant biota, must have substantial dissolved calcium (~1–2 mM, roughly on the order of mammalian extracellular fluid concentrations). Dissolved calcium is needed to keep carbon dioxide in solution for the photosynthetic activity of algae and aquatic plants, thereby establishing the base of the aquatic food pyramid.

The radius of the Ca^{2+} ion is just right to fit naturally into the folds of many proteins, coordinating with up to eight oxygen atoms in the peptide chain and its side groups. Calcium thus stabilizes critical tertiary structures of both catalytic and structural proteins (Carafoli and Penniston, 1985). This binding to key peptides is true, of course, for many metal cations, but most tend to be highly specific for one or two configurations (e.g., Fe, Mn, Cu, Zn, etc.). Magnesium, calcium's closest relative in the cell, and like calcium a divalent alkaline earth element, has a smaller ionic radius and does not bind as strongly as does calcium. Calcium, by contrast, binds avidly to a profusion of proteins, ranging from actin to calmodulin to the various *gla* proteins. Calcium's functionality is so broad, in fact, that essentially all cells have found it necessary to restrict calcium concentration in the cell sap to something like four to five orders of magnitude below that in the extracellular fluid (ECF) surrounding the cell. These low cytosolic concentrations are the context that permits cells to use calcium as a nearly universal second messenger. They do so by admitting controlled quantities into critical cellular compartments when specific functions are to be activated, and promptly pumping it out, either into the extracellular space or into intracellular vesicles, when the cell action is to be shut off. Intracellular storage of calcium is the rule, rather than the exception. Examples include the sarcoplasmic reticulum of muscle and calcium phosphate crystals in mitochondria. Calcium is so critical to intracellular function that most cells have developed means of maintaining their own supply. In general their dependence on extracellular calcium is limited to initiating the cascade by opening calcium channels in the cell membrane. Movement of ECF calcium into the cytosol through these channels then activates a much larger release of intracellular calcium stores, as in muscle contraction.

However, life at a higher, multicellular level requires integrative functions and, therefore, the maintenance of critical concentrations of many factors in the ECF of complex organisms. Here a higher calcium concentration (in the range of 1.25 mM) is essential for a variety of functions, ranging from neuronal synaptic transmission to blood clotting. While ECF $[Ca^{2+}]$ is essentially constant across the higher vertebrates, the means whereby it is stabilized vary. Fish and amphibia have access to the calcium in the surrounding water and buffer the concentration of calcium in their extracellular fluids by controlling fluxes across the gill membranes. However, terrestrial vertebrates, dependent upon periodic food ingestion for their calcium, need an internal source and sink of calcium for homeostasis. It is partly in this context that bone enters the scene.

Calcium and Bone in Evolutionary Perspective

While the most obvious feature of bone in terrestrial vertebrates, and particularly in humans, is its structural property,

it is likely that bone served somewhat different purposes in the early marine vertebrates (Urist, 1964). The fossil record indicates that bone evolved independently several times over the millennia of evolution — as dermal armor, as teeth, and as internal stiffening, often dropping out again in more modern descendants of ancestral bony members of the same classes. The internal stiffening and mechanical strength provided by bone, so obviously important on dry land, is of less significance in a buoyant medium, and there is a trend for fish to become less bony over the course of evolution. The modern sturgeon, a true bony fish by evolutionary origin, is essentially boneless today (except for the gill covers), but the fossil record shows that early sturgeons were quite as bony as most other modern fish. The *chondrichthyes* (sharks, skates, and rays), to cite another example, have only a cartilaginous skeleton, and yet do not lack for mechanical engineering efficiency.

Evolutionary biologists consider that the skeleton probably served an important homeostatic function, helping the organism maintain the constancy of critical elements in its internal milieu (Urist, 1962). That function is clearly evident in modern mammals, where the ion most prominently buffered by bone is calcium. There is reason to believe, however, that calcium may not have been the critical ion in marine vertebrates, since, as already noted, the surrounding sea provided a relatively large surplus of calcium relative to the ECF in most higher vertebrates. However, phosphorus is a trace element in seawater, and the phosphorus essential for intermediary metabolism, for DNA and RNA structure, and for so many catalytic functions, is acquired by marine vertebrates by ingesting the tissues of other organisms lower in the food chain. Hence, phosphorus needs to be rigidly conserved. Bone meets that need.

While the mechanisms by which bone serves a homeostatic function in terrestrial vertebrates are well worked out, it is less clear precisely how bone functions in maintaining internal homeostasis in fish. Fish produce many of the hormones involved in mammalian calcium and phosphorus homeostasis (calcitonin is an obvious example), but these agents do not seem to have the same effect on ECF [Ca^{2+}] in fish as in mammals. Furthermore it is not certain in fish how minerals are either added to the bony reserve or withdrawn from it.

Bone as the Body's Calcium Sink and Reserve

Without a constant supply of calcium in the fluid bathing the gill membranes, land-living vertebrates were confronted with the problem of maintaining constancy of extracellular fluid calcium levels in the intervals between feedings. This required a place to put calcium acquired from food in the absorptive phase and a place from which to draw calcium during fasting. Bone is that place. However, bone is not simply a passive reservoir. As noted elsewhere in this volume, calcium is stored in bone only in the process of mineralizing newly deposited bone matrix, that is, by adding new volumes of bone *tissue;* and it is withdrawn from bone only by resorption of old bone *tissue.* Thus the reservoir functions of bone are mediated by modulating, on a moment-to-moment basis, the balance between new bone formation and old bone resorption.

A good example of this modulation is afforded by what happens during calcium absorption from milk in infant mammals. The quantity of calcium ingested in a short period of time, coupled with the efficiency of absorption in infants and the small volume of the extracellular fluid water into which that calcium is dumped, are such that near fatal hypercalcemia would ensue if there were not some way to damp the absorptive rise in ECF calcium. This is accomplished by calcitonin-mediated suppression of osteoclastic bone resorption. Since bone formation is continuing, the mineral demands of recently deposited bone matrix effectively soak up the absorbed calcium. Then, as absorptive input decreases, bony resorption resumes. The result is a nearly steady input of calcium into the ECF, with the relative contributions of bone and gut varying inversely.

It is virtually certain that most of the skeletal control of extracellular calcium levels throughout life is exerted on the resorptive side of the remodeling apparatus, for the simple reason that osteoclastic activity is susceptible to very rapid response to humoral mediators, while mineralization is not. Once suitable crystal nuclei are formed (see Calcium in Bone, below), mineralization is mainly passive. The mineralization of newly formed bony units actually constitutes the principal systemic drain to which the control systems must respond (rather than functioning as a response mechanism itself).

An example of the reservoir function of bone is seen during annual spring antler formation in deer (Banks *et al.,* 1968). Rapid bone growth in the antler buds creates a greater calcium demand than the nutrient-poor, late winter and early spring foliage can satisfy. Since intestinal input cannot meet the demand, parathyroid hormone secretion increases and a burst of bone remodeling occurs throughout the entire skeleton. The first phase of bone remodeling is resorptive; hence a great deal of calcium is thereby released into the ECF, countering the drain of antler bone mineralization. Several weeks later, the skeletal remodeling loci reach their own formative stage, more nutrient-rich summer foliage has become available, and antler growth has slowed. The deer are then able to pay back the skeletal calcium loan from food sources. Something similar is seen in the deposition of medullary "egg bone"' early in the egg-laying cycle in birds. Such bone is then resorbed during later phases of egg formation, when its calcium both supports shell formation and helps solubilize protein being transported to the oviduct. The same type of phenomenon occurs in preparation for lactation in most mammals, with pregnancy commonly being a time of more positive calcium balance than can be accounted for by fetal mineralization, and then with substantial loss of bone during the hypoestrin state of lactation (Heaney, 1996a). For example, the nursing rat, across lactation of a full litter of pups, loses on the order of one-third of the skeletal mass she had at delivery (Brommage and DeLuca, 1985).

Thus, it is clear from the comparative biology of the skeleton that bidirectional remodeling imbalances (decreasing and then augmenting local bone mass) are capable of both removing and replacing calcium from bone by tiny minute-to-minute alterations of bone mass. Except for the accumulation of remodeling errors, this in-and-out process would not be expected to exert a deleterious effect on bone; in fact, it probably has a net beneficial effect on bone quality, inasmuch as evoked remodeling focuses preferentially on old, fatigue-damaged tissue, replacing it with fresh, new bone. However, when withdrawals are protracted or payback is incomplete or absent, structural elements may be lost (Fig. 1). When this occurs, the loss becomes irreversible, inasmuch as the scaffolding for osteoblastic replacement vanishes. Nutrient repletion can be expected only to fatten up existing structures, not replace lost ones. In this sense, calcium differs from a nutrient such as iron for which full repletion of functional iron mass is possible even after loss of a major fraction of total body iron stores.

There is an important asymmetry about this bidirectional flux of calcium in and out of bone through the remodeling cycle. While bone can be resorbed essentially without limit, there is a practical ceiling that governs how much calcium can be stored. Given an environmental abundance of calcium, bone mass is regulated not by nutrient availability but by a mechanical feedback loop that works to maintain bony strain under load at a constant level in all skeletal parts and regions. The regulation of this setpoint is complex and poorly understood, but it is influenced, at least in part, by estrogen [which explains why bone tissue is added to the skeleton at puberty (Gilsanz *et al.,* 1988) and during pregnancy (Heaney and Skillman, 1971), when estrogen levels rise, and withdrawn from it at menopause and during lactation (Brommage and DeLuca, 1985), when estrogen levels fall]. However, under a hormonal steady state, bone balance will become zero when the optimal level of strain is reached. Additional dietary calcium cannot be stored (see Defining the Calcium Requirement, below). The upshot is that, while the organism can withdraw calcium virtually without limit, storage is limited by the extent to which the skeleton continues to be subject to normal loading stresses, contingent upon preservation of structural elements.

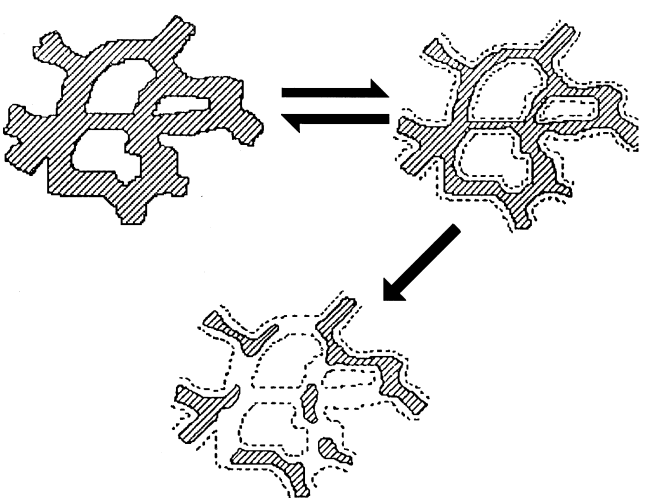

Figure 1 Schematic representation of the bidirectional flux of calcium in and out of the skeleton in a small volume of cancellous bone. Calcium is mobilized by resorbing bone tissue. So long as the basic structure is preserved, lost bone can be fully replaced. However, when whole structures are resorbed (i.e., trabecular plates penetrated and trabecular beams severed), replacement of lost bone becomes difficult or impossible. (Copyright Robert P. Heaney, 1995. Reproduced with permission.)

Calcium in Bone

The adult human body contains, on average, slightly more than 1 kg of calcium, better than 99% of which is in the form of bone and teeth. Calcium is the principal cation of bone, comprising slightly less than 40% of the mass of the bone mineral and slightly less than 20% of the dry weight of bone. Calcium exists in bone in a mineral form that is usually characterized as hydroxyapatite, i.e., $Ca_{10}(PO_4)_6(OH)_2$. This is only approximately correct, and it is more accurate to say, after Posner (1987), that bone mineral is a "structurally imperfect analogue of hydroxyapatite." Bone mineral contains, for example, carbonate, citrate, potassium, and magnesium, among other ionic species. Carbonate content is especially high. It varies fairly substantially from species to species, in humans comprising in the neighborhood of 6–9% of the mass of the mineral. Because the carbonate ion does not fit well into the hydroxyapatite crystal lattice, it is generally presumed to be located in superficial positions on the mineral crystals. The lability of bone carbonate, as reflected in changes in carbonate content with metabolic acidosis, suggests also that its location may be mostly on anatomic surfaces.

The crystals of bone exist in intimate association with the collagen fibers of the bone matrix. They are long and needle-shaped, are ~70 Å in diameter and from 200 to 3000 Å long, and are constrained in size and orientation by the dense, orderly packing of the matrix collagen fibrils, which are laid down before mineralization begins. Matrix, as deposited, consists of about half protein and half water. As mineralization proceeds, mineral crystals displace the water, aligning themselves with the collagen fibrils. Ultimately, at full mineralization, the extracellular bony material contains virtually no free water. One consequence is the fact that mineral ions deep to anatomical surfaces are frozen in place, neither exchanging with nor supporting the level of the corresponding ionic species in solution in the ECF.

The calcification of matrix presents an interesting illustration of the importance of specificity of crystal habitus and takes advantage of the marginal solubility characteristics of calcium phosphate. Both calcium and phosphate (the latter in the form of $H_2PO_4^-$ and HPO_4^{2-} circulate in the body fluids in solution and do not precipitate either in the bloodstream or in healthy body tissues. However, the same minerals, in exactly the same concentrations,

support mineralization when the blood flows past a bone-forming site. The reason, very simply, is that the concentrations of calcium and phosphate in ECF are such that body fluids are approximately half saturated with respect to $CaHPO_4$ (the most likely crystal form at physiological pH and pCO_2). However, bone mineralization is not simple precipitation. Rather, it involves the creation of a template for formation of a crystal more like hydroxyapatite or tricalcium phosphate [$Ca_9(PO_4)_6$]. Such minerals would not form spontaneously below pH 8; they are much less soluble, and body fluid concentrations of calcium and phosphate are approximately twice their K_{sp}. Local creation of such crystal nuclei is the means by which vertebrates have been able to control deposition of mineral, placing it only in loci specifically prepared to receive it, e.g., where it is needed to provide the necessary rigidity for the structural role of bone.

Noncollagenous matrix proteins are believed to play the critical role in configuring Ca^{2+} and PO_4^{3-} ions in space so as to create the hydroxyapatite template. Alkaline phosphatase, produced by the osteoblast late in the matrix deposition process, is believed to function by hydrolyzing pyrophosphate and organic phosphate esters present in the medium, which both makes extra phosphate available and removes components that otherwise function as crystal poisons, inhibiting crystal growth (Whyte, 1989).

The chemistry of formation of the apatite mineral can be summarized as

$$10\ Ca^{2+} + 3.5\ H_2PO_4^- + 2.5\ HPO_4^{2-} + 2H_2O \rightleftarrows Ca_{10}(PO_4)_6(OH)_2 + 13.5\ H^+.$$

The proportion of $H_2PO_4^-$ and HPO_4^{2-} in extracellular fluid at body pH is such that this reaction produces ~13 protons for each unit cell[1] of hydroxyapatite formed. These must, of course, be removed from the mineralizing environment, or the reaction would cease or tend to run in reverse. By the same token, ~13 protons must be produced by osteoclasts to solubilize one unit cell during bone resorption.

The Calcium Requirement

What the Requirement Ensures

The strength of bone, as with all material structures, resides in four features: the instrinsic strength of the mineral–matrix composite, the massiveness of the structure, the geometric arrangement of the bony elements in space, and the loading history of a structural element, expressed in accumulated fatigue damage. As I have noted above, calcium availability may influence the repair of fatigue damage, inasmuch as temporary episodes of calcium deficiency will evoke bone remodeling. But the principal mechanism by which calcium is recognized to influence bone strength is through its effect on bone mass. Since bone functions as the calcium nutrient reserve, it follows inexorably that any depletion of that reserve will carry with it a corresponding decrease in bone strength.

As already noted, the calcium needed for critical cell-metabolic functions is, in most cells, derived from intracellular stores of the mineral. Bone constitutes such a large reserve of calcium that cellular functions could virtually never deplete it, no matter how low the oral intake of the nutrient. The same is true for the maintenance of ECF [Ca^{2+}]. A mere 5 g of bone contains as much calcium as the entire extracellular fluid space of an adult human. The requirement for calcium relates thus, not to the metabolic role of the nutrient, but to building and maintaining the size of the calcium reserve, i.e., to its secondary function, bone strength.

Calcium in the Environment in Which *Homo sapiens* Evolved

The abundance of calcium in the biosphere, previously noted, is expressed in the relatively high calcium content of the foliage, tubers, nuts, and other plant foods available to herbivorous and omnivorous mammals. The massive skeletons of extinct herbivores, the exuberant racks of antlers of deer and elk, both prehistoric and modern, and the large volumes of calcium-rich milk produced by dairy cattle today are all testimony to the abundance of calcium in a plant-based diet. Omnivorous animals, in addition to the calcium from plants, had access to the calcium in bones of animal prey, calcium in the chitinous exoskeletons of insects, and calcium in insect larvae and grubs.

Analysis of the foods consumed on a year-round basis by chimpanzees, our closest primate relatives, indicates a calcium nutrient density in their diets of 2–2.5 mmol (80–100 mg) Ca/100 kCal (Eaton and Nelson, 1991). The !Kung people of South Africa have been found to have diets very nearly as high [1.75–2.0 mmol (70–80 mg) Ca/100 kCal]. Studies of other hunter–gatherer peoples indicate that their diets, too, have calcium nutrient densities in the range of those of the high primates. The energy expenditure of a hunter–gatherer or chimpanzee, scaled up to the body size of contemporary Western peoples, translates these nutrient density figures to a total calcium intake in the range of 50–75 mmol (2000–3000 mg)/day from plant sources. Riverine peoples, with bony fish in their diets, had still higher calcium intakes. By contrast with these pretechnological kinds of intakes, the diet calcium density of urbanized or industrialized nations is commonly under 0.6 mmol (24 mg)/100 kCal (Carroll *et al.,* 1983).

The reason for the difference between primitive and contemporary diets is expressed, graphically, in Fig. 2, which depicts schematically the effect on calcium nutrient density produced by the agricultural and pastoral revolutions (which can be dated to roughly 10,000 years ago, at least in the fertile crescent, and much more recently in the Western hemisphere and northern Europe). Domestication of animals and

[1]A unit cell, in this case containing 10 calcium ions, is the smallest, symmetrical repeating unit of the crystal lattice.

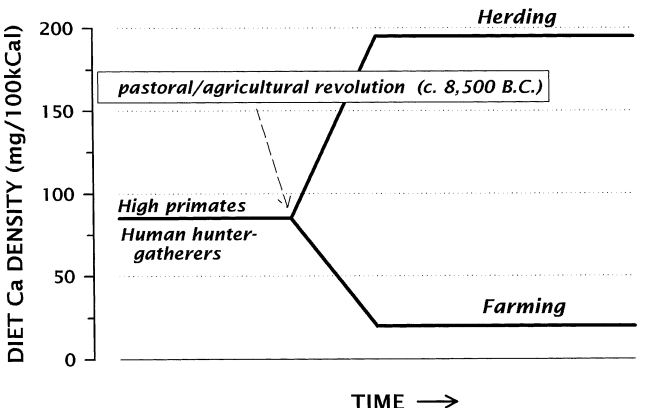

Figure 2 Schematic representation of the effect of the pastoral and agricultural revolutions on calcium nutrient densities of the diets of paleolithic humans. (Copyright Robert P. Heaney, 1995. Reproduced with permission.)

the development of flocks led to a nomadic lifestyle heavily dependent upon the milk produced by the pastoralists' herds. Farming, on the other hand, exploited natural hybrid forms of cereal grasses, which required humans for their propagation (mainly because the excess starch of the seed kernels made them too heavy for efficient dispersal by the wind). At the same time the extra starch of the hybrids made it possible to feed a great many more people. The hunter–gatherer lifestyle makes very inefficient use of the land, and population pressures were one reason for the shift to farming or herding.

With this divergence, the pastoralists thus had a substantial increase in the calcium density of their food supply, while the agriculturists had a substantial decrease. By contrast with milks [at calcium densities in the range of 27.5–50 mmol (110–200 mg)/100 kCal], cereals typically have calcium densities under 0.25 mmol (10 mg)/100 kcal. A contemporary example of a dominantly pastoral economy is provided by the Masai of East Africa, whose energy needs are largely met by fluid bovine milk, and whose calcium intakes, accordingly, are in the range of 150–175 mmol (6000–7000 mg)/day. It is likely that the actual calcium intake of the agriculturists was substantially higher than provided by the staple cereal grains, both because of other vegetables in the diet and because of adventitious calcium entering the food supply in the process of flour milling (Molleson, 1994). Grain was typically dehulled in limestone mortars, and the dehulled kernels then ground in limestone querns. Limestone is, of course, a calcium carbonate mineral; it is relatively soft and workable; and it undoubtedly added a great deal of calcium to the flour produced for bread making. Hence it is likely that only with the development of a more advanced technology, which allowed large-scale milling and the construction of mill stones from harder minerals (silicon based rather than calcium based), that the calcium intake of technologically advanced, urban peoples fell to present levels.

Physiological Adaptations to a High Calcium Intake

The abundance of calcium in the environment in which hominids evolved undoubtedly influenced the physiological mechanisms for extraction of calcium from the food supply and for conservation of absorbed calcium. Mammals typically have low intestinal calcium absorption efficiency, unregulated dermal losses, and poor renal conservation. The significance of these features is perhaps seen most clearly by way of contrast with the physiological adaptations to another nutrient, one which was scarce in the early hominid environment, i.e., sodium, for which absorption efficiency is complete and both dermal and urinary losses can be shut down to near zero. There is a cost to such conservation, of course, and it is likely that analogous mechanisms did not evolve for calcium because, given an environmental surfeit, they would have produced no selective advantage for their bearer. Further, efficient extraction of calcium from food sources would not only have been unnecessary; it would have been dangerous, for the excess would have had to be excreted, lest it lead to hypercalcemia and extraosseous calcification.

Exposure to chronic dietary calcium scarcity is a relatively modern phenomenon, as has been already noted, and fewer than 100 generations have elapsed for most of our lineages between the time of calcium surfeit and the present. This is far too few for the evolution of calcium-conserving mechanisms, particularly when the selective advantage of health at the end of life is much less strong than health during the reproductive years.

Studies Manipulating Calcium Intake

The importance of calcium intake on bone mass has been extensively documented in a number of species. As far back as 1929, Bauer, Aub, and Albright showed that cats developed severe bone loss when placed on low-calcium diets. This work has been replicated in rats and dogs (e.g., Bodansky and Duff, 1939) and has been repeated several times in cats (e.g., Jowsey and Gershon-Cohen, 1964). Figure 3, from one such study, depicts a classical nutritional experiment, in which a nutrient is first removed, the morbid result observed, and then the nutrient restored and recovery noted. The bone loss occurring under these circumstances is dependent upon intact parathyroid function (Jowsey and Raisz, 1968); in the absence of parathyroid hormone, the bone loss is prevented, although at a cost of severe hypocalcemia. These experiments, incidentally, highlight both the central role of bone as the calcium reserve for ECF calcium levels and the importance of parathyroid hormone in releasing calcium from bone to sustain ECF [Ca^{2+}].

Over 40 randomized controlled trials in humans have been published in recent years, establishing that elevating calcium intake enhances bone acquisition during growth, slows bone loss in postmenopausal women, and reduces fracture rates at spine, hip, and other extremity sites. These studies are reviewed in detail elsewhere (Heaney, 2000).

Figure 3 Effect of calcium deprivation and repletion on bone mass in cats, as revealed by micro X-rays of thin slices of undecalcified cat femora. The bone structure is shown (left) of a cat fed a normal, high-calcium diet, a cat (middle) fed a low-calcium diet for just 20 weeks, and a cat (right) depleted for 10 weeks and repleted for 10 weeks. Bone loss in the middle panel is evident. The right-hand panel shows partial healing. (Redrawn from Jowsey and Gershon-Cohen, 1964.)

One clear example of these effects is seen in the report by Chapuy *et al.* (1992) involving nearly 1800 French women, average age 84 (Fig. 4). Elevating calcium intake from ~13 mmol (520 mg)/day to ~42.5 mmol (1700 mg)/day reduced fracture rate at both hip and other extremity sites by 20–40% within 18 months of starting supplementation. The effect on bone mineral density (BMD) was fully as striking as the effect on fracture rate. Control subjects lost ~4.6% of the bone from the hip site over the 18 months of observation (an annual rate of ~3%/year), while the supplemented individuals gained 2.7%. The result was >7% difference in hip bone mass by 18 months. Clearly, 13 mmol Ca/day was not sufficient to prevent erosion of bone mass, while 42.5 mmol Ca/day was.

It may be that some of the benefit obtained in this trial was due to vitamin D repletion, and some also to the added phosphorus contained in the supplement (e.g., on muscle function and coordination); however, the bone mass effect observed in this study was large enough to account for much or all of the fracture difference in its own right. Furthermore, in two further trials in which the control and the calcium-supplemented individuals were both given vitamin D supplements, a similar bone-sparing and fracture-reducing effect was observed in the calcium-supplemented

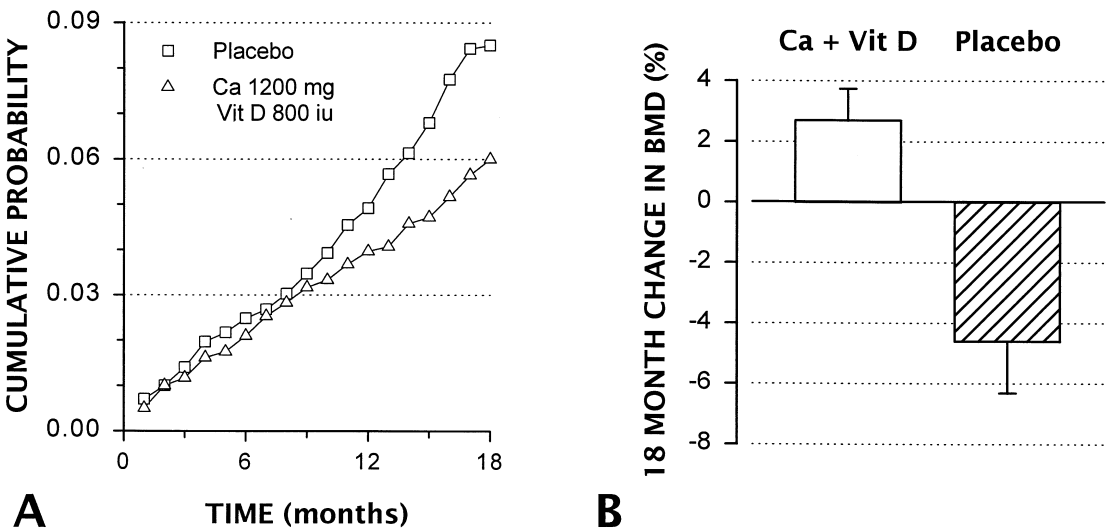

Figure 4 Effects of supplementation with calcium phosphate and vitamin D on hip fracture rate and hip BMD. The cumulative probability of fracture for the supplemented and unsupplemented groups is shown (A), as is the change from baseline in hip BMD for the two groups (B). (Redrawn from the data of Chapuy *et al.,* 1992.)

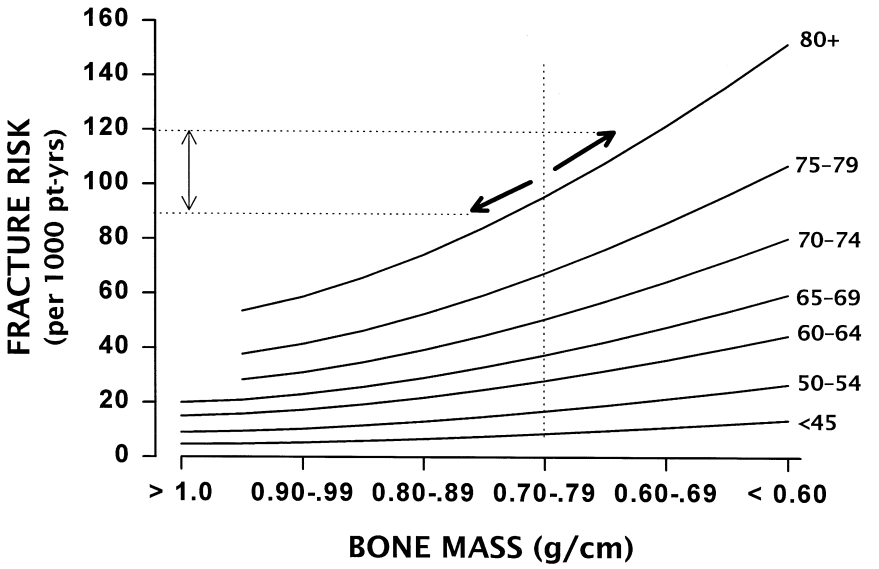

Figure 5 Age-specific fracture risk gradients for forearm BMD. Note the rise in risk with age, even holding BMD constant. Note also the increasing steepness of the gradients with age. A relatively small difference in BMD thus produces a greater fracture effect in the elderly than in younger individuals. (Redrawn from the data of Hui *et al.,* 1988.)

individuals (Chevalley *et al.,* 1994; Recker *et al.,* 1996). In a more recent study, contrasting calcium and vitamin D, Peacock *et al.* (2000) showed that, while calcium alone was able to prevent bone loss entirely, vitamin D alone was not. [It should be noted that blood 25(OH)D levels in Peacock's study were substantially higher than in the study by Chapuy *et al.,* and thus some beneficial effect of vitamin D in the French women cannot be excluded.]

While there is, obviously, a limit to how much fracture reduction can be achieved when one waits to ingest an adequate intake until old age, it is noteworthy that the elderly seem to be both more sensitive to calcium deprivation and more responsive to calcium supplementation than are younger individuals. This is illustrated, for example, in risk gradients for various ages reported by Hui *et al.* (1988) (Fig. 5). While the risk of fracture rises with declining bone mass at all ages, risk rises also with age, even holding bone mass constant. In fact, as Fig. 5 makes plain, the age effect is larger than the bone density effect. The gradient of risk on bone density also becomes steeper with age. Thus, while reducing bone loss in a 60-year-old woman would be expected to produce a modest fracture benefit, the same reduction in bone loss in an 85-year-old produces a much greater reduction in fracture risk. It is not certain why this should be so, but it is likely that the age effect itself is due to increased falling, poor reflex adjustment during the fall, decreased soft tissue padding over bony prominences, and increased intrinsic skeletal fragility from nonmass causes [trabecular disconnection and accumulated fatigue damage (Heaney, 1993a)]. Interaction between these factors may explain the disproportionately large benefit of altering just one of them (i.e., bone mass).

Defining the Calcium Requirement

The calcium requirement can be defined as the intake needed to support genetically programmed acquisition of bone during growth and to sustain acquired bone during maturity and the declining years of life. Because of differing absorption and retention efficiencies, individuals will inevitably have differing requirements. A recommended dietary allowance (RDA) is a figure designed to be at about the 95th percentile of individual requirements. Hence if everyone in a population were ingesting at least as much as the RDA, that intake would ensure that 95% would be getting what they need.

Calcium intake recommendations have undergone substantial revision over the past 10 years and the formats for presenting them have been altered as well. Table I sets forth both the earlier and the current recommendations, using a standardized format to facilitate their comparison. Perhaps the most important of the recent changes is the recognition that the requirement rises substantially in the elderly. This elevated need reflects the age-related decline in ability to adapt to low intakes, and thus in a sense uncovers the optimal intake for all ages, i.e., the intake for which no adaptation would be needed. It is worth recalling, in this connection, that even though the recommended intakes may seem high by contemporary practice, they are still only a fraction of what the primitive human intake would have been for individuals of modern body size.

As previously noted, calcium is a threshold nutrient. This means that, at subthreshold intakes, calcium retention is less than optimal. Bone gain during growth is then a direct function of intake (i.e., it is less than is genetically

Table I Various Estimates of the Calcium Requirement in Women[a]

Age	1989 RDA[b]	NIH[c]	1997 DRI[d]
1–5	800	800	600/1000
6–10	800	800–1200	1000/1600
11–24	1200	1200–1500	1600/1200
Pregnancy/lactation	1200	1200–1500	1200
24–50/65	800	1000	1200/1450
65–	800	1500	1450

[a]All values are given in mg, as this is how the respective bodies reported their recommendations. To convert to SI units, divide the values in the table by 40.

[c]NIH Consensus Conference: Optimal Calcium Intake (1994). *J. Am. Med. Assoc.* **272,** 1942–1948.

[d]"Dietary Reference Intakes for Calcium, Magnesium, Phosphorus, Vitamin D, and Fluoride. Food and Nutrition Board, Institute of Medicine." National Academy Press, Washington, DC, 1997. The figures given are calculated as RDAs, to facilitate comparison with earlier estimates. The published values were termed "AIs," which in this instance represent estimated *average* requirements (EARs). The RDA figures shown here are 20% higher than the corresponding EAR. The presence of two values in this column reflects the fact that the age categories for the DRIs overlapped those of the NIH.

programmed), while in the mature organisms, subthreshold intakes lead to actual bone loss. On the other hand, the threshold character of the relationship means that intakes above the threshold produce no additional bone effect (see also Bone as the Body's Calcium Sink and Reserve, above). These relationships are depicted schematically in Fig. 6. Because the approach to the threshold is asymptotic, it is difficult to define the precise point at which retention plateaus. For this reason current recommendations are

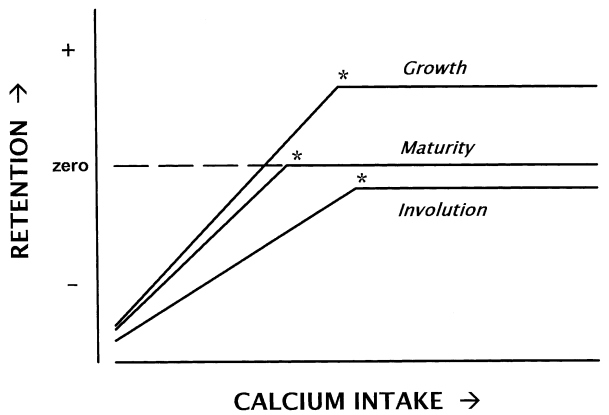

Figure 6 Schematic depiction of the relationship between calcium intake and skeletal retention at three life stages. Given sufficient intake, retention is positive during growth, zero at maturity, and variably negative during involution. Intakes above the threshold do not affect retention, but subthreshold intakes limit bone acquisition or lead to bone loss. The location of the minimum requirement is indicated by the asterisk above each line. (Copyright Robert P. Heaney, 1998. Reproduced with permission.)

actually somewhat conservative. Some hint that the optimal intake may be substantially higher than even the newer recommendations is provided by several lines of evidence. One comes from the balance studies of Heaney *et al.* (1978), in which the *mean* requirement to maintain zero balance in estrogen-deprived women was ~37.5 mmol (1500 mg). An RDA would, inevitably, be higher still. Another pointer in that direction is found in a randomized controlled trial in elderly women supplemented with calcium for 3 years (McKane *et al.,* 1996). Unsupplemented individuals, with intakes averaging close to 20 mmol (800 mg)/day (the then applicable RDA for the age), exhibited the high 24-hr integrated parathyroid hormone (PTH) levels, the enhanced PTH secretory reserve, and the elevated bone resorption which have all been taken to characterize the calcium and skeletal economies of the aged (Epstein *et al.,* 1986). By contrast, women supplemented to 60 mmol (2400 mg)/day decreased both their bone remodeling and parathyroid functional indices, restoring them to young adult normal values. The inference is that the increases in parathyroid cell mass and function represent not so much characteristics of old age as adaptive responses to long-standing calcium deprivation.

Contributing causes for this increased parathyroid activity in the elderly, aggravating the effect of low calcium intakes, include a decline in vitamin D status with age (reflecting both decreased solar exposure and decreased efficiency of skin conversion of 7-dehydrocholesterol to previtamin D) and declining absorption and conservation efficiency for dietary calcium. Holding calcium intake constant at about 20 mmol (800 mg)/day, gross absorption efficiency declines from a mean at age 40 of ~0.24, at a rate of 0.002/year through at least age 65, with a one-time additional drop of 0.02 at menopause (Heaney *et al.,* 1989). Over that period, the decline thus amounts to 0.07, or a fall of ~30% in absorptive efficiency. Nordin and others have shown also that renal conservation of calcium deteriorates across menopause (e.g., Nordin *et al.,* 1991). The net result is that extraction of ingested calcium from food falls with age and conservation of that which is absorbed falls as well. These and similar findings from a number of investigators are the basis for the jump to 36–38 mmol (1450–1500 mg)/day in the 1994 and 1997 recommendations of Table I.

It must be noted that the absorption values cited above are *gross* absorption, such as would be measured by calcium tracer flux from the intestinal lumen into the blood stream. They do not account for the contrary movement of calcium into the lumen in the digestive secretions and sloughed off mucosa (which turns over at a rate of ~20%/day). In adult women, this calcium from endogenous sources entering the intestinal stream amounts to ~3.5–3.75 mmol (140–150 mg)/day (Heaney and Recker, 1994). Most of this calcium is subject to the same absorptive probability as is ingested calcium, but given the low efficiency of calcium absorption in general, inevitably most endogenous calcium will be lost into the feces. Thus *net* absorption from intakes in the range of 20 mmol (800 mg)/day is on the order of only 15%

of ingested calcium. Not all of even this small amount of net calcium gain from the intestine can be retained, since the tiny elevation of blood calcium produced when calcium is absorbed elevates the filtered load at the kidney and leads to an increase in urinary calcium loss.[2] The net result of the low net absorption and poor renal conservation is that, even during times of calcium need, only a small fraction of an ingested load is retained. Further, at the higher intakes achieved by calcium supplements, *fractional* retention is smaller still, since absorption fraction declines with the logarithm of the intake load size (Heaney *et al.,* 1990; Heaney *et al.,* 2000).

Nutritional Factors Influencing the Calcium Requirement

It is a truism of nutritional science that nutrients interact with one another and thereby alter their mutual requirements. Thus, requirements of certain of the B vitamins and of ascorbic acid vary with total energy intake (and expenditure). The lack of evolutionary development of efficient conservation of calcium has rendered this nutrient unusually sensitive to such nutrient–nutrient interactions. Most of this interaction is expressed in urinary calcium excretion, which, for example, is strongly influenced by the ingested load of sodium and protein and by the acid/alkaline residue of the diet (Heaney, 1993b). The protein effect is mainly mediated by the sulfate load produced in the metabolism of sulfur-containing amino acids and amounts to ~1 mg/day of urinary calcium loss for every gram of ingested high-quality protein. The sodium effect is due to the fact that sodium and calcium share a common transport mechanism in the proximal tubule, and thus an increased filtered load of either ion will lead to increased excretion of the other. The magnitude of the sodium effect on the calcium economy is an increase of 0.5–1.5 mM of urine calcium for every 100 mM of sodium ingested (Devine *et al.,* 1995; Nordin *et al.,* 1993; Itoh *et al.,* 1996).

These effects are linear across the full range of intakes of both protein and sodium, from low to high, and are not, thus, consequences only of excessive intakes. With diets characteristic of typical North American and European women, sodium and protein account for ~100 mg/day of obligatory calcium loss through the kidneys. Given the extremely poor net absorption efficiency for calcium, these nutrients can thus easily account for up to 1000 mg/day of the calcium requirement. It has been noted, for example, that individuals with low, but nutritionally adequate, intakes of sodium and protein may have calcium requirements as low as 500 mg/day, whereas those with intakes more typical of contemporary patterns, may have intake requirements closer to 2000 mg/day. This quite extraordinary sensitivity of calcium to the intakes of other nutrients is but one more reflection of the lack of evolutionary acquisition of efficient mechanisms for calcium absorption and retention.

The well-documented effect of the acid/alkaline residue of the diet (Berkelhammer *et al.,* 1988; Sebastian *et al.,* 1994) is probably a function of the "hard" anions (sulfate, chloride), either ingested with food or produced in metabolism, and may not, therefore, be a fully additive effect to what has already been described for protein and salt. In any event, substitution of acetate or bicarbonate for chloride produces substantial reductions in urinary calcium loss and therefore in the ability to maintain calcium equilibrium on low calcium intakes.

It is important to stress this latter point, that these nutrient interactions negatively affect calcium balance mainly at low calcium intakes. This is because they limit an individual's ability to adapt to a low intake. At the higher intakes typical of those that prevailed during hominid evolution, adaptation is easily possible, and high protein intakes, for example, do not then have a negative effect on the skeleton. [Indeed, such evidence as is available indicates that the net effect of protein on the skeleton is distinctly positive, overall.]

Toxicity

It is possible to consume too much of any nutrient, and calcium is no exception. However, in healthy individuals, available evidence indicates that the toxic threshold is quite high. Many young adult males in the United States regularly consume >75 mmol (3000 mg)/day (Carroll *et al.,* 1983), and in pastoralist societies, such as the Masai of East Africa, calcium intakes regularly average >150 mmol (6000 mg)/day. In both instances, there are no known ill effects associated with such intakes. However, there are special circumstances in which high calcium intakes can definitely be harmful. Even at the low absorption fractions typical of high intakes, substantial quantities of calcium will enter the body and will need to be excreted in the urine (unless active bone building is occurring). Under conditions of dehydration or hypovolemia, perfusion of both bone and kidney can be sufficiently compromised so that absorbed calcium produces significant hypercalcemia. Likewise, under conditions of systemic alkalosis, large calcium intakes can produce renal calcinosis and severe impairment of kidney function. Furthermore, under these somewhat unusual and extreme circumstances, elements of positive feedback can cause the situation to deteriorate rapidly. Hypercalcemia impairs the ability of the kidney to retain water and thus aggravates a preexisting dehydration, with consequently worsening hypercalcemia. A fatal downward spiral can easily ensue. Published reports of such toxicity have generally involved intakes of >150 mmol (6000 mg)/day in individuals with preexisting impairments of water and electrolyte metabolism. Whatever the underlying cause, such

[2]This sensitivity of urine calcium to variations in the filtered load is a reflection of the previously mentioned lack of evolutionary development of efficient calcium conservation mechanisms.

problems can be easily handled by rehydration and by correction of the underlying abnormality, so long as these situations are recognized in time.

Kidney stones are perhaps the complication most often thought to be associated with high calcium intakes. However, this association has been largely speculative and is not based on clinical evidence. Most multiple regression analyses of risk factors for renal calculi have found either a very weak or no association at all for calcium intake. Two very large observational studies, in fact, found the converse (Curhan *et al.,* 1993, 1997). In the first, a prospective study of >45,000 men, there was an inverse correlation between calcium intake and stone formation; those with the highest calcium intakes had the lowest risk of kidney stones. This seeming paradox is explained by the fact that renal oxalate excretion in the urine is a more significant risk factor for calculi than is urine calcium. High calcium intakes bind oxalate both of dietary origin and that produced by bacterial fermentation in the gut before it can be absorbed; dietary calcium thereby lowers the renal oxalate burden. In fact, very large calcium supplements have long been standard therapy for the kidney stones occurring with intestinal hyperoxalosis, sometimes found in patients with short bowel syndromes.

In summary, the levels of calcium intake discussed in the foregoing sections of this chapter, as well as those needed to support osteoporosis pharmacotherapy (see Calcium and Osteoporosis Treatment, below), are well within the safety limits for the ingestion of this nutrient.

Interpretation of Published Reports

The importance of a high calcium intake for bone health has often been questioned (e.g., Kanis and Passmore, 1989) and has even more often been termed "controversial." This is because some studies showed strong effects of calcium intake on bone status, while others showed no benefit at all. "Confusing" would have been a more accurate term. There are several reasons for these apparent discrepancies, now sufficiently understood to remove any confusion that may remain.

First, as already noted, osteoporotic fracture is a distinctly multifactorial affair. Nutrition, and particularly calcium nutrition, is only one of many contributing factors. While calcium intake is, as the above discussion indicates, of critical importance in many individuals, it plays little or no role in others, just as iron intake is limiting in only certain forms of anemia. One example of this distinction is seen in menopausal bone loss, which is dominantly due to estrogen deficiency and cannot be substantially influenced by calcium intake (although estrogen-related loss may be exaggerated if calcium intakes are very low) (Heaney, 1990). This is seen, for example, in the fact that even intakes >75 mmol (3000 mg)/day, in the study by Elders *et al.,* (1991), were able only to slow menopausal loss, not prevent it.

However, menopausal loss is self-limited and is mostly confined to the 5-year period surrounding cessation of ovarian function. Every controlled trial of calcium supplementation in women >5 years postmenopausal has, without exception, shown a clear benefit on either bone loss or fracture rate or both. By contrast, roughly one out of five observational studies performed on women in this same age group have failed to show a calcium effect (Heaney, 1993b, 2000); this is now understood to be due to the weak ability to estimate calcium intake from food records, or food frequency questionnaires, no matter how carefully these methods are applied, resulting in substantial classification bias (Heaney, 1991, 1996b).[3] Usually in clinical science, one encounters positive results from observational studies, which are then sometimes not borne out in studies employing the more rigorous design of randomized controlled trials. With calcium, we have the paradoxical situation that the randomized controlled trials are essentially all positive, whereas some of the observational studies are not, and even those that are positive often show what appear to be weak effects. As the controlled trials show, it is not the effects that are weak, but the methods that must be employed in observational studies.

A final consideration relates to the uncritical use of transnational comparisons (e.g., Hegsted, 1986). Differences in fracture rate between ethnic and national populations have many bases, only some of them nutritional. An example is the lower hip fracture rates of contemporary Chinese and Blacks, despite mean calcium intakes for both groups that are lower than those of North American or European Caucasians. Behind this difference there is, first, the large effect of the other nutrients in the diet, previously described. Thus the predominantly vegetable-based and low-protein intakes of many Third World populations would be expected to lower their calcium requirements.

Similarly, there are major racial differences in ability to conserve calcium. American Blacks, for example, both absorb at higher efficiency for any given ingested intake and conserve better at the kidney than do Caucasians (Abrams *et al.,* 1995; Bell *et al.,* 1985, Aloia *et al.,* 1998, Cosman *et al.,* 1997). Thus they have lower calcium requirements. Finally, there are important racial differences in bone geometry that have their own effect on fracture rate. Hip axis length, for example, explains most or all of the difference between the hip fracture rates of Orientals and Caucasians, after adjusting for bone mass (Faulkner *et al.,* 1993; Nakamura *et al.,* 1994).

Instead of making cross-cultural comparisons, the correct approach is to assess the effect of nutrient intakes *within* a cultural and ethnic group. When this has been done, for example in both American Blacks and in Chinese,

[3]There are many sources of this estimation error. One of them, often ignored, is the fact that actual calcium contents of various foods vary over a roughly threefold range (from low to high) around the nominal values in the standard food tables.

bone mass and hip fracture rate are found to be inversely correlated with calcium intake, just as has been found for Caucasian populations (Anderson *et al.,* 1995; Hu *et al.,* 1993; Lau *et al.,* 1988).

Calcium and Osteoporosis Treatment

Effective osteoporosis treatments involve a combination of pharmacotherapy designed to reverse the negative remodeling balance prevailing in the skeleton and physical therapy designed both to increase function and to increase mechanical loading on the skeleton. Currently recommended calcium intakes are presumably adequate to sustain bone mass, but they may not be sufficient to permit bone gain in most individuals for reasons just noted (i.e., net absorption from such intakes is just sufficient to offset obligatory losses). Furthermore, there is essentially no evidence that calcium alone, in any quantity, will lead to substantial gain in bone in individuals who already have osteoporosis. The small increase noted in the study by Chapuy *et al.,* (1992) described above (Fig. 4) probably reflects a remodeling transient (Heaney, 1994) and not a new steady-state rate of change. However, effective *pharmacotherapy,* including fluoride (Pak *et al.,* 1995; Riggs *et al.,* 1990), the bisphosphonates (Liberman *et al.,* 1995; Black *et al.,* 1996; Cummings *et al.,* 1998; Harris *et al.,* 1999), the SERMS (Ettinger *et al.,* 1999), and PTH (Kurland *et al.,* 2000), does seem to be capable of increasing bone mass, for some of these agents at a rate of up to 10% per year. To realize this potential gain, and particularly to optimize it, calcium intakes must be above the maintenance level, i.e., for most osteoporotic individuals that means above 37.5 mmol (1500 mg)/day. Few controlled trials at such intakes have been done, so this conclusion is to some extent an inference from the data summarized in the foregoing.

There is, however, some evidence. With respect to fluoride, Dure-Smith and associates (1996) showed, during effective fluoride therapy, an extraordinary degree of bone hunger, suggesting the need for calcium intakes during fluoride therapy of perhaps as much as 62.5 mmol (2500 mg)/day. Other clear examples of the importance of ensuring adequate calcium intake when using other bone-active agents are provided by a series of recent papers. First is a metaanalysis of 31 controlled trials of estrogen replacement therapy (Nieves *et al.,* 1998), which showed that estrogen in trials using supplemental calcium (at an average intake of 1187 mg/day) produced bone responses more than twice as great as those that did not (at an average intake of 583 mg/day). Additionally, Recker *et al.,* (1999) showed that a reduced dose of estrogen (0.3 mg conjugated equine estrogens) produced a 5% increase in bone mass in women given supplemental calcium and vitamin D. By contrast, in at least three earlier trials without supplemental calcium, this estrogen dose was essentially ineffective.

Summary

Calcium is the principal cation of bone, making up ~20% of its dry weight. Bone constitutes a very large nutrient reserve for calcium in terrestrial vertebrates, a reserve that has acquired a major mechanical function. The requirement for calcium is related to the protection of this mechanical function, not to the metabolic functions of calcium, which could be adequately protected by a reserve several orders of magnitude smaller. Calcium was abundant in the environment in which hominids evolved and in the foods they ate. Probably as a consequence, efficient calcium conservation mechanisms did not develop. Contemporary diets are low in calcium by comparison, and our paleolithic physiologies are poorly adapted to them. Yet other features of the modern diet increase obligatory calcium loss and thereby reduce the ability to adapt to lowered intakes. The evidence is compelling that inadequate calcium intake weakens bone and contributes to the growing osteoporosis problem. A fully adequate calcium diet for persons 65 and older, consuming otherwise typical Western diets, would contain >37.5 mmol (1500 mg)Ca/day and perhaps as much as 60 mmol (2400 mg)/day.

CHAPTER 77

Calcium Receptors as Novel Drug Targets

Edward F. Nemeth
NPS Pharmaceuticals, Inc., Toronto, Ontario, Canada M5G 1K2

Introduction

Bone and mineral-related diseases comprise a diverse class of disorders affecting nearly every major organ system in the body. By far the most common disorder is osteoporosis, a disease characterized by reduced bone density and an increased susceptibility to fractures. Less common, but also associated with altered bone metabolism, are primary and secondary hyperparathyroidism. All these disorders are associated with aging, especially in women, and, as the world population ages, these diseases are becoming more prevalent. All these disorders might be treated with drugs that alter the circulating levels of parathyroid hormone (PTH).

PTH is the key endocrine factor in systemic Ca^{2+} homeostasis and many of its actions in this capacity involve moving Ca^{2+} between bone and blood. PTH can stimulate bone resorption or new bone formation depending on the levels of circulating hormone. Chronically elevated levels of plasma PTH stimulate osteoclastic bone resorption, resulting in net bone loss and osteopenia. In contrast, PTH stimulates new bone formation when plasma levels of PTH are elevated only briefly (see Chapter 75). The administration of exogenous PTH to cause a brief rise in plasma levels of PTH might be effective in treating osteoporosis. For treating primary and secondary hyperparathyroidism, however, there are no pharmaceuticals that effectively lower the chronically elevated levels of PTH that characterize both these disorders of parathyroid hormone. It is conceivable that drugs that either increased or decreased the secretion of PTH from the parathyroid glands could be useful in treating the various forms of hyperparathyroidism and/or osteoporosis.

Until recently, attempts to regulate secretion of PTH have either failed or achieved only limited success. The significant advance that enables the pharmacological manipulation of several different parathyroid cell functions, including PTH secretion, is understanding how plasma Ca^{2+} acts on parathyroid cells. The key element is the Ca^{2+} receptor, a G protein-coupled receptor whose primary physiological ligand is extracellular Ca^{2+} (see Chapter 23). This cell surface receptor enables parathyroid cells to detect and to respond to small changes in the concentration of extracellular Ca^{2+}. In its structural and functional properties, the Ca^{2+} receptor is akin to other cell surface receptors that initially transduce an extracellular signal into a cellular response. The major difference is that the ligand for the Ca^{2+} receptor is an inorganic ion rather than an organic molecule.

This chapter reviews the progress made in the discovery and development of small molecules that activate or inhibit the parathyroid Ca^{2+} receptor and thereby inhibit or stimulate secretion of PTH. In the first edition of *Principles,* Ca^{2+} receptors on C cells of the thyroid gland and on certain cells of bone were also reviewed in depth but they receive less attention in the present review. The enthusiasm for treating osteoporosis by altering secretion of calcitonin has diminished and, as discussed later, the expression of Ca^{2+} receptors on the various cells of bone is still controversial. In contrast, considerable progress has been made in developing drug candidates that either increase or decrease secretion of PTH. The drug candidate for treating hyperparathyroidism continues to advance toward pivotal Phase III trials and that for treating osteoporosis has entered the clinic. Manipulating the activity of the Ca^{2+} receptor pharmacologically is proving

to be a very effective way of altering at will the circulating level of PTH.

The Calcium Receptor

The Ca^{2+} receptor is a G protein-coupled receptor that shares structural homologies with other members of subfamily C receptors (see Chapter 23). This subfamily includes the metabotropic glutamate receptors (mGluRs) and γ-aminobutyric acid type B receptors ($GABA_BRs$). All these receptors are large by G protein-coupled receptor standards, particularly their extracellular domain, which is believed to bind the cognate physiological ligand glutamate, γ-aminobutyric acid, or extracellular Ca^{2+} (Takahasi *et al.,* 1993; Brauner-Osborn *et al.,* 1999; Hammerland *et al.,* 1999). The human parathyroid Ca^{2+} receptor encodes a protein of 1078 amino acids and it is 92 and 93% identical with the rat kidney and C cell and the bovine parathyroid cell Ca^{2+} receptors, respectively (Brown *et al.,* 1993). At present, only one gene coding for the Ca^{2+} receptor has been identified; no receptor subtypes have been found; splice variants of the Ca^{2+} receptor are few and of low abundance (Garrett *et al.,* 1995a).

Ca^{2+} receptors are expressed on many of the tissues involved in systemic Ca^{2+} homeostasis. In addition to parathyroid cells, parafollicular cells of the thyroid (C-cells) and many epithelial cells along the nephron express high levels of Ca^{2+} receptor messenger mRNA and protein (Brown *et al.,* 1995). In adults, the only other tissues expressing comparably high densities of the Ca^{2+} receptor are the pancreatic islets and the subfornical organ in the brain. At all these sites, the Ca^{2+} receptor messenger RNA transcripts appear to be identical and, as assessed by Western blotting, the final protein products expressed at the cell surface are similar. The major differences between Ca^{2+} receptors expressed in different tissues are posttranslational and seemingly involve different glycosylation patterns (Ray *et al.,* 1998; Bai, 1999).

The Ca^{2+} receptor is expressed at lower levels in other sites throughout the body, as recently summarized in extensive reviews (Brown *et al.,* 1999; Brown and MacLeod, 2001). There is no death of speculation regarding the functions of the Ca^{2+} receptor at these diverse sites but the only functions supported by sufficient evidence are those in parathyroid cells, C cells, and renal epithelial cells.

The Ca^{2+} receptor mediates the initial events of stimulus–secretion coupling in parathyroid cells. It is the key element in the primary physiological mechanism regulating PTH secretion. There are three separate lines of evidence supporting this conclusion. The first derives from molecular genetic studies of patients with the inherited disorders familial benign hypercalcemic hypercalciuria (FBHH) or autosomal dominant hypocalcemia (ADH). These disorders result from point mutations in the Ca^{2+} receptor gene, which result in receptor proteins having altered sensitivity to extracellular Ca^{2+} (Bassett and Thakker, 1995; Brown *et al.,* 1999). The mutated Ca^{2+} receptors in FBHH patients are less sensitive (or completely insensitive) to activation by extracellular Ca^{2+} and this molecular defect is manifest in the phenotype: these patients are hypercalcemic yet plasma PTH levels are normal (Pearce *et al.,* 1995; Pollack *et al.,* 1993). Conversely, the mutant Ca^{2+} receptors in ADH are more sensitive to activation by extracellular Ca^{2+} and these patients are hypocalcemic, but again plasma PTH levels are normal (Pollack *et al.,* 1993; Mancilla *et al.,* 1998). The second line of evidence is based on *in vitro* studies showing that the loss of responsivity to extracellular Ca^{2+} of cultured bovine parathyroid cells correlates with loss of mRNA for the Ca^{2+} receptor (Mithal *et al.,* 1995). Finally, and the focus of the present review, selective pharmacological manipulation of the Ca^{2+} receptor promptly alters PTH secretion *in vitro* or plasma levels *in vivo.*

C cells, like parathyroid cells, have long been known to respond to changes in plasma levels of Ca^{2+}. It seems likely that the Ca^{2+} receptor expressed in C cells functions similarly to that in parathyroid cells and is the essential molecule coupling changes in the levels of extracellular Ca^{2+} to hormone secretion. However, parathyroid cells and C cells use quite different transmembrane and intracellular signaling mechanisms to link the Ca^{2+} receptor to hormone secretion (Nemeth, 1996). In parathyroid cells, increasing the concentration of extracellular Ca^{2+} inhibits PTH secretion. Activation of the parathyroid Ca^{2+} receptor by extracellular Ca^{2+} leads to the rapid formation of inositol 1,4,5-trisphosphate and the mobilization of Ca^{2+} from cellular stores in addition to permitting influx of extracellular Ca^{2+}. The resulting increase in the concentration of cytoplasmic Ca^{2+} ($[Ca^{2+}]_I$) is thus associated with an inhibition of exocytotic hormone secretion, a peculiar relationship that runs counter to the general rule of stimulus–secretion coupling where cytoplasmic Ca^{2+} activates exocytosis. The Ca^{2+} receptor additionally couples through a pertussis toxin-sensitive G_i protein to inhibit adenylate cyclase activation by D_1 dopamine receptors (Chen *et al.,* 1989).

In C cells, increasing the concentration of extracellular Ca^{2+} stimulates calcitonin secretion. Again, activation of the Ca^{2+} receptor by extracellular Ca^{2+} results in a rapid increase in $[Ca^{2+}]_i$ and in this respect, secretion of calcitonin conforms to the general Ca^{2+} hypothesis of stimulus-secretion coupling. In the C cell, the Ca^{2+} receptor couples to voltage-sensitive Ca^{2+} channels and permits the influx of extracellular Ca^{2+} (Raue and Scherübl, 1995). The transmembrane mechanisms involved in this receptor–channel coupling remain unknown. Nearly all the studies on Ca^{2+} receptor coupling to signal transduction pathways in C-cells have used medullary thyroid carcinoma (MTC) cells. These mechanisms might not be representative of those used by the Ca^{2+} receptor in normal parafollicular cells. In rat and human MTC cells, increases in $[Ca^{2+}]_i$ elicited by increases in the concentration of extracellular Ca^{2+} result mostly from the influx of extracellular Ca^{2+} through voltage-sensitive Ca^{2+} channels. Increases in $[Ca^{2+}]_i$ mediated by these channels are important for the regulation of calcitonin secretion because dihydropyridines that activate or block voltage-sensitive Ca^{2+} channels have corresponding effects on secretion of

calcitonin in MTC cells (Hishikawa *et al.,* 1985; Muff *et al.,* 1988; Raue *et al.,* 1993; Scherübl *et al.,* 1993) and in authentic C cells *in vitro* (Cooper *et al.,* 1986). Increasing the concentration of extracellular Ca^{2+} does not evoke rapid increases in inositol phosphates in MTC cells (Fried and Tashjian, 1987) or the mobilization of intracellular Ca^{2+} that is detectable using fluorimetric indicators for cytoplasmic Ca^{2+} (Nemeth, 1987; Fajtova *et al.,* 1991). However, under some conditions (Yamashita and Hagiwara, 1990) and in some primary cultures of human MTC cells (Ridefelt *et al.,* 1994), it has been possible to demonstrate the mobilization of intracellular Ca^{2+} in response to the addition of external inorganic cations. These apparently discrepant observations might reflect the heterogeneous phenotype of different MTC preparations.

Regardless of the details of signal transduction, there is evidence that the Ca^{2+} receptor on C-cells, like the parathyroid Ca^{2+} receptor, is the pivotal molecule enabling these cells to alter secretion in response to changes in the plasma level of Ca^{2+}. Extracellular Ca^{2+} does not affect calcitonin secretion from the human MTC cell line TT (Haller-Brem *et al.,* 1987) and these cells do not express the Ca^{2+} receptor (Garrett *et al.,* 1995b). Authentic C cells and MTC cell lines that do respond to extracellular Ca^{2+} express the Ca^{2+} receptor (Lavigne *et al.,* 1998). There is, then, a tight correlation between the ability of extracellular Ca^{2+} to regulate calcitonin secretion and expression of the Ca^{2+} receptor in C cells. Perhaps the most compelling evidence is that detailed below showing that compounds which selectively activate or inhibit the Ca^{2+} receptor stimulate or inhibit calcitonin secretion *in vitro* and *in vivo.*

Pharmacology of the Calcium Receptor

The pharmacology of the Ca^{2+} receptor can be divided into *calcimimetics* and *calcilytics.* Calcimimetic ligands are those that mimic or potentiate the action of extracellular Ca^{2+} at the Ca^{2+} receptor; these ligands are agonists or allosteric activators of the receptor. Calcilytic ligands are Ca^{2+} receptor antagonists. Calcimimetics can be subdivided into *type I* and *type II* ligands. The former activate the Ca^{2+} receptor in the absence of extracellular Ca^{2+} and behave as true agonists, whereas type II calcimimetics act as allosteric activators. These are operational definitions based on the ability of the ligand to activate the Ca^{2+} receptor in the presence or absence of extracellular Ca^{2+}. The definition is based on functional effects and does not necessarily impart knowledge about the site on the receptor that binds the ligand.

Calcimimetics

From the outset, it was appreciated that the Ca^{2+} receptor is rather indiscriminate with respect to inorganic cations or molecules possessing net positive charges. A variety of inorganic di- and trivalent cations activate the Ca^{2+} receptor and include, in rank order of potency, $La^{3+} \cong Gd^{3+} > Be^{2+} > Ca^{2+} \cong Ba^{2+} > Sr^{2+} > Mg^{2+}$ (Nemeth, 1990). Likewise, many organic polycations activate the Ca^{2+} receptor and include simple polyamines (spermine), aminoglycoside antibiotics (neomycin), and polyamino acids (polylysine) or proteins (protamine) (Brown *et al.,* 1991a,b; Nemeth and Fox, 1999). All these charged ligands behave as type I calcimimetics; they are full agonists and activate the Ca^{2+} receptor in the absence of extracellular Ca^{2+}. While these calcimimetic ligands have been useful in some early studies of Ca^{2+} receptor function, they are far from ideal pharmacological ligands because they lack specificity and cannot be used effectively in tissues or *in vivo.*

The first class of compounds to be developed as selective ligands of the Ca^{2+} receptor are phenylalkylamines typified by NPS R-568 (Fig. 1). This compound does not affect the activity of mGluRs or various other G protein-coupled receptors at concentrations that maximally activate the Ca^{2+} receptor. Most of the phenylalkylamine compounds have at least one chiral carbon and exist as R- or S-enantiomers. Depending on the response measured, the R-enantiomer is 10- to 100-fold more potent than the corresponding S-enantiomer. For example, NPS R-568 increases $[Ca^{2+}]_i$ and inhibits PTH secretion from bovine parathyroid cells *in vitro* at concentrations between 3 and 100 nM, whereas NPS S-568 is without effect on either response at concentrations less than 3 μM (Nemeth *et al.,* 1998). These effects are dependent on the concentration of extracellular Ca^{2+} and NPS R-568 fails to alter parathyroid cell function when extracellular Ca^{2+} levels are reduced to levels below 0.1 mM. Type II calcimimetic compounds like NPS R-568 shift the concentration–response curve for extracellular Ca^{2+} to the left without affecting the maximal or minimal responses (Hammerland *et al.,* 1998; Nemeth *et al.,* 1998a). This effect of type II calcimimetic compounds

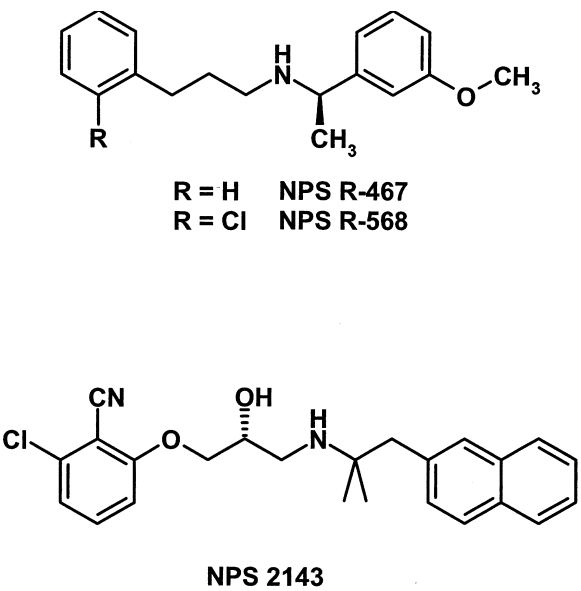

Figure 1 Structure of the calcimimetic compounds NPS R-467 and NPS R-568 and the calcilytic compound NPS 2143.

can be observed in heterologous expression systems and in authentic bovine parathyroid cells. These compounds therefore differ from the inorganic and organic polycations which act as agonists and can elicit responses in the nominal absence of extracellular Ca^{2+}.

Additional studies show that the type I and type II calcimimetic ligands act in different regions of the Ca^{2+} receptor to alter its activity. Using native and chimeric receptor constructs containing domains of the Ca^{2+} receptor and certain mGluRs, it has been shown that type I calcimimetic ligands act predominantly in the extracellular domain of the Ca^{2+} receptor, whereas type II calcimimetic compounds act within the transmembrane domain to cause receptor activation (Hammerland *et al.,* 1996; Hauache *et al.,* 2000). Thus, type I and type II calcimimetic ligands differ in both their presumed binding sites and their functional affects on Ca^{2+} receptor activity. The type II calcimimetic ligands act as positive allosteric modulators to increase the sensitivity of the Ca^{2+} receptor to activation by extracellular Ca^{2+}.

In normal rats, the oral administration of NPS R-568 causes a rapid fall in plasma levels of PTH, which is accompanied by hypocalcemia (Fig. 2). The fall in plasma levels of PTH precedes that of Ca^{2+} and the longer that PTH levels are depressed, the greater is the magnitude and duration of the hypocalcemia that is achieved by a given dose of compound (Fox *et al.,* 1999a). At higher doses, there is a transient increase in plasma levels of calcitonin although these type II calcimimetic compounds are about 50-fold more potent in decreasing plasma levels of PTH than in increasing those of calcitonin (Lavigne *et al.,* 1998; Fox *et al.,* 1999b).

The site of action of type II calcimimetic compounds *in vivo* has been determined by examining the effects of NPS R-568 or NPS R-467 on plasma levels of Ca^{2+} following systematic elimination of tissues expressing the Ca^{2+} receptor and which contribute to systemic Ca^{2+} homeostasis. The participation of renal Ca^{2+} receptors in the response to NPS R-568 was eliminated by an acute, total nephrectomy; this did not affect the hypocalcemic response elicited by NPS R-568 (Fox *et al.,* 1999a). Thus, type II calcimimetic compounds do not cause hypocalcemia by acting on Ca^{2+} receptors in the kidney. Selective surgical ablation of the thyroid, to eliminate C cells but leave the parathyroid glands intact, slowed the rate of onset but did not effect the magnitude of the hypocalcemia following administration of NPS R-568. In contrast, NPS R-568 failed to lower plasma levels of Ca^{2+} in thyroparathyroidectomized animals which were maintained at normocalcemia by continual infusion of PTH (Fox *et al.,* 1999b). Thus, hypocalcemia caused by administering type II calcimimetics results mostly from the ability of these compounds to inhibit secretion of PTH. In the rat, increased levels of calcitonin increase the rate of onset, but not the magnitude of hypocalcemia. These preclinical studies underscore the selectivity of these type II calcimimetic compounds and additionally highlight the pivotal role of the parathyroid Ca^{2+} receptor in regulating PTH secretion and systemic Ca^{2+} homeostasis.

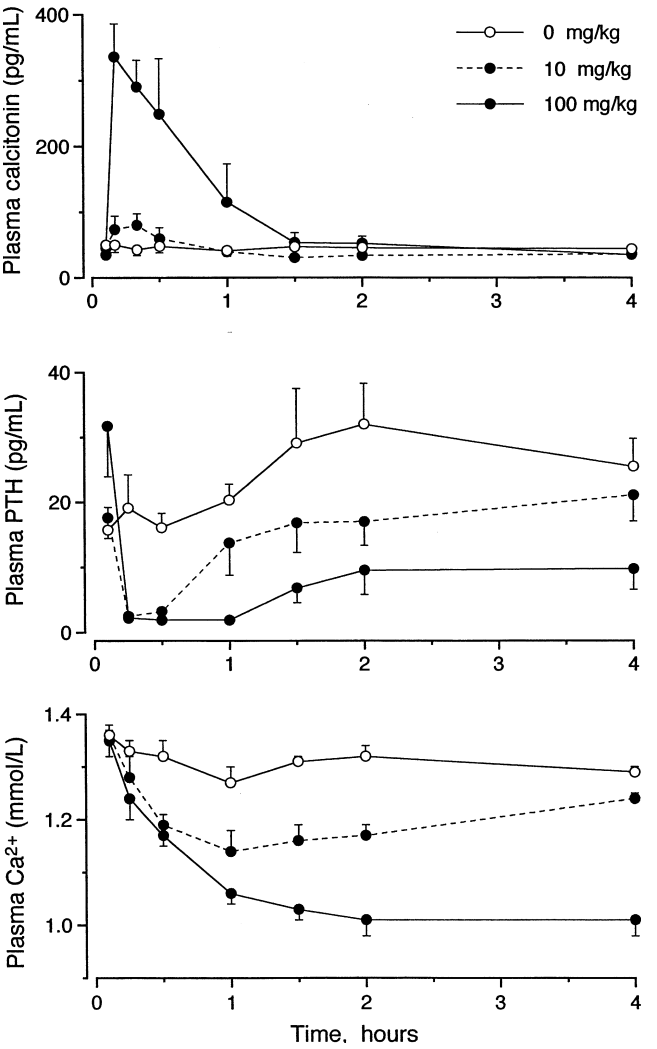

Figure 2 NPS R-568 decreases plasma levels of PTH and Ca^{2+} and increases those of calcitonin. NPS R-568 (or vehicle) was administered orally at the indicated dose to normal male rats. Note that the 10 mg/kg dose, which is close to the ED_{50} for depressing plasma PTH levels, is without effect on plasma levels of calcitonin (Fig. 2 in Nemeth *et al.,* 1996).

Calcilytics

A novel series of compounds acting as Ca^{2+} receptor antagonists has been reported (Fig. 1; Nemeth *et al.,* 2001). The prototype compound, NPS 2143, is the first *substance,* either atomic or molecular, shown to block Ca^{2+} receptor activity. The inhibitory effects of NPS 2143 are not dependent on the properties of the ligand used to activate the receptor in either heterologous expression systems or authentic cells. The potency and the efficacy of NPS 2143 is similar whether blocking cytoplasmic Ca^{2+} responses evoked by type I (Ca^{2+}) or type II (NPS R-467) calcimimetic ligands. NPS 2143 is without effect on the cytoplasmic Ca^{2+} responses elicited by activation of various native or chimeric mGluRs nor does it affect those in cells coexpressing the $GABA_BR1$ and R2. Calcilytic compounds like NPS 2143, when used under appropriate conditions, are potent and selective pharmacological tools

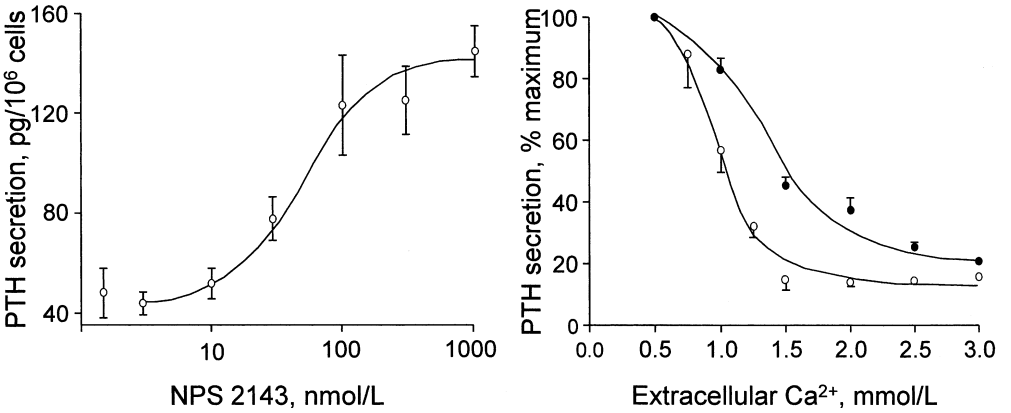

Figure 3 NPS 2143 stimulates PTH secretion from bovine parathyroid cells *in vitro.* (Right) Parathyroid cells were incubated in the presence (closed symbols) or absence of 300 nM NPS 2143 (Fig. 7 in Nemeth *et al.,* 2001).

to study the function of Ca^{2+} receptors expressed in normal and pathological tissues.

The effects of NPS 2143 on PTH secretion from bovine parathyroid cells mirror those of type II calcimimetic compounds. As noted above, these calcimimetics are positive allosteric modulators that shift the concentration–response curves of extracellular Ca^{2+} to the left without changing the maximum or minimum responses. NPS 2143 affects the agonist concentration–response curve in a converse manner: there is a shift to the right which is unaccompanied by changes in either the maximal or the minimal response (Fig. 3). These changes in the agonist concentration–response curves suggest that NPS 2143 decreases, whereas type II calcimimetic compounds increase the sensitivity of the Ca^{2+} receptor to activation by extracellular Ca^{2+}. Although the rightward shift of the concentration–response curve could indicate competitive inhibition by NPS 2143, the shifts in the concentration–response curve shown in Fig. 3 would also be produced by a noncompetitive antagonist acting on a tissue with a large receptor reserve (Zhu, 1993). As discussed below, there might be a large reserve of Ca^{2+} receptors on parathyroid cells.

NPS 2143 stimulates secretion of PTH from bovine parathyroid cells *in vitro* at concentrations similar to those that inhibit evoked increases in $[Ca^{2+}]_i$. When administered intravenously or by oral gavage to normal rats, the compound causes a rapid, three- to fivefold increase in plasma levels of PTH (Fig. 4; Nemeth *et al.,* 2001). These findings were comforting because it was never a certainty that a calcilytic compound would in fact stimulate PTH secretion. While intuitively appealing, this assumption rests solely on the finding that lowering the level of extracellular Ca^{2+} stimulates PTH secretion. This is not, however, equivalent to blocking the activity of the receptor in a normocalcemic setting. The

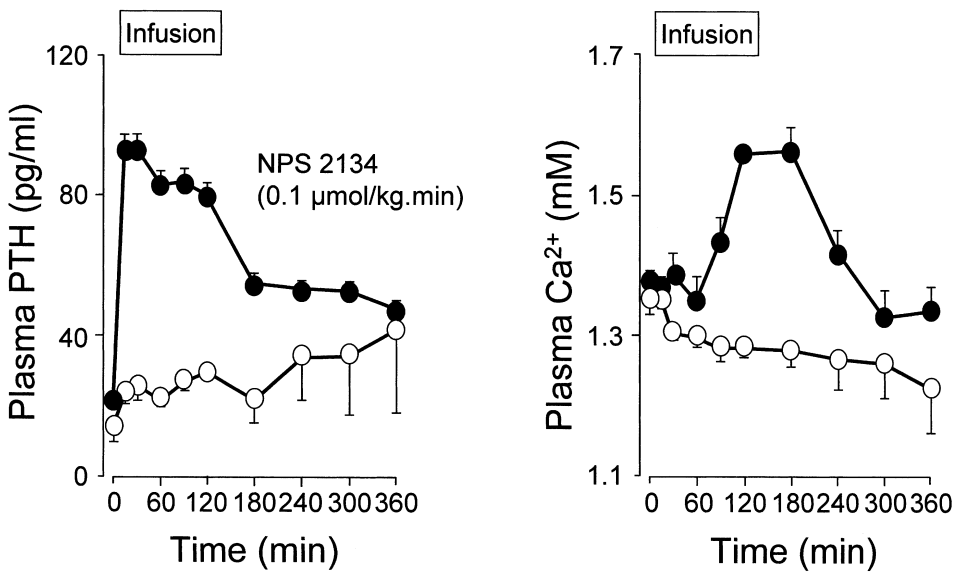

Figure 4 NPS 2143 rapidly increases circulating levels of PTH in normal rats. NPS 2143 was administered by infusing intravenously (0.1 μmol/kg·min; closed symbols) for 2 hr (Fig. 9 in Nemeth *et al.,* 2001).

stimulatory effects of NPS 2143 on PTH secretion *in vitro* and on circulating levels of hormone *in vivo* clearly underscores the key role of the Ca^{2+} receptor in controlling PTH secretion.

Pharmacological Selectivity of Calcium Receptor Ligands

Despite apparently similar Ca^{2+} receptors on parathyroid cells and on C cells, their pharmacological properties are different. An early example of this was noted with Mg^{2+}. Extracellular Mg^{2+} increases $[Ca^{2+}]_i$ in bovine parathyroid cells and in HEK 293 cells expressing the human, bovine, or rat Ca^{2+} receptor (Rogers *et al.,* 1995). Similar increases in the concentration of extracellular Mg^{2+}, however, fail to increase $[Ca^{2+}]_i$ in the MTC cell lines 44–2 or 6–23 (Nemeth, 1990; Fajtova *et al.,* 1991). Nonetheless, increased concentrations of extracellular Mg^{2+} stimulate secretion of calcitonin from authentic C cells *in vitro* (Bell, 1970; Radde *et al.,* 1969) and *in vivo* (Care *et al.,* 1971; Littledike and Arnaud, 1971; Pento *et al.,* 1974). Perhaps this discrepancy results from comparing MTC cells with authentic C cells since these cells are likely to express different phenotypes. This explanation cannot, however, account for the preferential activity of type II calcimimetics on secretion of calcitonin and PTH that is noted in normal rats *in vivo* (Fox *et al.,* 1999b). The Ca^{2+} receptor mRNAs expressed in rat parathyroid cells and C cells are identical and the final protein products are likewise similar (Garrett *et al.,* 1995b). Nonetheless, the type II calcimimetic compounds NPS R-467 and NPS R-568 depress plasma levels of PTH at doses 30- to 40-fold lower than those that increase plasma levels of calcitonin (Figs. 2 and 5).

The mechanisms(s) explaining the preferential inhibitory effects of NPS R-568 on PTH secretion is uncertain. At present, there is no evidence for grossly different posttranslational modifications of the Ca^{2+} receptor in parathyroid cells and C cells. One hypothesis we recently put forward was that perhaps the concentration–response curve for extracellular Ca^{2+} and calcitonin secretion was less steep than that for extracellular Ca^{2+} and PTH (Wada *et al.,* 1999). It appears, however, that the slope (Hill coefficient) of both curves are similar and that maximal secretory responses of both PTH and calcitonin are produced over a very narrow range of plasma Ca^{2+}, even though their ED_{50} values differ (Lavigne *et al.,* 1998; Fox *et al.,* 1999b). Another possibility is that different degrees of receptor occupancy may be required to alter secretion from parathyroid cells and from C cells. In this view, a lower fractional occupancy of the Ca^{2+} receptor is required to depress PTH secretion than is required to stimulate calcitonin secretion. NPS R-568 is correspondingly more potent in depressing plasma levels of PTH. Alternatively, or additionally, the different signaling pathways linking the Ca^{2+} receptor to PTH and to calcitonin secretion might also contribute to the preferential activity of type II calcimimetic compounds on parathyroid Ca^{2+} receptors.

Oligomerization of receptors might also contribute to the differential pharmacology of type II calcimimetic compounds. Many G protein-coupled receptors, including Ca^{2+} receptors (Bai *et al.,* 1998, 1999), have been shown to be expressed as homodimers in heterologous systems although there remain only a few studies in which any G protein-coupled receptor is expressed and functions as a dimer in cellular environments where they normally reside. It is not known if Ca^{2+} receptors are expressed as dimers in their

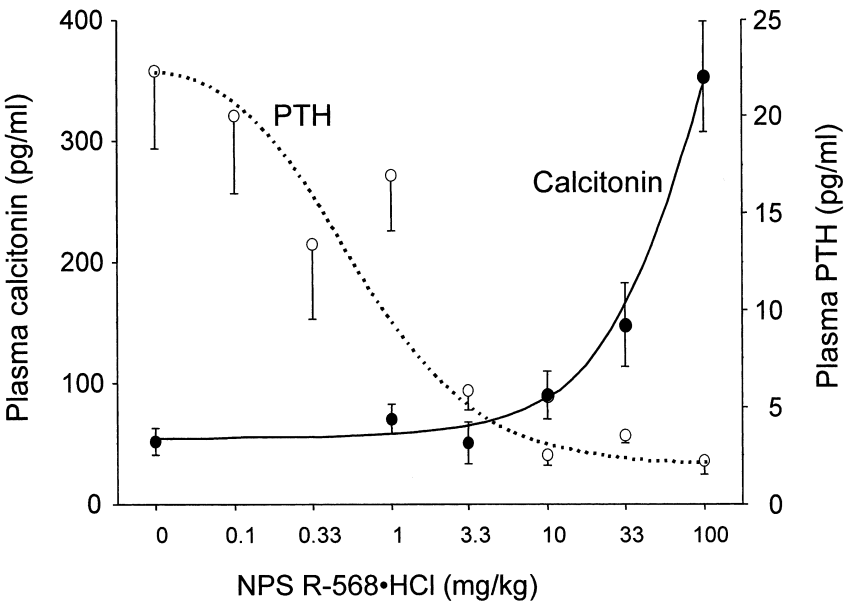

Figure 5 NPS R-568 preferentially acts on the parathyroid Ca^{2+} receptor. NPS R-568 was administered orally to normal rats and the changes in plasma levels of PTH and calcitonin determined 15 to 20 min later. (Redrawn from data in Fox *et al.,* 1999a,b.)

native environment or whether the pharmacological properties of Ca^{2+} receptor monomers and dimers are different.

Regardless of the molecular mechanism underlying the different pharmacology of C cells and parathyroid cells, the important finding is that PTH secretion can be preferentially regulated by a single compound. The preferential actions of type II calcimimetic compounds on parathyroid Ca^{2+} receptors might also apply to renal Ca^{2+} receptors and this would explain why renal Ca^{2+} receptors, although involved in Ca^{2+} transport in the kidney, are not necessary for the type II calcimimetics to cause hypocalcemia.

The Calcium Receptor in Hyperparathyroidism

One of the early uncertainties in developing calcimimetic compounds for treating hyperparathyroidism (HPT) was whether the disease process in some way altered the parathyroid Ca^{2+} receptor so that calcimimetics, while effective in normal animals and humans, were no longer capable of altering plasma levels of PTH in patients with primary or secondary HPT. No mutations, however, have yet been detected in the coding region of the Ca^{2+} receptor gene in pathological parathyroid glands from patients with primary or secondary HPT (Garrett *et al.,* 1995a; Hosokawa *et al.,* 1995; Cetani *et al.,* 2000). A consistent finding, however, is reduced expression of the Ca^{2+} receptor in both adenomatous and hyperplastic tissues (Kifor *et al.,* 1996; Farnebo *et al.,* 1997; Gogusev *et al.,* 1997; Kaneko *et al.,* 1999). This conclusion is based on semi quantitative analyses of Ca^{2+} receptor mRNA and staining intensities of parathyroid tissue using mono- or polyclonal antibodies against the Ca^{2+} receptor. Like the data for the vitamin D receptor (Fukuda *et al.,* 1993), nodular regions showed a greater loss of staining intensity for Ca^{2+} receptor when compared to adjacent areas of diffuse hyperplasia. Recent clinical results obtained in patients with primary HPT reveal a correlation between the level of parathyroid Ca^{2+} receptor expression, as judged by the intensity of staining of tissues with a polyclonal antibody to the Ca^{2+} receptor, and the PTH–Ca^{2+} set point—the set point was higher in those patients with glands having the least staining intensity (Cetani *et al.,* 2000). Thus, in contrast to the altered set points in genetic diseases of the Ca^{2+} receptor that result from changing the structure of the Ca^{2+} receptor, those in hyperparathyroidism result largely from changing the density of otherwise normal Ca^{2+} receptors. The issue was whether there were enough Ca^{2+} receptors expressed to permit regulation of PTH secretion by calcimimetic compounds.

Several different lines of evidence suggest that the apparently reduced expression of Ca^{2+} receptor protein in pathological parathyroid glands does not render such glands insensitive to calcimimetic compounds. First, secretion of PTH from adenomatous or hyperplastic parathyroid glands *in vitro* is inhibited by NPS R-568 (Nemeth, 1996) so, at least in these particular surgical tissue samples, there was enough Ca^{2+} receptor remaining to respond to this calcimimetic compound. Moreover, the potency of NPS R-568 is similar in normal rats or those with secondary HPT resulting from a 5/6 nephrectomy (Fox *et al.,* 2000). Finally, and most significantly, calcimimetic compounds lower plasma levels of PTH in patients with primary or secondary HPT. As detailed below, there has yet to be a patient dosed with a calcimimetic compound who did not show a rapid fall in plasma levels of PTH.

Primary Hyperparathyroidism

Primary hyperparathyroidism is an age-related disorder that afflicts postmenopausal women disproportionally. The disease is characterized by chronically elevated plasma levels of PTH and Ca^{2+} and usually results from a single adenoma or hyperplasia of the parathyroid glands (Heath, 1991). The manifestations of primary hyperparathyroidism may include bone loss, nephrolithiasis and nephrocalcinosis, gastrointestinal distress, muscular fatigue, and mental depression. Although many patients with hyperparathyroidism are apparently asymptomatic, it has been argued that these patients simply have not been followed long enough for symptoms to become manifest (Fischer, 1993). Moreover, because the incidence of primary hyperparathyroidism is age related, many of the rather vague symptoms such as muscular fatigue and depressed cognition may be interpreted as the normal aging process. Whether these so-called asymptomatic patients should be treated is controversial and at present the most widely followed practice is "watchful waiting" (Bilezikian, 1994).

There is somewhat less controversy regarding treatment of moderate and essentially none regarding treatment of severe forms primary hyperparathyroidism. The treatment of choice is surgical ablation of the offending gland(s) and, when performed by a skilled endocrine surgeon, the success (cure) rate is 95% (Clark, 1995). There are, however, many instances when surgery would not be elected if effective medical alternatives existed. These include patients who refuse surgery, are elderly, have comorbid conditions, or have undergone previous unsuccessful surgeries. Many patients with parathyroid carcinoma are not effectively treated by surgery (Shane and Bilezikian, 1982). In addition, there are those situations where it would be desirable to delay surgery or to stabilize plasma levels of Ca^{2+} prior to surgery. At present, there is no safe and effective means of managing these patients although a variety of different medical treatments have been tried (Stock and Marcus, 1994).

Medical treatments such as oral phosphate, calcitonin, or bisphosphonates are effective in temporarily reducing plasma levels of Ca^{2+} but often do not change or may even cause a further increase in PTH levels. For example, in a study of patients with mild primary HPT, 1 year of treatment with alendronate caused a temporary decrease in serum Ca^{2+} at 3 months but returned to hypercalcemic levels by 6 months and remained elevated thereafter. The

temporary decrease in serum Ca^{2+} triggered an increase in PTH levels which returned to pretreatment levels once serum Ca^{2+} rose (Rossini *et al.,* 2001). Another approach to treating primary HPT relies on the use of PTH receptor antagonists which have been shown in animal studies to block increases in plasma Ca^{2+} evoked by infusion of a PTH receptor peptide agonist (Rosen *et al.,* 1997). The competitive peptide antagonist BIM-44002, however, failed to lower plasma levels of PTH or Ca^{2+} when infused into patients with primary HPT. Estrogens and progestins have met with some success in normalizing plasma levels of Ca^{2+} but not those of PTH. All these therapies are aimed at treating the hypercalcemia but not the hyperparathyroidism itself. All these approaches are unlikely to be therapeutically useful because lowering Ca^{2+} will invariably stimulate secretion of PTH which, in turn, will defeat the intent of the treatment.

Additional approaches using drugs that act directly on parathyroid cells have also been explored. Inhibition of the biosynthesis of PTH with 1α-hydroxyvitamin D3 (Lind *et al.,* 1989) transiently lowered plasma levels of PTH but also caused hypercalcemia. Another approach has been to target cell surface receptors like the β-adrenergic or the H2-histaminergic receptors that are linked to a stimulation of PTH secretion. The receptor antagonists propranolol and cimetidine have been unequivocally ineffective in managing primary hyperparathyroidism (Fisken *et al.,* 1982; Gedik *et al.,* 1983; Robinson *et al.,* 1980). The somatostatin analog octreotide has been similarly ineffective in lowering PTH levels in patients with either primary or secondary HPT (Zielke *et al.,* 1997). The only approach that has never been tried is to target the primary physiological mechanism regulating PTH secretion, the Ca^{2+} receptor.

By targeting the Ca^{2+} receptor, parathyroid calcimimetic compounds offer the first "disease-designed" approach for treating primary hyperparathyroidism. The initial clinical trial in normal postmenopausal women showed that the oral administration of NPS R-568 was well tolerated and reduced plasma levels of PTH and Ca^{2+} (Health *et al.,* 1995). Doses of NPS R-568 that maximally depressed plasma levels of PTH were without effect on plasma levels of calcitonin. These findings in humans parallel those obtained in preclinical studies and show that plasma levels of PTH and calcitonin in humans can be differentially affected by a calcimimetic compound.

Calcimimetic compounds have been shown to be effective in reducing circulating levels of PTH and Ca^{2+} patients with primary HPT (Table I; Silverberg *et al.,* 1997; Shoback *et al.,* 2000). The oral administration of NPS R-568 to postmenopausal women with primary HPT caused a rapid and dose-dependent decrease in plasma levels of PTH (Fig. 6). The inhibitory effects of NPS R-568 were readily reversible and, depending on the dose, plasma PTH returned to predose levels with 2 to 8 hr. At low doses, there was a transient decrease in the level of PTH that was unaccompanied by a change in plasma levels of Ca^{2+}. At higher doses, the decrease in plasma PTH levels lasted longer and plasma Ca^{2+} levels started to fall about 1 hr after plasma PTH levels reached a nadir. Paralleling this hypocalcemic response was an increase in urinary Ca^{2+} excretion. This temporal relationship is consistent with a primary action of the calcimimetic to inhibit secretion of PTH and the hypocalcemic response is secondary to this lowering of plasma PTH levels.

Similar findings have recently been obtained in male and in female patients with primary HPT using a newer type II calcimimetic compound, AMG 073 (Shoback *et al.,* 2000). In this study, the calcimimetic compound or a placebo was administered orally twice a day for 15 days. There was a rapid, time- and dose-dependent reduction in circulating levels of PTH which reached a nadir 2 to 4 hr after the first dose and was correlated with plasma levels of AMG 073. Plasma levels of PTH and Ca^{2+} were lower throughout the 15-day treatment period. When dosing was terminated, plasma levels of PTH and Ca^{2+} returned to the abnormally high levels observed in patients prior to study. In this particular clinical study, there was no increase in urinary excretion of Ca^{2+} over the 15-day study period. The clinical experience with type II calcimimetic compounds parallels the results obtained in preclinical studies. Together, they provide compelling evidence showing that these compounds can selectively target the parathyroid Ca^{2+} receptor to preferentially lower plasma levels of PTH. Moreover, the receptor does not desensitize to daily treatment with type II calcimimetics for a period of 2 weeks.

Table I Clinical Experience with the Use of Calcimimetic Compounds in Patients with Primary HPT

Study	Patients and treatment regimen	Dose of calcimimetic	Percentage change in plasma PTH and Ca^{2+} levels
Silverberg *et al.,* 1997	20 Postmenopausal women; single ascending dose	Palcebo or 4 to 160 mg NPS R-568	PTH decreased 26 – 73% in a dose-dependent fashion; Ca^{2+} fell from 1.35 to 1.30 mM
Shoback *et al.,* 2000	22 Male and female patients; 2 doses/day for 15 days	Placebo or 30, 40, or 50 mg AMG 073	PTH decreased 47% and Ca^{2+} decreased 20%
Collins *et al.,* 1998	Male patient with parathyroid carinoma; dose every 6 hr for 600 days	300 or 600 mg NPS R-568/day	PTH decreased from 600 – 1050 to 250 – 600 pg/ml; Ca^{2+} decreased from 1.95 to 1.50 mM

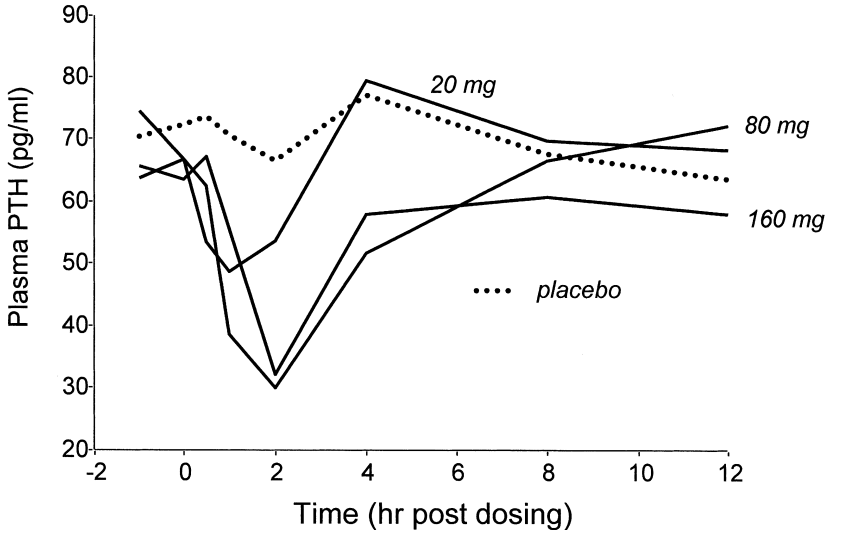

Figure 6 NPS R-568 lowers plasma levels of PTH in postmenopausal women with primary hyperparathyroidism. (Redrawn from data in Silverberg *et al.,* 1997.)

A rare but far more serious form of primary HPT results from a carcinoma of one of the parathyroid glands. In contrast to primary HPT resulting from an adenoma or hyperplasia, that due to a carcinoma is life-threatening. Patients with parathyroid carcinoma present with the signs and symptoms of frank hypercalcemia and often have hyperparathyroid bone disease (Shane and Bilezikian, 1982). Surgical treatment of this malignant form of primary HPT is considerably more difficult because of metastasis; multiple resections are common. In a male patient with severe hypercalcemia resulting from parathyroid carcinoma, NPS R-568 was able to lower plasma levels of PTH and return plasma Ca^{2+} to near normal levels (Collins *et al.,* 1998). Neither calcitonin, furosemide, hydration, nor the bisphosphonate pamidronate, consistently lowered plasma Ca^{2+} levels (Fig. 7) and plasma PTH levels were unaffected by these treatments. In contrast, daily oral dosing with NPS R-568 controlled plasma levels of PTH and Ca^{2+} for almost 2 months. At that time, plasma PTH levels began to increase but plasma Ca^{2+} levels did not. This patient was subsequently maintained on high doses of NPS R-568 (100 mg orally, every 6 hr) for over 600 days without any instances of hypercalcemic crisis or any adverse effects due to drug. At the very least, this study shows that tolerance to hypocalcemic effects of NPS R-568 does not develop within 2 years of daily dosing and that the compound is safe and well-tolerated.

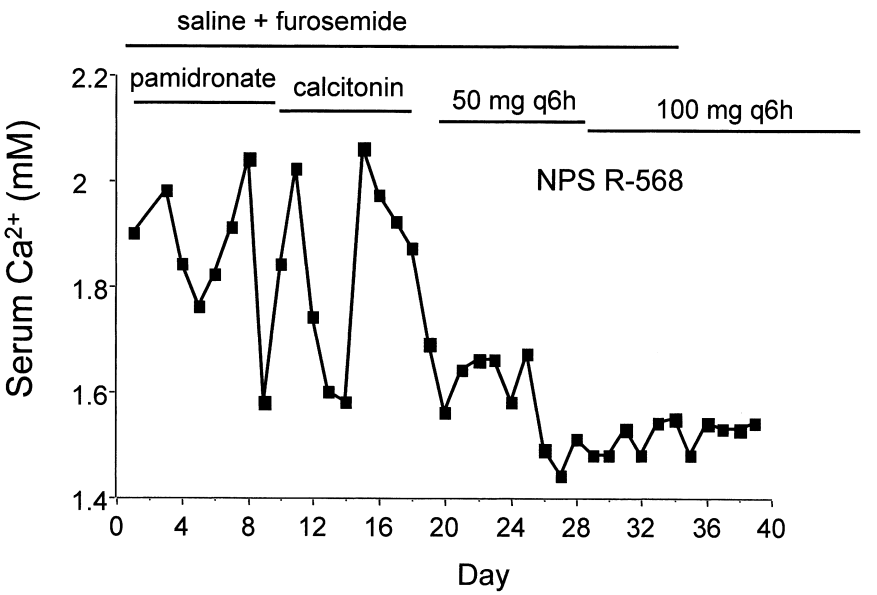

Figure 7 NPS R-568 lowers plasma levels of PTH in a male patient with parathyroid carcinoma (Fig. 1 in Collins *et al.,* 1998).

The initial clinical results obtained in patients with primary HPT arising from either benign or malignant tumors show that targeting the Ca^{2+} receptor with calcimimetic compounds is effective in lowering plasma levels of PTH and Ca^{2+}. In the setting of primary HPT, it is conceivable that a calcimimetic compound could be a stand-alone therapy.

Secondary Hyperparathyroidism

Secondary HPT can result from a variety of circumstances, including the normal aging process, but it is most often associated with chronic renal failure and most patients with end-stage renal disease (ESRD) suffer from secondary HPT (Coburn and Salusky, 1994). Secondary HPT is characterized by enlargement of all four parathyroid glands, principally through hyperplasia but also involving hypertrophy (Drüeke, 1995). The primary factors that lead to enlargement of the parathyroid glands are hypocalcemia, hyperphosphatemia, and lowered plasma levels of 1,25-dihydroxyvitamin D_3 (calcitriol). The mechanisms by which these factors lead to hyperplasia and hypertrophy of the parathyroid glands are not completely understood but each appears capable of acting wholly or partially independent of the others to cause secondary HPT. Resistance to the skeletal effects of PTH also contributes to the development of secondary HPT. Plasma levels of PTH increase very early on in the course of renal failure and may already be elevated when creatinine clearance reaches 60 ml/min (Fajtova *et al.,* 1995), well before the patient would be started on dialysis. The severity of secondary HPT, as indexed by enlargement of the parathyroid glands and increased circulating levels of PTH, often increases as the renal disease progresses from mild chronic renal insufficiency (CRI) to ESRD. Because the etiologies of chronic renal failure are diverse, the relative roles of phosphate, Ca^{2+}, and calcitriol in the development of secondary HPT may vary. This, in turn, may mandate different therapeutic strategies to treat secondary HPT depending on the relative contribution of the factors that cause it.

The management of HPT secondary to chronic renal failure has been covered extensively in recent reviews (Coburn and Salusky, 1994; Fournier *et al.,* 1992; Felsenfeld, 1997). The mainstays in treating secondary HPT are restriction of dietary phosphorous, administration of phosphate-binders and calcitriol or its analogs, and parathyroidectomy. Each of these therapies has met with success in some settings but none are ideal. Hypercalcemia is a common complication with calcium-containing phosphate-binders or with calcitriol and its analogs. Attempts to control plasma levels of PTH with calcitriol alone have not been overwhelmingly successful. Prospective studies have shown that calcitriol fails to lower plasma levels of PTH in many patients and in others it does so only at doses that elicit hypercalcemia and/or hyperphosphatemia (Herrmann *et al.,* 1994; Mazzaferro *et al.,* 1994; Quarles *et al.,* 1994a). The inconsistent response of PTH to calcitriol, which is most prominent in patients with long-established secondary HPT, could reflect variable loss of receptors for calcitriol in parathyroid tissue (Korkor, 1987; Merke *et al.,* 1987). Newer so-called "noncalcemic" analogs of calcitriol, like 19-nor-1-α-dihydroxyvitamin D_2 (Martin *et al.,* 1998) or 1α-hydroxyvitamin D_2 (Tan *et al.,* 1997; Frazão *et al.,* 2000), elicit fewer episodes of hypercalcemia but there is insufficient clinical experience with either analog to determine their efficacies in reducing plasma levels of PTH in patients who do not respond to calcitriol. Different therapies, either alone or in combination, may be required as the renal disease progresses. In general, however, it seems worthwhile to start treatment early in the course of renal failure because treatment in the predialysis period may retard the development of secondary HPT.

Preclinical Studies in Animal Models of Secondary Hyperparathyroidism

A series of collaborative investigations between NPS Pharmaceuticals and the Pharmaceutical Division of Kirin Brewery characterized the effects of calcimimetic compounds in several different rodent models of secondary HPT. CRI was usually produced by surgically removing most of the kidney (5/6 nephrectomy). This lesion could be combined with diets that differed in their calcium-to-phosphate ratios to produce a range of plasma PTH levels characteristic of mild, moderate, or severe forms of secondary HPT. The results that emerged from these studies not only showed the efficacy of calcimimetics in disease models but additionally provided pharmacological evidence showing that the Ca^{2+} receptor regulates proliferation of parathyroid cells.

In rats with secondary HPT resulting from CRI, the oral administration of NPS R-568 caused a dose-dependent decrease in plasma levels of PTH. The magnitude and rate of change of plasma PTH levels following orally administered compound were similar in normal animals or those with secondary HPT (Fox *et al.,* 1999c). Moreover, animals with mild (normal to 150 pg/ml PTH), moderate (150 to 500 pg/ml), or severe secondary HPT (>500 pg/ml) all responded similarly to the intraarterial injection of NPS R-568: the compound reduced plasma PTH levels by 82 to 94% within 20 min of dosing regardless of the initial plasma PTH level (Fox *et al.,* 1999c). Some of these animals had severe hyperphosphatemia and moderate hypocalcemia yet these two stimuli to PTH secretion could not prevent the depressive effect of NPS R-568 on plasma levels of PTH. Thus, activation of the Ca^{2+} receptor with NPS R-568 markedly lowers circulating levels of PTH irrespective of the severity of the secondary HPT or the magnitude of the hyperphosphatemia.

Despite reports showing a decreased expression of parathyroid Ca^{2+} receptor mRNA and protein in such animal models of secondary HPT (Mathias *et al.,* 1998; Brown *et al.,* 1999), there is apparently enough Ca^{2+} receptor

expressed to preserve responsivity to calcimimetic compounds. In fact, the potencies of NPS R-568 for lowering plasma levels of PTH and Ca^{2+} or for increasing those of calcitonin are the same in normal animals and those with CRI and moderate to severe secondary HPT (Fox *et al.,* 2000). Thus, PTH levels can be maximally suppressed by calcimimetic compounds even when Ca^{2+} receptor expression is reduced and during states of chronic hyperphosphatemia and/or hypocalcemia.

More long-term studies in rats with CRI have shown that the decreases in plasma levels of PTH caused by NPS R-568 have beneficial effects on some of the skeletal abnormalities which accompany secondary HPT (Wada *et al.,* 1998). Six weeks following a partial nephrectomy, animals had developed a mild to moderate secondary HPT with profound peritrabecular fibrosis; static and dynamic histomorphometry revealed a high turnover bone lesion. The daily oral administration of NPS R-568 during the last 5 weeks completely prevented the development of osteitis fibrosa and tended to normalize histomorphometric parameters. Daily treatment with NPS R-568 additionally restored the decreases in volumetric cortical bone mineral density and in cortical bone stiffness at the femoral midshaft which was observed in vehicle-treated CRI animals. The results obtained using rodent models of CRI-induced secondary HPT show that NPS R-568 consistently reduces plasma levels of PTH even following prolonged, daily administration. Tolerance to the effects of NPS R-568 do not develop in these animal models of secondary HPT. Moreover, the daily decreases in circulating levels of PTH caused by NPS R-568 translates into positive effects on high turnover bone abnormalities including the prevention or reversal of osteitis fibrosa.

In addition to effectively lowering plasma levels of PTH, calcimimetic compounds also block parathyroid gland hyperplasia resulting from CRI. As noted above, hypocalcemia, hyperphosphatemia, and lowered levels of calcitriol all contribute to parathyroid gland hyperplasia although the mechanisms they use to cause cellular proliferation and hypertrophy are uncertain. In fact, the effect of hypocalcemia on parathyroid gland histology is still controversial and either no effect or a stimulation of cell growth has been reported (Naveh-Many *et al.,* 1995; Wernerson *et al.,* 1991). These discrepant findings possibly reflect the difficulty inherent in any attempt to alter levels of plasma Ca^{2+} without affecting those of phosphate or calcitriol. Type II calcimimetic compounds offer a novel means of reassessing the role of plasma Ca^{2+} in parathyroid gland hyperplasia; they can trick the parathyroid cell into perceiving hypercalcemia despite a prevailing normo- or hypocalcemic state (Nemeth and Bennett, 1998).

Parathyroid gland hyperplasia begins within days following a partial nephrectomy in the rat (Denda *et al.,* 1996) and the initial studies examined the effects of NPS R-568 on parathyroid cell proliferation during the first 5 days of CRI in rats (Wada *et al.,* 1997). Bromodeoxyuridine (BrdU) was infused intraperitoneally throughout and NPS R-568 was administered orally twice a day during the last 4 days. As shown in Fig. 8, there was a threefold increase in cellular labeling with BrdU in partially nephrectomized animals which was blocked in a dose-dependent manner by treatment with NPS R-568. The inhibitory effect of NPS R-568 on BrdU labeling was specific for parathyroid cells and did not affect labeling of C cells, even at the high dose which stimulated calcitonin secretion. These findings suggest that the Ca^{2+} receptor mediates the effects of hypocalcemia on parathyroid cell proliferation. If the glands responded to the prevailing low calcium levels by a mechanism other than the Ca^{2+} receptor, then NPS R-568 would not have prevented the proliferative response to partial nephrectomy. The mechanisms linking the Ca^{2+} receptor to the regulation of cellular proliferation are present in parathyroid cells but not in C cells.

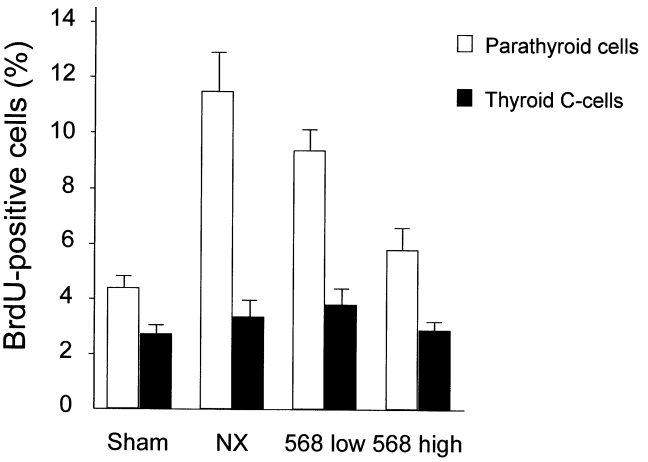

Figure 8 NPS R-568 blocks parathyroid cell proliferation in partially nephrectomized rats. NPS R-568 was administered orally twice a day at a dose of either 1.5 (568 low) or 15 mg/kg (568 high) (Fig. 4 in Wada *et al.,* 1997).

These initial findings prompted two long-term studies in rats with CRI. The first assessed whether initiating treatment with NPS R-568 soon after the development of CRI would prevent parathyroid gland hyperplasia (Wada *et al.,* 2000). CRI was induced by ligating the renal arteries and feeding the animals a diet high in phosphate content. Treatment with NPS R-568 was started 6 days after renal artery ligation and continued for 56 days. The vehicle-treated CRI animals developed severe secondary HPT with 10-fold elevations in circulating levels of PTH compared to sham-operated animals. Parathyroid gland volume was 2.8-fold higher in the former group of animals and this resulted mostly from an increase in cell number rather than cell volume. The enlargement and cellular hyperplasia of the parathyroid glands was completely prevented by treatment with NPS R-568.

The second study assessed whether treatment with NPS R-568 could halt the progression of parathyroid gland hyperplasia in animals with CRI (Chin *et al.,* 2000). Secondary HPT was allowed to develop for 11 weeks following a 5/6 nephrectomy before initiating treatment with NPS

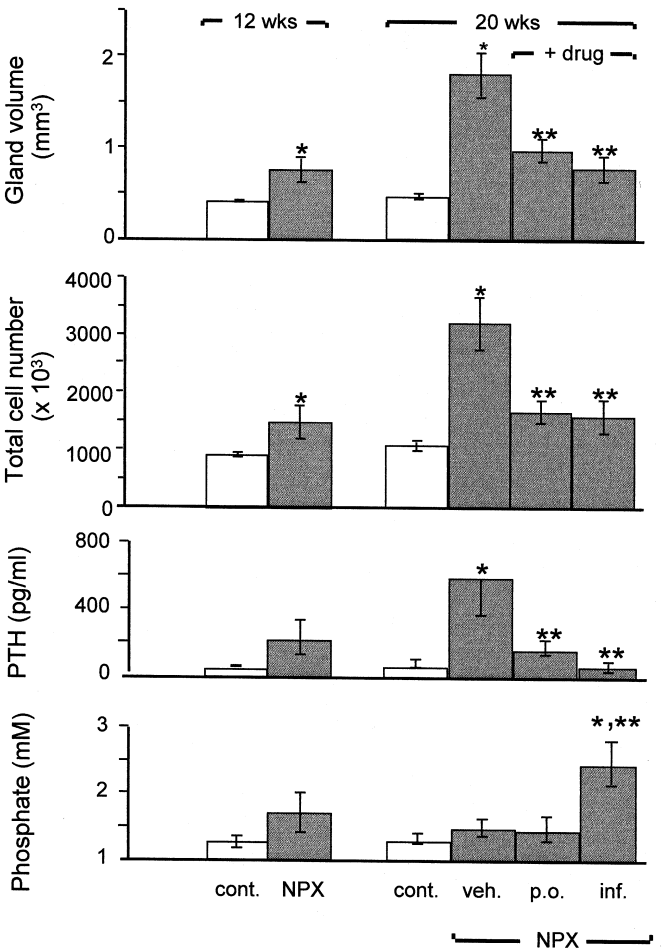

Figure 9 NPS R-568 blocks the progression of secondary hyperparathyroidism in CRI rats. NPS R-568 or vehicle was administered orally once a day (po; 10 μmol/kg) or continuously infused (inf; 20 μmol/kg/day) for 8 weeks beginning 11 weeks after a 5/6 nephrectomy (redrawn from data in Fox *et al.,* Chin *et al.,* 2000)

R-568 for 8 weeks. At 11 weeks following surgery, parathyroid gland volume was 1.9-fold larger in CRI animals and the glandular volume continued to increase in these animals another 2-fold by the end of the study. Parathyroid gland enlargement was paralleled by a 5.4-fold increase in plasma levels of PTH in vehicle-treated CRI animals which continued to increase another 2.6-fold during the last 8 weeks (Fig. 9). Secondary HPT continued to worsen during the course of this study, as indicated by continually rising levels of circulating PTH and progressive enlargement of the parathyroid glands. Daily oral administration of NPS R-568 completely blocked the progression of secondary HPT as indicated by either parameter (Fig. 9). Moreover, progressive increases in plasma PTH levels and parathyroid gland volume were completely prevented by NPS R-568 even when there was profound hypocalcemia, hyperphosphatemia, and lowered levels of 1,25-dihydroxyvitamin D_3 (Wada *et al.,* 2000; Chin *et al.,* 2000). Such findings suggest that the Ca^{2+} receptor plays the dominant role in regulating at least two different parathyroid cell functions: PTH secretion and cellular proliferation. Activating the Ca^{2+} receptor with a calcimimetic compound essentially neutralizes the stimulatory effects of hypocalcemia and dominates those of hyperphosphatemia and calcitriol.

These preclinical findings in rodent models of secondary HPT highlight the therapeutic potential of the parathyroid Ca^{2+} receptor. Because it controls both secretion and proliferation, compounds which activate it have the potential to halt the progression of secondary HPT. It is conceivable that identification of patients with CRI could lead to the prophylactic use of calcimimetic compounds. Treatment with a calcimimetic compound early in the course of renal failure might completely prevent the development of secondary HPT. At the very least, these studies demonstrate the efficacy of calcimimetic compounds in lowering plasma levels of PTH. So far, the results obtained in rodent models of secondary HPT have been reproduced in the clinic with high fidelity.

Clinical Studies in Patients with Secondary Hyperparathyroidism

Studies of the calcimimetic compounds NPS R-568 or AMG 073 in patients with secondary HPT generated results remarkably similar to those obtained in rodent models of this disease. The clinical experience gained with calcimimetic compounds for treating secondary HPT is summarized in Table II.

In the initial prospective, dose-finding pilot study, NPS R-568 was administered orally to seven male patients with secondary HPT at the start of a hemodialysis session and again 24 hr later (Antonsen *et al.,* 1998). Basal levels of PTH in these patients were around 200 pg/ml and fell by 40 or 60% within 1 hr after receiving a single dose of 40 or 80 mg NPS R-568. At the lower dose, plasma levels of PTH returned to basal values 4 hr after dosing but levels were still partially depressed 24 hr after the higher dose. The second administration of either dose when the patients were not receiving dialysis caused a similar percentage decrease in plasma PTH levels. The decreases in plasma PTH levels were accompanied by a lowering of whole blood Ca^{2+} which, even after the high dose of NPS R-568, remained above the lower limit of normal (1.1 mM) and none of the patients developed signs or symptoms of hypocalcemia. With the 80 mg dose, there was a twofold increase in the circulating levels of calcitonin which returned to baseline by 24 hr.

In another pilot study (Akizawa *et al.,* 1998), six male patients on hemodialysis received 100 or 200 mg NPS R-568 on each of two consecutive days, one of which included a dialysis session. The 100-mg dose produced results very similar to those obtained by Antonsen *et al.* (1998): a rapid, reversible decrease in plasma levels of PTH which, in five of the six patients, was unaccompanied by clinically significant hypocalcemia. At the 200-mg dose, plasma PTH levels were suppressed by 80% but, in five of the six patients, this was associated with hypocalcemia. In both of these pilot studies,

Table II Clinical Experience with the Use of Calcimimetic Compounds in Patients with Secondary HPT

Study	Patients and treatment regimen	Dose of calcimimetic	Percentage change in plasma PTH levels
Antonsen *et al.,* 1998	7 Hemodialysis patients with mild SHPT; 1 dose/day for 2 days	40 to 200 mg/day NPS R-568	PTH decreased 37 – 63%
Akizawa *et al.,* 1998	6 Hemodialysis patients with Moderate to severe SHPT; 1 dose/day for 2 days	100 to 200 mg/day NPS R-568	PTH decreased 59 – 73%
Goodman *et al.,* 2000a	21 Male or female hemodialysis patients with moderate to severe SHP; 1 dose/day for 15 days	Placebo or 100 mg/day NPS R-568	PTH decreased 30 – 70%
Goodman *et al.,* 2000b	30 Male or female hemodialysis patients with SHPT; 1 dose/day for 8 days	Placebo or 10 to 50 mg/day AMG 073	PTH decreased 25 – 40%
Coburn *et al.,* 2000	Male and female hemodialysis patients with SHPT; single dose	Placebo or 5 to 100 mg/day AMG 073	PTH decreased 40 – 60%
Lindberg *et al.,* 2000	Male or female hemodialysis patients; 1 dose/day; dose increased every 3 weeks for 12 weeks, final dose was maintained for 6 weeks	Placebo or 10 to 50 mg/day AMG 073	PTH decreased by 26% during the maintenance phase of the study

NPS R-568 was well-tolerated and, other than transient bouts of hypocalcemia at high doses, there were no drug-related adverse events.

In the study of Akizawa *et al.* (1998), plasma levels of PTH before treatment ranged from 1400 to 2350 pg/ml in four of the six patients so these patients had severe secondary HPT. Nonetheless, a single oral 100-mg dose of NPS R-568 decreased plasma PTH levels by about 60% within 2 hr in each of these patients (Fig. 10). These findings in patients on dialysis parallel those obtained in rodent models of secondary HPT and show that the efficacy of calcimimetic compounds is similar in mild or severe cases of the disease.

The results obtained in these pilot studies were confirmed and extended in a randomized, double-blind, placebo-controlled, multicenter trial designed to assess the safety and efficacy of repeated oral doses of NPS R-568 in patients with ESRD and receiving hemodialysis three times per week (Goodman *et al.,* 2000a). Sixteen patients of either gender and with pretreatment serum PTH levels ranging from 300 to 1200 pg/ml received a 100-mg tablet of NPS R-568 once a day for 15 days. All patients treated with NPS R-568 showed a prompt decrease in plasma levels of PTH which reached a nadir within 2 hr and slowly returned to about 80% of pretreatment levels by 24 hr (Fig. 11). By the

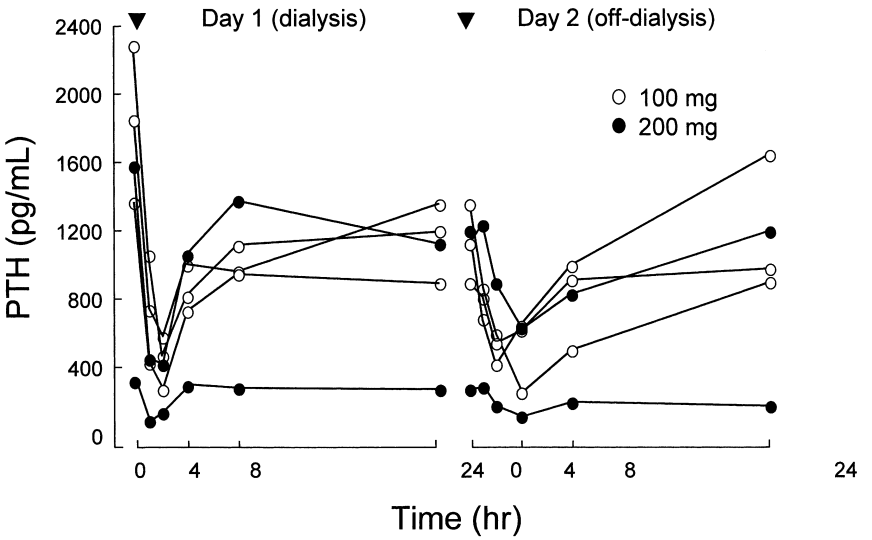

Figure 10 NPS R-568 rapidly lowers plasma PTH levels in patients on hemodialysis. (Redrawn from data in Akizawa *et al.,* 1998.)

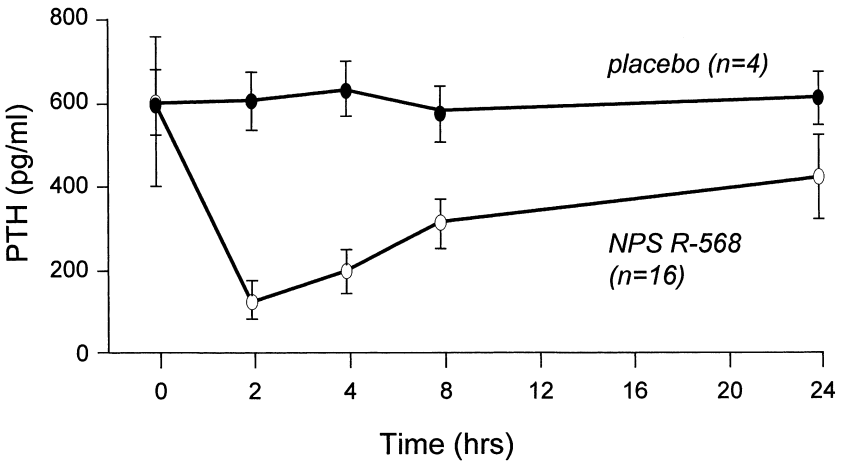

Figure 11 NPS R-568 lowers plasma PTH levels in male or female patients on hemodialysis (Fig. 1 in Goodman *et al.,* 2000a).

second day of dosing, serum PTH levels were significantly lower in calcimimetic-treated patients and, with daily dosing, they continued to decline until around day 10, at which time they were about 30% of pretreatment values. When dosing with NPS R-568 was discontinued on day 15, serum PTH levels began to rise and returned to pretreatment levels within 9 days. In contrast, serum PTH levels in patients receiving placebo continued to rise throughout the 24-day study period.

In general, multiple dosing with NPS R-568 was safe and well-tolerated. The most serious complication was hypocalcemia and at a dose of 100 mg NPS R-568, nearly half the treated patients developed hypocalcemia; it resolved in some when the dose was reduced to 50 mg/day. It is important to note, however, that all the patients were also receiving calcium supplements and vitamin D sterols throughout the course of the study. It is likely that adjusting the dose of one or both of these treatments would have prevented hypocalcemia in patients receiving the calcimimetic compound, a maneuver not permitted by the study protocol. On the other hand, the ability of NPS R-568 to lower circulating levels of PTH even in the face of hypocalcemia underscores the efficacy of the phenylalkylamine calcimimetics. Moreover, these compounds lowered PTH levels in patients already receiving optimal therapy with calcium and vitamin D (*vida infra*).

Despite the profound efficacy and general safety of NPS R-568 in patients with secondary HPT, this compound is not without its blemishes. The bioavailability of NPS R-568 is $<5\%$ and it is metabolized by hepatic cytochrome P_{450} enzymes, specifically the CYP2D6 enzyme. Around 5–7% of the population, depending on race, express an isozyme with substantially reduced enzymatic activity and therefore metabolize NPS R-568 slowly. To avoid these liabilities, clinical trials have continued with a backup compound, AMG 073. This compound, like NPS R-568, is a type II calcimimetic which acts allosterically on the Ca^{2+} receptor. It is similar in potency to NPS R-568 at inhibiting PTH secretion from bovine parathyroid cells *in vitro* (around 30 nM) but has improved bioavailability and is not metabolized by CYP2D6.

The safety and efficacy of AMG 073 in hemodialysis patients has been evaluated in three clinical trials (Table II). The effects of AMG 073 on plasma levels of PTH were similar in rate and magnitude to those described above for NPS R-568 whether administered as a single oral dose (Coburn *et al.,* 2000) or as daily doses for 8 days (Goodman *et al.,* 2000b) or 18 weeks (Lindberg *et al.,* 2000). Together, these three studies describe 102 instances of secondary HPT and every patient treated with AMG 073 showed a prompt fall in circulating levels of PTH. This occurred even in the presence of hypocalcemia and during optimal therapy with phosphate binders and vitamin D. Presumably, circulating levels of PTH had already been suppressed to the maximal extent possible with these conventional therapies. The ability of calcimimetic compounds to further lower PTH in patients already receiving phosphate binders and vitamin D highlights the deficiencies of the current standard of care for ESRD patients.

The decrease in circulating levels of PTH following administration of AMG 073 was associated with a decrease in serum levels of Ca^{2+} and phosphate; thus the Ca^{2+} times phosphate ($Ca \times P$) product decreased (Goodman *et al.,* 2000b; Lindberg *et al.,* 2000). While the reduction of this product is a much desired outcome in treating secondary HPT, the mechanism explaining this reduction is somewhat uncertain. There is no evidence to suggest that calcimimetic compounds lower the $C \times P$ product by allowing these ions to accumulate in soft tissues. In fact, at least in normal rodents, NPS R-568 causes hypocalcemia without affecting the rate of clearance of $^{45}Ca^{2+}$ from the circulation (Fox *et al.,* 1999a), a finding which has been interpreted to reflect diminished bone turnover resulting from a decrease in plasma PTH levels. Thus, understanding how calcimimetics

lower the Ca × P product in ESRD patients might not be a question of asking "Where are Ca^{2+} and phosphate going?" but rather "Where are they not coming from?"

Temporary vs Sustained Decreases in Circulating Levels of PTH

Inherent in the mechanism of action of calcimimetic compounds is their ability to alter plasma PTH levels in a manner that has not been possible previously. The only treatments that directly affect parathyroid cell function act on the synthesis, rather than the secretion of PTH (Naveh-Many and Silver, 1990). This is certainly true for calcitriol and, if phosphate acts directly on parathyroid cells, this might be how it acts as well. Because of this action, the suppressive effects of calcitriol on plasma levels of PTH, when they do occur, are slow in onset and in recovery. In contrast, because it targets the Ca^{2+} receptor, a single oral dose of a calcimimetic compound can lower plasma levels of PTH to a nadir within 30 min and levels can return to near baseline within 24 hr. Thus, a calcimimetic compound causes an intermittent, rather than sustained decrease in circulating levels of PTH (Fig. 12). The overall profile of the change in plasma PTH will vary depending on the dosing regimen and the pharmacokinetic properties of the particular calcimimetic compound being studied. The intriguing issue here is whether oscillating decreases in plasma levels of PTH, when compared to sustained decreases, will have different effects on bone quality.

It is generally accepted that plasma levels of PTH should be maintained at levels two- to three-fold higher than the upper limit of normal to overcome skeletal resistance to PTH and to avoid adynamic bone disease (Goodman *et al.,* 1994; Sherrard *et al.,* 1993). Oscillatory, in contrast to sustained changes in plasma levels of PTH might tend to reduce skeletal resistance to this hormone. Oscillatory decreases in plasma PTH levels might in themselves have different effects on bone than do sustained decreases. As described below, the catabolic effect of PTH on bone resulting from sustained elevations reverses to an anabolic effect when plasma levels of PTH increase intermittently. It has therefore been proposed that intermittent decreases in abnormally raised levels of plasma PTH might have effects on bone quality similar to those achieved by intermittent increases above normal (Nemeth and Bennett, 1998; Nemeth and Fox, 1999). Some evidence supporting this hypothesis has now appeared.

Using a partially nephrectomized rat model of uremia, Schmitt *et al.* (2000) compared the effects of the PTH fragment 1–37 on longitudinal growth when administered intermittently by subcutaneous injection or continuously by infusion. The twice daily administration of PTH fragment 1–37, but not its continuous infusion, improved longitudinal growth in uremic animals.

The effects of intermittent or sustained decreases in plasma levels of endogenous PTH were studied in a rodent model of uremia produced by adriamycin. Rats treated with adriamycin develop glomerular sclerosis which, after several months, results in a mild secondary HPT. Plasma levels of Ca^{2+} and phosphate are normal but vitamin D sterols are greatly reduced and there is massive proteinuria (Ishii *et al.,* 2000). Despite the mild secondary HPT, the renal osteodystrophy is characterized by a low turnover bone lesion with osteopenia and osteomalicia. Circulating levels of PTH were decreased in an oscillatory manner by the daily oral administration of NPS R-568 or they were continuously suppressed by the subcutaneous infusion of this compound. Oral administration, but not continuous infusion of NPS R-568, increased trabecular bone volume and bone mineral density (Fig. 13). Thus, oscillatory decreases in plasma

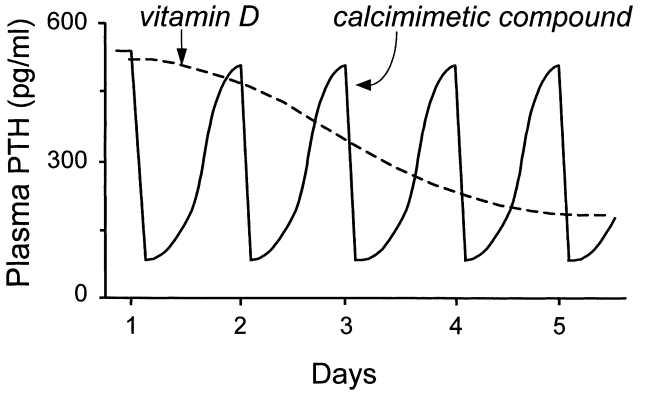

Figure 12 Contrasting effects of calcimimetic compounds and vitamin D sterols on the dynamics of changes in circulating levels of PTH (Fig. 1 in Nemeth and Bennett, 1998).

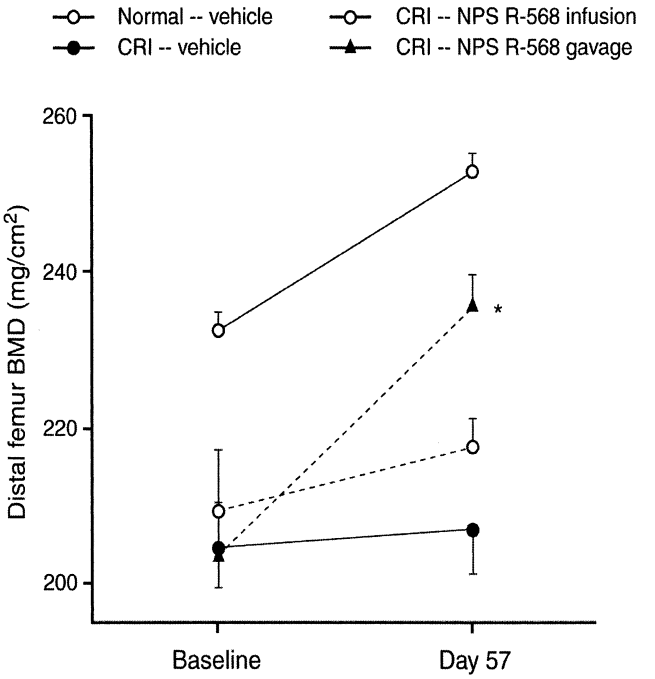

Figure 13 Bone mineral density in the distal femur is increased by daily oral administration of NPS R-568 (10 mg/kg) for 56 days in rats with CRI induced by adriamycin. In contrast, the continuous infusion of NPS R-568 (4.5 mg/kg/day) was without effect (Fig. 3 in Ishii *et al.,* 2000).

levels of PTH have markedly different effects on bone than do sustained decreases and, at least in this animal model of CRI, the intermittent decreases in plasma PTH levels had an "anabolic-like" effect on bone.

Osteoporosis

Because PTH plays such an important role in bone metabolism, there has been considerable interest in determining if abnormal plasma levels of this hormone might contribute to the development or progression of osteopenia. Although the role of PTH in the pathogenesis of type I osteoporosis remains controversial, there is scant evidence to suggest that it plays an important role (Silverberg and Bilezikian, 1994). In women with type I osteoporosis, it has generally been found that plasma levels of PTH are normal or slightly reduced (Gallagher, 1990). In contrast, a number of studies have implicated PTH in the pathogenesis of type II osteoporosis because there is an age-related increase in circulating levels of PTH in both men and women (Blumsohn and Eastell, 1995). This results largely from age-related decreases in renal function resulting in decreased levels of calcitriol, which, in turn, leads to decreased intestinal Ca^{2+} absorption. The systemic result is not that different from that seen in CRI. Consequently, there is increased secretion of PTH and type II osteoporosis could result partly from "senile secondary hyperparathyroidism."

PTH increases bone turnover but the resulting overall effect on bone mineral density is highly dependent on the temporal changes in the circulating levels of PTH. Thus, sustained elevations in plasma PTH levels, such as occur in PTH, lead to increased bone resorption and a net decrease in bone mass at most skeletal sites (Antonsen and Sherrard, 1995; Silverberg *et al.,* 1995). In contrast, temporary increases in plasma levels of PTH or its 1–34 fragment, achieved by the daily (or near daily) injection of either peptide, stimulate new bone formation in animal models of osteopenia (Mosekilde *et al.,* 1991; Dempster *et al.,* 1993; Kimmel *et al.,* 1993; Li and Wronski, 1995; Ejersted *et al.,* 1995a,b; Fox *et al.,* 1997) and in clinical studies of osteoporotic women or men (Reeve, 1996; Lindsay *et al.,* 1997; Hodsman *et al.,* 1997; Lane *et al.,* 1998; Fujita *et al.,* 1999; Rittmaster *et al.,* 2000). The results of these studies using intermittent administration of peptides demonstrate that PTH is a potent anabolic agent that increases bone mineral density and bone strength to a greater extent than that achieved by antiresorptive therapies (Mosekilde *et al.,* 1994; Søgaard *et al.,* 1994; Hodsman *et al.,* 1997; Lindsay *et al.,* 1997; Lane *et al.,* 1998; Fujita *et al.,* 1999; Rittmaster *et al.,* 2000). The profound stimulatory effect of these peptides on bone formation has generated interest in the use of PTH or its fragments as a novel anabolic therapy for osteoporosis. However, the therapeutic use of these peptides is compromised by the need for systemic administration of a costly biological product. Calcilytic compounds might provide an alternative approach to systemic administration of PTH by increasing the circulating levels of endogenous PTH (Nemeth, 1996). Preclinical studies using the calcilytic compound NPS 2143 in ovariectomized (OVX) rat models of osteopenia have generated results consistent with this hypothesis.

Daily oral administration of NPS 2143 for 5 weeks increased circulating levels of PTH and increased bone turnover in osteopenic OVX rats (Gowen *et al.,* 2000). When administered together with 17β-estradiol, the calcilytic compound stimulated new bone formation in the proximal tibial metaphysis and increased bone mass in the distal femur (Figs. 14 and 15). Thus, the increases in circulating levels of endogenous PTH evoked by a calcilytic compound are sufficient to cause an anabolic effect on bone.

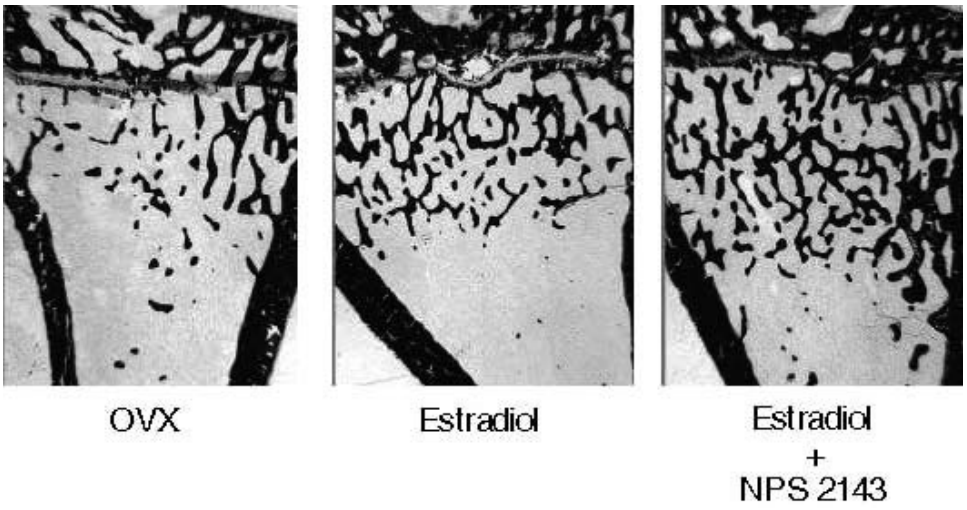

Figure 14 Treatment with NPS 2143 and estrogen increases trabecular bone volume in the proximal tibia of OVX rats. Rats were treated for 5 weeks with vehicle or subcutaneous infusion of estrogen with or without daily oral administration of 100 μmol/kg NPS 2143 (Fig. 6 in Gowen *et al.,* 2000).

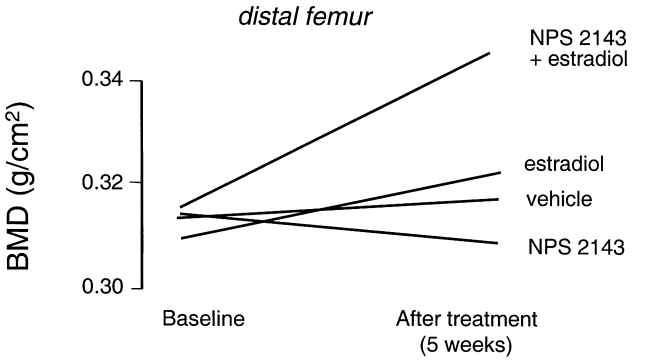

Figure 15 Treatment with NPS 2143 and estrogen increases bone mineral density in the distal femur of OVX rats, treated for 5 weeks as described in the legend to Fig. 14 (Fig. 8 in Gowen *et al.,* 2000).

One concern of repeated daily dosing with a calcilytic compound is the potential for inducing parathyroid cell proliferation. It is well recognized that parathyroid glands are larger in rats fed a diet containing low amounts of calcium (Ham *et al.,* 1940). Weanling rats fed a low-calcium diet for 3 weeks showed markedly increased parathyroid cell proliferation (Naveh-Many *et al.,* 1995). On the other hand, in older rats, comparable in age to those used in studies on OVX, the glandular enlargement accompanying calcium deficiency resulted exclusively from hypertrophy of the parathyroid cells and not from hyperplasia (Wernerson *et al.,* 1991). Daily oral dosing of OVX rats with NPS 2143 for 5 weeks did not increase parathyroid cell proliferation, neither by itself nor when administered together with estrogen (Gowen *et al.,* 2000).

The first calcilytic compounds have entered the clinic so it will soon be known if such compounds can cause an equally large increase in circulating levels of PTH in humans and do so, moreover, only transiently.

Calcium Receptors in Skeletal Tissue

There are a number of unresolved issues which, to various degrees, impact the therapeutic usefulness of any drug acting on the Ca^{2+} receptor. Some of the more basic issues of Ca^{2+} receptor biology, like the cellular distribution of the Ca^{2+} receptor throughout the body or the possibility of other, as yet unidentified Ca^{2+} receptors, are unknown or incomplete. This is a particularly significant issue for the development of calcilytic compounds for treating osteoporosis because there remains some controversy regarding the expression of the Ca^{2+} receptor in skeletal tissue. This issue was covered in detail previously (Nemeth, 1996) and the studies since then have failed to resolve it. There is evidence for extracellular Ca^{2+} sensing mechanisms in some osteoblastic cell lines (Quarles *et al.,* 1994b), osteoclastoma giant cells (Seuwen *et al.,* 1999), and normal rabbit osteoclasts (Steffey and Nemeth, 1993) which are pharmacologically different from that of the parathyroid. Many of the discrepant findings are based on studies using transformed osteoblastic cell lines whose fidelity to the normal phenotype is suspicious. The value of data derived from such cells is always tainted by this caveat. On the other hand, studies using normal tissues or cells have provided rather compelling evidence for expression of the Ca^{2+} receptor at certain skeletal sites. Using a number of different methods, Chen *et al.,* (1989) showed expression of the Ca^{2+} receptor in mouse, rat, and bovine cartilage and bone. In the latter tissue, they were able to detect Ca^{2+} receptor transcripts in osteoblasts, osteocytes, and some marrow cells, but only rarely in osteoclasts. The Ca^{2+} receptor might be expressed only transiently, during certain stages in a cellular lineage, and this effervescent appearance could make its detection problematic.

The possible significance of this issue for the use of calcilytic compounds as drugs resides in the nature of G protein-coupled receptor antagonists. In general, antagonists of these receptors do not show tissue selectively like the corresponding agonists or allosteric activators. Indeed, in rats, the potencies of NPS 2143 for increasing circulating levels of PTH and decreasing those of calcitonin are similar. Thus, there are reasons to suppose that calcilytic compounds will act with similar potencies on Ca^{2+} receptors throughout the body, including those seemingly expressed in skeletal tissues. Although NPS 2143 did not affect a number of indices of bone turnover *in vitro* (Gowen *et al.,* 2000), at this time it's actions on bone *in vivo* cannot be assumed to result solely from changes in circulating levels of PTH.

Conclusion

The Ca^{2+} receptor continues to evolve as a viable therapeutic target for treating hyperparathyroidism and osteoporosis. The discovery and development of potent and selective calcimimetic and calcilytic compounds has demonstrated that circulating levels of endogenous PTH can be altered at will by pharmacologically tuning the sensitivity of the Ca^{2+} receptor to extracellular Ca^{2+}. Additionally, these compounds have permitted Ca^{2+} receptor functions to be studied *in vivo* and this, in turn, has revealed the important role of the Ca^{2+} receptor in regulating parathyroid cell proliferation. Finally, these compounds demonstrate the potential therapeutic benefits to be gained by directly controlling secretion of PTH from the parathyroid glands.

Although discussion of the possible therapeutic significance of drugs acting on the Ca^{2+} receptor has been considered from the viewpoint of changing levels of endogenous PTH, it is possible that this receptor regulates many other functional cellular responses. Conceivably, drugs acting on Ca^{2+} receptors to alter these other responses could be useful in treating disorders beyond HPT and osteoporosis.

CHAPTER 78

Bisphosphonates

Mechanisms of Action

Herbert Fleisch,[*] Alfred Reszka,[†] Gideon Rodan,[†] and Michael Rogers[‡]

Introduction

The bisphosphonates are a class of drugs developed over the past three decades for use in various diseases of bone, tooth, and calcium metabolism. Known to chemists since the mid 19th century, they were first synthesized in Germany (Menschutkin, 1865) and were used mainly in the textile, fertilizer, and oil industries to prevent scaling because of their property to inhibit calcium carbonate precipitation (Blomen, 1995). This chapter will cover the history of the development, chemistry, biological actions, and clinical applications of these compounds, but in the context of this volume will focus primarily on mechanisms of action. Emphasis will be given to newer developments, the reader can consult other recent reviews for additional information (Ebetino *et al.,* 1998; Fleisch, 1998, 2000; Rodan, 1998; Russell *et al.,* 1999; Russell and Rogers, 1999).

History of Bisphosphonate Development for Use in Bone Diseases

Our knowledge of the biologic characteristics of bisphosphonates dates back over 30 years, the first report appearing in 1968 (Fleisch *et al.,* 1968). The concept was derived from earlier studies on inorganic pyrophosphate which were found to prevent both the formation (Fleisch and Neuman, 1961) and dissolution of calcium phosphate *in vitro* (Fleisch *et al.,* 1966). Since pyrophosphate was subsequently shown to prevent ectopic calcification *in vivo* and to be present in urine and plasma (Fleisch and Bisaz, 1962), it was suggested to be a physiological regulator of calcification and perhaps also of decalcification *in vivo* (Fleisch *et al.,* 1966). Due to its rapid hydrolysis, pyrophosphate found therapeutic use only in scintigraphy and in toothpaste, added to prevent dental calculus. This prompted the search for analogs, which would display similar physicochemical properties, but resist enzymatic hydrolysis and metabolism. The bisphosphonates fulfilled these conditions.

Chemistry and General Characteristics

Bisphosphonates are compounds characterized by two C–P bonds. When the two C–P bonds are on a single carbon atom (P–C–P), they are analogs of pyrophosphate (P–O–P) and are called geminal bisphosphonates, because the carbon is at the central or geminal position (Fig. 1). The P–C–P bonds of the geminal bisphosphonate are stable to heat and most chemical reagents and are completely resistant to enzymatic hydrolysis. Only geminal bisphosphonates seem to have a strong activity on the skeleton. For the sake of simplicity they are generally called bisphosphonates.

The P–C–P structure allows a great number of possible variations, either by changing the two lateral chains on the carbon atom or by esterifying the phosphonate groups. Many bisphosphonates have been studied in animals. Each bisphosphonate has its own physicochemical and biologic characteristics, which implies that one cannot extrapolate automatically the findings from one compound to another, with respect to its actions. The ones in Fig. 2 have been investigated in humans in bone disease, eight of them being commercially available today.

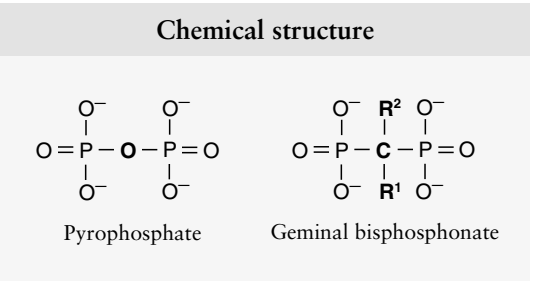

Figure 1 Chemical structure of pyrophosphate and bisphosphonates.

Physicochemical Effects

As anticipated, the physicochemical effects of most bisphosphonates are very similar to those of pyrophosphate. Thus, most inhibit the formation and aggregation of calcium phosphate crystals (Francis, 1969; Francis *et al.,* 1969; Fleisch *et al.,* 1970) and slow down their dissolution (Fleisch *et al.,* 1969; Russell *et al.,* 1970). These effects are related to the marked affinity of these compounds for the surface of solid phase calcium phosphate (Jung *et al.,* 1973), where they interfere with both crystal growth and dissolution. Binding can be bidentate through the two phosphonates, as is the case for clodronate, or it can be tridentate (Barnett and Strickland, 1979) through a third moiety, such as a hydroxyl or a nitrogen attached to the carbon atom, as is the case for most bisphosphonates used clinically today. The third binding site increases the affinity to mineral and hence the inhibitory effect on calcification.

Biological (Pharmacological) Effects

Inhibition of Bone Resorption

Bisphosphonates proved to be very powerful inhibitors of bone resorption when tested in a variety of conditions both *in vitro* and *in vivo.*

IN VITRO

Bisphosphonates block bone resorption induced by various means in organ and cell culture. In the former, they decrease the destruction of bone in embryonic long bones and in neonatal calvaria (Fleisch *et al.,* 1969; Russell *et al.,* 1970; Reynolds *et al.,* 1972). In cell culture, the bisphosphonates inhibit the formation of pits by isolated osteoclasts cultured on mineralized substrata (Flanagan and Chambers, 1989; Sato and Grasser, 1990). With few exceptions, the correlation between bisphosphonate potency *in vitro* and that *in vivo* was rather poor (Green *et al.,* 1994).

IN VIVO

Normal Animals In growing rats, bisphosphonates block degradation of both bone and cartilage, thus suppressing the remodeling of the metaphysis which becomes club-shaped and radiologically denser than normal (Schenk *et al.,* 1973). This effect is used as a model, the "Schenk assay," to study the potency of bisphosphonates (Schenk *et al.,* 1986). The inhibition of endogenous bone resorption has also been documented by ^{45}Ca kinetic studies and by markers of bone resorption (Gasser *et al.,* 1972). Effects occur within 24–48 hr and are therefore slower than that of calcitonin (Mühlbauer and Fleisch, 1990).

The decrease in resorption caused by bisphosphonates is accompanied by a positive calcium balance (Gasser *et al.,* 1972) and an increase in mineral content of bone. This is possible because of an increase in intestinal absorption of calcium consequent to an elevation of $1,25(OH)_2$ vitamin D. Bone formation also decreases after a certain time, attributed to "coupling" between formation and resorption. The main effect is, therefore, a reduction in bone turnover and some increase in bone mineral content. The increase in bone balance and the decrease in turnover are the reasons for administering these compounds to humans with osteoporosis.

Less is known about the effect in normal adult animals. In dogs and minipigs, long-term administration of alendronate did not lead to an increase in bone mass (Peter *et al.,* 1996). This might be explained by the physiological biomechanical homeostasis of bone structure, which would eliminate an unnecessary excess of bone. A 3-year clinical study of alendronate showed normal bone quality in transiliac bone biopsies (Chavassieux *et al.,* 1997), while a recent 7-year study showed safe and continuous increases in bone mineral density (Tonino *et al.,* 2000). These studies suggest that concerns about dangers of long-term use of therapeutic doses may not be warranted.

Animal Models of Hyperresorptive Diseases Bisphosphonates can also prevent experimentally induced increases in bone resorption. They impair, among others, resorption induced by agents such as parathyroid hormone, $1,25(OH)_2$ vitamin D, and retinoids (Fleisch *et al.,* 1969; Russell *et al.,* 1970). The effect on retinoid-induced hypercalcemia was developed into a rapid screening assay for new compounds (Trechsel *et al.,* 1987). Of special clinical interest are models of osteoporosis and tumor bone disease.

Osteoporosis. The first experimental model in which bisphosphonates prevented bone loss was limb immobilization by sciatic nerve section (Michael *et al.,* 1971; Mühlbauer *et al.,* 1971). Frequently used models also involve ovariectomy (Shiota, 1985; Thompson *et al.,* 1992) or orchidectomy (Wink *et al.,* 1985) in various species. In all osteoporosis models investigated the following bisphosphonates were shown to prevent bone loss: alendronate, clodronate, etidronate, ibandronate, incadronate, minodronate, olpadronate, pamidronate, risedronate, tiludronate, and zoledronate. However, it should be noted that many of these experiments were performed in growing animals, in which it is often difficult to assess to what extent the effect on bone density or bone mass is due to inhibition of sex steroid deficiency-induced bone loss, or of the bone resorption associated with modeling and remodeling during growth. Bisphosphonates were also

Fleisch, "Bisphosphonates in Bone Disease — From the Laboratory to the Patient." Academic Press, 2000, with copyright permission from the author. *(continued)*

effective in preventing bone loss in animals treated with corticosteroids (Jee *et al.,* 1981) or thyroid hormone (Yamamoto *et al.,* 1993). In another model, developed to mimic osteolysis and aseptic loosening around total hip arthroplasty, alendronate also inhibited bone destruction (Shanbhag *et al.,* 1997). Finally, of clinical importance is the finding that treatments such as prostaglandins, IGF-1, and PTH, which increase bone formation, remain effective when coadministered with bisphosphonates, sometimes resulting in additive effects on bone mass (Jee *et al.,* 1993; Takano *et al.,* 1996).

The question of bisphosphonate effects on the mechanical properties of the skeleton has also been addressed. This issue is of importance since long-lasting, excessive inhibition of bone resorption might lead to increased fragility. Numerous studies have shown that, when not given in excess, bisphosphonates produce an improvement in bone biomechanical

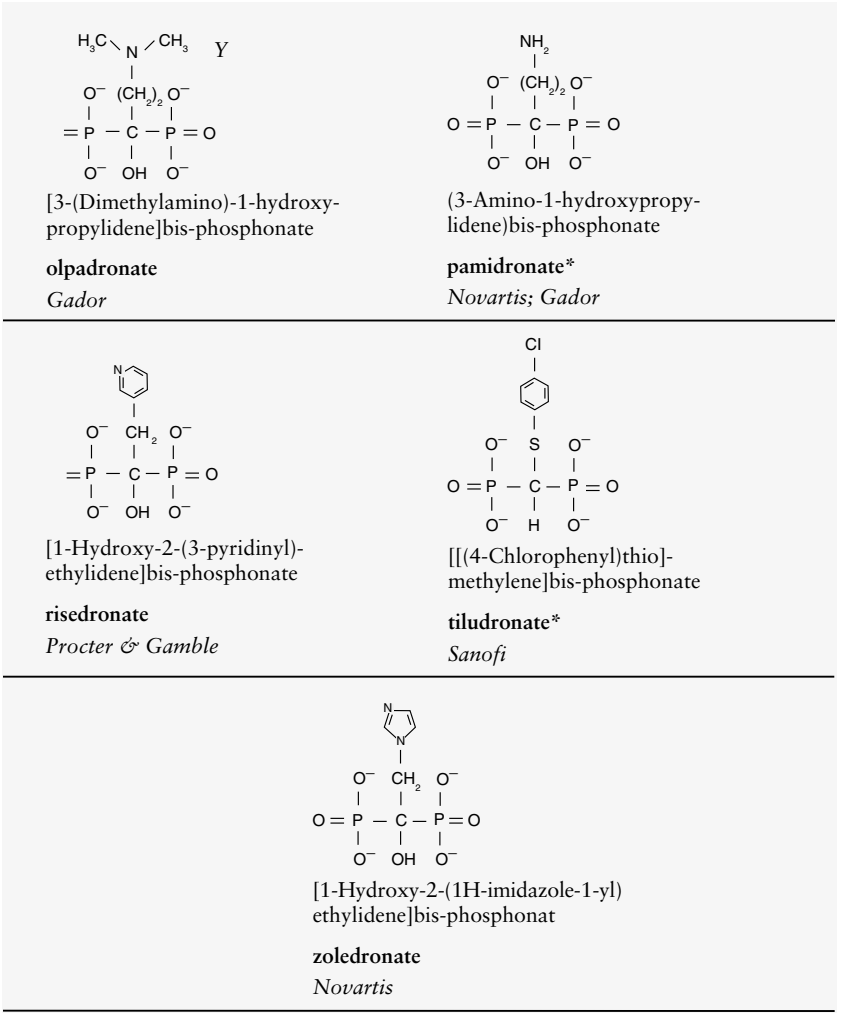

Figure 2 (*continued*)

properties, including torsional torque, ultimate bending strength, stiffness, maximum elastic strength, Young's modulus of elasticity, and others, both in normal animals and in experimental models of osteoporosis. This is the case for all the bisphosphonates mentioned above and was seen in various animals, although most experiments have been performed in the rat (Geusens *et al.,* 1992; Toolan *et al.,* 1992; Ammann *et al.,* 1993; Balena *et al.,* 1993; Guy *et al.* 1993; Ferretti *et al.,* 1993; Motoie *et al.,* 1995; for review see Ferretti, 1995).

Mechanisms of action in osteoporosis. Bisphosphonate improvement of mechanical strength may not be caused uniquely by an increase in bone mass, as previously thought, but also by an improvement in architecture and probably a reduction in bone remodeling. Indeed, a higher number of bone remodeling sites, in which there is excessive osteoclastic destruction of bone, leads to the development of areas of stress concentration and hence to increased fracture risk. Bisphosphonates may serve as a means of reducing these effects, thus reducing the incidence of new fractures. The prevention of bone loss is probably explained to a large extent by the decrease in bone turnover. The initial rise in bone mass is due to "filling of the remodeling space"; in other words bone formation continues to rebuild basic multicellular units (BMUs) initiated prior to bisphosphonate treatment, while fewer new BMUs are initiated. In addition, some bone can be lost at each BMU, because a greater amount of bone is resorbed than formed. The decrease in turnover would therefore slow down total bone loss. Furthermore, bisphosphonates also act at individual BMUs by decreasing the depth of resorption (Balena *et al.,* 1993; Boyce *et al.,* 1995). Both effects will lead to a decreased number of trabecular perforations, thus reducing the decrease in bone strength and the occurrence of fractures.

Another mechanism may be related to the increase in mineralization associated with lower bone turnover (Meunier and Boivin, 1997; Boivin *et al.,* 2000). A lower turnover will lengthen the life span of the BMU, thus permitting it to mineralize more completely, which will increase mineral content, measured as BMD, independent of effects on bone mass. This has been described in alendronate-treated baboons (Meunier and Boivin, 1997) and more recently in osteoporotic women (Boivin *et al.,* 2000). However, the above mechanisms may not fully explain the continuous increase in spinal BMD

observed during 7 years treatment of postmenopausal women with alendronate (Tonino *et al.,* 2000), which led to suggestions that bisphosphonates could stimulate bone formation, possibly by preventing osteoblast apoptosis (Plotkin *et al.,* 1999).

Tumor induced bone resorption. Bisphosphonates very effectively inhibit tumor-induced bone resorption, both *in vitro* and *in vivo,* when osteolysis is induced by circulating humoral factors as well as by local tumor invasion. All bisphosphonates which had previously been found to inhibit bone resorption were active in the tumor models, notably alendronate, clodronate, etidronate, ibandronate, incadronate, olpadronate, pamidronate, and risedronate.

In Vitro When added *in vitro,* bisphosphonates inhibit the bone-resorbing effect of supernatants of various cancers in mice calvaria (Galasko *et al.,* 1980). Inhibition was also seen when the bisphosphonates were injected into the mice before explantation of the calvaria (Jung *et al.,* 1981).

In Vivo Many types of tumor cells have been used in various *in vivo* models, such as bladder tumors, rat mammary adenocarcinoma, prostate adenocarcinoma, myeloma, and melanoma. Perhaps the best host is the nude mouse (Nemoto *et al.,* 1990; Sasaki *et al.,* 1995, 1998, 1999; Hiraga *et al.,* 1996a,b; Yoneda *et al.,* 2000). The first such studies performed showed that the humoral hypercalcemia induced by subcutaneously implanted Walker 256 carcinoma cells or by implanted Leydig tumor cells (Martodam *et al.,* 1983; Jung *et al.,* 1984; Guaitani *et al.,* 1985) could be partially prevented. Bisphosphonates also prevent or slow down bone resorption due to actual tumor invasion, as shown in several models.

One of the questions raised pertains to effects on the skeletal tumor burden. While earlier results showed no effect or even some increase, newer findings in nude mice displayed a decrease (Sasaki *et al.,* 1995, 1998, 1999; Yoneda *et al.,* 1997). This might be secondary to a local decrease in the liberation or production of tumor-stimulating cytokines such as transforming growth factor (TGF-β) and insulin-like growth factors (IGFs) following a reduction in osteolysis, thereby interfering with the "seed and soil" interactions between tumor cells and the bone microenvironment.

The effect on the development of the implanted tumors in the soft tissues is controversial, some studies showing no bisphosphonate effect and others an increase (Kostenuik *et al.,* 1993; Sasaki *et al.,* 1995; Stearns and Wang, 1996). Another open question is the effect on the osteoblastic process initiated by prostate tumor cells. In animals bisphosphonates had no effect (Pollard *et al.,* 1985), although a desirable effect was reported in humans, possibly again acting through inhibition of bone resorption, which is also present in these cancers. It should be stated that, in general, animal models are notoriously poor predictors of the efficacy of antitumor agents.

Mechanisms of action in tumor bone disease. It was generally thought that the bisphosphonates did not directly inhibit the multiplication of tumor cells, and were therefore probably not active on the tumor itself, but exerted their action by inhibiting the osteolytic process. As a secondary consequence, multiplication of tumor cells may be decreased, possibly in part because of a decrease of local cytokines stimulating tumor cell replication, released when bone is resorbed (Guise, 1997, 2000). However, it was recently reported that bisphosphonates induce *in vitro* apoptosis of myeloma cells, albeit at relatively high concentrations (Shipman *et al.,* 1997, 1998). Furthermore bisphosphonates also inhibit the adhesion of breast and prostate tumor cells onto bone matrices *in vitro* (Van der Pluijm *et al.,* 1996; Boissier *et al.,* 1997; Magnetto *et al.,* 1999). Effects on tumor attachment were seen both when the bone matrix was pretreated with and when the tumor cells were exposed to the bisphosphonate. *In vivo,* owing to the rapid accumulation of bisphosphonate in bone, the brief serum half-life, and low serum concentrations (n*M*), effects of bisphosphonates are produced primarily by the bisphosphonate on the bone surface. The degree to which tumor cells are exposed to bone-associated bisphosphonate *in vivo,* therefore, remains to be established.

Other models of bone resorption. Of interest in the dental field is the fact that bisphosphonates also slow down periodontal bone destruction in animal models of spontaneous and induced periodontitis (Shoji *et al.,* 1995; Reddy *et al.,* 1995; O'Uchi *et al.,* 1998). Furthermore, they inhibit tooth movement and alveolar bone resorption induced by orthodontic procedures, and these effects can be achieved when the compounds are administered topically (Adachi *et al.,* 1994; Yaffe *et al.,* 1997; Kaynak *et al.,* 2000).

Last, several bisphosphonates, especially risedronate, were reported to inhibit local bone and cartilage resorption, preserve the joint architecture, and decrease the inflammatory reaction in various types of experimental arthritis (Francis *et al.,* 1989; Österman *et al.,* 1994).

Relative Potency of Various Bisphosphonates on Inhibition of Bone Resorption

The activity of bisphosphonates on bone resorption in the models described above varies greatly from compound to compound (Shinoda *et al.,* 1983), which is not the case for the inhibition of mineralization. For etidronate, one of the first bisphosphonates to be investigated, the dose required to inhibit resorption is relatively high, greater than 1 mg/kg/day parenterally. Since this dose is similar to that which impairs normal mineralization, one of the aims of bisphosphonate research has been to develop compounds with a more powerful antiresorptive activity and lesser inhibition of mineralization. The first of these, clodronate, is more potent than etidronate (Fleisch *et al.,* 1969; Russell *et al.,* 1970) and less active in inhibiting normal mineralization (Schenk

et al., 1973). Later, pamidronate was found to be still more active (Lemkes *et al.,* 1978), and today compounds have been developed that are up to 10,000 times more powerful inhibitors than etidronate in inhibiting bone resorption in animals (reviewed in Fleisch, 2000). Perhaps the best way to compare potency in humans, bypassing the differences in oral bioavailability, is to examine maximally effective intravenous doses in hypercalcemia of malignancy, a condition produced by massive bone resorption. Bisphosphonate treatment is typically given in one or two intravenous doses. As a result, urinary and serum markers for resorption are typically normalized within 48 hr and resorption control can last up to about a month. Maximally effective doses of alendronate (15 mg), ibandronate (6 mg), pamidronate (90 mg), and zoledronate (2–4 mg) results in normalization of serum calcium in 77–100% of patients, depending on the study (Nussbaum *et al.,* 1993a,b; Ralston *et al.,* 1997; Body *et al.,* 1999). This suggests an overall spread in potency of about 40-fold, 6-fold if pamidronate is excluded. In animal studies the spread in potency is approximately 1000-fold for these bisphosphonates (Fleisch, 2000). Therefore, while rank ordering for potency in animals is predictive, the actual potency range is narrower in patients and has to be determined in the clinic.

Structure–Activity Relationship for Bone Resorption

Prior to elucidation of the bisphosphonate molecular target it was difficult to establish a mechanism-based structure–activity relationship. The length of the aliphatic carbon was found to be important and adding a hydroxyl group to the carbon atom at position 1 increases potency and binding to bone (Shinoda *et al.,* 1983; van Beek *et al.,* 1996). Derivatives with an amino group at the end of the side chain are very active, the highest activity being found with a backbone of four carbons, as present in alendronate (Schenk *et al.,* 1986). A primary amine is not necessary for this activity since dimethylation of the amino nitrogen of pamidronate, as seen in olpadronate, increases potency (Boonekamp *et al.,* 1987). Potency is still further increased when other groups are added to the nitrogen, as seen in ibandronate, which is extremely potent (Mühlbauer *et al.,* 1991). Cyclic geminal bisphosphonates are also very potent, especially those containing a nitrogen atom in the ring, such as risedronate (Sietsema et *al.,* 1989). The most potent compounds described so far, zoledronate (Green *et al.,* 1994) and minodronate, belong to this class. The effect of nitrogen has not yet been analyzed by molecular modeling of the interactions with the bisphosphonate target (see below), a three-dimensional structural requirement and intramolecular bonds are obviously involved. Indeed, stereoisomers of the same chemical structure have shown a 10-fold difference in activity (Takeuchi *et al.,* 1993).

Mechanisms of Action on Bone Resorption

General Concepts

Our understanding of the mode of action of the bisphosphonates has made great progress in the past few years. There is no doubt that the action *in vivo* is mediated mostly, if not completely, through mechanisms other than the physicochemical inhibition of crystal dissolution, initially postulated. Many of these mechanisms have been unraveled and more than one mechanism may be operating simultaneously.

The fact that bisphosphonates appear to act, when administered at therapeutic doses, only on bone, is due to their special affinity to this tissue. They are deposited preferentially, not in newly formed bone as previously thought, but under the osteoclasts (Sato *et al.,* 1991; Azuma *et al.,* 1995). The relative deposition on bone forming and bone resorbing areas depends upon the amount of bisphosphonate administered. When the pharmacologically active dose is small, as in the case of the more powerful bisphosphonates such as alendronate, the resorbing surface is preferentially labeled by radioactive bisphosphonate. When larger amounts are given in order to achieve pharmacological effectiveness, as in the case of etidronate, the resorption and formation surfaces are about equally labeled (Masarachia *et al.,* 1996). It has been calculated that the concentration under the osteoclasts can reach relatively high levels in the resorption lacuna, in the range of 0.1–1 mM (Sato *et al.,* 1991).

ACTIONS AT THE MOLECULAR LEVEL

It was shown that in addition to its role in targeting bisphosphonates to bone, the P–C–P backbone also substitutes for phosphate in various enzymatic reactions. The R^2 group on the carbon helps determine the specificity of these interactions. Bisphosphonates were shown to inhibit protein tyrosine phosphatases (PTPs), and inhibition of PTPs with other agents was shown to inhibit bone resorption (Schmidt *et al.,* 1996; Endo *et al.,* 1996; Murakami *et al.,* 1997; Opas *et al.,* 1997; Skorey *et al.,* 1997). However, the IC_{50}s for inhibition of several PTPs by the bisphosphonates tested correlated poorly with their potency for inhibition of bone resorption, suggesting that this was not the major antiresorptive mechanism. Recent studies point more convincingly to other mechanisms of action, which are reviewed below. Regarding the different mechanisms described, it is worth considering the possibility that any primary mechanism of action for a given bisphosphonate may occur in addition to the background inhibition of PTPs or other enzymes, such as the vacuolar ATPase, which was shown to be inhibited by tiludronate (David *et al.,* 1996). Indeed, since tiludronate is poorly metabolized into a nonhydrolyzable ATP analog (described below), or is unstable as such, it remains difficult to prioritize among the three possible mechanisms of action of this bisphosphonate. Furthermore, as intracellular concentrations of bisphosphonates increase, inhibition of secondary enzyme(s) may assume greater prominence in their overall effect.

Several recent breakthrough studies examining bisphosphonate mechanism of action have uncovered the primary sites of inhibition, that account for most of the potency of clinically used bisphosphonates. These studies paint a compelling picture pointing to two general classes of bisphosphonates: those that are metabolized within the cell to form toxic analogs of ATP (e.g., clodronate, etidronate, tiludronate) and those that inhibit farnesyl diphosphate synthase (e.g., alendronate, ibandronate, incadronate, olpadronate, pamidronate, risedronate, zoledronate). The properties that segregate bisphosphonates (BPs) into these two classes appears to be a function of the moieties attached to the geminal carbon at R^2, which can vary in size and complexity (Fig. 2). Without regard to size or shape, the prevailing determinant for mechanism of action of the bisphosphonates used in the clinic relates to the presence or absence of a nitrogen atom located three to five positions away from the geminal carbon of the P–C–P backbone in the R^2 group. Those that contain nitrogen, hereafter referred to as N-BPs, inhibit farnesyl diphosphate (FPP) synthase with IC_{50}s in the nanomolar range, while the non-N-BPs are metabolized to cytotoxic ATP analogs. Throughout the remainder of this section, the salient features of these two classes of bisphosphonate are discussed.

Metabolism of Non-N-BPs to ATP Analogs Studies in the 1970s suggested that clodronate and etidronate could affect a variety of intracellular metabolic processes, including glycolysis, lactate production, fatty acid oxidation, adenylate cyclase and phosphohydrolases (Fast *et al.,* 1978; Felix *et al.,* 1976, 1981). Since bisphosphonates are close structural analogs of inorganic pyrophosphate, it is perhaps not surprising that they can affect a wide variety of enzymes and metabolic pathways. However, none of these effects satisfactorily explain the ability of clodronate and etidronate to inhibit osteoclast function and cause osteoclast apoptosis.

The first clue to the likely molecular mechanism of action of clodronate and etidronate arose from studies using methylenebisphosphonate (medronate) as a marker to study intracellular pH in single-celled amebae of the slime mold *Dictyostelium discoideum* (Klein *et al.,* 1999). Using ^{31}P NMR to study the pH-dependent δ-shift of the phosphonate groups in medronate, new peaks were identified in the ^{31}P NMR spectrum of medronate-treated amebae. These peaks were identified as nonhydrolyzable, methylene-containing analogs of adenosine triphosphate (ATP) and diadenosine tetraphosphate (Ap_4A). The metabolites, $AppCH_2p$ and $AppCH_2ppA$, contained the P–C–P moiety of medronate in place of a P–O–P moiety (Fig. 3), and were thus resistant

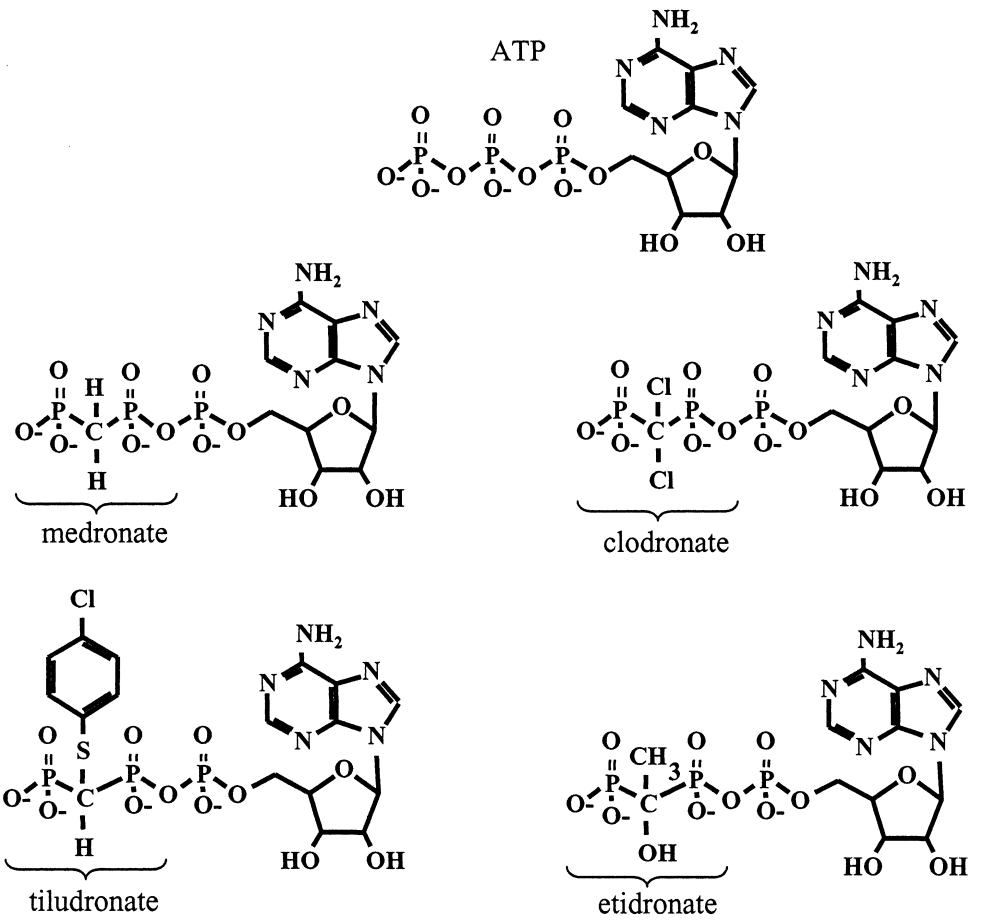

Figure 3 The structure of ATP and the AppCp-type metabolites of medronate, clodronate, etidronate, and tiludronate.

to hydrolysis. More recently, FPLC and UV absorbance as well as ^{31}P NMR analysis showed that clodronate and certain other bisphosphonates (etidronate, fluoromethylene bisphosphonate, difluoromethylene bisphosphonate, hydroxymethylene bisphosphonate) (Fig. 2) are metabolized to methylene-containing (AppCp-type) analogs of ATP, but not to analogs of Ap_4A (Rogers *et al.,* 1992, 1994; Pelorgeas *et al.,* 1992). Interestingly, bisphosphonates with larger R^2 side chains (such as the amino- alkyl bisphosphonates and heterocycle-containing bisphosphonates), which poorly resemble pyrophosphate, are not metabolized (with the exception of tiludronate). Similar results were obtained using cell-free extracts of human HL60 cells as well as human cell lines, in particular J774 macrophages which (like osteoclasts and *Dictyostelium* amebae) are highly endocytic and may internalize bisphosphonates more efficiently than most other cell types (Rogers *et al.,* 1996, 1997; Frith *et al.,* 1997; Benford *et al.,* 1999). Liposome-encapsulated bisphosphonates are internalized even more effectively by phagocytic cells, leading to greater accumulation of intracellular AppCp-type metabolites (Frith *et al.,* 1997). Preliminary studies suggest that up to 50% of clodronate internalized intracellularly is metabolized by macrophages *in vitro* to $AppCCl_2p$, which may reach an intracellular concentration as high as 1 mM (Mönkkönen *et al.,* 2000a).

A much more sensitive approach than FPLC/UV absorbance or ^{31}P NMR for the detection of AppCp-type metabolites of bisphosphonates has recently been reported, using a combination of ion pairing HPLC and electrospray ionization mass spectrometry (Auriola *et al.,* 1997; Mönkkönen *et al.,* 2000b). This method can detect $\geqslant 0.5\ \mu M$ AppCp-type metabolites in cell extracts. Using this method, the metabolites of clodronate, etidronate and tiludronate have been unequivocally identified, since the metabolites fragment upon collision-induced dissociation (bombardment with electrons), giving rise to a characteristic pattern of ions that are detected by ion-pairing electrospray mass spectrometry (Benford *et al.,* 1999; Auriola *et al.,* 1997; Mönkkönen *et al.,* 2000b) (Fig. 3). Using this method of analysis, N-BPs, such as alendronate, pamidronate, and ibandronate, do not appear to be metabolized by macrophages (Benford *et al.,* 1999).

The incorporation of bisphosphonates into AppCp-type nucleotides is probably achieved through interactions with the family of Type II aminoacyl-tRNA synthetases (which utilize the amino acids Asn, Asp, Gly, His, Lys, Phe, Ser) (Rogers *et al.,* 1994, 1996). These enzymes play an essential role in protein synthesis (Fig. 4), since they catalyze the condensation of an amino acid with ATP (Appp) to form an aminoacyl-adenylate (amino acid-AMP), releasing pyrophosphate (P–O–P) in a reversible reaction (reaction I). The aminoacyl-adenylate then condenses with a molecule of tRNA to form aminoacyl-tRNA, utilized for ribosome-dependent translation of mRNA into protein (reaction II). It appears that tiludronate and bisphosphonates with short side chains (but not more potent bisphosphonates that contain a nitrogen in the R^2 side chain) can replace P-O-P in the active site of Type II aminoacyl-tRNA synthetases, but not Type I enzymes. Since bisphosphonates (P–C–P) resemble pyrophosphate (P–O–P) in structure, the reverse reaction of (I) can occur with P–C–P in place of P–O–P, to form an analog of ATP (AppCp) containing the bisphosphonate (reaction III), a reaction demonstrated more than 30 years ago (Zamecnik and Stephenson, 1968). For medronate, difluoromethylenebisphosphonate, and hydroxymethylenebisphosphonate (but not clodronate or etidronate), AppCp can be further metabolized (to AppCppA, an analog of AppppA), by the condensation of ATP with AppCp to form AppCppA + AMP (reaction IV) (Rogers *et al.,* 1994; Zamecnik, 1983).

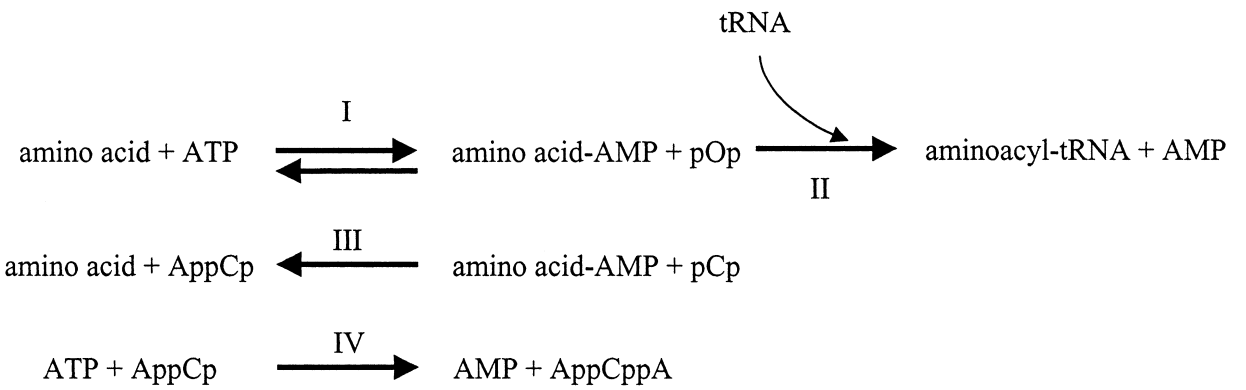

Figure 4 The mechanism by which aminoacyl-tRNA synthetase enzymes catalyze the formation of AppCp-type metabolites of bisphosphonates. An amino acid condenses with ATP (Appp) to form an aminoacyl-adenylate (amino acid-AMP), releasing pyrophosphate (pOp) in a reversible reaction (I). The aminoacyl-adenylate then condenses with a molecule of tRNA to form aminoacyl-tRNA (reaction II). Since bisphosphonates (pCp) resemble pyrophosphate in structure, the reverse reaction of (I) can occur with pCp in place of pOp, to form an analog of ATP (AppCp) containing the bisphosphonate. $AppCH_2p$, the metabolite of medronate, can condense with another molecule of ATP (reaction IV) to form an AppCppA-type nucleotide (i.e., $AppCH_2ppA$).

Although it was considered for many years that bisphosphonates were metabolically inert, the discovery that some could be metabolized intracellularly to AppCp-type nucleotides by cells *in vitro* suggested the possibility that their anti-resorptive effect may be due to the accumulation of these metabolites in osteoclasts *in vivo* (Frith *et al.,* 1997). The ability of osteoclasts to metabolize clodronate and etidronate *in vitro* has recently been confirmed, using HPLC-electrospray mass spectrometry to identify $AppCCl_2p$ in extracts of purified rabbit osteoclasts. Furthermore, the $AppCCl_2p$ metabolite of clodronate was found in extracts of osteoclasts purified by magnetic bead separation following injection of rabbits with clodronate, confirming that osteoclasts can metabolize clodronate *in vivo* (Frith *et al.,* 2000).

Inhibition of the Mevalonate Pathway by N-BPs It was while searching for squalene synthase inhibitors that the N-BPs incadronate (YM175), ibandronate, pamidronate, and alendronate were found to inhibit the mevalonate/cholesterol biosynthetic pathway (Amin *et al.,* 1992, 1996). Etidronate and clodronate, which lack nitrogen in the R^2 side chain, were inactive in the same assays. Whereas incadronate and ibandronate were shown to potently inhibit squalene synthase, alendronate and pamidronate were inactive, yet nonetheless inhibited sterol biosynthesis with IC_{50}s of 170 and 420 nM, respectively. This suggested the presence of a target upstream in the mevalonate pathway (Fig. 5, see also color plate).

FPP Synthase as the Molecular Target of the N-BPs In recent studies, (van Beek *et al.,* 1999a,b; Bergstrom *et al.,* 2000; Dunford *et al.,* 2001) the upstream enzyme inhibited by all of the N-BPs examined to date was identified as FPP synthase (Table I). The most potent anti-resorptive N-BPs such as zoledronate and minodronate (YM-529) are extremely potent inhibitors of FPP synthase (IC_{50} 3nM with respect to recombinant human FPP synthase; Dunford *et al.,* 2001). The discovery of these inhibitory activities revealed several interesting findings: (A) While alendronate is a specific inhibitor of FPP synthase, ibandronate and incadronate inhibit both squalene synthase and FPP synthase (Amin *et al.,* 1992; van Beek *et al.,* 1999b; Bergstrom *et al.,* 2000; Dunford *et al.,* 2001). The specificity of the other N-BPs remains to be determined. (B) While in enzymatic assays risedronate is 90-fold more potent than alendronate for inhibition of purified FPP synthase (Bergstrom *et al.,* 2000), it is only 5-fold more potent in crude enzyme preparations (Dunford *et al.,* 2001) and approximately equipotent for increasing bone mineral density after oral administration (5 mg po qd, 2 years) in the clinic (Bone *et al.,* 1997; Fogelman *et al.,* 2000). This suggests that differences in pharmacokinetics, pharmacodynamics, binding to bone (van Beek *et al.,* 1994, 1998), osteoclast targeting, cell permeability, or intracellular protein binding between these mechanistically similar bisphosphonates contribute significantly to their ultimate potency. (C) While risedronate is a potent inhibitor of FPP synthase, modifications (e.g., addition of a methyl group) to the structure of the R^2 side chain that influence the position of the nitrogen group in relation to the phosphonate groups give rise to analogs that are markedly less potent inhibitors of FPP synthase and less effective inhibitors of bone resorption *in vivo.* Furthermore, for a wide range of N-BPs, there is a significant correlation between potency for inhibition of FPP synthase and anti-resorptive potency *in vivo,* pointing to FPP synthase as the major molecular target of the N-BPs (Dunford *et al.,* 2001). (D) Consistent with the initial findings (Amin *et al.,* 1992), neither clodronate nor etidronate showed any significant inhibitory activity against FPP synthase (van Beek *et al.,* 1999b; Bergstrom *et al.,* 2000; Dunford *et al.,* 2001). Detailed enzymological studies will be needed to better understand the kinetics and reversibility of N-BP inhibition of FPP synthase.

Recently, computer modeling has been used to suggest that N-BPs may inhibit FPP synthase by acting as isoprenoid transition-state analogs (Martin *et al.,* 1999). The phosphonate groups of bisphosphonates appear to fit into the diphosphate binding site of the enzyme, thus explaining why modifications to either or both of the phosphonate groups (such as methylation) prevents these compounds from inhibiting protein isoprenylation (discussed below) and reduces anti-resorptive potency (Ebetino and Jamieson, 1990; Luckman *et al.,* 1998a). Importantly, this would confirm the view that the two phosphonate groups have a dual purpose (Rogers *et al.,* 1995; Luckman *et al.,* 1998a), being required for the molecular mechanism of action as well as for targeting to bone mineral (as discussed above). Furthermore, it has been suggested that the nitrogen in the R^2 side chain may act as a carbocation transition state analog, which could be stabilized by oxygen atoms in the active site cleft of FPP synthase (Martin *et al.,* 1999). The length and orientation of the bisphosphonate R^2 side chain could affect the interaction of the nitrogen in the side chain with amino acid residues in the active site cleft, hence explaining why minor changes to the structure or conformation of the side chain also affect the ability to inhibit protein isoprenylation (Luckman *et al.,* 1998b) and markedly influence anti-resorptive potency (Shinoda *et al.,* 1983; Schenk *et al.,* 1986; Sietsema *et al.,* 1989; van Beek *et al.,* 1994; Rogers *et al.,* 1995). However, the exact manner in which bisphosphonates bind to and inhibit FPP synthase remain to be clarified.

Inhibition of FPP Synthase Blocks Protein Isoprenylation and Sterol Synthesis The mevalonate pathway is not only responsible for the production of cholesterol but also isoprenoid lipids such as isopentenyl diphosphate (IPP) (five carbon), FPP (15 carbon), and geranylgeranyl diphosphate (GGPP) (20 carbon), the latter two being substrates for protein isoprenylation. Isoprenylation involves the transfer of a farnesyl or geranylgeranyl lipid group onto a cysteine residue in characteristic carboxy-terminal (e.g., CAAX) motifs (Zhang and Casey, 1996; Sinensky, 2000), giving rise to farnesylated and geranylgeranylated proteins. Most of the isoprenylated proteins identified to date are small GTPases

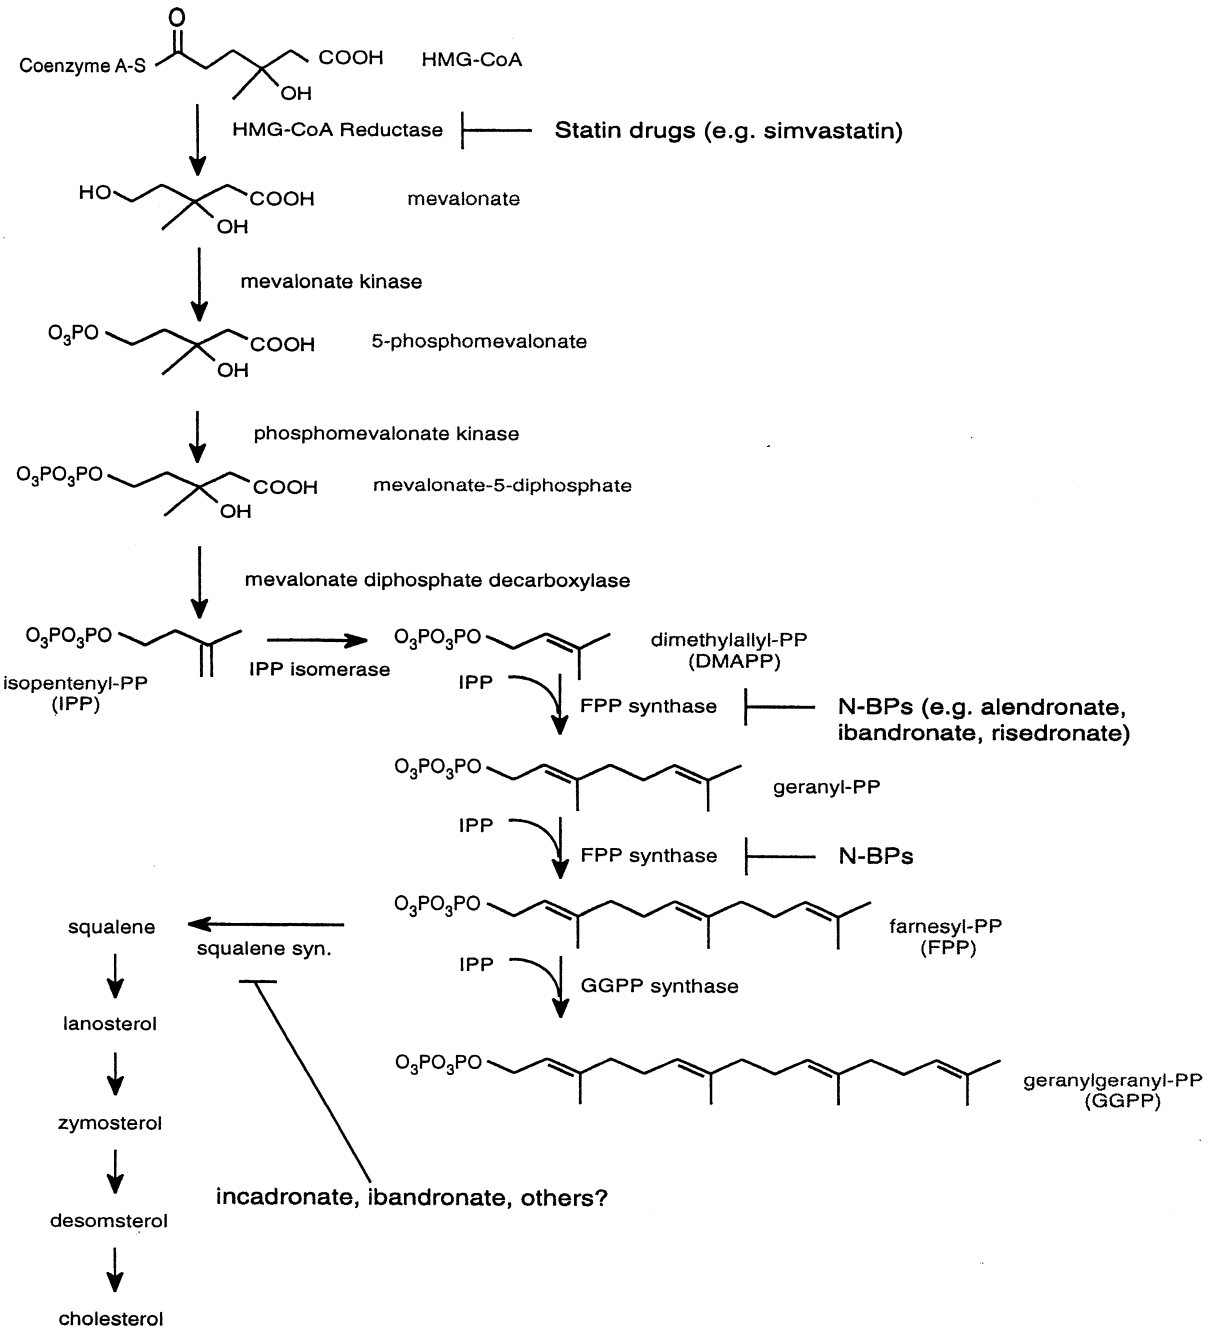

Figure 5 Metabolites in red may act via feedback to suppress HMG-CoA reductase expression in the osteoclast *in vivo*. N-BP inhibition of FPP synthase blocks (1) farnesylation, (2) geranylgeranylation, and (3) cholesterol synthesis. GGPP, required for geranylgeranylation, is the critical lost metabolite in the osteoclast. (See also color plate.)

(the majority of which are geranylgeranylated) (Zhang and Casey, 1996), which are important signaling proteins that regulate a variety of cell processes important for osteoclast function, including cell morphology, integrin signaling, membrane ruffling, trafficking of endosomes, and apoptosis (Ridley *et al.,* 1992; Ridley and Hall, 1992; Zhang *et al.,* 1995; Clark *et al.,* 1998). Isoprenylation is required for the correct function of these proteins, since the lipid isoprenyl group serves to anchor the proteins in cell membranes and may also participate in protein–protein interactions (Zhang and Casey, 1996).

The ability of N-BPs to inhibit protein isoprenylation was first directly demonstrated using J774 macrophages, where the N-BPs risedronate, incadronate, ibandronate, and alendronate were found to prevent the incorporation of [^{14}C]mevalonate into isoprenylated proteins (both farnesylated and geranylgeranylated proteins), whereas the bisphosphonates that lack a nitrogen in the R^2 side chain (clodronate and etidronate) had no effect (Benford *et al.,* 1999; Luckman *et al.,* 1998b). Risedronate almost completely inhibited protein isoprenylation at a concentration of

Table I Inhibition of FPP Synthase by Various Bisphosphonates

Bisphosphonate	IC_{50} (nM) Purified recombinant human[a]	IC_{50} (nM) Recombinant human[b]	IC_{50} (nM) Murine endogenous[c]
Alendronate	340	50	500
Ibandronate		20	310
Incadronate		30	
Minodronate		3	
Pamidronate	500	200	850
Risedronate	3.9	10	100
Zoledronate		3	20
Clodronate	NA $\leqslant$ 350,000	NA $\leqslant$ 100,000	NA $\leqslant$ 100,000
Etidronate	80,000	NA $\leqslant$ 100,000	NA $\leqslant$ 100,000

Note. Analyses of FPP synthase inhibition were performed using purified [a]recombinant human enzyme (Bergstrom *et al.,* 2000), [b]recombinant human enzyme in *E. coli* lysate (Dunford *et al.,* 2001), or [c]endogenous murine enzyme in J774 macrophage lysate (Dunford *et al.,* 2001). NA, not active/negligible inhibition.

10^{-5} M, which is similar to the concentration that affects osteoclast viability *in vitro* (Sato and Grasser, 1990; Carano *et al.,* 1990; Breuil *et al.,* 1998) and, based on findings for alendronate, could be achieved within the osteoclast resorption lacuna (Sato *et al.,* 1991). N-BPs (zoledronate, risedronate, ibandronate, alendronate, pamidronate) also inhibit protein isoprenylation in osteoclasts *in vitro.* Alendronate has been shown to inhibit incorporation of [^{14}C]mevalonate into either isoprenylated proteins or sterols (nonsaponifiable lipid) in purified murine osteoclasts (Bergstrom *et al.,* 2000), while another study found that the N-BPs alendronate, ibandronate, pamidronate, risedronate, and zoledronate, but not the non-N-BPs clodronate, etidronate or tiludronate, prevented incorporation of mevalonate into isoprenylated proteins in purified rabbit osteoclasts (Coxon *et al.,* 2000). Inhibition of protein isoprenylation in osteoclasts was dose-dependent, with alendronate inhibition at $\geqslant$15 μM, while zoledronate was effective at $\geqslant$10 μM (Bergstrom *et al.,* 2000; Coxon *et al.,* 2000).

Evidence of Bisphosphonate Action in Vivo The molecular actions of the bisphosphonates, described above, has recently been confirmed *in vivo* (Fisher *et al.,* 2000; Frith *et al.,* 2000). Direct demonstration of inhibition of FPP synthase *in vivo* is not possible, thus necessitating the use of surrogate markers for measuring this effect. In one study, the previously documented feedback regulation of HMG-CoA reductase expression by mevalonate pathway metabolites, illustrated by the induction of HMG-CoA reductase in the liver of lovastatin treated rats (Singer *et al.,* 1988), was examined (Fisher *et al.,* 2000). Rats were therefore administered bisphosphonate and expression of HMG-CoA reductase was examined in the proximal tibia. The N-BPs alendronate, ibandronate, and risedronate, but not clodronate or etidronate (which lack nitrogen), suppressed expression of HMG-CoA reductase in the osteoclast. While all three N-BPs induced changes in HMG- CoA reductase expression in the osteoclast, no changes were seen in other bone- or marrow-associated cells. This is consistent with the observed targeting of alendronate to the osteoclast and not the osteoblast, observed previously (Sato *et al.,* 1991; Masarachia *et al.,* 1996). This effect on HMG-CoA reductase expression appeared to be mediated, in part, by the accumulation of metabolites upstream of FPP synthase, since coadministration of simvastatin along with alendronate partially blocked the effect. The loss of HMG-CoA reductase expression along with inhibition of FPP synthase in the osteoclast, could potentially have additive effects on the mevalonate/cholesterol biosynthetic pathway.

In another study (Frith *et al.,* 2000), osteoclasts were examined for the actions of both alendronate and clodronate. In the case of alendronate, geranylgeranylation of the small GTPase Rap1A was measured as a surrogate marker for inhibition of FPP synthase in osteoclasts isolated and purified from rabbits that had been administered with either alendronate or clodronate *in vivo.* Whereas alendronate suppressed Rap1A geranylgeranylation in osteoclasts, but not other marrow- and bone-derived cells, clodronate was without effect. Furthermore, osteoclasts purified from clodronate-treated rabbits were found to contain the metabolite App-CCl_2p consistent with the evidence described above that this bisphosphonate has a distinct mechanism of action which does not involve inhibition of the mevalonate pathway. In light of these convincing proofs and the sizable body of *in vitro* evidence, the data strongly support the division of bisphosphonates so far into two general classes, based on their interaction with FPP synthase to suppress protein isoprenylation (the N-BPs) or their interaction with aminoacyl-tRNA synthetases to form cytotoxic ATP analogs (the non-N-BPs).

Cellular Level Actions The relationship between molecular action and anti-resorptive effects is perhaps best

documented for the N-BPs, whereby inhibition of FPP synthase appears to be integral to inhibition of bone resorption (Luckman *et al.,* 1998b, Fisher *et al.,* 1999; van Beek *et al.,* 1999c). This was clearly demonstrated by the complete restoration of bone resorption in the presence of inhibitory concentrations of alendronate and of osteoclast number in ibandronate-treated mouse metacarpal bones *in vitro* by addition of components of the mevalonate pathway, which bypass the site of bisphosphonate enzyme inhibition (Fisher *et al.,* 1999; van Beek *et al.,* 1999c). Among several downstream metabolites, only geranylgeraniol, a lipid alcohol that can replenish geranylgeranyl diphosphate, prevented inhibition of osteoclast formation and bone resorption by these N-BPs. Furthermore, the effects of lovastatin and mevastatin (which also inhibit bone resorption, prevent osteoclast formation in bone marrow cultures, and disrupt the actin cytoskeleton of osteoclasts), can also be completely blocked by addition of geranylgeraniol, but not farnesol or squalene, to osteoclast cultures (Fisher *et al.,* 1999; Woo *et al.,* 2000). Finally, a selective inhibitor of protein geranylgeranylation (GGTI-298) also inhibits bone resorption *in vitro* (Coxon *et al.,* 2000). Taken together, these observations strongly suggest that the ability to inhibit bone resorption is a consequence of loss of geranylgeranylated proteins.

The inhibition of FPP synthase by the N-BPs causes a block in the formation of isoprenoids and sterols as discussed above. This leaves several possible downstream pathways that might be implicated in N-BP inhibition of bone resorption. A number of pathways leading away from FPP synthase are linked to the regulation of gene transcription via nuclear transcription factors such as SREBP, LXR, FXR, and PPARα (Forman *et al.,* 1995; Janowski *et al.,* 1996; Hanley *et al.,* 2000; also reviewed in Edwards and Erickson, 1999). FPP and GGPP can serve as precursors for the isoprenylation of proteins, such as small GTPases, which regulate cell growth, differentiation, and survival, cytoskeletal organization and vesicular trafficking. Indeed it was originally hypothesized (Luckman *et al.,* 1998b) that inhibition of the mevalonate pathway by N-BPs and loss of isoprenylation of small GTPases such as Rho, Rac, cdc42, and Rab might account for many or all, of the various effects on osteoclast function, including loss of the ruffled border and disruption of the actin cytoskeleton (Sato *et al.,* 1991; Sato and Grasser, 1991; Selander *et al.,* 1994), altered trafficking of membranes and intracellular proteins such as the osteoclast proton ATPase (Carano *et al.,* 1990; Zimolo *et al.,* 1995), disrupted intracellular signaling by integrins (Fong and Ingber, 1996) and the induction of osteoclast apoptosis (Hughes *et al.,* 1995; Ito *et al.,* 1998, 1999; Reszka *et al.,* 1999). At the cellular level four mechanisms could be involved in bisphosphonate action (Fig. 6). These are discussed below in the context of how molecular action triggers these responses.

1. Inhibition of Osteoclast Recruitment Several bisphosphonates inhibit osteoclast differentiation in various systems of cells (Hughes *et al.,* 1989) and bones (Boonekamp *et al.,*1987) in culture. Some experiments suggest that the effect occurs at the terminal step of the differentiation process (Löwik *et al.,* 1988). At least for alendronate, addition of geranylgeraniol, a lipid alcohol used to replace the isoprenylation substrate geranylgeranyl diphosphate, was shown to partially block the inhibitory effects of N-BP on the osteoclast differentiation process (Fisher *et al.,* 1999).

2. Inhibition of Osteoclast Adhesion to the Mineralized Matrix One study *in vitro* reports that osteoclast adhesion to bone can be inhibited by alendronate (Colucci *et al.,* 1998), although the mechanism involved is unknown. Whether this takes place *in vivo* is not yet established, however, the number of osteoclasts on the bone surface increases shortly after bisphosphonate treatment (Fisher *et al.,* 2000). There is excellent evidence that bisphosphonates can inhibit the adhesion of tumor cells *in vitro* (Van der Pluijm *et al.,* 1996; Boissier *et al.,* 1997).

3. Shortening of the Osteoclast Lifespan It was reported that bisphosphonates induce osteoclast apoptosis, both *in vitro* and *in vivo,* both in normal mice and in mice with increased bone resorption (Hughes *et al.,* 1995). A recent study showed that the action of the bisphosphonates in inducing osteoclast apoptosis is direct, i.e., resulting from intracellular action within the osteoclast (Reszka *et al.,* 1999). This is true for both classes of BP. There can be no doubt that a postapoptotic osteoclast is incapable of bone resorption. However, it is important to note that apoptosis may only be the primary mechanism of bone resorption inhibition by clodronate and etidronate but not the N-BPs (Halasy-Nagy *et al.,* 1999).

For the non-N-BPs such as clodronate, the induction of apoptosis is likely due to the formation of toxic ATP analogs. In accord, the chemically synthesized metabolite of clodronate (AppCCl_2p), when liposome-encapsulated, has been shown to reduce cell viability much like clodronate itself (Frith *et al.,* 1997). The ability of AppCCl_2p to cause osteoclast apoptosis may be related to inhibition of the adenine nucleotide translocase (Lehenkari *et al.,* 2000), a component of the permeability transition pore complex in the inner mitochondrial membrane. This could lead to disruption of the mitochondrial membrane potential (Benford *et al.,* 2001) and the release of Apaf-1 and cytochrome C, causing the subsequent activation of pro-apoptotic caspases (Cohen, 1997; Crompton *et al.,* 1999; Nicholson, 1999).

The likelihood that N-BPs cause apoptosis by interfering with signaling pathways downstream of isoprenylated proteins in osteoclasts was bolstered by the observation that protein synthesis was necessary for the induction of apoptosis by N-BPs and statins (which also prevent isoprenylation) (Coxon *et al.,* 1998). N-BP-induced and statin-induced macrophage apoptosis occurs after a lag period of 15–24 hr, while in the osteoclast apoptosis is observed at $\geqslant$12 hr, although other inducers can act within 2–4 h (Reszka *et al.,* 1999). Ultimately, the importance of inhibition of FPP

synthase and the identification of possible downstream pathways was established through the demonstration that pro-apoptotic activities of the N-BPs are blocked simply by replacing lost mevalonate pathway metabolites. By adding back the metabolites, FPP and GGPP (or the more cell-permeable alcohol forms, farnesol and geranylgeraniol respectively) in J774 or JJN-3 cells, alendronate- or incadronate-induced apoptosis is blocked (Luckman *et al.,* 1998b; Shipman *et al.,* 1998; Benford *et al.,* 1999). Induction of osteoclast apoptosis by alendronate and risedronate, but not clodronate or etidronate, was blocked by addition of geranylgeraniol, but not farnesol, suggesting that only geranylgeranylation was critical (Reszka *et al.,* 1999). Consistent with this, an inhibitor of geranylgeranylation (GGTI-298), but not farnesylation (FTI-277), can induce osteoclast apoptosis *in vitro* (Coxon *et al.,* 2000).

The signaling pathways involving geranylgeranylated small GTPases such as Rho, Rac, and cdc42 that are affected by bisphosphonates and that lead to osteoclast apoptosis remain to be determined. However, Mst1 has been identified as one pro-apoptotic signaling intermediate downstream of the bisphosphonates that activated during apoptosis by N-BPs, lovastatin and clodronate (Reszka *et al.,* 1999). This kinase acts as both a substrate for caspases 3 and 7 and as an activator of these caspases (Graves *et al.,* 1998). Caspase cleavage of Mst1 results in a highly active kinase that is itself capable of initiating apoptosis. It has been very recently shown that caspase 3 is the major effector caspase activated in osteoclasts undergoing apoptosis following treatment with a range of bisphosphonates *in vitro* (Benford *et al.,* 2001).

4. Direct Inhibition of Osteoclast Activity While the former three mechanisms will lead to a decrease in the number of osteoclasts which is usually seen after longer treatment, the fourth will lead to inactive osteoclasts, often seen already at the beginning of treatment. It was reported long ago that, following bisphosphonate administration, osteoclasts show changes in morphology and appear inactive (Schenk *et al.,* 1973). The changes are numerous (Sato and Grasser, 1990) and include alterations in the cytoskeleton, including actin (Sato *et al.,* 1991; Selander *et al.,* 1994; Murakami *et al.,* 1995) and vinculin (Murakami *et al.,* 1995) as well as disruption of the ruffled border (Schenk *et al.,* 1973; Sato *et al.,* 1991). Another observation that defines the N-BPs as a class and calls to question the roles of recruitment, apoptosis, or adhesion to bone in N-BP inhibition of bone resorption, is the increase in osteoclast number found *in vivo* after treatment with alendronate, ibandronate, and risedronate, but not clodronate or etidronate (Fisher *et al.,* 2000). Unlike in previous studies where increased osteoclast numbers seen after alendronate treatment were associated with increased bone surface (Seedor *et al.,* 1991; Bikle *et al.,* 1994), the increase in osteoclast number was recently observed within 48 hr of treatment (Fisher *et al.,* 2000), which is generally considered to be the first time point at which inhibition of bone resorption occurs.

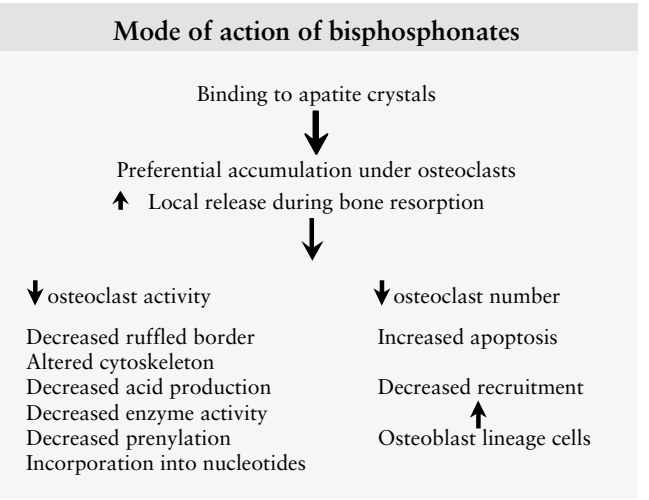

Figure 6 Summary of the effects of bisphosphonates on the osteoclast. Reproduced from H. Fleisch, "Bisphosphonates in Bone Disease — From the Laboratory to the Patient." Academic Press, 2000, with copyright permission from the author.

For the various cellular effects of the bisphosphonates on the osteoclast described above (Fig. 6), it is necessary for the bisphosphonates to either bind to or enter the cells, as has been shown to be the case *in vivo* (Sato *et al.,* 1991; Masarachia *et al.,* 1996). However, another possibility that cannot be excluded is that in addition bisphosphonates could act through the intermediary of other cells such as the osteoblast. Low amounts of bisphosphonates were shown to induce osteoblasts to secrete a factor that inhibits osteoclastic recruitment (Sahni *et al.,* 1993; Nishikawa *et al.,* 1996; Vitté *et al.,* 1996). Such an effect on osteoblasts *in vitro* is consistent with the observation that bisphosphonates can be taken up by various mammalian cell types *in vitro.* The cellular uptake is mostly into the cytosol and *in vitro* the concentration reached can be very high (Felix *et al.,* 1984). However, intracellular levels in osteoblasts *in vivo* were below the limit of autoradiographic detection, in radioisotope studies which visualized alendronate in rat osteoclasts (Sato *et al.,* 1991; Masarachia *et al.,* 1996).

Inhibition of Calcification

Like pyrophosphate, bisphosphonates can inhibit calcification *in vivo.* Thus, among others, they prevent experimentally induced calcification of many soft tissues when given parenterally or orally (Fleisch *et al.,* 1970), as well as ectopic ossification. Topical administration leads to a decreased formation of dental calculus (Briner *et al.* 1971).

If administered in sufficiently high doses, bisphosphonates can also impair the mineralization of normal calcified tissues such as bone, cartilage, dentine, and enamel (King *et al.,* 1971; Schenk *et al.,* 1973). The amount required to produce this effect varies somewhat according to the bisphosphonate

used, the animal species, and the length of treatment. However, in contrast to bone resorption where the different compounds vary greatly in their activity, they inhibit mineralization at similar doses. For most species that dose is in the order of 1–10 mg of compound phosphorus per kg per day parenterally. There is a close relationship between the ability of a bisphosphonate to inhibit calcium phosphate precipitation *in vitro* and its effectiveness at inhibiting calcification *in vivo* (Fleisch *et al.,* 1970; Trechsel *et al.,* 1977; van Beek *et al.,* 1994). Therefore, the mechanism for this effect is likely to be a physicochemical one. It is possible that other cellular effects, for example changes in the bone matrix, are involved but this remains to be proven. The inhibition of mineralization can lead to fractures (Flora *et al.,* 1980) and to impaired healing of the fractures (Fleisch, 2001). Although the inhibition is eventually reversed after discontinuation of the drug, the propensity to inhibit the calcification of normal bone has hampered the therapeutic use of bisphosphonates for ectopic calcification. However, this is not the case for their use to inhibit bone resorption, since bisphosphonates have now been developed that can inhibit resorption at doses 1000 times lower than those inhibiting mineralization. The doses used to inhibit resorption do not impair fracture healing either, when assessed by estimating biomechanical properties (Fleisch, 2001).

Other Effects

It has been suggested that bisphosphonates may also increase bone formation. Thus very low concentrations of bisphosphonates were found to increase the multiplication of various cells, including bone cells (Guenther *et al.,* 1981). Bisphosphonates were also reported to stimulate colony formation, nodule formation, mineralization, and osteocalcin synthesis in cell cultures of animal and human bone (Tsuchimoto *et al.,* 1994 Giuliani *et al.,* 1998). Furthermore, it was shown that the amount of bone formed in an individual BMU is somewhat increased during bisphosphonate treatment (Balena *et al.,* 1993; Boyce *et al.,* 1995). Thus, bisphosphonates might, under certain conditions, increase bone formation *in vivo*. However, this still needs to be confirmed.

Some reported bisphosphonate effects are difficult to explain based on their action on bone. Thus several bisphosphonates inhibit local cartilage resorption, preserve the joint architecture, and decrease the inflammatory reaction in several types of experimental arthritis, e.g., induced by Freund's adjuvant, carrageenin or collagen (Francis *et al.,* 1972, 1989; Dunn *et al.,* 1993). This effect is especially pronounced when the bisphosphonates (in particular clodronate) are encapsulated in liposomes (van Lent *et al.,* 1994; Kinne *et al.,* 1995). The fact that not only bone resorption is decreased, but also the inflammatory reaction in the joint and in the paw itself is diminished (Österman *et al.,* 1994), suggests that mechanisms other than those acting on bone are at work, possibly involving the mononuclear phagocyte system. These results open the exciting possibility of using bisphosphonates in inflammatory arthritis, given either systemically or locally, possibly encapsulated in liposomes. A recent study by Barrera *et al.* (2000) confirmed that a single intraarticular injection of lipo-clodronate caused depletion of synovial macrophages and was well tolerated in patients with rheumatoid arthritis.

Pharmacokinetics

Bisphosphonates are synthetic compounds, not found to occur naturally in animals or humans. No enzymes capable of cleaving the P-C-P bond have been discovered. The bisphosphonates studied and reported so far, including alendronate, clodronate, etidronate, pamidronate, and tiludronate, appear to be absorbed, stored, and excreted from the body unaltered, except for the incorporation of etidronate, clodronate, and pamidronate into ATP inside the osteoclast, described above. (For reviews see Papapoulos, 1995; Lin, 1996; Porras *et al.,* 1999).

Intestinal Absorption

The bioavailability both in animals and in humans is low, probably because of low lipophilicity and high negative charge. It ranges from <1 to 10% of an oral dose, is generally higher in the young, sometimes higher at higher doses, and shows a great inter- and intraspecies variation (Michael *et al.,* 1972; Recker and Saville, 1973; Yakatan *et al.,* 1982). It is generally lower for the more potent bisphosphonates. Absorption occurs to the largest extent in the small intestine and appears to occur by passive diffusion, possibly through a paracellular pathway (Boulenc *et al.,* 1993). It is diminished when the drug is given with meals, in the presence of calcium, and interestingly, also when given with coffee, tea, or orange juice (Gertz *et al.,* 1995).

Distribution

About two-thirds or more of etidronate and clodronate, half of pamidronate, but a much smaller fraction of other bisphosphonates, such as alendronate, are ultrafiltrable when in the blood. The values are strongly species dependent. The remainder is either bound to proteins, especially albumin (Lin *et al.,* 1994), or present in very small aggregates (Wiedmer *et al.,* 1983).

Between 30 and 70% of absorbed bisphosphonates are taken up by bone, the remainder being rapidly excreted in the urine (Michael *et al.,* 1972; Yakatan *et al.,* 1982). The uptake varies with species, gender, and age and can differ among compounds. While it is below 30% or less for clodronate, it is about 50% for etidronate and higher for pamidronate and alendronate. Sometimes bisphosphonates can deposit in other organs such as the stomach, liver, and

spleen. Part, if not all, of this extraosseous deposition appears to be due to the formation of complexes, occurring when too much compound is infused too rapidly. If given at therapeutic doses and infused slowly, extraosseous deposition seems to be negligible.

The half-life of circulating bisphosphonates is short, in the order of minutes in the rat (Bisaz *et al.,* 1978) and around 0.5 to 2 hr in humans. The rate of uptake in bone is very fast, bone clearance being compatible with complete first passage extraction from the circulation by the skeleton (Bisaz *et al.,* 1978). Skeletal uptake might therefore be determined to a large extent by the bone vascularization. Soft tissues are thus exposed to these compounds for short periods only, which explains their bone-specific effects.

When bisphosphonates are given at clinical doses to humans, there seems to be no saturation of the total skeletal uptake, at least not within periods as long as years or decades. In contrast, the anti-resorbing activity rapidly reaches a maximum, both in animals (Reitsma *et al.,* 1980) and in humans (Garnero *et al.,* 1994). The fact that a plateau of activity is reached despite continuous bisphosphonate accumulation in the skeleton, is consistent with entombment of the compound, where it is inactive since it is not accessible to the osteoclasts on the bone surface.

From the skeleton the bisphosphonates are liberated to a small extent by physicochemical mechanisms, such as ion exchange, but for the largest part they are released only when the bone in which they are deposited is resorbed (Kasting and Francis, 1992). Thus the half-life in the body depends upon the rate of bone turnover. It has been estimated to be up to 1 year in mice or rats (Mönkkönen, *et al.,* 1990), and much longer, up to 10 years, in humans (Kasting and Francis, 1992). It is possible that some of the administered bisphosphonate can stay in the skeleton for life. This is also true for other "bone seekers" such as tetracyclines, heavy metals, and fluoride.

Renal Clearance

The renal clearance of bisphosphonates is high. When taking into account that they are only partially ultrafiltrable, it can be as high as that of inulin or even higher, suggesting a secretory component (Troehler *et al.,* 1975; Lin *et al.,* 1992). Urinary excretion is decreased in renal failure and the removal by peritoneal dialysis is poor, which has to be accounted for when the compounds are administered to patients with kidney disease.

Clinical Use and Efficacy

As mentioned in the Introduction, in the context of this volume this chapter focuses primarily on the mechanism of action of bisphosphonates; however, we would be remiss not to briefly review the extensive current clinical use of these compounds in the treatment of many skeletal disorders. There are now safe and effective treatments for osteoporosis in both women and men; for glucocorticoid-induced osteoporosis, Paget's disease, bone metastases, and hypercalcemia of malignancy. Treatment of other conditions, e.g., osteogenesis imperfecta, are under investigation. In the following section, we briefly summarize the use and efficacy of bisphosphonates for these indications.

Postmenopausal Osteoporosis

Bisphosphonates Increase BMD

The three bisphosphonates currently available in many countries for the prevention and/or treatment of osteoporosis include (cyclical) etidronate, daily alendronate or risedronate and weekly alendronate. Etidronate administered at 400 mg per day orally for 2 weeks, followed by 11 weeks calcium alone increases BMD at the lumbar spine (LS) by 2.3 to 5.2%, at the femoral neck (FN) by up to 1.9%, and at trochanter (TR) by up to 2.9% relative to baseline (Watts *et al.,* 1990; Meunier *et al.,* 1997; Herd *et al.,* 1997). In the placebo groups, there were typically decreases in BMD at these sites (vs baseline) by up to −2.3 to + 1.2%, −2.0% and −0.6%, respectively. After treatment discontinuation, BMD declined by 1.4% (LS) and −0.9% (FN) at 12 months. In a separate 3-year etidronate study BMD increased from baseline by 5.7% (LS), 1.4% (FN), and 7.1% (TR), while in placebo, changes were 0.17% (LS), −2.97% (FN), and 1.5% (TR) (Montessori *et al.,* 1997). Relative risk of fractures at the hip or spine were not determined in the aforementioned studies, owing in part to the small population size.

Alendronate is perhaps the most extensively studied drug so far for the prevention and treatment of postmenopausal osteoporosis. The longest patient follow-up (Tonino *et al.* 2000) reported the 7-year findings of the twice extended original phase III study (Liberman *et al.,* 1995; Tucci *et al.,* 1996). The 7-year cumulative increases in BMD (versus baseline) were 11.4% (LS), 4.9% (FN), and 9.5% (TR) with daily 10-mg dosing, which was significantly higher at LS than the 5-year BMD (9.4%). Increases in BMD similar to those produced by 10 mg per day were observed when patients were given 20 mg daily for 3 years followed by 2 years with 5 mg daily. Most importantly, upon discontinuation, there was no change in BMD in the 2-year follow-up period.

Treatment for shorter duration showed rapid dose-dependent increases in BMD at the various sites. For example in a 2-year study 5 mg oral alendronate daily, increased BMD (from baseline) by 6.2% (LS), 1.9% (FN), and 4.1% (TR), while with 2.5 mg, the increases were 4.1% (LS), 0% (FN), and 1.8% (TR) (Bone *et al.,* 1997). A similar study comparing responses to 2.5 or 5 mg oral dosing in women of either Asian or Caucasian descent showed similar changes in spinal BMD in the two groups (Wasnich *et al.,* 1999). These findings were consistent across multiple studies (e.g., Adachi *et al.,* 2001; Tucci *et al.,* 1996; Liberman *et al.,* 1995). Alendronate

administered orally once weekly at 70 mg for 1 or 2 years produced very similar increases in BMD to 10 mg daily dosing, 5.1% (once weekly) vs 5.4% (daily) at LS, 2.3% vs 2.9% (FN), and 3.9% vs 4.4% (TR) observed after 12 months of treatment, which fell within equivalence bounds (Schnitzer *et al.,* 2000). The increases seen at 24 months remained comparable and were even closer.

Risedronate has also been studied extensively, using either 2.5 or 5 mg daily oral dosing. Two years of continuous daily treatment with 5 mg oral risedronate increased LS BMD by either 1.4% (vs −4.3% in placebo) or to 4.1% (vs 0% in placebo), resulting in a consistent increase of 4.1 to 5.6% over placebo (Mortensen *et al.,* 1998; Fogelman *et al.,* 2000). Discontinuation for 12 months resulted in a decline in LS BMD of 3.7% (−2.3% vs baseline), while in the placebo group BMD had further declined by 1.3% (to −5.6% vs baseline) (Mortensen *et al.,* 1998). At FN and TR, increases were 1.3 to 2.6% and ≈0.5 to 2.7%, respectively (vs baseline), while in the placebo group, BMD had declined by 1.0 to 2.4% and 0.6 to 2.8%, respectively. The 2.5-mg oral dosing increased BMD by1.4% (vs 0%, in placebo) at LS, 0.9% (vs −1.0% in placebo) at FN, and 1.7% (vs −0.6% in placebo) at TR (Fogelman *et al.,* 2000). After 3 years with 5 mg oral dosing, increases in BMD were 5.4% (LS), 1.6% (FN), and 3.3% (TR), while changes in the placebo group were 1.1% (LS), −1.2% (FN), and −0.7% (TR) (Harris *et al.,* 1999).

Bisphosphonates Reduce Fracture Risk

The best evidence for treatment-related fracture reduction reported so far was obtained with the oral bisphosphonates alendronate and risedronate. A 3-year study with alendronate showed 47 and 49% reductions in vertebral fractures and 51 and 56% reductions in hip fractures in women with a *T* score of ⩽−2.1 and −2.5, respectively (Black *et al.,* 1996, 2000). After 4 years treatment, women with an existing vertebral fracture showed a 47% reduction in vertebral fractures and a 51% reduction in hip fractures (Black *et al.,* 2000).

Analysis of the cumulative proportion of new fractures in women treated with alendronate, that already had a vertebral fracture or a BMD of $T \leqslant -2.5$, showed significant risk reduction of 59% for clinical vertebral fractures by 12 months, 27% for any clinical fracture, and 63% reduction for hip fracture by 18 months, 26% for nonvertebral fractures by 24 months, and 34% reduction for wrist fractures by 30 months (Black *et al.,* 2000).

Three years of treatment with risedronate of women who had two or more prevalent vertebral fractures at baseline reduced the risk of vertebral fracture by 49% and the risk of nonvertebral fractures by 33% in Reginster *et al.* (2000). In the HIP study, women with a *T* score of ⩽−4.0 or a combination of a *T* score of ⩽−3.0 with a hip axis length of ⩾11.1 cm showed a significant 40% reduction in hip fracture risk (McClung *et al.,* 2001). Within this group, the presence of a prevalent vertebral fracture at baseline reduced the risk of hip fracture with treatment by a significant 60%, while those lacking any vertebral fracture at baseline had a 40% (NS) risk reduction. In a separate arm, women aged ⩾80 years with ⩾1 clinical risk factor for hip fracture showed a 20% (NS) reduction in risk of hip fracture. The combined effect in all subgroups was a significant 30% reduction in the risk of hip fracture.

Several mechanisms are probably responsible for the reduction in fracture risk produced by bisphosphonate treatment (see above under mechanism of action) including increase in BMD, caused in part by increased mineralization, and the reduction in the number of bone resorption sites, reflected in reduced turnover markers.

Glucocorticoid-Induced Osteoporosis

Although glucocorticoid induced osteoporosis is caused, at least in part, by inhibition of bone formation, bisphosphonates have been very effective in treating and preventing this condition and several are approved for this indication (for review see Adachi and Ioannidis, 2000). Cyclical etidronate increased BMD in the lumbar spine by 3.8% relative to placebo in 1 year, daily alendronate by 3.3% in 1 year and 4.7% in 2 years, and daily risedronate by 2.6% in 1 year. Each of these bisphosphonates reduced vertebral fractures relative to placebo (Adachi *et al.,* 2001; Wallach *et al.,* 2000).

Paget's Disease

The earliest studies demonstrating the effectiveness of bisphosphonates for normalizing bone resorption in Paget's disease were performed with etidronate (Smith *et al.,* 1971). Several bisphosphonates have since been approved for the treatment of Paget's disease and are today the treatment of choice for this condition (for review see Grauer *et al.,* 1999). Since Paget's disease is characterized by highly active bone resorption, virtually every bisphosphonate considered for clinical use has been evaluated in this disease using various oral (tiludronate, olpadronate) or intravenous (pamidronate, zoledronate, ibandronate) regimens (Laroche *et al.,* 1999; Gonzalez and Mautalen, 1999; Buckler *et al.,* 1999).

They are administered at higher doses than those prescribed for osteoporosis, e.g., 40 mg per day alendronate or 30 mg per day risedronate, given for a limited period of time, 6 and 3 months, respectively, for these two agents. This regimen normalized alkaline phosphatase (ALP) in 63% of the patients on alendronate and 77% of those on risedronate. Most interestingly, the patients entered a long-term remission; after 18 months 86% of alendronate patients and 53% of risedronate patients still had normal ALP and were free of symptoms.

Tumor Bone Disease

The most common human tumors, breast and prostate cancer, as well as many other solid tumors, e.g., lung carcinoma

and melanoma, have frequent skeletal complications: osteolytic or osteoblastic metastases and tumor-induced hypercalcemia. Bisphosphonate treatment, in addition to antitumor therapy, has become the standard of care for these patients (for recent reviews see Major *et al.,* 2000; Diel *et al.,* 2000).

In tumor-induced hypercalcemia, most often due to the secretion by the tumor of parathyroid hormone-related peptide, bisphosphonates are given intravenously after adequate hydration. Calcium levels drop significantly after 48 hr and are fully normalized at 10 days in 69.7% of patients receiving 90 mg pamidronate i.v. and 88.4% of patients given 4 mg zoledronate i.v. The median duration of complete response was 18 days for pamidronate and 32 days for 4 mg and 43 days for 8 mg zoledronate, respectively (Major *et al.,* 2001).

The efficacy of bisphosphonates in the treatment of bone metastases is not as well established. Randomized studies with 1600–3200 mg oral clodronate per day yielded conflicting results, the positive ones showing fewer skeletal complications, but no survival advantage (with the exception of Diel *et al.,* 1998). Intravenous pamidronate given to patients with multiple myeloma was reported to decrease pain and slow down the deterioration in performance (Berenson and Lipton, 1999) without extending survival. When given to breast cancer patients, the median time to first skeletal complication is delayed by about 7 months and bone pain is reduced, again without extending survival (Hortobagyi *et al.,* 1996, 1998). It is possible that the more potent bisphosphonates currently in development, such as zoledronate or ibandronate, will have more pronounced effects on bone metastases. A most desirable goal is to reduce their incidence to begin with.

Other Diseases

There are many other conditions in which osteoclastic bone resorption is increased, either due to inflammation, such as in rheumatoid arthritis and periodontal disease, or to genetic mutations, such as in osteogenesis imperfecta and fibrous dysplasia. So far, no placebo-controlled randomized studies have shown bisphosphonate suppression of bone loss in either the periarticular lesions of rheumatoid arthritis or in periodontal disease. On the other hand, observational studies have shown significant improvement in osteogenesis imperfecta (Plotkin and Glorieux, 2000) and polyostotic fibrodysplasia (Zacharin and O'Sullivan, 2000) with intravenous pamidronate treatment.

Animal Toxicology

Toxicological animal studies have been published on alendronate, clodronate, etidronate, incadronate, pamidronate, and tiludronate. Acute, subacute, and chronic administration in several animal species have, in general, revealed little toxicity. Teratogenicity, mitogenicity, and carcinogenicity tests have been negative. When bisphosphonates are administered subcutaneously, local toxicity can occur, with local necrosis. This is especially the case for the N-containing derivatives. Mild hypocalcemia due to inhibition of bone resorption was observed at high doses. Acute systemic toxicity and hypocalcemia can also be caused following intravenous administration of high doses of less potent bisphosphonates by the formation of complexes with calcium. Some renal alterations can occur.

The chronic toxicity of the bisphosphonates is extremely low. This is probably due in part to their strong affinity for bone, which allows them to be cleared rapidly from blood. The toxic effects occur in general when doses substantially larger than those which inhibit bone resorption are used. As for polyphosphates and phosphate itself, the first alterations are usually seen in the kidney (Alden *et al.,* 1989; Cal and Daley-Yates, 1990). The liver, as well as the testis, the epididymis, the prostate, and possibly the lung, can in some cases also show changes.

Following the appearance in humans of gastrointestinal adverse events, after oral administration of N-containing bisphosphonates (De Groen *et al.,* 1996), the effects of oral bisphosphonates were studied in animals. Alendronate, given orally to rats at suprapharmacological doses, has been reported to occasionally induce gastric and esophageal erosions and ulcerations and delay healing of indomethacin-induced gastric erosions. These effects are not attributable to changes in gastric acid secretion, or prostaglandin synthesis, but are thought to be due to a topical irritant effect. Similar effects were reported with etidronate, risedronate, and tiludronate when given at pharmacologically equivalent doses. These effects were obtained at doses equivalent to (Peter *et al.,* 1998a) or much larger than the ones given in humans (Blank *et al.,* 1997; Elliott *et al.,* 1998; Peter *et al.,* 1998b).

To address the issue of mechanism, recent studies have examined apoptosis and suppression of cell growth in *in vitro* models for the esophageal stratified epithelium and the large intestine (Mönkkönen *et al.,* 2000c; Reszka *et al.,* 2000, 2001). In CACO-2 intestinal epithelium cells and in Ch1.Es esophageal fibroblasts, the N-BPs-induced apoptosis, which could be blocked with the addition of geranylgeraniol (Mönkkönen *et al.,* 2000; Reszka *et al.,* 2000). This suggested that N-BP inhibition of protein geranylgeranylation was instrumental in the apoptotic response. In normal human epidermal keratinocytes (Reszka *et al.,* 2001) and, as a second phenotype, in CACO- 2 cells, growth suppression was observed in response to N-BP treatment. In the keratinocyte, used as a model for stratified squamous epithelium lining the esophagus, this was associated with both suppression of cholesterol biosynthesis and protein geranylgeranylation, and was linked to a block in the phosphorylation of the growth regulatory protein retinoblastoma, loss of cdk2 and cdk4 expression, and enhanced association of these cdks with the inhibitors $p21^{waf1}$ and $p27^{kip1}$ (Reszka *et al.,* 2001). These recent *in vitro* studies, suggest that the N-BP-induced gastrointestinal irritation and/or delayed repair of irritation are

mediated by inhibition of FPP synthase in the affected tissues. These findings await *in vivo* validation.

The most relevant toxicity associated with the low potency bisphosphonate etidronate is the inhibition of bone and cartilage calcification, as described above (King *et al.,* 1971; Schenk *et al.,* 1973). This effect starts to occur in animals at parenteral doses of approximately 5–10 mg P/kg daily. The radiological appearance resembles rickets or osteomalacia, although there are some histological differences. Fractures can occur after long-term administration of high doses and are probably the result of defective mineralization (Flora *et al.,* 1980). Developmental disturbances of enamel can also appear at high systemic doses. This problem is not observed with the more potent bisphosphonates in current use, as these are administered at far lower doses.

Last, at least certain bisphosphonates, such as etidronate and pamidronate, cross the placenta and can affect the fetus. Very large doses can lead to a decrease in the number of live pups, to fetal abnormalities of the skeleton and the skin, and to malformations and hemorrhages (Eguchi *et al.,* 1982; Graepel *et al.,* 1992; Okazaki *et al.,* 1995). In view of these results, bisphosphonates should not be administered to pregnant women.

To summarize this section, bisphosphonates are the most effective anti-osteoporosis treatment to date, are the treatment of choice for Paget's disease and hypercalcemia of malignancy, are the standard of care for bone metastases, and have potential uses in several other skeletal conditions, all with a very good safety profile.

CHAPTER 79

Fluoride in Osteoporosis

Johann D. Ringe
Medizinische Klinik 4, Klinikum Leverkusen, University of Cologne, Leverkusen 51375, Germany

Introduction

Fluoride is an indispensable trace element with a recommended daily dose of 1.5 to 4 mg (Mertz, 1981). As is true for other essential trace elements, deficiency or excess has clinical consequences: intakes below the recommended daily dose result in growth and development retardation, while long-term high intake leads to hyperostosis or skeletal sclerosis. The latter was described for the first time in the 1940s after observation of cases with severe endemic or industrial fluorosis (Möller and Gudjonsson, 1932; Roholm, 1937; Shortt *et al.,* 1937). The same is true for the teeth. Excessive intake of fluoride may produce dental fluorosis while adequate supply reduces the risk of caries. In this latter regard, a highly successful water and topical fluoridation program has dramatically reduced the prevalence and severity of dental caries.

Success with the use of fluoride as a therapeutic agent for the skeleton has been harder to accomplish. There is no doubt that pharmacological doses of fluoride stimulate osteoblastic bone formation and significantly augment bone mass. In fact, fluoride is the most potent anabolic substance for bone available today (Caverzasio *et al.,* 1998). Positive effects on bone mass in human subjects are well documented. It is relatively bone specific, very inexpensive, and can be administered orally.

The seemingly narrow therapeutic window for the effects of fluoride on the skeleton, however, has hampered progress in this field. Despite nearly four decades of clinical experience with fluoride, uncertanties still exist about the quality of the newly formed bone tissue and the effectiveness of fluoride treatment in reducing vertebral fracture rate (Heaney, 1994). Large studies to evaluate definitively vertebral fracture rates are not available due, in part, to the low price of fluoride salts and the lack of patent protection of the product. Ringe and Meunier (1995) have therefore labeled fluoride as an orphan drug.

This point has kept major pharmaceutical companies from investing in fluoride therapy despite its obvious potential. (Kleerekoper, 1998)

Pharmacology

Gastrointestinal Absorption

A clear distinction should be made between the two mainly used fluoride salts: sodium fluoride (NaF) and monofluorophosphate (MFP) (Delmas *et al.,* 1990). NaF has been studied in the plain generic form, different types of enteric-coated tablets, or as a slow-release preparation. Since the application of plain NaF is accompanied by a high rate of mainly epigastric side effects (Riggs *et al.,* 1990; Kleerekoper *et al.,* 1991), this fluoride salt is usually given as enteric-coated and/or sustained-release tablets.

In the stomach, fluoride is absorbed by passive nonionic diffusion in the form of hydrogen fluoride (HF), the amount of HF formed being dependend on gastric acidity. Absorption is more rapid and more complete in the fasting state, when the gastric contents are more acidic. Fluoride not absorbed in the stomach is readily absorbed from the upper small intestine. Following a single oral dose of NaF administered after an overnight fast, peak serum fluoride levels are achieved rapidly with the plain form, at approximately 30 min, while this peak is delayed by up to 2–3 hr with some slow-release preparations. While intestinal absorption of NaF is as high as 95% when used as a plain preparation, different preparations may reduce the bioavailability of the fluoride ions to variable degrees (Table I). The major advantage of delayed-release and/or enteric-coated preparations lies in their fewer side effects.

Disodium-monofluorophosphate (Na_2PO_4F) usually called MFP has the same high intestinal absorption rate as plain NaF (95–100%), but a significantly lower rate of gastrointestinal

Table I Differentiated Dosage of Fluoride Using Sodium Fluoride (NaF) or Monofluorophosphate (MFP) Based on Fluoride Content and Bioavailability from the Two Salts

	NaF	MFP
Range of usual dosages/day (mg)	50–80	100–200
Fluoride content per 100 mg (mg)	45.5	13.2
Mean bioavailability (%)	60[a]	95
Average absorbed fluoride from 100 mg substance (mg)	27.3	12.5
Equivalent total amount needed if 15 mg fluoride lons is to be absorbed (mg)	55	120

[a]Average estimated bioavailability; depends on type of enteric-coated or sustained-release preparation.

side effects (Müller *et al.,* 1992). This fluoride compound dissociates in a acqueous milieu into Na+ and $(FPO_3)_2$ ions. The monofluorophosphate ion is absorbed before hydrolisis mainly in the upper small intestine. It then becomes hydrolyzed by alkaline phosphatases in the intestinal mucosa into fluoride and phosphate ions. The low rate of epigastric side effects of MFP are due to the fact that no irritating free fluoride ions are released in the gastrointestinal tract before absorption (Müller *et al.,* 1992). New sustained-release formulations of MFP are being investigated (Erlacher *et al.,* 1995).

Effects of Food and Calcium

Another important difference between the two fluoride salts is the effect of food and the presence of calcium in the gut on their respective absorption and bioavailability. Given the marked gastric irritability of plain NaF, and the need to provide adequate calcium during long-term treatment of osteoporosis with fluoride, interference by calcium with fluoride absorption has major therapeutic implications. Ekstrand and Spak (1990) demonstrated that after ingestion of a solution containing 20 mg of NaF, peak plasma concentration achieved was 848 ± 116 ng/ml at 0.46 ± 0.17 hr. When NaF was supplied as a 20-mg sustained-release tablet, absorption was delayed (1.85 ± 0.63 hr) and a lower peak plasma level was achieved (336 ± 58 ng/ml). Absorption was further delayed (2.86 ± 1.75 hr) and lower peak plasma levels were achieved (252 ± 86 ng/ml) when the tablet was coadministered with 500 mg of calcium carbonate. In a separate study, enteric-coated NaF was administered in two divided doses of 10 mg each, 12 hr apart. Peak plasma levels after the morning dose taken following an overnight fast were obtained at 3.3 hr. Peak plasma levels following the second dose given after just 4 hr without food were not obtained until 6.1 hr later. Assuming 100% bioavailability from the solution of fluoride, they concluded that bioavailability from sustained-release NaF was approximately 90%, reducing to approximately 65% with enteric-coated tablets, and further reduced to 30–40% if calcium and/or food had been previously ingested.

Pak *et al.* (1986, 1989) have evaluated the absorption of a slow-release preparation of NaF (SR-NaF). Not only was there a delayed absorption, but total absorption as assessed by the area under the curve (AUC) of plasma F levels as a function of time postadministration was markedly decreased. This resulted in a flatter pharmacokinetic dynamic for F than with other preparations, a potential advantage since it seems to be important to avoid high peak serum levels (Table VI).

It is recommended that NaF be taken separate from the time of administration of calcium. In contrast, MFP is generally administered together with calcium in the same tablets because there is no interaction with calcium in the upper gastrointestinal tract. When MFP is taken with meals, a slower kinetics of fluoride absorption ensues, which helps to avoid excessively high plasma levels.

Serum Levels

In normal adults, who are not knowingly ingesting fluoride fasting plasma levels range from 0.5 to 2.3 μM (8.5–45 ng/ml). Concentrations progressively increase with age (Husdan *et al.,* 1976). The "therapeutic window" has been estimated at between 5 and 10 μM (95–195 ng/ml) (Taves, 1970) but the evidence to support this therapeutic window is quite limited. On the basis of different studies relating the dose of NaF to the annual rate of increase in bone mass Kleerekoper and Balena (1991) found that a dose less than 30 mg/day (=13.7 mg fluoride ions) is the minimum dose at which an effect of bone mass is seen. Doses between 30 and 50 mg/day cause is a rapid increase in anabolic effect of fluoride; above that dose, a flattening of the dose–response curve occurs. This relatively narrow dose–response range is consistent with a narrow therapeutic window, such as the postulated twofold concentration range of 5–10 μM. The major concern about exceeding the therapeutic window for serum F is predominantly related to potential long-term deleterious effects on the skeleton.

Renal Excretion

After absorption fluoride is either deposited in bone or excreted by the kidney. Renal excretion of fluoride is positively correlated with serum fluoride levels (Ekstrand *et al.,* 1978). Some investigators have suggested that renal fluoride excretion can be used as an index to predict the skeletal response to fluoride therapy. Duursma *et al.* (1987, 1990) found a significant positive correlation between changes in average BMD values and 24-h urinary excretion of F in patients treated with fluoride for 1 year or more. The positive relationship could reflect simply the higher serum concentrations of fluoride achieved (Kraenzlin *et al.,* 1990).

The extrarenal clearance of fluoride (about 80 ml/min) reflects mainly accretion into bone (Ekstrand *et al.,* 1978). On average, about 50% of the absorbed fluoride dose is deposited in the skeleton, and most of the remainder is excreted in the urine. The uptake of fluoride by the bone tissue is not homogeneous, with a higher proportion taken

up by cancellous sites than by cortical sites. This may account for the heterogeneous response of different skeletal regions observed in clinical studies.

It should be emphasized that, inasmuch as the kidney is the major excretory route for fluoride, patients with impaired renal function should be given fluoride cautiously. Fluoride is not contraindicated but the dosage must be carefully adjusted depending upon the fluoride serum level.

Effects on Bone Cells

There is general agreement that fluoride stimulates bone formation directly without the need of prior bone resorption, a point that may help to explain why this element is so effective in increasing bone mass. The first *in vitro* evidence that fluoride acts directly on osteoblasts to stimulate proliferation was reported by Farley *et al.,* in 1983. These studies were prompted by earlier bone morphometric studies showing that the positive effect of fluoride treatment on bone balance was due mainly to augmented bone formation without increased bone resorption. The increased formation rate was related to an increased number of osteoblasts (Briancon and Meunier, 1981).

The *in vitro* mitogenic activity of fluoride was confirmed subsequently by several groups studying for bone cells of different species, including humans (Bellows *et al.,* 1990; Marie *et al.,* 1990; Khokher and Dandona, 1990). The optimal *in vitro* mitogenic dose of fluoride varies depending on culture conditions ranging between 5 and 100 μM, which encompasses the effective serum fluoride level of about 10 μM in treated patients (Libanati *et al.* 1996). It has been demonstrated that fluoride treated bone tissue is more resistant to resorption than untreated bone (Grynpas and Cheng, 1988). This is more likely to be the consequence of a more stable crystal lattice of fluorapatite as compared to hydroxyapatite than any direct inhibitory effect of F on osteoclasts (Eannes and Reddi, 1979). In isolated systems, doses of NaF up to 500 μM (substantially greater concentrations than are seen with NaF therapy) are without effect on osteoclasts. Higher doses are cytotoxic to both osteoclasts and osteoblast (Bellows *et al.,* 1990). Except at these very high concentrations, osteoclast number, resorption depth, and other histologic features of bone resorption are affected minimally by NaF therapy.

Molecular Mechanisms of Action

The precise mechanism(s) of the bone-specific mitogenic potential of fluoride is still unknown. Several hypotheses have been proposed, but none explains all observations made so far. Fluoride requires the presence of a bone cell growth factors, such as insulin-like growth factor I (IGF-I) or transforming growth factor β (TGF-β) to stimulate bone cell proliferation (Libanati *et al.,* 1996). Therefore, fluoride may be considered as a mitogen enhancer rather than a bone cell mitogen per se. Furthermore, the mitogenic effect of fluoride is dependent on the phosphate concentration of the medium. Finally, there is evidence that fluoride acts more on progenitor cells and preosteoblasts, which produce large amounts of growth factors, with only small effects on mature osteoblasts (Kassem, 1994). Still unexplained also is the cell and tissue specificity of fluoride's mitogenic action. Recent studies indicate that an increased level of tyrosyl phosphorylation of a protein that regulates mitosis (MAP kinase) could be involved (Lau and Baylink, 1998). The most likely explanation for the increased tyrosyl phosphorylation of key mitogenic proteins is the ability of fluoride to inhibit a specific osteoblastic phosphotyrosyl protein phosphatase (PTPP). Interestingly, this growth factor dependent tyrosine phosphorylation pathway of fluoride action is enhanced further in the presence of aluminum (Caverzasio *et al.,* 1996).

Side Effects

No teratogenic effects attributable to fluoride have been observed at therapeutic doses in human subjects. The two main adverse effects during fluoride therapy are gatrointestinal and osteoarticular effects. Gastrointestinal side effects occur more frequently when non-enteric-coated NaF is used. A typical example was provided by the two aforementioned American double-blind studies (Riggs *et al.,* 1990; Kleerekoper *et al.,* 1991) using simple capsules containing plain NaF. In contrast, epigastric symptoms are rarely reported with sustained-release and/or enteric-coated NaF tablets (Pak *et al.,* 1986), and when they do occur they are mild in nature. When MFP is used, it is rare to note gastric side effects. The better gastric tolerance of MFP compared with NaF has also been documented by a gastroscopic study (Müller *et al.,* 1992).

Osteoarticular symptoms mostly affecting the ankles or the calcaneus are referred to as "lower limb pain syndrome" (O'Duffy *et al.,* 1986). Pronounced cases appear on the roentgenogram as low-contrast intraosseous coarsening (Fig. 1) and as hot spots on the scintigram. They tend to correspond to mineralization defects located in the microcallus of trabecular microfractures (Boivin *et al.,* 1991). If treatment is discontinued for 4 to 6 weeks, symptoms abate and radiological findings return to normal. Therapy may then be started again with an initially lower dose.

Calcium Deficiency and Stress Fractures.

Very rapid and large increases in bone formation in response to fluoride may lead to calcium deficiency, undermineralization of newly formed osteoid, and secondary hyperparathyroidism (Duursma *et al.,* 1987; Dure-Smith *et al.,* 1996). The evidence that osteomalacia can occur during fluoride treatment is documented by morphometric studies Libanati *et al.,* 1996). Low urinary calcium excretion developing during fluoride therapy is a marker for calcium deficiency. Fluoride therapy should always be combined with calcium supplements (500–1000 mg/day) and in

Figure 1 Lateral X-ray of ankle region of 74-year-old patient with postmenopausal osteoporosis with severe "osteoarticular pain" during treatment with MFP/calcium. In the distal tibia a horizontal intraosseous area of coarsening can be identified parallel to the joint surface (lower limb pain syndrome).

Figure 2 Lateral X-ray of the lumbar spine of a 58-year-old woman. Iatrogenic fluorosis already 3 years after start of fluoride treatment (fluorosis type I, see text).

elderly persons combined also with vitamin D supplements (e.g., 800 IU vitamin D, 1200 mg calcium per day). In some cases, a short-term treatment with an active metabolite (alfacalcidol 1 μg/day) may be indicated to normalize bone mineralization more rapidly.

When calcium deficiency is severe, fluoride-induced osteomalacic stress fractures may occur. Classical Looser zones may be seen radiologically. With adequate calcium/vitamin D, fluoride is unlikely to be associated with osteomalacia. In studies reporting an increased risk of peripheral fractures during fluoride therapy very often no clear distinction was made between true fractures, stress fractures, Looser zones, or subjects with lower limb pain syndrome (Riggs *et al.,* 1990)

Iatrogenic Fluorosis

Iatrogenic fluorosis is not a drug side effect as such but the result of incorrect therapy. We observed two forms. The first type very quickly (often in less than 24 months) produces a distinct sclerosed bone structure in the lateral roentgenogram or the spine. In such cases it has always been found in retrospect that the diagnosis of osteoporosis was based on a poor X-ray film; i.e., that osteoporosis was probably not present at the start of fluoride treatment. An individually strong response to fluoride therapy might be involved or a potentiation of fluoride effect by aluminum (Caverzasio *et al.,* 1996). The second type of iatrogenic fluorosis occurs in patients with established osteoporosis only after excessively long-term and/or high dosage fluoride treatment, i.e., usually after 6–10 years. While in the first type normally shaped vertebrae show a more or less white, ivory-like appearance (Fig. 2), for the second type, coarsening of the previously impressed end plates and a remarkable thickening of the trabeculae are characteristic (Fig. 3).

Prevention of Osteoporosis

Over the past three decades, the classical indication for fluoride was mainly established postmenopausal osteoporosis (Ringe, 1997), with the aim of continuously increasing

Figure 3 Lateral X-rays of the lumbar spine of a 68-year-old woman with established osteoporosis. (Left) At onset of treatment, fractures at L1 and L2. (Right) After 8 years high-dose fluoride therapy (36 mg fluoride ions per day) iatrogenic fluorosis and new fractures at L3 and L4 (fluorosis type II, see text).

bone mineral density (BMD) at the lumbar spine and thereby decreasing vertebral fracture incidence. Theoretically bone-forming drugs should be able to increase bone mass above the critical fracture threshold in all stages of osteoporosis. It must be taken into consideration, however, that the lower the initial bone mass the more advanced is the microarchitectural deterioration of spongy bone. If an anabolic treatment is only able to increase the diameter of the remaining trabeculae this treatment should start also as early as possible and would be of limited value in the very advanced cases of osteoporosis. On the other hand, in healthy postmenopausal women with mild osteopenia (i.e., rather well-preserved trabecular bone connectivity and still extended endosteal surfaces) an anabolic substance might be extremely effective (Kleerekoper and Mendlovic, 1993; Ringe, 1997). This interesting concept of an early therapy of postmenopausal spinal osteoporosis has never been tested in sufficiently large trials.

Only three small fluoride studies have been performed to prevent osteoporosis, or increase BMD, in early postmenopausal women with moderate osteopenia (Pouilles *et al.,* 1991; Affinito *et al.,* 1993; Sebert *et al.,* 1995). Consistent increases in lumbar spine BMD were recorded, but the studies were too small to evaluate fracture events.

Combinations of fluoride with hormone replacement therapy (HRT) are more effective than fluoride alone. Gambacciani *et al.* (1995) were able to show that a dose as low as 10 mg fluoride ions per day given as MFP was associated with a significant additive effect on lumbar spine BMD in early postmenopausal women in comparison with that seen with HRT alone. Alexandersen *et al.* (1999) studied 100 healthy postmenopausal women treated with four different regimens: HRT, MFP, HRT + MFP, or placebo. In the combined treatment group they found a strong synergistic effect of HRT and MFP and biochemical markers, indicating a dissociation of bone formation and resorption.

Water Fluoridation

Although the benefit of fluoridation of drinking water in the prevention of dental caries has been overwhelmingly substantiated (McDonagh *et al.,* 2000), the effects on BMD and fracture rates turned out inconsistent (Ringe, 1998).

The majority of evidence regarding the effect of fluoride in drinking water on fracture incidence is based on comparisons of fracture rates by geographic regions with different concentrations of fluoride in drinking water either naturally or adjusted.

In 1955, Leone *et al.* observed that radiographic signs of osteoporosis were substantially less severe in people living in Bartlett County, Texas, with a water fluoride content of 8 ppm (ppm = mg/kg) than in Framingham, Massachusetts, with a water fluoride content of 0.09 ppm. This observation led to a study in two communities in North Dakota with different water fluoride levels. Higher BMD by X-ray in 300 subjects living in the high-fluoride area was noted. They also noted a significant reduction in osteoporotic fractures in the lumbar vertebrae in the women in this community. However, there was no difference in the prevalence of these fractures in the men in the two areas (Bernstein *et al.,* 1966).

A rather large number of studies comparing rates of fractures specific for age and sex between fluoridated and nonfluoridated communities have variously found that exposure to fluoride by water increases the risk of hip and other nonvertebral fractures (Danielson *et al.,* 1991; Jacobsen *et al.,* 1990), has no effect on fracture incidence (Madans *et al.,* 1983; Cooper *et al.,* 1990), or decreases the risk of hip fractures (Simonen and Laitinen, 1985; Jacobsen *et al.,* 1993).

In a more recent study from Germany, data from two towns of the former German Democratic Republic could be compared (Lehmann *et al.,* 1998). In the city of Chemnitz drinking water had been fluoridated with 1 ppm (1 mg/liter) for a period of 30 years, while the town of Halle had no fluoridation during the same interval. Calculating age-adjusted incidences, significantly fewer hip fractures occurred in Chemnitz in both men and women (Fig. 4). However, the authors found no significant differences in BMD values in the populations of the two towns and speculated that with 1 ppm fluoride no anabolic blood level of fluoride can be reached. The lower fracture rate, however, could be

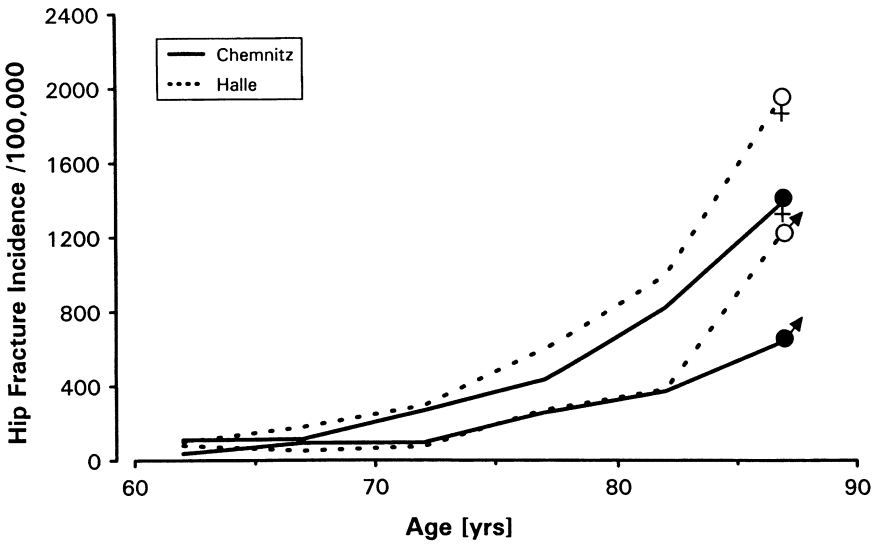

Figure 4 Annual incidences of hip fractures given in 5-year groups for men and women in the towns of Chemnitz with water fluoridation, and Halle without fluoridation (solid line, Chemnitz; dotted lines, Halle). (According to Lehmann *et al.,* 1998.)

explained by a higher content of less soluble fluorapatite in the skeletons of the population of Chemnitz, i.e., a long-lasting lowered rate of bone resorption (Allolio and Lehmann, 1999). Very recently a large prospective multicenter study on 9704 elderly women was published (Phipps *et al.,* 2000). The aim of this study was to determine whether, on an individual level, older women with long-term exposure to fluoridated water had different BMD and fracture rates compared with women with no exposure. The women, all ambulatory and without bilateral hip replacement, had been enrolled during 1986–1988. Of the total, 7129 could provide information on exposure to fluoride for each year from 1950 to 1994. The BMD results of this study are given in Table II. In women with continuous exposure (group C) BMD was 2.5% higher at the lumbar spine, 2.6% higher at the femoral neck, and 1.9% lower at the distal radius ($P < 0.001$ for all three sites). Women in group C had a significantly reduced risk of hip fractures (RR, 0.69; 95% confidence interval, 0.50 to 0.96; $P = 0.028$). The relative risk for vertebral fractures was reduced to 0.73 (confidence interval, 0.55–0.97; $P=0.033$). There was no significant effect on fracture incidence in women with intermittent "mixed exposure" (Table III).

These findings may have enormous importance for public health. It is the first prospective study with adequate power to examine the risk of specific fractures associated with fluoride on an individual rather than community basis. The study shows that long-term exposure to fluoridated water will lead to a significant reduction in the incidence of hip and vertebral fractures in elderly women. The authors conclude that fluoridation may be one of the most cost effective methods for reducing the incidence of fractures related to osteoporosis (Phipps *et al.,* 2000).

Table II Multivariate Adjusted Bone Mineral Density (g/cm^2) by Exposure to Fluoride in Drinking Water 1971–1990 (Phipps *et al.,* 2000)

Category	A No exposure	B Mixed exposure	C Continuous exposure
Patients (*n*)	2563	1348	3218
Mean age (years)	74,5	74,2	73,9
Lumbar spine	0.849	0.853	0.871*
Fem. neck	0.647	0.652	0.664*
Distal radius	0.371	0.362	0.364*

*P value A vs C. 0.001.

Treatment of Established Postmenopausal Osteoporosis

Earlier Clinical Trials

There is a large body of radiologic and densitometric evidence that long-term fluoride treatment increases bone mass mainly at bone sites with a high proportion of trabecular

Table III Reduced Risk of Incident Fractures According to Exposure to Fluoride in Drinking Water (Phipps *et al.,* 2000)

	Mixed exposure	Continuous exposure
Spine	$P = 0.096$	$P = 0.033$
Hip	$P = 0.126$	$P = 0.028$
Wrist	$P = 0.628$	$P = 0.051$

bone (Ringe *et al.,* 1978; Eriksen *et al.,* 1988; Kleerekoper and Mendlovic, 1993).

The first controlled study showing a positive effect of 50 mg/day NaF on vertebral fracture incidence was published by a French group in 1988 (Mamelle *et al.,* 1988). These findings were supported by a large retrospective American study showing a correlation between increase in vertebral mineral density and decrease in fracture rate (Farley *et al.,* 1992). In 1990–1991, however, two placebo-controlled studies reported a discrepancy between gain in BMD and fracture rates (Riggs *et al.,* 1990; Kleerekoper *et al.,* 1991). In the very often cited study of Riggs *et al.* (1990), 75 mg/day of plain NaF had been given over 4 years. The gain of bone density at the spine was 36% at the end of the study (= 9% increase per annum). There was also a small increase at the proximal femur but a significant loss at the radius although 1500 mg calcium was supplemented daily. The reason was obviously the very high fluoride dose corresponding to approximately 34 mg bioavailable fluoride ions per day. Doubts concerning fluoride therapy were fueled by this widely publicized study and the other study with similar design and results (Kleerekoper *et al.,* 1991), because the rate of vertebral fractures after 4 years was not significantly lower in the fluoride–calcium group than in the placebo–calcium group.

An extension and new analysis of the Riggs study, however, published 4 years later, showed a reduction of the vertebral fracture rate with lower fluoride doses; i.e., it was conceded that the original dosage of fluoride was too high (Riggs *et al.,* 1994).

More Recent Studies

Several important studies have appeared since 1994, demonstrating positive effects of a long-term fluoride therapy on fracture incidence in postmenopausal osteoporosis (Pak *et al.,* 1994, 1995; Farrerons *et al.,* 1997; Reginster *et al.,* 1998). These studies were performed with NaF or MFP at different doses but for all the range of daily applicated bioavailable fluoride ions was between 10 and 20 mg.

The 4-year study of Reginster *et al.* (1998) was a randomized, double-blind, controlled trial in 200 cases of postmenopausal osteoporosis (initial lumbar spine BMD <-2.5 *T* score). There was a progressive but moderate increase at the spine reaching 10% after 4 years. The rate of new vertebral fractures after 4 years was significantly lower for the MFP group with 2.4% than in the calcium group with 10%. Obviously a slow and moderate increase of BMD appeared to be better than a rapid and high gain in BMD (e.g., 36% after 4 years in the Riggs study (1990)).

Despite these very positive results, the discussion of the definitive clinical value of fluoride treatment is not at its end. In a randomized controlled French study of 2 years duration with four different treatment arms, no significant effect of fluoride on fracture rate could be documented in comparison to vitamin D/calcium supplementation (Meunier *et al.,* 1998). On the other hand, a prospective controlled study from our group performed on 134 women with established postmenopausal osteoporosis showed a dose-dependent fracture-reducing potency (Ringe *et al.,* 1999).

In this three-arm study, all patients received 1000 mg calcium per day and group A additionally a low-dose intermittent fluoride schedule (114 mg MFP = 15 mg fluoride ions, 3 months on, 1 month off), group B a higher continuous fluoride dosage (152 mg MFP = 20 mg fluoride ions), and group C no fluoride. Table IV shows the yearly and total incidences of new vertebral fractures for the three groups. Although the annual increase in lumbar spine BMD was lower in group A than in group B (4.2% versus 6.5%) the lowest fracture rate was found in group A. The statistical analysis proves significantly lower fracture rates for both fluoride groups as compared to calcium alone, but no significant difference between the two fluoride regimens (Ringe *et al.,* 1999). Furthermore the incidence of the lower limb pain syndrom was significantly lower in group A with lower dose intermittent application of fluoride. Intermittent fluoride therapy had previously found significant advantages of intermittent administration by histomorphometric analysis (Schnitzler *et al.,* 1997).

Altogether today much more positive results are documented in the literature than negative experiences. A meta-analysis, however, is difficult because of the aforementioned differences in the fluoride salts used, preparations, and

Table IV Effects of Two Different Fluoride/calcium Regimens or Calcium Alone on the Incidence of New Vertebral Fractures (Ringe *et al.,* 1999)

	Group A (MFP/Ca intermittent)	Group B (MFP/Ca continuous)	Group C (Ca only)
After 1 year	4/4 (10.5)	10/6 (16.2)	9/9 (21.9)
After 2 years	4/4 (11.4)	6/6 (18.7)	16/14 (35.9)
After 3 years	1/1 (3.1)	1/1 (3.3)	11/11 (32.4)
Within 3 years	9/8	17/12	36/30
Patient-years	105	100	114
New fractures per 100 patient-years	8.6	17.0	31.6

Note. Values are number of fractures/number of patients (%).

dosages in the different studies. As an additional explanation for discrepant study results, Kleerekoper (1998) suggests that the trials have included patients with different severity of disease and that there may be a point in the bone loss spectrum at which even a potent bone-stimulating agent such as fluoride is ineffective.

Effect on Cortical Bone

Hodsman and Droost reported that patients who did not respond to NaF with an increase in spinal bone mass had no change in forearm BMD, while those who did increase spinal bone mass lost bone from the forearm at the remarkable rate of 7.7% per year (Hodsman and Droost, 1989). Similarly, Christiansen *et al.* (1980) reported a 3.6% annual rate of loss of forearm bone mass in their fluoride-treated patients, but this was not different from the 3.3% annual rate of loss in their placebo-treated patients. In this preventive trial comparing fluoride and HRT the fluoride dose of 20 mg NaF per day (= 9.1 mg fluoride ions) was obviously below the therapeutically effective threshold of 10 mg fluoride ions per day. Most earlier studies had reported no significant changes in forarm BMD during fluoride therapy. In our own first study from 1978 there was even an increase at the radius shaft and distal radius (Ringe *et al.,* 1978). In the two placebo-controlled American studies the one of Riggs *et al.* (1990) reported a decrease at the radius while the one of Kleerekoper *et al.* (1991) found no effect, although the same fluoride regimen was used in both studies. Those who report an increased loss of appendicular (cortical) bone in fluoride-treated patients have postulated that the increase in spinal bone mass occurs at the expense of the appendicular skeleton (Hodsman and Droost, 1989; Riggs *et al.,* 1990). They have postulated further that this phenomenon may explain the alleged increased occurrence of appendicular fractures in fluoride-treated patients. There are several reasons to question this hypothesis. The appendicular fractures that have been attributed to fluoride therapy are predominantly incomplete stress fractures of the lower extremities. These fractures (see Side Effects above) are felt not to result from accelerated bone loss but from excess osteoid accumulation.

Taken together we conclude that the effect of fluoride on cortical bone may be in part dose dependent. With high fluoride dosage and very rapid increase of trabecular bone formation, slight decreases in cortical bone may occur, especially in patients with simultaneous calcium/vitamin D insufficiency. Important advantages of the low dose fluoride therapy are a continuous moderate increase of trabecular bone and no decreases or even slight increases of cortical bone (Peichl *et al.,* 1995; Ringe *et al.,* 1999).

Hip Fractures

An increased rate of hip fractures during fluoride therapy was reported in 1984 and 1990 by Gutterigde *et al.,* and again by Hedlund and Gallagher in 1989. These studies were confounded because most individual cases showed significant problems contributing to an increased hip fracture risk (e.g., advanced age, frequent falls, renal insufficiency, osteomalcia). Especially renal insufficiency may be a risk if the fluoride dosage is not adjusted.

A multicenter retrospective analysis undertaken by Riggs *et al.* (1987) evaluated more than 1000 patient years on fluoride treatment and did not confirm an augmented risk for hip fractures. In all larger controlled studies that appeared since that analysis, again no increased rate of hip fractures could be documented (Ringe, 1998). In summary there is no evidence at this time that fluoride increases or decreases the incidence of hip fractures.

Fluoride in Male and Corticoid-Induced Osteoporosis

Bone mineral density results from individual male subjects or small male cohorts in mixed patient groups suggested that the anabolic effect of fluoride is similar in men and women (Ringe, 1997). There is only one larger prospective controlled study which included only male patients (Ringe *et al.,* 1998). In that study of 64 men with primary osteoporosis without fractures at onset we used a rather low fluoride dose giving 114 mg/day MFP (=15 mg fluoride ions) intermittently 3 months on, 1 month off plus 1000 mg/day calcium continuously. We found a moderate but highly significant increase of lumbar spine BMD, amounting to 9% after 3 years and even small increases at the radius shaft and femoral neck (Fig. 5). In comparison to the controls this treatment was able to reduce significantly the rate of vertebral fractures over 3 years; i.e., fluoride treatment with the adopted schedule was able to reduce the rate of patients developing established osteoporosis. The moderate increase of 3% per year at the lumbar spine is consistent with the results of Reginster *et al.* (1998) in postmenopausal osteoporosis.

The therapeutic potential of fluoride salts in glucocorticoid-induced osteoporosis on bone density has been shown in different studies (Meys *et al.,* 1993; Rizzoli *et al.,* 1995; Guaydier-Souquieres *et al.,* 1996; Lippuner *et al.,* 1996) but fracture data are not available. In these studies again mixed female/male patient groups were evaluated.

Fluoride in Combined Treatment Regimens

A combined treatment with an anabolic and antiresorptive drug may have additive effects on BMD and could improve microarchitectural quality of the newly formed bone. In an early study from the Mayo Clinic with five different treatment groups the one with NaF + HRT + calcium + vitamin D was the most effective in terms of reducing the vertebral fracture rate (Riggs *et al.,* 1982). As mentioned above (see prevention) fluoride given together with HRT led to very encouraging results (Gambacciani

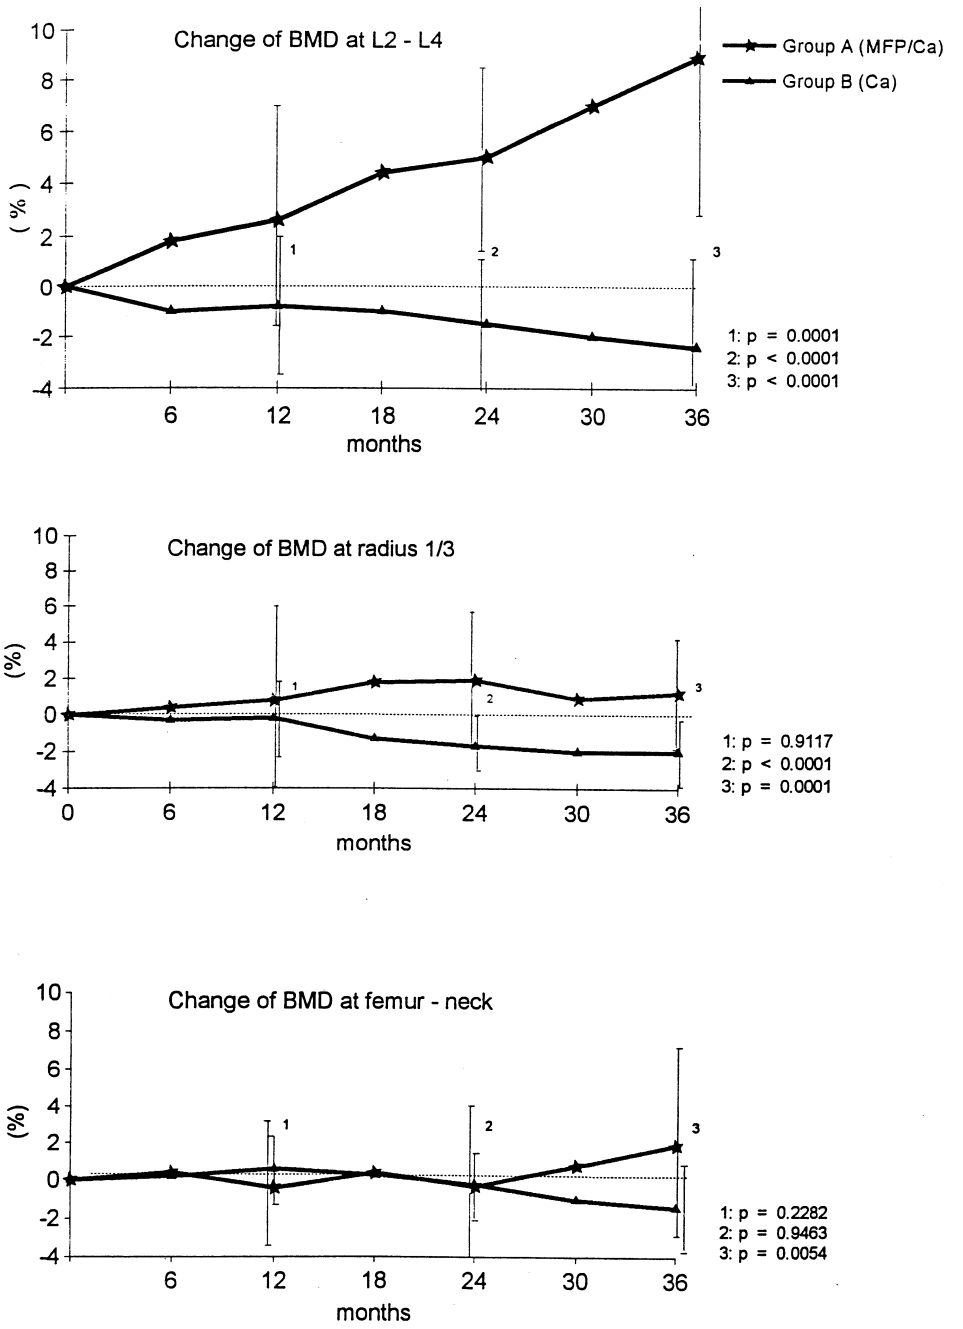

Figure 5 Percentage BMD changes from baseline in osteoporotic men treated for 3 years with low-dose intermittent fluoride plus calcium or calcium alone (Ringe *et al.,* 1998).

et al., 1995; Alexandersen *et al.,* 1999). Our results from a trial in 60 women with established postmenopausal osteoporosis using a low dose intermittent MFP-regimen plus HRT confirm these very positive results (Ringe *et al.,* 1999b). A multicenter trial studying the combination fluoride/raloxifen will soon be finished.

The combination fluoride/etidronate was studied for the first time by Lems *et al.* (1997) in 47 patients with corticoid-induced osteoporosis. After 2 years lumbar spine BMD increased 9.3% in the etidronate/fluoride patients and only 0.3% in the etidronate monotherapy group. A pilot study included 35 postmenopausal women with advanced osteoporosis: average initial lumbar spine BMD, −3.9 *T* score; average number of vertebral fractures, 7 per patient (unpublished results). Patients were treated cyclically either with 14 days 400 mg etidronate followed by 76 days with 20 mg MFP plus 1200 mg calcium and 800 IU vitamin D (EFCaD group) or the same without fluoride (ECaD group). Table V shows the average BMD changes at the lumbar spine, total hip, and femoral neck after 12 and 24 months of therapy for both groups. At all sites the EFCaD group shows significantly higher increase rates than the ECaD

Table V Average Percentage Changes of BMD at the Lumbar Spine, Total Hip, and Femoral Neck after 12 and 24 Months of Therapy in 35 Postmenopausal Women with Severe Osteoporosis Treated Either with Etidronate/Calcium/Vitamin D (ECaD) or Etidronate/Fluoride/Calcium/Vitamin D (EFCaD) (own Unpublished Results)

	ECaD $n = 17$			EFCaD $n = 18$		
Months	L2–L4	Total hip	Femur neck	L2–L4	Total hip	Femur neck
12	1.6	1.5	0.3	10.2	5.1	3.6
24	2.6	1.7	0.6	14.5	5.6	3.4

group. In this context the study of Guanabens *et al.* (2000) on 118 patients with severe postmenopausal osteoporosis is of great interest. The authors directly compared the therapeutic effects of 50 mg enteric-coated NaF with the classical intermittent etidronate/calcium regimen. At 36 months the mean change from baseline of the lumbar spine bone density in the fluoride group was 8.5% and in the etidronate group 3.6% ($P < 0.01$). The total number of new vertebral fractures was significantly lower in the fluoride group but the difference in the number of patients with new fractures did not reach statistical significance.

Another ongoing trial from our group studied the combination fluoride/alendronate in men and women again in selected severe cases of osteoporosis. The results so far from combined fluoride/bisphosphonate therapies are very encouraging in terms of BMD effects. To prove the superiority of fluoride/bisphosphonate versus fluoride or bisphosphonate alone a large study with fractures as the primary end point is needed. Histological examinations at least in a subgroup would be of high interest.

Persisting Problems and Future Perspectives of Fluoride Therapy

It must be emphasized that the existing therapeutic data on fluoride treatment of osteoporosis do not reach the level of evidence-based medicine. As already mentioned, the big problem with fluoride is the low price and the lack of protection by a patent. That means that very large studies with enough power to assess definitely the therapeutic efficacy will probably never be performed. A metaanalytic approach looking at all randomized controlled studies may come to wrong conclusions due to considerable differences in dosage and bioavailability of fluoride between studies depending on used fluoride salts and the respective galenic preparations. Accordingly one recent analysis on 11 trials published between 1980 and 1998 including older studies with high dose fluoride (35 mg ions per day) and newer trials with lower doses (15–20 mg ions per day) concluded that fluoride increases lumbar spine BMD but does not reduce the incidence of vertebral fractures (Haguenauer *et al.,* 2000). Furthermore, is was stated that increasing the dose of fluoride will increase the risk of nonvertebral fractures and gastrointestinal side effects without any effect on the vertebral fracture rate, i.e., a possible advantage of lower fluoride doses can be anticipated. A metaanalysis including only studies with low fluoride dosage published between 1994 and 2000 will come to positive effects on lumbar spine BMD and vertebral fracture rate (unpublished results). Obviously the selection of included papers is crucial in every metaanalytic approach.

As long as no other potent osteoanabolic substances are available fluoride should be kept within the choice of therapeutics for osteoporosis. Accepting a certain therapeutic value of a low dose and well controlled fluoride therapy, the low price may be an important advantage, especially in countries with limited resources for the health care system. In some European countries and especially in Germany, where fluoride was approved for treatment of osteoporosis more than 20 years ago, several groups have long-time favorable clinical experience with fluoride and there is accumulated evidence that with enterocoated NaF or with retarded preparations of NaF or MFP using lower doses than in the past (between 10 and 20 mg bioavailable fluoride ions per day), fluoride therapy is rather safe and may lead to a significant decrease in vertebral fractures.

With doses below 10 mg per day no significant effects on BMD can be expected (Christiansen *et al.,* 1980; Grardel, 1995). The increase of BMD at the spine should be only moderate, between 4 and 6% per year (Riggs *et al.,* 1994). With the recommended dosage the risk of hip fractures is not increased (Ringe, 1998). Some studies show even moderate positive effects on cortical bone. Taking into account the recommendations of Table VI the therapeutic results with fluoride can be improved. The most important point is to reach a stimulation of osteoblasts with the lowest possible

Table VI Strategies for Improving Fluoride Treatment and Practical Recommendations

1. Avoid calcium deficiency and secondary hyperparathyroidism (calcium and vitamin D supplementation or vitamin D-hormone)
2. Avoid high fluoride content of bone:
   - —use lowest fluoride dose that stimulates osteoblasts (serum fluoride ride 5–10 μM?)
   - —intermittent fluoride regimen?
   - —slow-release fluoride? (no plasma peaks after ingestion)
3. Combination with antiresorptive drugs (e.g., HRT, SERMs, BP)
4. Control treatment carefully and stop fluoride application after 3 to 4 years
5. Adapt fluoride dosage or stop it in renal insufficiency
6. Reduce fluoride dosage if alkaline phosphatase increases more than 50% of pretreatment value
7. Monitoring of serum fluoride and/or bone fluoride content?

dose and thereby to keep the fluoride content of bone tissue at a low level. Furthermore there is increasing evidence that the combination of fluoride with calcium and vitamin D is very important to improve safety and therapeutic results (Dure-Smith *et al.,* 1996; Orcel and Sebert, 1997; Ringe, 1997). Future studies with fluoride should also focus on early stages of postmenopausal, corticoid-induced or male osteoporosis. It can be assumed that the better preserved the connectivity of trabecular bone is, the better the therapeutic results could be with an osteoanabolic treatment. Another interesting aspect for the future of fluoride remains the possibility of combining this potent anabolic substance with one of the different existing antiresorptive drugs.

CHAPTER 80

The Pharmacology of Estrogens in Osteoporosis

Robert Lindsay and Felicia Cosman

Helen Hayes Hospital, West Haverstraw, New York 10993; and Department of Medicine, Columbia University, New York, New York 10027

Introduction

Control of bone remodeling is intimately linked to estrogen status in the human female and perhaps also in the human male. Consequently, loss of estrogen production by the ovary, which occurs in all women at menopause, is associated with increased activation of remodeling and an alteration in the equilibrium between bone resorption and formation (Lindsay, 1995). The consequence is loss of bone tissue with accompanying microarchitectural damage that leads to increased bone fragility, commonly called osteoporosis (Consensus Development Conference, 1993). Estrogen intervention restores bone remodeling to its premenopausal equilibrium and prevents bone loss. Observational and some clinical trial data suggest that estrogens also reduce the risk of fractures (Weiss *et al.,* 1979; Hutchinsen *et al.,* 1979; Paganini *et al.,* 1981; Kreiger *et al.,* 1982; Kiel *et al.,* 1987; Lindsay, 1995; Lindsay, 1980; Komulainen, 1998; Herrington, 2000), the only clinical consequence of osteoporosis. The precise mechanism by which estrogens control bone remodeling is still obscure, although significant advances in our understanding have been made in recent years. In this chapter, we will review the current status of our knowledge of the actions of sex steroids in both prevention and treatment of osteoporosis in postmenopausal women.

Responses to Estrogen Administration

Biochemistry

When estrogens are administered to estrogen-deficient women, there is a reduction in bone remodeling that can be monitored biochemically (Siebel *et al.,* 1993). During the initial weeks of therapy, there is a gradual decline in biochemical resorption such that of as the pyridinoline cross-linking molecules (Delmas, 1995). There is a similar but more delayed decline in biochemical measures of bone formation, such as osteocalcin and bone-specific alkaline phosphatase. The timing of these biochemical changes is presumed to represent an initial rapid reduction in activation of new remodeling sites. Since resorption is the initial event in remodeling, a decline in the rate at which new remodeling sites are coming "on-line," initiated at the start of treatment, would produce a reduced supply of the products of resorption into the circulation. Formation follows resorption and is a more prolonged process. Consequently, formation would be expected to continue unabated in those remodeling sites activated before treatment until the osteoblast teams complete their work. Thus, markers of formation in serum decline more gradually (Delmas, 1995). These modifications in skeletal remodeling may occur in part through direct effects of estrogens on bone cells and indirectly by increased resistance to the bone-resorbing effects of parathyroid hormone. Accompanying these changes in skeletal metabolism are modifications in calcium homeostasis, including reduced renal excretion of calcium, improved hydroxylation of 25(OH)D to $1,25(OH)_2D$, and improved calcium absorption across the intestine. In some studies, declining remodeling within the skeleton is also associated with a small fall in serum calcium and a rise in PTH which might affect the renal and intestinal calcium handling.

Bone Density

The consequence of these alterations in skeletal homeostasis is preservation of bone mass, which has been detailed in

many controlled studies (Lindsay, *et al.,* 1976, 1978, 1980, 1984; Horsmann *et al.,* 1977; Christiansen and Rodbro, 1983). Most studies in which estrogens are given during active bone loss provide evidence of a gradual increase in measured bone mass or density that occurs primarily during the first 1–2 years of treatment. It has been assumed that this phenomenon results from the reduced activation of remodeling, which would mean that at any time point after initiation of therapy, there would be a smaller proportion of the skeleton undergoing the remodeling process. The consequence would be an apparent gradual increase in bone mass, without the necessity of an anabolic effect of estrogen. This increment would be time dependent during the early months of treatment as completing remodeling sites gradually filled with new bone tissue, and bone mass would be expected to be relatively stable thereafter. (Delmas, 1995). Indeed, all agents that act by reducing bone remodeling produce the same effect during the first 1–2 years of treatment. The magnitude of the effects vary dependent upon the site measured (the spine usually produces greater increases) and the magnitude of the reduction in remodeling (bisphosphonates and estrogen are most potent).

In long-term studies with estrogens, there are somewhat divergent results, possibly due to a variety of issues. First, it is clear that the long-term compliance with estrogen is less than perfect, and consequently bone loss, which is known to restart when treatment is stopped, might be expected to be seen among some individuals who are not compliant with treatment (Lindsay *et al.,* 1978; Christiansen and Christiansen, 1981). Second, the response of the skeleton may be variable and dependent upon the bone measured. For example, the vertebral bodies contain the highest proportion of cancellous bone and produce the greatest initial response to estrogen. Some data suggest that there is very little subsequent loss in the vertebrae, while the hip may be more sensitive to other factors, especially physical activity (Lindsay, 1995; Orwoll *et al.,* 1996). Thus, although initial cross-sectional data suggested very little loss of bone from any skeletal sites, more recent longitudinal data has confirmed some slow loss (~0.5% per year) from the hip in patients who have been on long-term estrogen (<5 years).

When estrogen therapy is discontinued, there is an immediate increase in bone remodeling that is reminiscent of ovariectomy (Lindsay *et al.,* 1978; Christiansen and Christiansen, 1981). The consequence of this is an increase in the rate of bone loss (Lindsay *et al.,* 1978; Greenspan *et al.,* 1999). The longer the process of bone loss continues the more the treated population will begin to resemble an untreated population in terms of bone density. More than 20 years ago we demonstrated that the effects of 4 years of estrogen intervention were virtually lost 4 years after estrogens had been discontinued (Lindsay *et al.,* 1978).

Effects on Fracture

The consequence of reduced bone turnover and prevention of bone loss is a reduction in the risk of fracture. Numerous epidemiological studies have shown that estrogen exposure is associated with a reduction in the risk of fractures of the hip and wrist (Lindsay *et al.,* 1976, 1978a,b; 1980a; 1984; Horsman *et al.,* 1977; Christiansen and Christiansen, 1981; Christiansen and Rodbro, 1983). In general, there appears to be about a 50% reduction in hip fracture risk. More recent data indicate that the estrogen effect is greatest among those currently taking treatment, and those who began earliest (Cauley *et al.,* 1995). These epidemiological data are compatible with the prospective effects on bone mass and emphasize the importance of continued therapy to obtain the maximum effects on fracture. Since menopause occurs at the average age of 50 years, and hip fracture affects women over 70 years mostly, this may mean 20–30 years of treatment or even treatment for life may be necessary. Controlled clinical trial data suggest a reduction of 50–80% in the risk of vertebral fractures, when estrogens are used for prevention (Lindsay *et al.,* 1980a), or treatment (Lufkin, 1992). One recent clinical trial has confirmed the effects of HRT on clinical nonvertebral fractures in a recently menopausal population (Komulainen 1998). However, in one study of HRT's effects on cardiovascular disease, the largest outcome study completed as yet using HRT, there was an equal number of fractures in the HRT and placebo arms, casting doubt on fracture efficacy (Hulley *et al.,* 1998). It is important to emphasize that that study recruited women based upon cardiac history without regard to skeletal status, which was largely unknown. Moreover, there was a high incidence of obesity in that population which might have reduced the likelihood of a significant estrogen effect on fractures. There was no comprehensive evaluation of vertebral compression fracture, since spine radiographs were not routinely performed. However there did not appear to be a reduction in height loss. In another smaller study in which cardiac outcomes were also assessed by cardiac catherization, while there was no effect on atheroma, there was a reduction in the number of clinical fractures. Thus, despite one negative study, most data support a fracture benefit for estrogens.

Route of Administration

The evidence suggests that the route of estrogen administration required to obtain a skeletal effect is irrelevant and that if adequate doses are given, reduced bone remodeling results (Christiansen and Lindsay, 1991). Thus, data obtained from transdermal, percutaneous, subcutaneous, as well as oral administration all confirm skeletal conservation. In contrast, vaginal estrogen administration does not appear to result in high enough estrogen levels in circulation to exert an effect on skeletal remodeling. For oral doses the equivalent of 0.625 mg of conjugated estrogen is sufficient for most individuals, but effects on bone remodeling and skeletal mass can be seen at lower doses (Lindsay *et al.,* 1984). Whether fractures can be reduced by lower doses is not known. For transdermal estrogens, the 50-mg patch, which results in estradiol levels in circulation of ~50 pg/ml, appears sufficient (Lufkin *et al.,* 1992). Some data suggest that higher doses of estrogen produce greater effects on bone mass, but no head-to-head comparisons with lower doses have been attempted (Savvas *et al.,* 1992).

Presently, data demonstrate that all estrogens used in the postmenopausal population produce skeletal effects. For some, such as conjugated equine estrogens, the data include dose–response and fracture outcomes. For others, more limited data on bone mass are available, often without good dose–response data. Synthetic estrogens such as those used in the oral contraceptive also produce skeletal effects in estrogen-deficient individuals (Lindsay *et al.,* 1976). Indeed ethinyl-estradiol in doses between 5 and 10 μg/day prevents bone loss. In addition at the 5 μg dose there appears to be a modest increase when norethindrone (1 mg/day) is combined with the estrogen. However, whether the oral contraceptive, with doses of ethinyl-estradiol between 20 and 30 μg per day, produces much in the way of alterations in skeletal homeostasis in premenopausal women is far from known.

Reduction in skeletal remodeling is an effect that can be produced with other steroids. Progestins given to postmenopausal women also produce reductions in bone remodeling and prevention of bone loss (Lindsay *et al.,* 1978). The required doses are greater than those normally used in estrogen-deficient women (20 mg/day for medroxyprogesterone acetate and 5 mg/day for norethindrone) (Lindsay *et al.,* 1978; Gallagher and Kable, 1991). The addition of a C-21 progestin in more conventional doses to estrogen therapy, does not modify the estrogen response significantly (PEPI). As noted in the previous paragraph there are some data suggesting an additive effect of the 19-nortestosterone derivative norethindrone when given in combintaion with 5 μg of ethinyl-estradiol (Speroff, 1996). Whether this occurs with other combinations is not known and there are no fracture data with combinations to determine if there is an additive effect on fractures. On the other hand, some evidence suggests that the progestins, when used by themselves for contraceptive purposes in premenopausal estrogen-replete women, will actually be detrimental to skeletal health, presumably by reducing endogenous production of estrogen by the ovary (Mark, 1994). There is no evidence that progestin creams can result in high enough circulating levels of progesterone to produce skeletal effects.

The activity of progestins on bone is also evident in the data published on tibolone (Lindsay *et al.,* 1980; Milner *et al.,* 2000; Castelo-Branco, 2000). This steroid is related to norethindrone and thus is a 19-nortestosterone derivative. It has androgenic, progestogenic, and weak estrogenic activity. In doses that do not appear to stimulate the endometrium, it produces estrogen-like effects in bone. Thus, tibolone can be considered the first tissue-selective compound, although its tissue spectrum of activity produces some effects related to its androgenicity and progestin activity rather than its estrogen action.

Estrogens are potent hormones with effects on multiple tissues. Some of these effects confer significant benefit and some significant risk to the postmenopausal women. One clear-cut benefit of hormone replacement therapy (HRT) is on suppression of menopausal symptoms, such as hot flashes and vaginal dryness. Many of the other potential benefits of HRT, however, have not been proven. It is unclear whether estrogens affect the risk of cardiovascular disease. A large body of clinical trial data indicates that estrogen improves intermediate markers of cardiovascular health, including cholesterol and other lipoproteins, and the vasodilatory coronary artery response to acetylcholine. Observational data suggest a clinical benefit as well, however two separate clinical trials (mentioned above) showed a lack of efficacy against clinical heart disease outcomes (HERS) (Hulley *et al.,* 1998) and a lack of regression of coronary artery plaque (Herrington *et al.,* 2000), in those women assigned to estrogen or HRT. There are insufficient clinical trial data to connect HRT to cognitive function, dementia, and urogenital symptoms such as incontinence. HRT increases the risk of venous thromboembolic disease threefold and the risk of gallbladder disease twofold.

Estrogens also cause endometrial hyperplasia and increase the risk of endometrial malignancy (Jick *et al.,* 1979; Shapiro *et al.,* 1985). Protection of the endometrium is the only rationale for the prescription of a progestin along with estrogen to postmenopausal women (Woodruff and Pickar, 1994). There is also concern that long-term therapy with estrogen may increase the risk of breast cancer, although the epidemiological data available are by no means consistent on this point (Barrett-Connor, 1989). In general, however, it appears as though long-term estrogen intervention ($<$10–15 years) produces a modest increase in breast cancer risk, particularly in thin women. From the few epidemiological data available, the point estimate of relative risk appears to be between 1.15 and 1.40 and is probably related to dose as well as duration. This raises concern when long-term therapy for prevention of hip fracture is considered.

Consequently there has been considerable interest in the idea that estrogen analogs might be found that would provide the beneficial effects of estrogen on bone, brain, and heart, without endometrial or breast stimulation. Since there appears to be a single estrogen receptor, it is at first glance difficult to believe that separation of estrogen effects by tissue might be possible. However, with improved understanding of the molecular biology of estrogen action, it has become possible to hypothesize how estrogens might act differently in different tissues.

Estrogen Actions

The molecular actions of estrogens have been reviewed in detail elsewhere in this book. Estrogen receptors are members of the steroid receptor family that include thyroid hormone, vitamin D, and retinoids among their ligands as well as sex steroids and adrenal steroids (Auchus and Fugue, 1994). In cells that express estrogen receptors, estrogens produce a potential cascade of gene activation that is dependent on a variety of intracellular factors. Generally responsive cells contain 10,000–100,000 receptors, and clearly the concentration of receptors is one variable that might affect response (in general lower levels appear in nonreproductive cells) (Brown, 1994). The receptor–ligand complex binds to DNA with high affinity that is dependent on the integrity of the amino acid sequence related to the

base of the first zinc finger on the C region of the receptor (Picard *et al.,* 1990). Ligand binding alters the conformation of the receptor, exposing the DNA binding domain. In addition, while ligand binding is usual for dimerization, DNA binding and subsequent transcription activity, the ER can activate genes in the absence of ligand. Other transcription activators may also modulate the responsivity of the genome to ER even in the presence of ligand (Ronies and Spelsberg, 1989; Brown, 1994).

Given the complexity of the system, it is not difficult to suggest how estrogen responsivity might be modulated. Abnormal receptors, or abnormal conformational changes in the receptor upon ligand binding, the absence of cofactors, or the alteration in the response elements of target genes all might modify the cellular responses to estrogen (Auchus and Fugue, 1994). Tissue selectivity of estrogen response could be obtained by differences in receptor number or the expression of factors within the cells of that tissue influencing the cascade, for example, the capability to phosphorylate the ER ligand complex.

Several genes are targets for estrogen actions including nuclear proto-oncogenes (c-*fos,* c-*myc,* and c-*jun*), and the estrogen responses include expression of several genes including growth factors and cytokines (Murphy and Murphy, 1994).

The estrogen target that is responsible for the effects of these agents in bone is still not clearly understood. Osteoblasts have been shown to have estrogen receptors (Eriksen *et al.,* 1988; Komm *et al.,* 1988), but very variable responses to estrogen in osteoblasts or osteoblast cell lines have been published (Turner *et al.,* 1994). Indeed some evidence suggests that only cells transfected with a functional estrogen receptor will respond to estrogens (Ernst *et al.,* 1991). Some data suggest that osteoclasts also respond directly to estrogens (Oursler *et al.,* 1991). The strongest evidence of estrogen receptors in osteoclasts comes from studies of avian osteoclasts. Rat osteoclasts probably do not respond to estrogens, and there is almost no information on human osteoclasts (Arnett *et al.,* 1996). The most likely cell targets for estrogen appear to be other constituent cells of bone marrow. Release of second messengers, such as TGF-β, or reduction in secretion of cytokines, such as IL-1 or IL-6, could produce estrogen effects by reducing the recruitment and maturation of osteoclasts (Oursler *et al.,* 1991; Turner *et al.,* 1994). Estrogen has also been reported to cause osteoclast apoptosis, although not in all systems (Arnett *et al.,* 1996). Finally, estrogens also have effects on calcium homeostasis. Estrogens reduce urinary calcium loss and, at the renal level, cause an increase PTH activity. Estrogens, however, increase skeletal resistance to the resorptive stimulatory effects of PTH without appearing to interfere with the anabolic effects of PTH (Cosman *et al.,* 1993). Estrogens also stimulate intestinal absorption of calcium, perhaps directly or by modulating the effects of PTH on the renal 1α-hydroxylase, thereby increasing the supply of 1,25-dihydroxyvitamin D. Whether these effects of estrogen on the calcium homeostatic system are primary or secondary to the skeletal effects of estrogens is not clear.

The knowledge that estrogen responsivity may vary from tissue to tissue has clearly heightened interest in the concept of the ideal estrogen. Such a compound would produce the beneficial effects of estrogen on bone, cardiovascular system, brain, and urogenital tissues without stimulating endometrial growth or producing effects on mammary tissue that might increase the risk of breast cancer. Several compounds are under investigation for such activities. The first noted is tibolone, which clearly produces bone effects at doses that do not appear to produce much endometrial stimulation. It is not at clear, however, whether tibolone can reduce the risk of ischemic heart disease. Since the effects of estrogen on the cardiovascular system probably include multiple effects on lipid metabolism and on the physiology of the circulatory system, further investigation of this compound would seem to be warranted, even though it does not produce an estrogen-like response in terms of circulating lipoproteins. The realization that tamoxifen exerted estrogen-like effects in some cell systems stimulated evaluation of its effects in women who were being given tamoxifen as adjuvant treatment for breast cancer (Cosman and Lindsay, 1999). Surprisingly these women were not losing bone when compared with postmenopausal controls. Formal controlled clinical trials confirmed that tamoxifen does appear to conserve bone mass and produce estrogen-like effects on lipoprotein metabolism (Cosman and Lindsay, 1999). Tamoxifen also stimulates the endometrium, albeit weakly, and endometrial cancer is a recognized risk of long-term tamoxifen treatment. Knowledge of these effects awakened interest in the pharmaceutical industry in compounds that might have tamoxifen-like effects on breast cancer but would produce estrogen-like effects on bone and cardiovascular diseases. Raloxifene, a benzothiaphene, is now available for prevention and treatment of osteoporosis. Raloxifene and tamoxifen produce similar estrogen-like effects on bone in ovariectomized rats (Black *et al.,* 1994). However, raloxifene appears to have little stimulatory effects on rat uterus. Raloxifene reduces bone remodeling and prevents bone loss in postmenopausal women. Raloxifene reduces the risk of vertebral fractures, but did not have a statistically significant effect on nonvertebral fractures (Ettinger *et al.,* 1999). The use of raloxifene in clinical practice is strongly influenced by its capacity to reduce the clinical appearance of ER-positive breast cancer over a 4-year period. Raloxifene also lowers circulating low-density lipoprotein similar to estrogen, although no increase in high-density lipoprotein was seen as is usually the case with oral estrogens (Draper *et al.,* 1996). Raloxifene increases the risk of deep vein thrombosis and pulmonary embolism to the same degree as HRT. Clearly compounds such as raloxifene will be powerful tools in the dissection of the mechanisms of estrogen action at the molecular level. The realization that different cells respond to estrogen-like molecules in different ways also raises the intriguing question of whether compounds can be found that reduce the

recruitment and activity of osteoclasts, like estrogen, and produce lesser effects on bone formation. Tamoxifen, for example, appears to have more potent effects on bone resorption *in vitro* than estrogens, perhaps by being a more potent stimulator of osteoclast apoptosis. Clomiphene also increases trabecular thickness in rats, an effect not usually associated with estrogens.

CHAPTER 81

Vitamin D and Analogs

Glenville Jones
Department of Biochemistry, Queen's University, Kingston, Ontario, Canada K7L 3N6

Introduction

Vitamin D, its metabolites and analogs constitute a valuable group of compounds which can be used to modulate many aspects of osteoblast and osteoclast biology. The parent vitamin (or UV light which substitutes for any vitamin D pharmaceutical preparation as a source of the parent vitamin) has been used as a treatment for rickets and osteomalacia since its discovery in the 1920s. The first analog of vitamin D, dihydrotachysterol, was developed in the 1930s before the elucidation of the metabolism of vitamin D. In fact, it was not until the discovery of the principal metabolites: 25-hydroxyvitamin D_3 (25-OH-D_3) and 1α,25-dihydroxyvitamin D_3 (1α,25-$(OH)_2D_3$), in the early 1970s that further generations of vitamin D analogs were developed (DeLuca, 1988; Jones and Calverley, 1993). With the understanding of the molecular action of the hormonal form, 1α,25-$(OH)_2D_3$, has come an appreciation that it is not only a *calcemic agent,* regulating calcium and phosphate transport but also a *cell-differentiating agent,* promoting the terminal development of a number of cell types including the osteoclast, the enterocyte and keratinocyte (Miyaura *et al.,* 1981). Thus, pharmaceutical companies have striven hard in the 1980s and 1990s to separate these two properties and thereby develop synthetic vitamin D analogs with specialized "calcemic" and "noncalcemic" (cell-differentiating) uses (Calverley and Jones, 1992; Bouillon *et al.,* 1995). From this type of research has come several "low-calcemic" agents in recent years in the form of calcipotriol, OCT, 19-nor-1α,25-$(OH)_2D_2$, and 1α-OH-D_2, which have found widespread use in dermatology and hyperparathyroidism. Other analogs are under development for use in metabolic bone diseases, osteoporosis, and cancer (Jones *et al.,* 1998). This chapter will review the spectrum of compounds available, possible uses of these compounds and their potential mechanisms of action.

Pharmacologically Important Vitamin D Compounds

Vitamin D compounds can be subdivided into three major groups, listed in Tables I through III and described below.

Vitamin D and Its Natural Metabolites

Table I lists some of the important metabolites of vitamin D_3. During the early 1970s most of these compounds were first isolated and identified by GC-MS and then their exact stereochemical structure determined (DeLuca, 1988). This led to chemical synthesis of the naturally occurring isomer and testing in various biological assays *in vitro* and *in vivo.* Currently, only the compounds representing the main pathway of vitamin D activation, namely vitamin D_3, 25-hydroxyvitamin D_3 (25-OH-D_3), and 1α,25-$(OH)_2D_3$, are synthesized for use as drugs. One exception to this is 24(*R*),25-$(OH)_2D_3$, which was synthesized in Israel by Teva Pharmaceuticals and sold as Secalciferol.

Table I Vitamin D and Its Natural Metabolites

Vitamin D metabolites [ring structure][a]	Side chain structure (R)	Site of synthesis	Relative VDR-binding affinity[b]	Relative DBP-binding affinity[c]	Reference
Vitamin D_3[1]		Skin	≤0.001	3,180	—
25-OH-D_3[1]		Liver	0.1	66,800	Blunt *et al.,* 1968
1,25-$(OH)_2D_3$[3]		Kidney	100	100	Fraser and Kodicek 1970; Holick *et al.,* 1971.
24(*R*),25-$(OH)_2D_3$[1]		Kidney	0.02	33,900	Holick *et al.,* 1972
1,24(*R*),25-$(OH)_3D_3$ [3]		Target tissues[d]	10	21	Holick *et al.,* 1973
25(*S*),26-$(OH)_2D_3$[1]		Liver?	0.02	26,800	Suda *et al.,* 1970

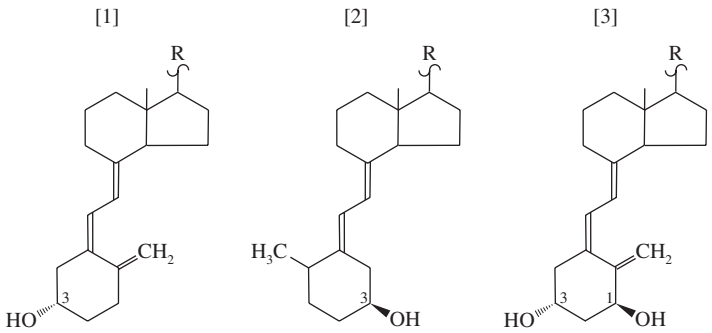
Vitamin D Nucleus



Vitamin D Prodrugs

Table II lists some of the important prodrugs of vitamin D. All of these compounds require a step (or more) of activation *in vivo* before they are biologically active. Included here is vitamin D_2 which is derived from the fungal sterol, ergosterol, by irradiation. Since vitamin D_2 is found rarely in nature and is hard to detect in humans eating nonfortified foods, we can consider it to be an artificial form of vitamin D or prodrug. Vitamin D_2 possesses two specific modifications of the side chain (see Table II) but is still able to undergo the same series of activation steps as vitamin D_3, giving rise to 25-OH-D_2, 1α,25-$(OH)_2D_2$, and 24,25-$(OH)_2D_2$. Two other prodrugs, 1α-OH-D_3 and 1α-OH-D_2, were synthesized in the early 1970s (Barton *et al.,* 1973; Paaren *et al.,* 1978) as alternative sources of 1α,25-$(OH)_2D_3$ and 1α,25-$(OH)_2D_2$, respectively, that in the process circumvent the renal 1α-hydroxylase enzyme, which was shown to be tightly regulated and prone to damage in renal disease.

The final compound in the list, dihydrotachysterol (DHT) has lived a complex history as a prodrug. Originally it was believed to be "active" when converted to 25-OH-DHT by virtue of an A-ring rotated 180° such that the 3β-hydroxyl function assumes a pseudo-1α-hydroxyl position (Jones *et al.,* 1988). The mechanism of action of DHT has become less clear with the description of the extrarenal metabolism of 25-OH-DHT to 1α,25-$(OH)_2$-DHT and 1β,25-$(OH)_2$-DHT, two further metabolites which have greater biological activity than either 25-OH-DHT or DHT itself (Qaw *et al.,* 1993).

Table II Vitamin D Prodrugs

Vitamin D prodrugs [ring structure][a]	Side chain structure (R)	Company	Possible target diseases	Mode of delivery	Reference
1α-OH-D_3[3]		Leo	Osteoporosis	Systemic	Barton *et al.,* 1973

Vitamin D Analogs

Table III lists some of the most promising vitamin D analogs of 1α,25-$(OH)_2D_3$ already approved by governmental agencies or currently under development by various industrial/or university research groups. Since the number of vitamin D analogs synthesized now lists in the hundreds, the table is provided mainly to give a flavor of the structures experimented with thus far, the worldwide nature of the companies involved and the broad spectrum of target diseases and uses.

The first generation of calcitriol analogs included molecules with fluorine atoms placed at metabolically vulnerable positions in the side chain and resulted in highly stable and potent "calcemic" agents such as 26,27-F_6-1α,25-$(OH)_2D_3$. More recently, attention has focused on features which make the molecule more susceptible to clearance, such as in calcipotriol (MC903), where a C22=C23 double bond, a 24-hydroxyl function, and a cyclopropane ring have been introduced into the side chain or in 22-oxacalcitriol (OCT) where the 22-carbon has been replaced with an oxygen atom. Both modifications have given rise to highly promising analogs (Kragballe, 1992; Abe-Hashimoto *et al.,* 1993).

The C-24 position is a favorite site for modification and numerous analogs contain 24-hydroxyl groups, e.g., 1α, 24(*S*)-$(OH)_2D_2$ and 1α,24(*R*)-$(OH)_2D_3$ (Strugnell *et al.,* 1995). Other analogs contain multiple changes in the side chain in combination including: unsaturation; 20-epimerisation, 22-oxa replacement; homologation in the side chain or terminal methyl groups. The resultant molecules such as EB1089 and KH1060 are attracting strong attention of researchers because of greatly increased potencies *in vitro* and are being pursued as possible anti-cancer and immunomodulatory compounds, respectively. KH1650 is a potential second-generation anti-psoriatic.

Few attempts have been made thus far to modify the nucleus of calcitriol. The Roche compound 1α,25-$(OH)_2$-16-ene-23-yne-D_3 touted as an anti-tumor compound *in vivo* possesses a D-ring double bond. Declercq and Bouillon have introduced a series of biologically active analogs without the C/D rings but with a rigid backbone to maintain the spatial arrangement of the A-ring hydroxyl groups and the side chain (Verstuyf *et al.,* 2000). Relatively recently, the A-ring substituted 2-hydroxypropoxy-derivative, ED71, has been tested as an anti-osteoporosis drug. The Abbott compound, 19-nor-1α,25-$(OH)_2D_2$, lacks a 19-methylene group and is styled upon the *in vivo* active metabolite, 1α,25-$(OH)_2$

Table III Analogs of 1,25-$(OH)_2D_3$

Vitamin D analog [ring structure][a]	Side chain structure (R)	Company	Possible target diseases	Mode of delivery	Reference

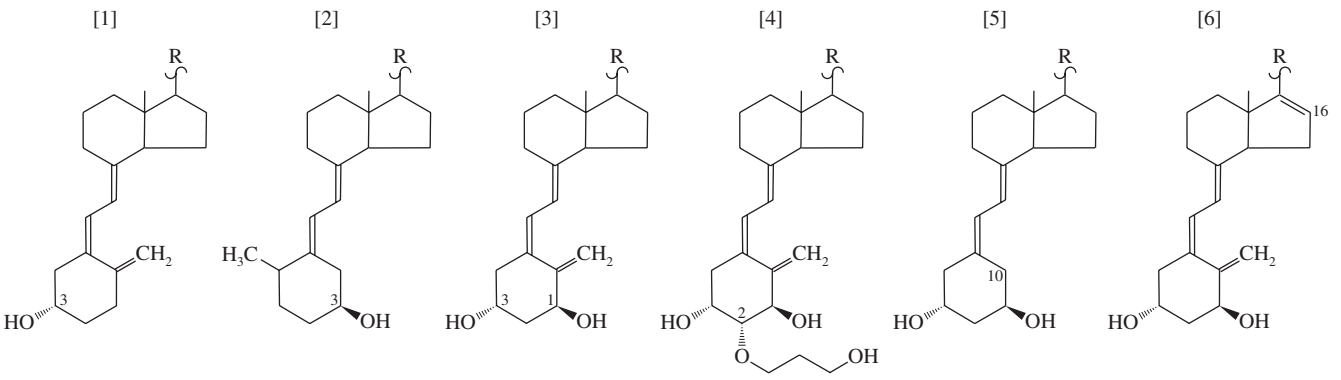
[a] Structure of the vitamin D nucleus (secosterol ring structure).

Vitamin D Nucleus



DHT_2, formed from dihydrotachysterol, which retains biological activity though the C-19 methylene is replaced by a C-19 methyl. Many other compounds have been developed with rigid or altered *cis*-triene structures (Okamura *et al.,* 1995) or modifications of the 1α- ,3β- , or 25-hydroxyl functions not for the purpose of developing active molecules for use as drugs but in order to allow us to establish minimal requirements for biological activity in structure/activity studies (Calverley and Jones,1992; Bouillon *et al.,* 1995). One series of compounds not depicted in Table III are the substituted biphenyls developed by Ligand, representing totally synthetic scaffolds selected by high-throughput screening, which show weak VDR-binding but good transactivation through VDRE-driven, vitamin D-dependent genes and produce hypercalcemia *in vivo* (Boehm *et al.,* 1999). Accordingly, this is the first class of vitamin D mimics that lack the conventional *cis*-triene secosteroid structure while maintaining the spatial separation of the A-ring and side-chain hydroxyl functions needed to bind to certain residues of the ligand-binding pocket of the VDR.

Clinical Applications of Vitamin D Compounds

The clinical usefulness of vitamin D analogs has been reviewed comprehensively by both Bikle (1992) and Bouillon *et al.* (1995) in overviews and also within this book. This chapter summarizes some of the highlights in this area.

Rickets and Osteomalacia

When the nutritional basis of rickets and osteomalacia became apparent in the first half of the 20th century, vitamin D (particularly vitamin D_2 because it was less expensive) became the treatment of choice for these diseases. Of course, prophylactic vitamin D in the form of supplements to milk, margarine, and bread have replaced much of the need for therapeutic vitamin D. In fact, since then rickets has become very uncommon in North America because vitamin D supplementation is required by law, whereas it was quite common before the practice of food fortification and it is still more prevalent in the world where food fortification is not permitted.

On the other hand, vitamin D deficiency is still quite prevalent in the elderly and usually is treated with modest doses of vitamin D (Chapuy *et al.,* 1992). In fact in recent years, several world, continent-wide, and national food agencies have put out new guidelines raising the recommendations for vitamin D intake for all age groups, but particularly for those in the postmenopausal category, to try to ensure adequate intakes irrespective of geographical, dietary, and sun exposure differences (US National Academy of Sciences Reference Intakes, 1997; FAO/WHO Nutritional Guidelines, 2000). However, the need for the use of expensive pharmaceutical preparations containing calcitriol or its analogs is usually not warranted.

Osteoporosis

While the etiology of this disease is complex and likely to be multifactorial (Seeman *et al.,* 1995; Nordin, 1997), there have been consistent claims that levels of 1α,25-$(OH)_2D_3$ are low in osteoporosis (Riggs and Melton,1992). In addition, the recent debate over VDR genotypes correlating with bone mineral density (Morrison *et al.,* 1994; Whitfield *et al.,* 2000) suggests some genetically inherited vitamin D-related basis exists for susceptibility to osteoporosis. As a consequence it is not surprising that clinical trials of 1α-OH-D_3 (Orimo *et al.,* 1987), 1α-OH-D_2 (Gallagher *et al.,* 1994), and 1α,25-$(OH)_2D_3$ (Gallagher *et al.,* 1989; Ott and Chestnut, 1989; Tilyard *et al.,* 1992) have been undertaken. Modest gains in bone mineral density and reductions in fracture rates are reported in many of these studies, and this subject has been reviewed recently by Seeman *et al.* (1995).

With the demonstration that ovariectomy results in enhanced interleukin-6 (1L-6) and interleukin-11 (1L-11)-mediated osteoclast recruitment and increased bone resorption has come a clearer understanding of the molecular processes underlying postmenopausal osteoporosis (Manolagas and Jilka, 1995). These theories focusing on osteoblast/osteoclast communication have been extended with the discovery of osteoprotegerin and its ligand (also known as RANKL) and how agents such as 1α,25-$(OH)_2D_3$ can influence osteoclastogenesis and bone resorption (Aubin and Bonnelye, 2000). Although 1α,25-$(OH)_2D_3$ treatment might be expected to exacerbate the excessive bone resorptive component of osteoporosis, the vitamin D hormone also raises plasma Ca^{2+} levels and stimulates synthesis of bone matrix formation in osteoblasts. In fact Raisz and coworkers (Hock *et al.,* 1986) have shown that pharmacological doses of 1α,25-$(OH)_2D_3$ administered to rats, in great excess over the doses used in osteoporosis, result in hypercalcemia and nephrocalcinosis which is accompanied by a hyperosteoid or undermineralized condition in the long bones. Thus, the use and effectiveness of vitamin D metabolites are controversial. Nevertheless, the experience seems to have been that beneficial effects can be observed and bone loss reduced, but at the expense of occasional hypercalcemia. In North America, where dietary Ca intakes and absorption are higher, this has led to intolerable side effects and the use of 1α,25-$(OH)_2D_3$ and 1α-OH-D_3 for the treatment of osteoporosis. As a result some pharmaceutical companies have sought to synthesize "milder" but "longer-lived" calcitriol analogs for use in osteoporosis. ED-71 represents such an analog which by virtue of an A-ring substituent at C-2 and tighter-binding affinity to DBP has a longer $t_{1/2}$ in the plasma (Nishii *et al.,* 1993). ED-71 has performed well at restoring bone mass without causing hypercalcemia in long-term studies involving ovariectomized rats (Okano *et al.,* 1991).

Renal Osteodystrophy

Renal failure is accompanied by hypocalcemia and secondary hyperparathyroidism, both of which are relieved by the administration of a 1α-hydroxylated vitamin D

preparations. Both oral 1α-OH-D_3 and 1α,25-$(OH)_2D_3$ raise plasma Ca^{2+} concentrations and, in addition, lower PTH levels partly by raising [Ca^{2+}] and shutting off PTH secretion and partly by direct action on the PTH gene promoter. Slatopolsky and colleagues (Delmez *et al.,* 1989) showed that intravenous infusion of "active" vitamin D preparations results in a more effective suppression of plasma PTH levels without such a profound increase in plasma [Ca^{2+}]. Subsequent work has employed "low-calcemic" vitamin D analogs such as OCT or 19-nor-1α,25-$(OH)_2D_2$ as substitutes for the more calcemic natural hormone (Brown *et al.,* 1989; Slatopolsky *et al.,* 1995). The FDA recently approved both oral and intravenous 1α-OH-D_2 (trade name Hectorol) for the treatment of secondary hyperparathyroidism. In clinical trials, 1α-OH-D_2 effectively suppressed PTH in renal failure patients with very low incidences of hypercalcemia and hyperphosphatemia (Frazao *et al.,* 2000).

Psoriasis and Cancer

The demonstration that 1α,25-$(OH)_2D_3$ is an anti-proliferative, pro-differentiating agent for certain cell types *in vivo* and many cell lines *in vitro* suggested that vitamin D analogs might offer some relief in hyperproliferative disorders such as psoriasis and cancer. Early psoriasis trials with 1α,25-$(OH)_2D_3$ were moderately successful but plagued with hypercalcemic side effects. Modifications to the protocol included:

(a) administration of the calcitriol overnight when intestinal concentrations of [Ca^{2+}] were low
(b) substitution of "low-calcemic" analogs for the calcitriol.

According to Holick (1995), oral calcitriol is an effective treatment for psoriasis when administered using an overnight protocol. However, by far the most popular treatment for psoriasis is the topical administration of the "low-calcemic" analog calcipotriol, formulated as an ointment (Kragballe, 1992). When given orally, calcipotriol is ineffective due to the fact that it is rapidly broken down (Binderup and Bramm, 1988). When given topically as an ointment, calcipotriol survives long enough to cause improvement in over 75% of patients (Kragballe *et al.,* 1991). Both 1α,25-$(OH)_2D_3$ and calcipotriol are effective in psoriasis because they block hyperproliferation of keratinocytes, increase differentiation of keratinocytes and help suppress local inflammatory factors through their immunomodulatory properties. Calcipotriol is now approved worldwide for use in psoriasis. The success of calcipotriol has spawned development of second-generation analogs.

Several vitamin D analogs have been tried with some degree of success in various types of cancer. In mice inoculated with fulminant leukemia, moderate leukemia, or slowly progressive leukemia, the Roche compound 1α,25-$(OH)_2$-16-ene-23-yne-D_3 administered at 1.6 μg/qod was significantly more effective than 0.1 μg/qod 1α,25-$(OH)_2D_3$ at increasing survival time even though the 1α,25-$(OH)_2D_3$-treated group developed mild hypercalcemia and the analog-treated animals remained normocalcemic (Zhou *et al.,* 1990). With the analog EB1089, the promising anti-proliferative effects seen *in vitro* and in the NMU-induced mammary-tumor model have been extended into the clinic (Colston *et al.,* 1992). Early trials in limited numbers of breast cancer patients have been followed up with more extensive ongoing Phase II and Phase III clinical trials in a number of different cancers (Gulliford *et al.,* 1998; Evans *et al.,* 2000). The results remain promising. Following similarly promising results in Phase I clinical trials, another analog 1α-OH-D_2, is currently undergoing Phase II trials for the treatment of advanced prostate cancer.

The principal problem in anti-cancer studies involving orally administered vitamin D compounds is hypercalcemia. Though the newer analogs appear to be less calcemic than calcitriol itself, they still retain some ability to raise serum calcium; they are not "noncalcemic" as is sometimes claimed. It remains uncertain whether we will ever develop a vitamin D compound devoid of calcemic activity while retaining sufficient anti-proliferative activity to be valuable in cancer.

Immunosuppression

The immunosuppressive properties of 1α,25-$(OH)_2D_3$ and its analogs have been the subject of two excellent reviews (Bouillon *et al.,* 1995; Van Etten, 2000). 1α,25-$(OH)_2D_3$ or its analogs have been shown to be of benefit in autoimmune diseases (Lemire and Clay, 1991), to suppress the onset of Type I diabetes in NOD mice (Mathieu *et al.,* 1995), and to work synergistically with cyclosporine to provide immunosuppression in transplantation medicine (Mathieu *et al.,* 1994a). This latter development has led to some optimism that coadministration of a vitamin D analog with cyclosporine can reduce the dosage of the latter drug and minimize the serious side effects associated with its use. Several studies (Mathieu *et al.,* 1995, 1994b; Veyron *et al.,* 1993) have focused on the immunosuppressive effects of Leo drugs, KH1060 and 20-epi-1α,25-$(OH)_2D_3$, both of which contain the 20-*S* side-chain configuration. Nevertheless, it remains unclear if drugs that show strong promise in certain immunological screening tests *in vitro* will prove to be effective immunomodulators *in vivo.*

Criteria That Influence Pharmacological Effects of Vitamin D Compounds

Activating Enzymes

It has been shown using *in vitro* models that some vitamin D compounds lacking 1α-hydroxylation (e.g., 24(*R*),25-$(OH)_2D_3$) are capable of interacting with the vitamin D receptors (VDRs) and transactivating reporter genes but this occurs only at high concentrations of ligand (Uchida *et al.,* 1994). It seems unlikely that these concentrations will be reached *in vivo* except in hypervitaminosis D. Most of the compounds described in Tables I and II lack vitamin D

biological activity *unless* they are activated *in vivo.* This is particularly the case for the parent vitamin D_3 itself, for its main circulating form 25-OH-D_3 or for any of the prodrugs listed in Table II. Vitamins D_2 and D_3 depend upon both the liver 25-hydroxylase and kidney 1α-hydroxylase enzyme systems in order to be activated, whereas most prodrugs require only a single step of activation. Indeed, the 1α-OH-D drugs were designed to overcome the tightly regulated 1α-hydroxylase step which is easily damaged in chronic renal failure. In essence, prodrugs depend on the weakly regulated 25-hydroxylase step in the liver for activation. In recent years, the cytochrome P450 thought to be responsible for 25-hydroxylation of vitamin D_3, CYP27A, has been cloned and shown to be a bifunctional polypeptide that executes both activation of vitamin D_3 and the 27-hydroxylation of cholesterol during bile acid biosynthesis (Okuda *et al.,* 1995). However, the CYP27A enzyme has a relatively low affinity for vitamin D, does not 25-hydroxylate vitamin D_2, and when mutated results in cerebrotendinous xanthomatosis not rickets. Consequently, another "physiologically relevant" 25-hydroxylase may exist. However, it is clear that CYP27A efficiently 25-hydroxylates 1α-OH-D_3 to give 1α,25-$(OH)_2D_3$ (Guo *et al.,* 1993); and is present in a variety of tissues as well as the liver (e.g., kidney and bone). In fact studies (Ichikawa *et al.,* 1995; Jones *et al.,* 1999a) suggest that cultured bone cells and even keratinocytes are able to synthesize 1α,25-$(OH)_2D_3$ from 1α-OH-D_3. If these findings can be extrapolated to the *in vivo* situation, the implications of this work are that vitamin D target cells may have some ability to synthesize the active form from a prodrug *without* the need for the hormone to enter the bloodstream.

The ability of extrarenal tissues to 1α-hydroxylate various 25-hydroxylated metabolites and analogs has always been a controversial story. However, it is widely believed that 1α-hydroxylase activity is associated with cells of the myelomonocytic lineage in certain granulomatous conditions (e.g., sarcoidosis) (Adams and Gacad, 1985). Thus 25-OH-D can be converted to 1α,25-$(OH)_2D_3$ in sarcoid patients, a step that is not subject to tight regulation by the renal 1α-hydroxylase enzyme and thus potentially likely to result in hypercalcemia. Exposure of such patients to sunlight or administration of 25-OH-D results in excessive levels of 1α,25-$(OH)_2D_3$. The recent cloning of the cytochrome P450 representing the1α-hydroxylase (officially named CYP27B) (St. Arnaud *et al.,* 1997; Takeyama *et al.,* 1997) has been followed by confirmation that the new cytochrome can be expressed extrarenally in skin and lung cancer cells (Fu *et al.,* 1997; Jones *et al.,* 1999b), but there is currently little information for why the tight regulation of the 1α-hydroxylase is lost in certain clinical situations such as sarcoidosis.

Most of the calcitriol analogs listed in Table III are thought to be active as such, not requiring any step of activation prior to their action on the transcriptional machinery or in nongenomic pathways. It remains a theoretical possibility though that the biological activity of one of these parent analogs could be altered by enzyme systems *in vivo,* either by the generation of a more potent metabolite or by giving rise to a less active but more long-lived catabolite.

Vitamin D-Binding Protein

The vitamin D-binding protein (DBP) serves several functions including providing transport for a lipid-soluble vitamin D analog. Most of the analogs of calcitriol, designed to date, contain modifications to the side chain and this is detrimental to binding to DBP. Several analogs, for example calcipotriol or OCT, have very weak affinities for DBP, reduced by two to three orders of magnitude relative to 1α,25-$(OH)_2D_3$. This property has important implications for metabolic clearance rates, delivery to target cells and tissue distribution (Bouillon *et al.,*1991; Kissmeyer *et al.,* 1995). Detailed studies with one analog, OCT, have shown it to bind primarily to β-lipoprotein and exhibit an abnormal tissue distribution *in vivo,* with abnormally high concentrations in the parathyroid gland (Tsugawa *et al.,* 1991). It was thus proposed that this unusual distribution may make OCT a useful systemically administered drug in the treatment of hyperparathyroidism.

Another vitamin D analog with a modified side chain is 20-epi-1α,25-$(OH)_2D_3$, where the 20-*S* configuration of the side chain is opposite to the normal 20-*R* configuration. The DBP binding affinity of this analog is virtually unmeasurable because it does not displace [^{3}H]25-OH-D_3 from the plasma binding protein (Dilworth *et al.,* 1994). Confirmation that this is indeed the case comes from GH-reporter gene transactivation assays where 20-epi-1α,25-$(OH)_2D_3$ transactivates equally well in COS cells incubated in the presence and absence of fetal calf serum (as a source of DBP). On the other hand, 1α,25-$(OH)_2D_3$-induced GH reporter gene expression is sensitive to DBP in the external growth medium, requiring 2-fold less hormone in the absence of DBP as in its presence (Dilworth *et al.,* 1994). It therefore appears that analogs which bind DBP less well than 1α,25-$(OH)_2D_3$ derive a target cell advantage over the natural hormone, *if they are able to find alternative plasma carrier proteins to transport them to their target cells.* However, these same alternative plasma carriers presumably result in changes in the tissue distribution and hepatic clearance of analogs over the natural metabolites of vitamin D. The recent development of a DBP-knockout mouse (Safadi *et al.,* 1999) permits the study of alternate vitamin D analog transport mechanisms in an *in vivo* setting.

Vitamin D Receptor/RXR/VDRE Interactions

Previous chapters in this book have established that 1α,25-$(OH)_2D_3$ is able to work through a VDR-mediated genomic mechanism to stimulate transcriptional activity at vitamin D-dependent genes. Considerable progress has been made recently toward delineating the precise conformational changes which take place when the natural ligand binds to the VDR (Wurtz *et al.,* 1997; Rochel *et al.,* 2001);

and the nature of the postligand binding transcriptional events which occur, particularly the nature of the coactivator proteins involved (Rachez and Freedman *et al.,* 2000; Kato *et al.,* 2000). These developments have improved our thinking about how and where analogs might act differently from $1\alpha,25\text{-}(OH)_2D_3$ in the transcriptional cascade. Whether $1\alpha,25\text{-}(OH)_2D_3$ works through other non-VDR-mediated mechanisms to produce physiologically relevant effects is a question that currently remains unproven but this question is also important to our understanding of the pharmacological effects of vitamin D analogs.

Much evidence exists to support the viewpoint that vitamin D analogs mimic $1\alpha,25\text{-}(OH)_2D_3$ and use a genomic mechanism. The first clue that vitamin D analogs can work through a VDR-mediated transcriptional mechanism came 15 years ago from the bone resorption studies reported by Stern (1981). Stern showed that there exists a strong correlation between chick intestinal VDR binding of an analog and its potency in a [^{45}Ca] rat bone resorption assay. This suggests that a vitamin D analog is only as good as its affinity for the VDR. Certainly there are some apparent exceptions to this general rule but in the view of this reviewer they are not discrepancies that cannot be explained by other considerations such as DBP-binding or pharmacokinetics. Preliminary results with the analogs KH1060, EB1089, and 20-epi-$1\alpha,25\text{-}(OH)_2D_3$ (Binderup *et al.,* 1991) suggested that they might be active in immunoregulatory roles at concentrations orders of magnitude below their affinities for the VDR (e.g., at as low as 10^{-15} M for KH1060, whereas it binds VDR at 10^{-11}M). More recently results (Yang and Freedman, 1999; Dilworth *et al.,* 1994, 1997) suggest that 20-epi compounds including KH1060 are consistently only one to two orders of magnitude more potent than $1\alpha,25\text{-}(OH)_2D_3$ in gene transactivation assays and in differentiation assays, a difference that could be explained by fine-tuning the transcriptional model of analog action (eg by including pharmacokinetic considerations) rather than discarding the genomic hypothesis altogether. The majority of researchers agree with this view and are searching for differences in the newly delineated transcriptional machinery which might explain qualitative and quantitative differences between $1\alpha,25\text{-}(OH)_2D_3$ and its analogs.

Over the past decade it has been clearly established that the liganded VDR functions transcriptionally as a vitamin D–VDR–RXR heterodimer (Macdonald *et al.,* 1993; reviewed in Haussler *et al.,* 1998) and not as a VDR–VDR homodimer (Carlberg, 1995). The role of the RXR ligand is still controversial, many studies suggesting pan RAR and RXR ligands such as 9-*cis* retinoic acid inhibit VDR–RXR heterodimer formation while other studies demonstrate synergistic effects of pure RXR ligands (so called rexinoids) and $1\alpha,25\text{-}(OH)_2D_3$ on VDR–RXR driven transcription at a CYP24–VDRE (Zou *et al.,* 1997). Whether vitamin D analogs might differ from $1\alpha,25\text{-}(OH)_2D_3$ and act transcriptionally through VDR–VDR homodimers or other VDR–nuclear transcription factor heterodimers are ideas that have been considered as theoretical possibilities, and in some cases even shown to occur weakly *in vitro,* but largely dismissed as occurring *in vivo.*

Adding to the complexity of the target cell action of $1\alpha,25\text{-}(OH)_2D_3$, and thus that of vitamin D analogs, is the type and context of the VDRE involved (Haussler *et al.,* 1998). One possibility is that vitamin D analogs could show selectivity for certain genes based upon the type of VDRE within their promoter. Morrison and Eisman (1991) showed that a noncalcemic analog such as calcipotriol is capable of transactivating a calcemic VDRE such as the human osteocalcin promoter–VDRE placed in front of the CAT reporter gene and stably transfected into ROS 17/2 cells. One interpretation of this experiment is that a noncalcemic analog with good VDR affinity is just as calcemic as $1\alpha,25\text{-}(OH)_2D_3$ if it can be delivered to the target cell. Another idea put forward by Morrison and Eisman (1991) is that noncalcemic analogs may be capable of stimulating both cell-differentiating and calcemic genes but that the former genes require only a short pulse of analog to effect a switch in the cell cycle, whereas the latter genes require a sustained concentration of the vitamin D ligand. The concentration of $1\alpha,25\text{-}(OH)_2D_3$ may be sustained *in vivo* by renal synthesis and some protection by DBP, whereas systemically administered noncalcemic analogs reach a high initial concentration but do not bind DBP and are rapidly metabolized and cleared. This hypothesis remains to be adequately tested.

Carlberg *et al.* (1994) has also tested the idea that other vitamin D analogs (EB1089 and KH1060) might favor one specific VDRE using the mouse osteopontin gene VDRE (DR3-type) and the same human osteocalcin VDRE that Morrison and Eisman used. Carlberg *et al.* (1994) found that $1\alpha,25\text{-}(OH)_2D_3$ and the two analogs are unable to differentiate between the two different types of VDRE. Though many VDREs have been postulated in the literature it seems that the direct repeat-3 spacer type (DR3) of VDRE seems to be the sequence which is gaining widespread acceptance as the most physiologically relevant (Haussler *et al.,* 1998; Jones *et al.,* 1998). Whether other more exotic DR4, DR6, or inverted palindrome (IP9) nucleotide sequences are recognized by the analog-VDR/RXR complex *in vivo* still remains unclear (Carlberg, 1995). Even with the DR-3 type of VDRE, the gene and cell context seems to be important in determining the transactivation produced by the vitamin D analog. The work of Williams' laboratory (Brown *et al.,* 1994; Williams *et al.,* 1995; Kane *et al.,* 1996) suggests that $1\alpha,25\text{-}(OH)_2D_3$, KH1060, and EB1089 show different patterns of gene activation in bone marrow, osteoblastic cells (ROS17/2, ROS25/1, and UMR106), and intestine (HT29 and CaCo-2) which appear to be gene and cell-specific. Part of the explanation for gene- and tissue-specific effects probably lies in the influence of neighboring response elements to the VDRE and the binding of tissue-specific transcription factors at these sites. The laboratories of Lian and Stein have elegantly demonstrated (Guo *et al.,* 1997) that the response to $1\alpha,25\text{-}(OH)_2D_3$–VDR–RXR complex to the gene promoter of the osteocalcin gene in osteoblasts depends upon occupancy of an adjoining YY1 binding site which allows

for temporal changes in responsiveness to $1\alpha,25\text{-}(OH)_2D_3$. Though this work explains why $1\alpha,25\text{-}(OH)_2D_3$ might have gene- and tissue-specific effects, it does not explain the analog-specific differences in Williams' work.

As alluded to above, the emergence of important new information about (a) the structure of the ligand-binding domain of the VDR and (b) coactivator characterization and involvement in the $1\alpha,25\text{-}(OH)_2D_3$–VDR–RXR transcriptional machinery have opened up additional possibilities about where vitamin D analogs might differ in their action from the natural ligand. Evidence suggests that the "Trap Door Hypothesis" for retinoid binding to RAR/RXR (Renaud *et al.,* 1995) also applies to $1\alpha,25\text{-}(OH)_2D_3$ binding to VDR. In this model, $1\alpha,25\text{-}(OH)_2D_3$ binding to a central binding pocket triggers a dramatic conformational change of helix 12, a domain close to the C-terminus of the VDR, such that it moves from a position on the exterior of the VDR to one within the interior of the receptor, thereby closing the access channel to the ligand binding pocket. In the process, amino acid residues of the AF-2 domain which are hidden in the unliganded VDR become exposed in the liganded VDR and are now available to interact with coactivator proteins. The recruitment of coactivators to the $1\alpha,25\text{-}(OH)_2D_3$–VDR–RXR subsequently lead to the recruitment of other transcription factors which result in chromatin remodeling and gene transcription.

In the execution of this work, members of Moras' laboratory have modeled the ligand-binding pocket of VDR and shown it to be able to accommodate with ease several other analogs depicted in Table III (Rochel *et al.,* 2001). Though many of the active vitamin D analogs, especially the 20-epi analogs, have bulky side chain substituents or radically different side chain orientations (Yamamoto *et al.,* 1999), the pocket appears to have a great reserve capacity for binding (Rochel *et al.,* 2001). As a result, from modeling alone it is difficult to forecast radical changes in VDR conformations as a result of binding to these different analogs. Nevertheless, there is some indirect evidence, most notably from experiments measuring susceptibility to protease digestion, that subtle differences do occur in VDR–RXR containing transcription complexes when different ligands are used (Peleg *et al.,* 1995; Carlberg *et al.,* 1995; *et al.,* Van den Bemd, 1996). Binding of 20-epi-analogs (e.g., MC1288 and KH1060) to the VDR results in increased resistance to protease digestion as compared to $1\alpha,25\text{-}(OH)_2D_3$, which has been interpreted as evidence for differences in accessibility of protease to cleavage sites (Peleg *et al.,* 1995). Interestingly, there appears to be a direct correlation between transactivation activity of an analog and the resistance of the VDR-transactivation complex to protease, a relationship that applies to different analogs and even to metabolites from a single analog (Peleg *et al.,* 1995; Liu *et al.,* 1997; Van den Bemd *et al.,* 2000). Because the rearrangement in helix 12 of the VDR brings about exposure of the AF-2 domain and this is critical to coactivator binding, it might be expected that subtle conformational differences in VDR observed for different vitamin D analogs might also be reflected in differences in coactivator recruitment.
