Contents

VOLUME 1

Contributors xiii
Preface to the Second Edition xxi
Preface to the First Edition xxiii

PART I
BASIC PRINCIPLES

A. Cell Biology

CHAPTER 1
Structure and Development of the Skeleton 3
Sandy C. Marks, Jr., and Paul R. Odgren

CHAPTER 2
Biomechanics of Bone 17
Dennis M. Cullinane and Thomas A. Einhorn

CHAPTER 3
Embryonic Development of Bone and the Molecular Regulation of Intramembranous and Endochondral Bone Formation 33
Andrew C. Karaplis

CHAPTER 4
Mesenchymal Stem Cells and Osteoblast Differentiation 59
Jane E. Aubin and James T. Triffitt

CHAPTER 5
Transcriptional Control of Osteoblast Differentiation and Function 83
Thorsten Schinke and Gerard Karsenty

CHAPTER 6
The Osteocyte 93
P. J. Nijweide, E. H. Burger, and J. Klein-Nulend

CHAPTER 7
Cells of Bone: Osteoclast Generation 109
Naoyuki Takahashi, Nobuyuki Udagawa, Masamichi Takami, and Tatsuo Suda

CHAPTER 8
Osteoclast Function: Biology and Mechanisms 127
Kalervo Väänänen and Haibo Zhao

CHAPTER 9
Integrin and Calcitonin Receptor Signaling in the Regulation of the Cytoskeleton and Function of Osteoclasts 141
Le T. Duong, Archana Sanjay, William Horne, Roland Baron, and Gideon A. Rodan

CHAPTER 10
Apoptosis in Bone Cells 151
Brendan F. Boyce, Lianping Xing, Robert J. Jilka, Teresita Bellido, Robert S. Weinstein, A. Michael Parfitt, and Stavros C. Manolagas

CHAPTER 11
Involvement of Nuclear Architecture in Regulating Gene Expression in Bone Cells 169
Gary S. Stein, Jane B. Lian, Martin Montecino, André J. van Wijnen, Janet L. Stein, Amjad Javed, and Kaleem Zaidi

B. Biochemistry

CHAPTER 12
Type I Collagen: Structure, Synthesis, and Regulation 189
Jerome Rossert and Benoit de Crombrugghe

CHAPTER 13
Collagen Cross-Linking and Metabolism 211
Simon P. Robins and Jeffrey D. Brady

CHAPTER 14
Bone Matrix Proteoglycans and Glycoproteins 225
Pamela Gehron Robey

CHAPTER 15
Osteopontin 239
Masaki Noda and David T. Denhardt

CHAPTER 16
Bone Proteinases 251
Richard C. D'Alonzo, Nagarajan Selvamurugan, Stephen M. Krane, and Nicola C. Partridge

CHAPTER 17
Integrins and Other Cell Surface Attachment Molecules of Bone Cells 265
Michael A. Horton, Stephen A. Nesbitt, Jon H. Bennett, and Gudrun Stenbeck

CHAPTER 18
Intercellular Junctions and Cell–Cell Communication in Bone 287
Roberto Civitelli, Fernando Lecanda, Niklas R. Jørgensen, and Thomas H. Steinberg

C. Bone Remodeling and Mineral Homeostasis

CHAPTER 19
Histomorphometric Analysis of Bone Remodeling 303
Susan M. Ott

CHAPTER 20
Phosphorus Homeostasis and Related Disorders 321
Marc K. Drezner

CHAPTER 21
Magnesium Homeostasis 339
Robert K. Rude

CHAPTER 22
Metals in Bone: Aluminum, Boron, Cadmium, Chromium, Lead, Silicon, and Strontium 359
Felix Bronner

CHAPTER 23
Biology of the Extracellular Ca^{2+}-Sensing Receptor (CaR) 371
Edward M. Brown

D. The Hormones of Bone

CHAPTER 24
Receptors for Parathyroid Hormone (PTH) and PTH-Related Peptide 389
Thomas J. Gardella, Harald Jüppner, F. Richard Bringhurst, and John T. Potts, Jr.

CHAPTER 25
Parathyroid Hormone: Molecular Biology 407
Justin Silver, Tally Naveh-Many, and Henry M. Kronenberg

CHAPTER 26
Parathyroid Hormone–Receptor Interactions 423
Michael Chorev and Michael Rosenblatt

CHAPTER 27
Actions of Parathyroid Hormone 463
Janet M. Hock, Lorraine A. Fitzpatrick, and John Bilezikian

CHAPTER 28
Renal and Skeletal Actions of Parathyroid Hormone (PTH) and PTH-Related Protein 483
F. Richard Bringhurst and Gordon J. Strewler

CHAPTER 29
Physiological Actions of Parathyroid Hormone (PTH) and PTH-Related Protein: Epidermal, Mammary, Reproductive, and Pancreatic Tissues 515
John J. Wysolmerski, Andrew F. Stewart, and T. John Martin

CHAPTER 30
Vascular, Cardiovascular, and Neurological Actions of Parathyroid-Related Protein 531
Thomas L. Clemens and Arthur E. Broadus

CHAPTER 31
1α,25(OH)$_2$Vitamin D$_3$: Nuclear Receptor Structure (VDR) and Ligand Specificities for Genomic and Rapid Biological Responses 545
Anthony W. Norman

CHAPTER 32
Vitamin D Gene Regulation 573
Sylvia Christakos

CHAPTER 33
Photobiology and Noncalcemic Actions of Vitamin D 587
Michael F. Holick

CHAPTER 34
Structure and Molecular Biology of the Calcitonin Receptor 603
Deborah L. Galson and Steven R. Goldring

CHAPTER 35
Calcitonin Gene Family of Peptides: Structure, Molecular Biology, and Effects 619
Kenneth L. Becker, Beat Müller, Eric S. Nylén, Régis Cohen, Jon C. White, and Richard H. Snider, Jr.

CHAPTER 36
Amylin and Calcitonin Gene-Related Peptide 641
Ian R. Reid and Jill Cornish

E. Other Systemic Hormones That Influence Bone Metabolism

CHAPTER 37
Estrogens and Progestins 655
David Rickard, Steven A. Harris, Russell Turner, Sundeep Khosla, and Thomas C. Spelsburg

CHAPTER 38
Selective Estrogen Receptor Modulators 677
Douglas B. Muchmore and Geoffrey Greene

CHAPTER 39
Mechanisms of Estrogen Action in Bone 693
Roberto Pacifici

CHAPTER 40
Thyroid Hormone and Bone 707
Paula H. Stern

CHAPTER 41
Clinical and Basic Aspects of Glucocorticoid Action in Bone 723
Barbara E. Kream and Barbara P. Lukert

CHAPTER 42
Effects of Diabetes and Insulin on Bone Physiology 741
Johan Verhaeghe and Roger Bouillon

CHAPTER 43
Androgens: Receptor Expression and Steroid Action in Bone 757
Kristine M. Wiren and Eric S. Orwoll

CHAPTER 44
Kinins and Neuro-osteogenic Factors **773**
Ulf H. Lerner and Pernilla Lundberg

F. Local Regulators

CHAPTER 45
The Role of Insulin-like Growth Factors and Binding Proteins in Bone Cell Biology **801**
Cheryl A. Conover and Clifford Rosen

CHAPTER 46
Platelet-Derived Growth Factor and the Skeleton **817**
Ernesto Canalis and Sheila Rydziel

CHAPTER 47
Fibroblast Growth Factor (FGF) and FGF Receptor Families in Bone **825**
Marja M. Hurley, Pierre J. Marie, and Robert Z. Florkiewicz

Index for Volumes 1 and 2 853

VOLUME 2

Contributors xi
Preface to the Second Edition xix
Preface to the First Edition xxi

CHAPTER 48
Vascular Endothelial Growth Factors **883**
Shun-ichi Harada and Kenneth A. Thomas

CHAPTER 49
Transforming Growth Factor-β **903**
L. F. Boneward

CHAPTER 50
Bone Morphogenetic Proteins **919**
Vicki Rosen and John M. Wozney

CHAPTER 51
Bone Morphogenetic Protein Receptors and Actions **929**
Kohei Miyazono

CHAPTER 52
Colony-Stimulating Factors **943**
Willy Hofstetter and Matthew T. Gillespie

CHAPTER 53
Local Regulators of Bone: IL-1, TNF, Lymphotoxin, Interferon-γ, IL-8, IL-10, IL-4, the LIF/IL-6 Family, and Additional Cytokines **961**
Mark C. Horowitz and Joseph A. Lorenzo

CHAPTER 54
Prostaglandins and Bone Metabolism **979**
Carol C. Pilbeam, John R. Harrison, and Lawrence G. Raisz

CHAPTER 55
Nitric Oxide and Other Vasoactive Agents **995**
Lee D. K. Buttery, Lucia Mancini, Niloufar Moradi-Bidhendi, Meg C. O'Shaughnessy, Julia M. Polak, and Iain MacIntyre

PART II
MOLECULAR MECHANISIMS OF METABOLIC BONE DISEASES

CHAPTER 56
Molecular Basis of PTH Overexpression **1017**
Geoffrey N. Hendy and Andrew Arnold

CHAPTER 57
Familial Benign Hypocalciuric Hypercalcemia and Neonatal Primary Hyperparathyroidism **1031**
Ghada El-Hajj Fuleihan, Edward M. Brown, and Hunter Heath III

CHAPTER 58
Multiple Endocrine Neoplasia Type 1 **1047**
Maria Luisa Brandi, Cesare Bordi, Francesco Tonelli, Alberto Falchetti, and Stephen J. Marx

CHAPTER 59
The Role of the *RET* Protooncogene in Multiple Endocrine Neoplasia Type 2 **1067**
Robert F. Gagel and Gilbert J. Cote

CHAPTER 60
Systemic Factors in Skeletal Manifestations of Malignancy **1079**
Janet E. Henderson, Richard Kremer, and David Goltzman

CHAPTER 61
Local Factors in Skeletal Malignancy **1093**
Gregory R. Mundy, Toshiyuki Yoneda, Theresa A. Guise, and Babatunde Oyajobi

CHAPTER 62
Molecular Basis of PTH Underexpression **1105**
R. V. Thakker

CHAPTER 63
Jansen's Metaphysical Chondrodysplasia and Blomstrand's Lethal Chondrodysplasia: Two Genetic Disorders Caused by PTH/PTHrP Receptor Mutations **1117**
Harald Jüppner, Ernestina Schipani, and Caroline Silve

CHAPTER 64
Pseudohypoparathyroidism **1137**
Michael A. Levine

CHAPTER 65
Other Skeletal Diseases Resulting from G Protein Defects: Fibrous Dysplasia of Bone and McCune–Albright Syndrome **1165**
Lee S. Weinstein

CHAPTER 66
Osteogenesis Imperfecta **1177**
David W. Rowe

CHAPTER 67
Hereditary Deficiencies in Vitamin D Action **1195**
Uri A. Liberman

CHAPTER 68
Oncogenic Osteomalacia **1209**
Kenneth W. Lyles

CHAPTER 69
Osteopetrosis **1217**
L. Lyndon Key, Jr., and William L. Ries

CHAPTER 70
Hypophosphatasia: Nature's Window on Alkaline Phosphatase Function in Man **1229**
Michael P. Whyte

CHAPTER 71
Paget's Disease of Bone **1249**
Frederick R. Singer and G. David Roodman

CHAPTER 72
Genetic Determinants of Bone Mass and Osteoporotic Fracture **1259**
Stuart H. Ralston

CHAPTER 73
Pathophysiology of Osteoporosis **1275**
Gideon A. Rodan, Lawrence G. Raisz, and John P. Bilezikian

CHAPTER 74
Evaluation of Risk for Osteoporosis Fractures **1291**
Patrick Garnero and Pierre D. Delmas

PART III
PHARMACOLOGICAL MECHANISMS OF THERAPEUTICS

CHAPTER 75
Parathyroid Hormone **1305**
A. B. Hodsman, D. A. Hanley, P. H. Watson, and L. J. Fraher

CHAPTER 76
Calcium **1325**
Robert P. Heaney

CHAPTER 77
Calcium Receptors as Novel Drug Targets 1339
Edward F. Nemeth

CHAPTER 78
Bisphosphonates: Mechanisms of Action 1361
Herbert Fleisch, Alfred Reszka, Gideon A. Rodan, and Michael Rogers

CHAPTER 79
Fluoride in Osteoporosis 1387
Johann D. Ringe

CHAPTER 80
The Pharmacology of Estrogens in Osteoporosis 1401
Robert Lindsay and Felicia Cosman

CHAPTER 81
Vitamin D and Analogs 1407
Glenville Jones

CHAPTER 82
Molecular and Clinical Pharmacology of Calcitonin 1423
Mone Zaidi, Angela M. Inzerillo, Bruce Troen, Baljit S. Moonga, Etsuko Abe, and Peter Burckhardt

CHAPTER 83
Growth Hormone and Insulin-like Growth Factor-I Treatment for Metabolic Bone Diseases 1441
Clifford J. Rosen

CHAPTER 84
Anabolic Steroid Effects on Bone in Women 1455
Azriel Schmidt, Shun-ichi Harada, and Gideon A. Rodan

CHAPTER 85
Estrogen Effects on Bone in the Male Skeleton 1467
John P. Bilezikian, Sundeep Khosla, and B. Lawrence Riggs

CHAPTER 86
Mechanisms of Exercise Effects on Bone 1477
Robert Marcus

PART IV
METHODS IN BONE RESEARCH

CHAPTER 87
Application of Transgenic Mice to Problems of Skeletal Biology 1491
Stephen Clark and David Rowe

CHAPTER 88
Use of Cultured Osteoblastic Cells to Identify and Characterize Transcriptional Regulatory Complexes 1503
Dwight A. Towler and Rene St. Arnaud

CHAPTER 89
Current Methodologic Issues in Cell and Tissue Culture 1529
Robert J. Majeska and Gloria A. Gronowicz

CHAPTER 90
Biochemical Markers of Bone Metabolism 1543
Markus J. Seibel, Richard Eastell, Caren M. Gundberg, Rosemary Hannon, and Huibert A. P. Pols

CHAPTER 91
Methods and Clinical Issues in Bone Densitometry and Quantitative Ultrasonometry 1573
Glen M. Blake and Ignac Fogelman

CHAPTER 92
Controversial Issues in Bone Densitometry 1587
Paul D. Miller

CHAPTER 93
Macro- and Microimaging of Bone Architecture 1599
Yebin Jiang, Jenny Zhao, and Harry K. Genant

CHAPTER 94
Transilial Bone Biopsy **1625**
Robert R. Recker and
M. Janet Barger-Lux

CHAPTER 95
Animal Models in Osteoporosis Research **1635**
Donald B. Kimmel

CHAPTER 96
Defining the Genetics of Osteoporosis: Using the Mouse to Understand Man **1657**
C. J. Rosen, L. R. Donahue, and W. G. Beamer

Index for Volumes 1 and 2 1667

Contributors

Numbers in parentheses indicate the volume and pages on which the authors' contributions begin.

Etsuko Abe (2:1423)
Departments of Medicine and Geriatrics, Mount Sinai Bone Program, Mount Sinai School of Medicine, and Bronx Veterans Affairs Geriatrics Research Education and Clinical Center (GRECC), New York, New York 10029

Andrew Arnold (2:1017)
Center for Molecular Medicine and Division of Endocrinology and Metabolism, University of Connecticut School of Medicine, Farmington, Connecticut 06030

Jane E. Aubin (1:59)
Department of Anatomy and Cell Biology, University of Toronto, Toronto, Ontario, Canada M5S 1A8

M. Janet Barger-Lux (2:1625)
Osteoporosis Research Center, Creighton University, Omaha, Nebraska 68131

Roland Baron (1:141)
Department of Cell Biology and Orthopedics, Yale University School of Medicine, New Haven, Connecticut 06510

W. G. Beamer (2:1657)
The Jackson Laboratory, Bar Harbor, Maine 04609

Kenneth L. Becker (1:619)
Veterans Affairs Medical Center and George Washington University, School of Medicine, George Washington University, Washington, DC 20422

Teresita Bellido (1:151)
Division of Endocrinology and Metabolism, Center for Osteoporosis and Metabolic Bone Diseases, Central Arkansas Veterans Healthcare System, University of Arkansas for Medical Sciences, Little Rock, Arkansas 72205

Jon H. Bennett (1:265)
Department of Oral Pathology, Eastman Dental Institute, London WC1X 8LD, United Kingdom

John P. Bilezikian (1:463; 2:1275; 2:1467)
Departments of Medicine and Pharmacology, College of Physicians and Surgeons, Columbia University, New York, New York 10032

Glen M. Blake (2:1573)
Department of Nuclear Medicine, Guy's Hospital, London SE1 9RT, United Kingdom

L. F. Bonewald (2:903)
Department of Medicine, Division of Endocrinology and Metabolism, University of Texas Health Science Center at San Antonio, San Antonio, Texas 78284

Cesare Bordi (2:1047)
Department of Pathology and Laboratory Medicine, Section of Anatomic Pathology, University of Parma, 1-43100 Parma, Italy

Roger Bouillon (1:741)
Laboratorium voor Experimentele Geneeskunde en Endocrinologie, Katholieke Universiteit Leuven, 3000 Leuven, Belgium

Brenda F. Boyce (1:151)
Department of Pathology and Laboratory Medicine, University of Rochester Medical Center, Rochester, New York 14642

Jeffrey D. Brady (1:211)
Skeletal Research Unit, Rowett Research Institute, Aberdeen AB21 9SB, Scotland

Maria Luisa Brandi (2:1047)
Department of Internal Medicine, University of Florence, 6-50139 Florence, Italy

F. Richard Bringhurst (1:389; 1:483)
Departments of Medicine and Pediatrics, Endocrine Unit, Harvard Medical School, Massachusetts General Hospital, Boston, Massachusetts 02114

Arthur E. Broadus (1:531)
Section of Endocrinology, Department of Internal Medicine, Yale University School of Medicine, New Haven, Connecticut 06510

Felix Bronner (1:359)
Department of BioStructure and Function, The University of Connecticut Health Center, Farmington, Connecticut 06030

Edward M. Brown (1:371; 2:1031)
Endocrine Hypertension Division, Brigham and Women's Hospital and Harvard Medical School, Boston, Massachusetts 02115

Peter Burckhardt (2:1423)
University Hospital, 1011 Lausanne, Switzerland

E. H. Burger (1:93)
Department of Oral Cell Biology, ACTA-Virje Universiteit, 1081 BT Amsterdam, The Netherlands

Lee D. K. Buttery (2:995)
Tissue Engineering Centre, Imperial College School of Medicine, Chelsea and Westminster Campus, London SW10 9NH, United Kingdom

Ernesto Canalis (1:817)
Saint Francis Hospital and Medical Center, and the University of Connecticut School of Medicine, Hartford, Connecticut 06105

Michael Chorev (1:423)
Division of Bone and Mineral Metabolism, Charles A. Dana and Thorndike Memorial Laboratories, Department of Medicine, Beth Israel Deaconess Medical Center and Harvard Medical School, Boston, Massachusetts 02215

Sylvia Christakos (1:573)
Department of Biochemistry and Molecular Biology, University of Medicine and Dentistry of New Jersey, New Jersey Medical School, Newark, New Jersey 07103

Roberto Civitelli (1:287)
Departments of Medicine and Cell Biology and Physiology, Division of Bone and Mineral Diseases, Washington University School of Medicine and Barnes-Jewish Hospital, St. Louis, Missouri 63110

Stephen Clark (2:1491)
Department of Genetics and Developmental Biology, University of Connecticut Health Center, Farmington, Connecticut 06030

Thomas L. Clemens (1:531)
Division of Endocrinology & Metabolism, University of Cincinnati College of Medicine, Cincinnati, Ohio 45267

Régis Cohen (1:619)
University of Paris, Hôpital Avicenne, Bobigny, France

Cheryl A. Conover (1:801)
Mayo Clinic and Foundation, Rochester, Minnesota 55905

Jill Cornish (1:641)
Department of Medicine, University of Auckland, Auckland, New Zealand

Felicia Cosman (2:1401)
Helen Hayes Hospital, West Haverstraw, New York 10993; and Department of Medicine, Columbia University, New York, New York 10027

Gilbert J. Cote (2:1067)
Department of Endocrine Neoplasia and Hormonal Disorders, University of Texas M.D. Anderson Cancer Center, Houston, Texas 77030

Dennis M. Cullinane (1:17)
Department of Orthopaedic Surgery, Boston University Medical Center, Boston, Massachusetts 02118

Richard C. D'Alonzo (1:251)
Department of Physiology and Biophysics, Robert Wood Johnson Medical School, Piscataway, New Jersey 08854

Benoit de Crombrugghe (1:189)
University of Texas M.D. Anderson Cancer Center, Houston, Texas 77030

Pierre D. Delmas (2:1291)
INSERM Unit 403, Hôpital E. Herriot, and Synarc, Lyon 69003, France

David T. Denhardt (1:239)
Department of Cell Biology and Neuroscience, Rutgers University, Piscataway, New Jersey

L. R. Donahue (2:1657)
The Jackson Laboratory, Bar Harbor, Maine 04609

Marc K. Drezner (1:321)
Department of Medicine, Section of Endocrinology, Diabetes, and Metabolism, University of Wisconsin, Madison, Wisconsin 53792

Le T. Duong (1:141)
Department of Bone Biology and Osteoporosis, Merck Research Laboratories, West Point, Pennsylvania 19486

Richard Eastell (2:1543)
Clinical Sciences Center, Northern General Hospital, Sheffield S5 7AU, United Kingdom

Thomas A. Einhorn (1:17)
Department of Orthopaedic Surgery, Boston University Medical Center, Boston, Massachusetts 02118

Ghada El-Hajj Fuleihan (2:1031)
Calcium Metabolism and Osteoporosis Program, American University of Beirut, Beirut 113-6044, Lebanon

Alberto Falchetti (2:1047)
Department of Internal Medicine, University of Florence, 6-50139 Florence, Italy

Lorraine A. Fitzpatrick (1:463)
Department of Medicine, Mayo Clinic and Foundation, Rochester, Minnesota 55905

Herbert Fleisch (2:1361)
University of Berne, Berne CH-3008, Switzerland

Robert Z. Florkiewicz (1:825)
Ciblex Corporation, San Diego, California 92121

Ignac Fogelman (2:1573)
Department of Nuclear Medicine, Guy's Hospital, London SE1 9RT, United Kingdom

L. J. Fraher (2:1305)
Department of Medicine and the Lawson Health Research Institute, St. Joseph's Health Centre, and the University of Western Ontario, London, Ontario, Canada N6A 4V2

Robert F. Gagel (2:1067)
Division of Internal Medicine, University of Texas M.D. Anderson Cancer Center, Houston, Texas 77030

Deborah L. Galson (1:603)
Department of Medicine, Harvard Medical School, and Division of Rheumatology, Beth Israel Deaconess Medical

Center, and the New England Baptist Bone & Joint Institute, Boston, Massachusetts 02215

Thomas J. Gardella (1:389)
Departments of Medicine and Pediatrics, Endocrine Unit, Harvard Medical School, Massachusetts General Hospital, Boston, Massachusetts 02129

Patrick Garnero (2:1291)
INSERM Unit 403, Hôpital E. Herriot, and Synarc, Lyon 69003, France

Harry K. Genant (2:1599)
Osteoporosis and Arthritis Research Group, Department of Radiology, University of California, San Francisco, San Francisco, California 94143

Matthew T. Gillespie (2:943)
St. Vincent's Institute of Medical Research, Fitzroy, Victoria 3065, Australia

Steven R. Goldring (1:603)
Department of Medicine, Harvard Medical School, and Division of Rheumatology, Beth Israel Deaconess Medical Center, and the New England Baptist Bone & Joint Institute, Boston, Massachusetts 02215

David Goltzman (2:1079)
Calcium Research Laboratory, Royal Victoria Hospital, Montreal, Quebec, Canada H3A 1A1

Geoffrey Greene (1:677)
Ben May Institute for Cancer Research, University of Chicago, Chicago, Illinois 60637

Gloria A. Gronowicz (2:1529)
Department of Orthopaedics, University of Connecticut School of Medicine, Farmington, Connecticut 06032

Theresa A. Guise (2:1093)
Department of Medicine, University of Texas Health Science Center, San Antonio, Texas 78284

Caren M. Gundberg (2:1543)
Department of Orthopedics and Rehabilitation, Yale University School of Medicine, New Haven, Connecticut 06520

D. A. Hanley (2:1305)
Division of Endocrinology and Metabolism, Faculty of Medicine, University of Calgary, Calgary, Alberta, Canada

Rosemary Hannon (2:1543)
Division of Clinical Sciences (NGHT), University of Sheffield, Northern General Hospital, Sheffield S5 7AU, United Kingdom

Shun-ichi Harada (2:883; 2:1455)
Department of Bone Biology and Osteoporosis Research, Merck Research Laboratories, West Point, Pennsylvania 19486

Steven A. Harris (1:655)
Bayer Corporation, West Haven, Connecticut 04516

John R. Harrison (2:979)
Department of Orthodontics, University of Connecticut Health Center, Farmington, Connecticut 06030

Robert P. Heaney (2:1325)
Creighton University, Omaha, Nebraska 68178

Hunter Heath III (2:1031)
Lilly Research Laboratories, Eli Lilly and Company, Indianapolis, Indiana 46285

Janet E. Henderson (2:1079)
Department of Medicine, Lady Davis Institute, Montreal, Quebec, Canada H3T 1E2

Geoffrey N. Hendy (2:1017)
Calcium Research Laboratory, Royal Victoria Hospital, and Departments of Medicine and Physiology, McGill University, Montreal, Quebec, Canada H3A 1A1

Janet M. Hock (1:463)
Department of Anatomy and Cell Biology, Indiana University School of Medicine, Indianapolis, Indiana 46202

A. B. Hodsman (2:1305)
Department of Medicine and the Lawson Health Research Institute, St. Joseph's Health Centre, and the University of Western Ontario, London, Ontario, Canada N6A 4V2

Willy Hofstetter (2:943)
Department of Clinical Research, Group for Bone Biology, University of Berne, CH-3010 Berne, Switzerland

Michael F. Holick (1:587)
Boston University School of Medicine, Boston, Massachusetts 02118

William Horne (1:141)
Department of Cell Biology and Orthopedics, Yale University School of Medicine, New Haven, Connecticut 06510

Mark C. Horowitz (2:961)
Departments of Orthopaedics and Rehabilitation, Yale University School of Medicine, New Haven, Connecticut 06520; and the Department of Medicine, The University of Connecticut Health Center, Farmington, Connecticut 06032

Michael A. Horton (1:265)
Department of Medicine, Bone and Mineral Center, The Rayne Institute, University College London, London WC1E 6JJ, United Kingdom

Maria M. Hurley (1:825)
Department of Medicine, Division of Endocrinology and Metabolism, The University of Connecticut Health Center, Farmington, Connecticut 06032

Angela M. Inzerillo (2:1423)
Departments of Medicine and Geriatrics, Mount Sinai Bone Program, Mount Sinai School of Medicine, and Bronx Veterans Affairs Geriatrics Research Education and Clinical Center (GRECC), New York, New York 10029

Amjad Javed (1:169)
Department of Cell Biology and UMass Cancer Center, University of Massachusetts Medical School, Worcester, Massachusetts 01655

Yebin Jiang (2:1599)
Osteoporosis and Arthritis Research Group, Department of Radiology, University of California, San Francisco, San Francisco, California 94143

Robert L. Jilka (1:151)
Division of Endocrinology and Metabolism, Center for Osteoporosis and Metabolic Bone Diseases, Central Arkansas Veterans Healthcare System, University of Arkansas for Medical Sciences, Little Rock, Arkansas 72205

Glenville Jones (2:1407)
Department of Biochemistry, Queen's University, Kingston, Ontario, Canada K7L 3N6

Nikklas R. Jørgensen (1:287)
Osteoporosis Research Clinic, Copenhagen University Hospital, Hvidovre DK-2650, Denmark

Harald Jüppner (1:389; 2:1117)
Department of Medicine, Endocrine Unit, and Mass-General Hospital for Children, Massachusetts General Hospital, and Harvard Medical School, Boston, Massachusetts 02114

Andrew C. Karaplis (1:33)
Department of Medicine and Lady Davis Institute for Medical Research, Division of Endocrinology, Sir Mortimer B. Davis–Jewish General Hospital, McGill University, Montreal, Quebec, Canada H3T 1E2

Gerard Karsenty (1:83)
Baylor College of Medicine, Houston, Texas 77030

L. Lyndon Key, Jr. (2:1217)
Department of Pediatrics, General Clinical Research Center, Medical University of South Carolina, Charleston, South Carolina 29425

Sundeep Khosla (1:655; 2:1467)
Department of Internal Medicine, Division of Endocrinology and Metabolism, Mayo Clinic and Foundation, Rochester, Minnesota 55905

Donald B. Kimmel (2:1635)
Department of Bone Biology and Osteoporosis Research, Merck Research Laboratories, West Point, Pennsylvania 19486

J. Klein-Nulend (1:93)
Department of Oral Cell Biology, ACTA-Vrije Universiteit, 1081 BT Amsterdam, The Netherlands

Stephen M. Krane (1:251)
Department of Medicine, Harvard Medical School, Boston, Massachusetts 02114

Barbara E. Kream (1:723)
Department of Medicine, Division of Endocrinology and Metabolism, University of Connecticut Health Center, Farmington, Connecticut 06030

Richard Kremer (2:1079)
Calcium Research Laboratory, Royal Victoria Hospital, Montreal, Quebec, Canada H3A 1A1

Preface to the Second Edition

The success of the first edition of *Principles of Bone Biology* clearly indicated that this text met an important need in our field. Well-worn copies (often with a cracked spine!) can be found on the shelves of bone biology research laboratories and offices throughout the world. We knew from the outset that undertaking the first edition would include a commitment to producing a second one. Advances in bone biology over the past five years have moved forward at a dizzying pace, clearly justifying the need for a second edition at this time. The elucidation of the molecular interactions between osteoblasts and osteoclasts is one of many examples documenting this point. Studies of animals in which critical genes have been deleted or over-expressed have produced some surprises and added still further complexity to what we have already recognized as an extremely complex regulatory system controlling the development and maintenance of skeletal structures. These and many other advances have provided the background for further development of effective therapeutic approaches to metabolic bone diseases.

In preparing the second edition, we have asked all authors to provide extensive revisions of their chapters. Additionally, the second edition features new authors who have written 10 new chapters. Some chapters from the first edition have been consolidated or otherwise reconfigured to keep the total number of chapters essentially the same as in the first edition. Although the number of chapters and their organizational structure has been retained, the extraordinary amount of new information has led to an increase in size of many of the chapters along with more extensive referencing. As a result, the substantially larger second edition is being published in two volumes. Each volume contains a full table of contents and full indexing to help the reader find specific information. The somewhat smaller individual volumes should be easier to handle and hold up better to the extensive use we expect from readers.

As was the case in the first edition, we asked our authors to meet a tight schedule so that the text would be as up-to-date as possible. We are indebted to our many authors who successfully met this challenge. The updated chapters as well as the new ones have, therefore, been written in such a way that the newest and most exciting breakthroughs in our field are still fresh. This task could not have been completed without the help of the staff at Academic Press. We acknowledge, in particular, Jasna Markovac and Mica Haley. They have been enormously helpful in all phases of this effort.

We have enjoyed very much the task of bringing this second edition to you. We trust that this second edition will be even more useful to you than the first. Enjoy the book!

John P. Bilezikian
Lawrence G. Raisz
Gideon A. Rodan

Preface to the First Edition

The world of modern science is undergoing a number of spectacular events that are redefining our understanding of ourselves. As with any revolution, we should take stock of where we have been, where we are, and where we are going. Our special world of bone biology is participating in and taking advantage of the larger global revolution in modern science. Often with shocking but delightful suddenness, we are gaining new insights into difficult issues, discovering new concepts to explain old observations, developing new approaches to perennial mysteries, and applying novel technological advances from other fields to our own. The pace with which the bone world is advancing is impressive not only to the most ardent optimists, who did not expect so much so soon, but also to the more sober minded who, only several years ago, would have brushed off the notion that progress could come with such lightening speed.

The rationale for this book is rooted in the recognition of the revolution in bone biology. We need a new repository of knowledge, bringing us both to the core and to the edge of our universe. Our goal is to provide complete, truly up-to-date, and detailed coverage of this exciting and rapidly developing field. To achieve this, we assembled experts from all over the world and asked them to focus on the current state of knowledge and the prospects for new knowledge in their area of expertise. To this end, *Principles of Bone Biology* was conceived. It is designed to be useful to students who are becoming interested in the field and to young investigators at the graduate or postgraduate level who are beginning their research careers. It is also designed for more established scientists who want to keep up with the changing nature of our field, who want to mine this lode to enrich their own research programs, or who are changing their career direction. Finally, this book is written for anyone who simply strives for greater understanding of bone biology.

This book is intended to be comprehensive but readable. Each chapter is relatively brief. The charge to each author has been to limit size while giving the reader information so complete that it can be appreciated on its own, without necessary recourse to the entire volume. Nevertheless, the book is also designed with a logic that might compel someone to read on, and on, and on!

The framework of organization is fourfold. The first 53 chapters, in a section titled "Basic Principles," cover the cells themselves: the osteoblast, the osteoclast, and the osteocyte; how they are generated; how they act and interact; what turns them on; what turns them off; and how they die. In this section, also, the biochemistry of collagenous and noncollagenous bone proteins is covered. Newer understandings of calcium, phosphorus, and magnesium metabolism and the hormones that help to control them, namely, parathyroid hormone, vitamin D metabolites, calcitonin, and related molecules, are presented. A discussion of other systemic and local regulators of bone metabolism completes this section.

The second section of this book, "Molecular Mechanisms of Metabolic Bone Diseases," is specifically devoted to basic mechanisms of a variety of important bone diseases. The intention of these 17 chapters is not to describe the diseases in clinical, diagnostic, or therapeutic terms but rather to illustrate our current understanding of underlying mechanisms. The application of the new knowledge summarized in Part I to pathophysiological, pathogenetic, and molecular mechanisms of disease has relevance to the major metabolic bone disorders such as osteoporosis, primary hyperparathyroidism, and hypercalcemia of malignancy as well as to the more uncommon disorders such as familial benign hypocalciuric hypercalcemia, pseudohypoparathyroidism, and osteopetrosis.

The third section of this book, "Pharmacological Mechanisms of Therapeutics," addresses the great advances that have been made in elucidating how old and new drugs act to improve abnormalities in bone metabolism. Some of these drugs are indeed endogenous hormones that under

specified circumstances are useful therapies: estrogens, vitamin D, calcitonin, and parathyroid hormone are representative examples. Others agents such as the bisphosphonates, fluoride, and calcium are reviewed. Finally, agents with therapeutic potential but still in development such as calcimimetics, insulin-like growth factors, transforming growth factor, bone morphogenetic protein, and fibroblast growth factor are presented with a view to the future. The intent of this 12-chapter section is not to provide step-by-step "how-to" instructions for the clinical uses of these agents. Such prescribing information for established therapies is readily found in other texts. Rather, the underlying mechanisms by which these agents are currently believed to work is the central point of this section.

The fourth and final section of this book, "Methods in Bone Research," recognizes the revolution in investigative methodologies in our field. Those who want to know about the latest methods to clone genes, to knock genes out, to target genes, and to modify gene function by transfection and by transcriptional control will find relevant information in this section. In addition, the selection and characteristics of growth conditions for osteoblastic, osteoclastic, and stem cells; animal models of bone diseases; assay methodologies for bone formation and bone resorption and surrogate bone markers; and signal transduction pathways are all covered. Finally, the basic principles of bone densitometry and bone biopsies have both investigative and clinical relevance. This 15-chapter section is intended to be a useful reference for those who need access to basic information about these new research technologies.

The task of assembling a large number of international experts who would agree to work together to complete this ambitious project was formidable. Even more daunting was the notion that we would successfully coax, cajole, and otherwise persuade authors of 97 chapters to complete their tasks within a six-month period. For a book to be timely and still fresh, such a short time leash was necessary. We are indebted to all the authors for delivering their chapters on time.

Finally, such a monumental undertaking succeeds only with the aid of others who helped conceive the idea and to implement it. In particular, we are grateful to Jasna Markovac of Academic Press, who worked tirelessly with us to bring this exciting volume to you. We also want to thank Tari Paschall of Academic Press, who, with Jasna, helped to keep us on time and on the right course. We trust our work will be useful to you whoever you are and for whatever reason you have become attracted to this book and our field. Enjoy the book. We enjoyed editing it for you.

CHAPTER 1

Structure and Development of the Skeleton

Sandy C. Marks, Jr., and Paul R. Odgren
Department of Cell Biology, University of Massachusetts Medical School, Worcester, Massachusetts 01622

Introduction

This brief overview of the structure and development of the skeleton focuses primarily on bone and its cells (Fig. 1). We review the structure and function of these cells, their divisions of labor within the skeleton, the emerging complexities of their changing regulation with age, and the emerging knowledge of the molecular regulation of the skeleton. We also look briefly at emerging knowledge of molecular regulation of the skeleton. Because neither the complexities of the cellular microenvironment nor the influences of nonosseous tissues on bone cells can be duplicated *in vitro,* these parameters of bone metabolism must be evaluated eventually in the complexities of the *in vivo* environment. To assist both the reader and the investigator in interpreting these and other studies of the structure, development, and regulation of bone, we offer a brief critical analysis review of various methods used to examine bone metabolism.

The interested reader is referred to reviews of this topic from different perspectives (Buckwalter *et al.,* 1996a,b; Hall, 1987; Marks and Popoff, 1988; Schenk, 1992).

Cells of The Skeleton: Development, Structure, and Function

Bone is a highly specialized form of connective tissue that is nature's provision for an internal support system in all higher vertebrates. It is a complex living tissue in which the extracellular matrix is mineralized, conferring marked rigidity and strength to the skeleton while still maintaining some degree of elasticity. In addition to its supportive and protective functions, bone is a major source of inorganic ions, actively participating in calcium homeostasis in the body. There is increasing evidence that the central control of development and renewal of the skeleton is more sophisticated than previously appreciated (Ducy *et al.,* 2000).

Bone is composed of an organic matrix that is strengthened by deposits of calcium salts. Type I collagen constitutes approximately 95% of the organic matrix; the remaining 5% is composed of proteoglycans and numerous noncollagenous proteins (see chapters to follow). Crystalline salts deposited in the organic matrix of bone under cellular control are primarily calcium and phosphate in the form of hydroxyapatite.

Morphologically, there are two forms of bone: cortical (compact) and cancellous (spongy). In cortical bone, densely packed collagen fibrils form concentric lamellae, and the fibrils in adjacent lamellae run in perpendicular planes as in plywood (Fig. 2). Cancellous bone has a loosely organized, porous matrix. Differences between cortical and cancellous bone are both structural and functional. Differences in the structural arrangements of the two bone types are related to their primary functions: cortical bone provides mechanical and protective functions and cancellous bone provides metabolic functions.

Bone Cell Structure and Function

Bone is composed of four different cell types (Fig. 1). Osteoblasts, osteoclasts, and bone lining cells are present on bone surfaces, whereas osteocytes permeate the mineralized interior. Osteoblasts, osteocytes, and bone-lining cells originate from local osteoprogenitor cells (Fig. 3A), whereas osteoclasts arise from the fusion of mononuclear

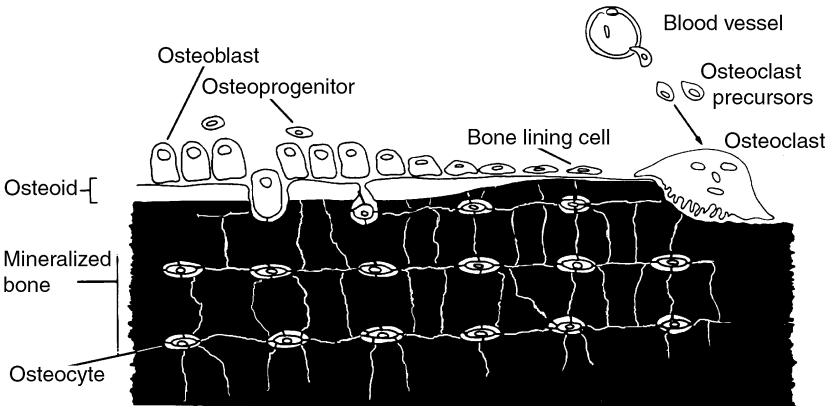

Figure 1 The origins and locations of bone cells. Taken from Marks and Popoff (1988). Reprinted by permission of John Wiley and Sons, Inc.

precursors, which originate in the various hemopoietic tissues. The apical and basal surfaces of bone cells are defined in an opposite sense from those of epithelia. Apical surfaces are those that are attached to the extracellular matrix and basal surfaces are those that are away from the matrix.

Osteoblasts are fully differentiated cells responsible for the production of the bone matrix. Portions of four osteoblasts are shown in Figs. 2 and 3B. An osteoblast is a typical protein-producing cell with a prominent Golgi apparatus and well-developed rough endoplasmic reticulum. It secretes the type I collagen and the noncollagenous proteins of the bone matrix (see Chapters 4 and 5). The staggered overlap of the individual collagen molecules provides the characteristic periodicity of type I collagen in bone matrix. Numerous noncollagenous proteins have been isolated from bone matrix (Sandberg, 1991), but to date there is no consensus for a definitive function of any of them.

Osteoblasts regulate mineralization of bone matrix, although the mechanism(s) is not completely understood. In woven bone, mineralization is initiated away from the cell surface in matrix vesicles that bud from the plasma membrane of osteoblasts. This is similar to the well-documented role of matrix vesicles in cartilage mineralization (Hohling *et al.,* 1978). In lamellar bone, the mechanism of mineralization appears to be different. Mineralization begins in the hole region between overlapped collagen molecules where there are few, if any, matrix vesicles Landis *et al.,* 1993) and appears to be initiated by components of the collagen molecule itself or noncollagenous proteins at this site. Whatever the mechanisms of mineralization, collagen is

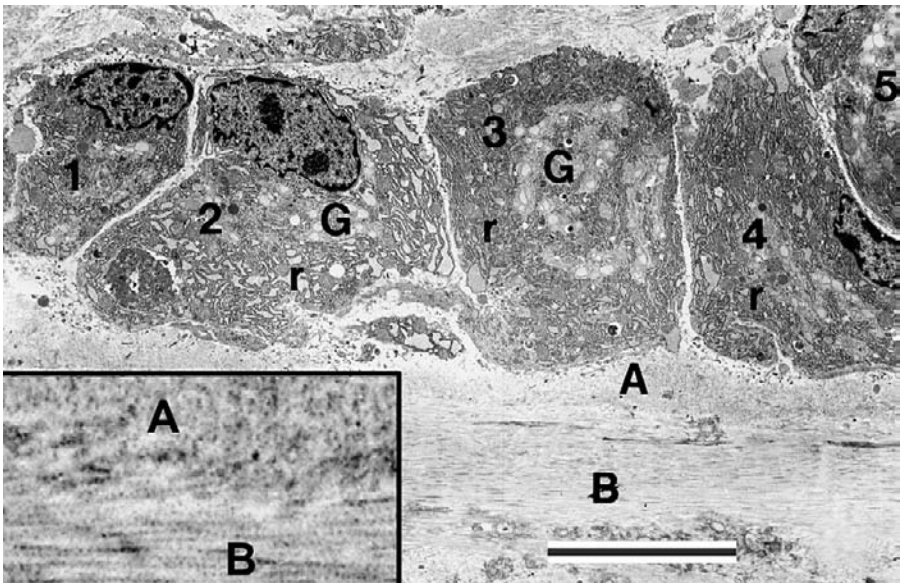

Figure 2 Transmission electron micrograph of osteoblasts (numbered) on a bone surface in which the collagenous matrix has been deposited in two layers (A and B) at right angles to each other. The Golgi apparatus (G) and rough endoplasmic reticulum (r) are prominent cytoplasmic organelles in osteoblasts. (Original magnification: ×2800. Bar: 0.1 μm.)

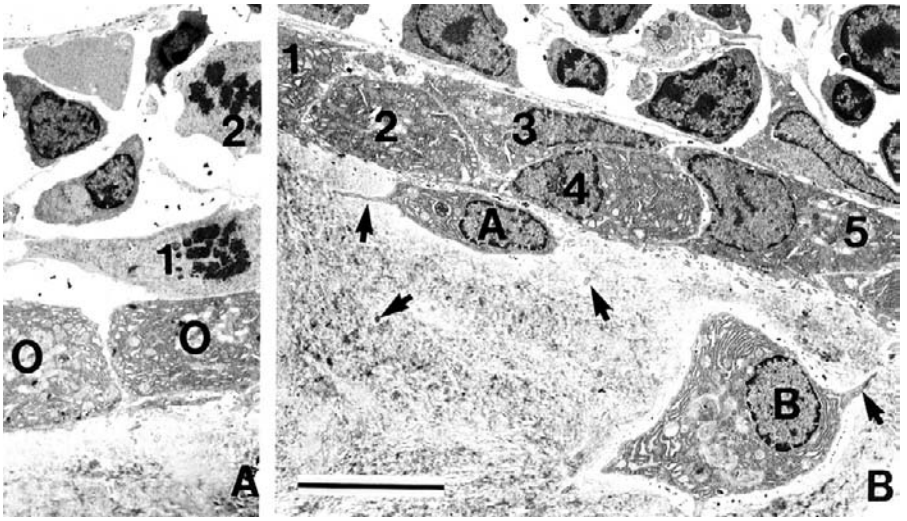

Figure 3 (A) Transmission electron micrograph of an osteoblast (O) and daughter cells (1 and 2) of a dividing osteoprogenitor cell. (Original magnification: ×2100.) (B) Transmission electron micrograph of five osteoblasts (numbered) and two osteocytes (A and B) in the process of being embedded in bone matrix. (Original magnification: ×2100. Bar: 0.1 μm.)

at least a template for its initiation and propagation and there is always a layer of unmineralized bone matrix (osteoid) on the surface under osteoblasts. Matrix deposition is usually polarized toward the bone surface, but periodically becomes generalized, surrounding the osteoblast and producing the next layer of osteocytes. Deposition of mineral makes the matrix impermeable, and to ensure a metabolic lifeline, osteocytes establish numerous cytoplasmic connections with adjacent cells before mineralization.

The osteocyte (Fig. 3B) is a mature osteoblast within the bone matrix and is responsible for its maintenance (Buckwalter *et al.,* 1996a). These cells have the capacity not only to synthesize, but also to resorb matrix to a limited extent. Each osteocyte occupies a space, or lacunae, within the matrix and extends filopodial processes through canaliculi in the matrix (Figs. 4A and B) to contact processes of adjacent cells (Figs. 5A and B) by means of gap junctions. Because the diffusion of nutrients and metabolites through the mineralized matrix is limited, filopodial connections permit communication between neighboring osteocytes, internal and external surfaces of bone, and with the blood vessels traversing the matrix. The functional capacities of osteocytes can be easily ascertained from their structure. Matrix-producing osteocytes have the cellular organelles characteristic of osteoblasts (Fig. 5A), whereas osteolytic osteocytes contain lysosomal vacuoles and other features typical of phagocytic cells (Fig. 5B). (For a review of osteocyte functions, see Chapter 6.)

Bone lining cells are flat, elongated, inactive cells that cover bone surfaces that are undergoing neither bone formation nor resorption (Fig. 6). Because these cells are inactive, they have few cytoplasmic organelles. Little is known regarding the function of these cells; however, it has been speculated that bone lining cells can be precursors for osteoblasts.

Osteoclasts are large, multinucleated cells that resorb bone (Fig. 7). When active, osteoclasts rest directly on the bone surface and have two plasma membrane specializations: a ruffled border and a clear zone. The ruffled border is the central, highly infolded area of the plasma membrane where bone resorption takes place. The clear zone is a microfilament-rich, organelle-free area of the plasma membrane that surrounds the ruffled border and serves as the point of attachment of the osteoclast to the underlying bone matrix. Active osteoclasts exhibit a characteristic polarity. Nuclei are typically located in the part of the cell most removed from the bone surface and are interconnected by cytoskeletal proteins (Watanabe *et al.,* 1995). Osteoclasts contain multiple circumnuclear Golgi stacks, a high density of mitochondria, and abundant lysosomal vesicles that arise from the Golgi and cluster near the ruffled border. A molecular phenotype for osteoclasts is emerging (Horne, 1995; Sakai *et al.,* 1995) (see Chapters 7, 8, and 9).

Cellular Divisions of Labor within the Skeleton

Cartilage and bone are two tissues that comprise the skeleton. Despite their shared supportive functions, these tissues are dramatically different (i.e., matrix composition and mineralization state). The cellular activities that occur in each of the two tissues, however, are limited to matrix formation, matrix mineralization, and matrix resorption. In each tissue, different cell types perform different, yet sometimes overlapping, functions (Fig. 8). In cartilage, matrix is produced and mineralized by chondrocytes. Mineralization and resorption of cartilage are activities associated with hypertrophied chondrocytes.

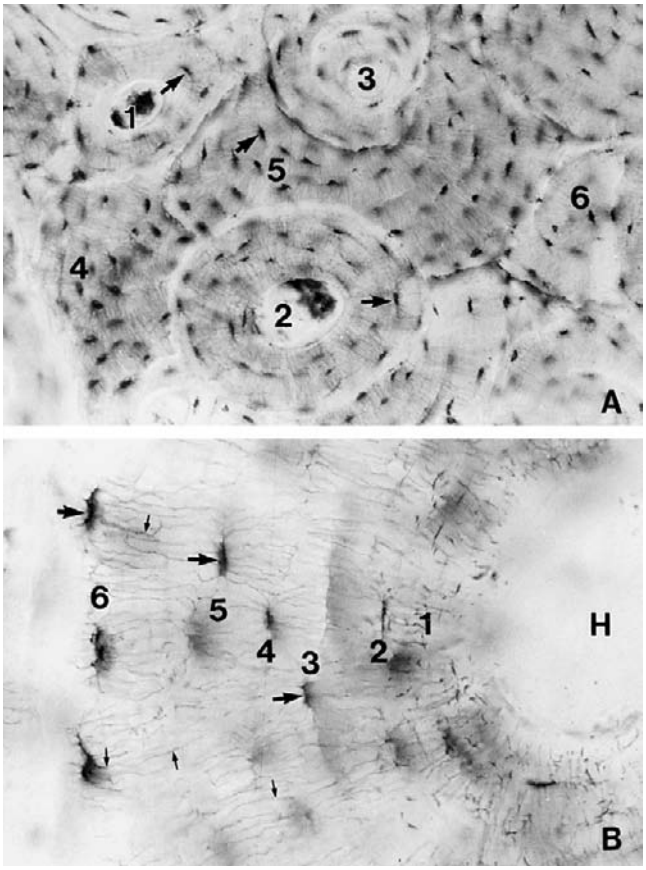

Figure 4 (A) A thin-ground crosssection of human cortical bone in which osteocyte lacunae (arrows) and canaliculi have been stained with India ink. Osteocytes are arranged around a central vascular channel to constitute Haversian systems. Active Haversian systems (1, 2, and 3) have concentric lamellae in this plane. Older Haversian systems (4, 5, and 6) have had parts of their original territories invaded and remodeled. This is seen most clearly where 2 and 3 have invaded the territory originally occupied by 5. (Original magnification: ×185. Bar: 50 μm.) (B) Higher magnification of part of a Haversian system showing the successive layering (numbers) of osteocytes (large arrows) from the central core (H) that contains the vasculature. Small arrows identify the canaliculi that connect osteocyte lacunae in different layers. (Original magnification: ×718. Bar: 50 μm.)

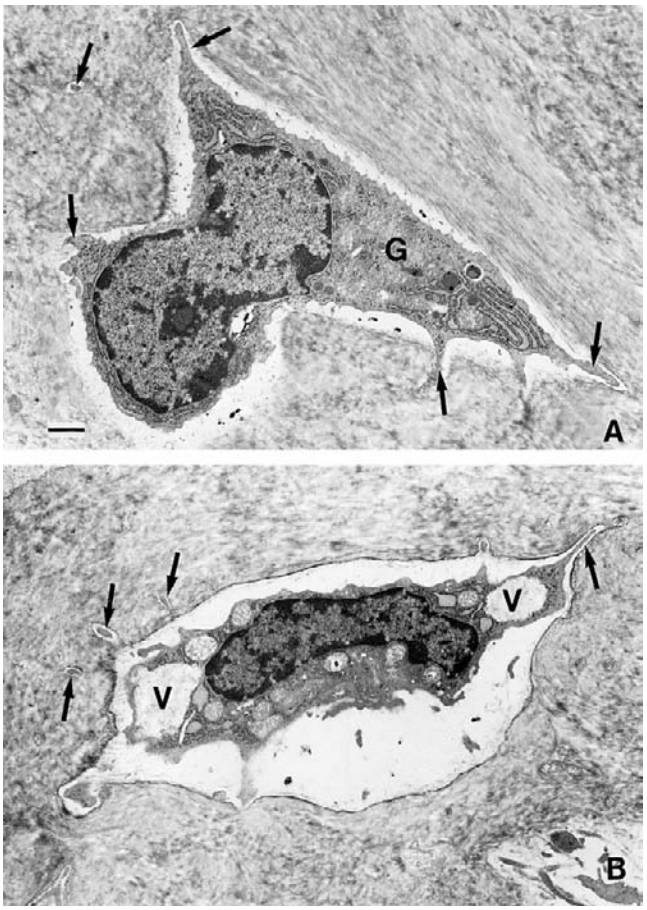

Figure 5 Transmission electron micrographs of two osteocytes of different phenotype and functional states. Young osteocytes (A) have nuclear and cytoplasmic features of osteoblasts: a euchromatic nucleus with a prominent nucleolus, a large Golgi apparatus (G), prominent rough endoplasmic reticulum, and numerous cytoplasmic processes (arrows) projecting into the surrounding matrix. Some older osteocytes (B) can have an osteolytic phenotype with increased lacunar volume, an electron-dense lacunar surface, condensed nuclei, and numerous cytoplasmic vacuoles. (Original magnification: ×7000. Bar: 0.01 μm.)

However, cartilage mineralized in the growth plate is resorbed by osteoclasts (see Figs. 12 and 13). In bone, matrix is produced and mineralized by osteoblasts and osteocytes. Resorption occurs primarily by osteoclasts, but localized perilacunar resorption may occur around osteocytes (Fig. 5B).

Coordination of Cellular Activities during Skeletal Development and Maturation

Variable Activities of Skeletal Cells

The activities of skeletal cells vary considerably over the life span of the organism. This is necessary to build a mineralized tissue where there was none before and to maintain it after reaching maturity. The variable activities of bone formation and resorption in relation to each other during the human life cycle are summarized in Fig. 9. The first two decades are devoted to development of the skeleton, called modeling. During this period, bone formation necessarily precedes and exceeds bone resorption. Thus, although these activities are related temporally and spatially, they are uncoupled in the sense that they are unequal. During the next three decades (and beyond) the adult skeleton is maintained by removing and replacing a fraction each year. This remodeling begins with a localized resorption that is succeeded by a precisely equal formation of bone at the same site (Parfitt, 1994). Thus, bone formation equals bone resorption, a process called coupling (see the section that follows, Fig. 10). In compact bone, resorption by osteoclasts produces a cutting cone through Haversian systems, and the subsequent reformation of these systems produces osteons of unequal age, size, and configurations (Fig. 4A). Sometime after the fifth decade, the formative phase of the remodeling sequence

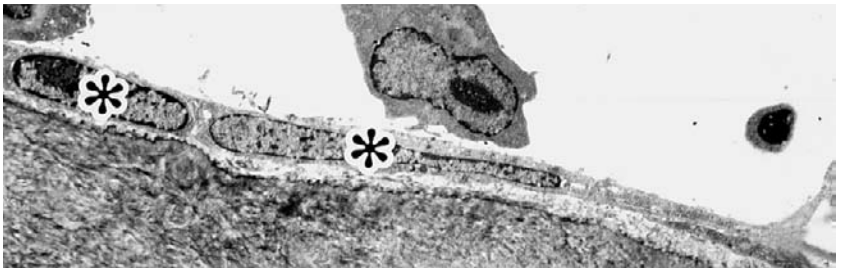

Figure 6 Transmission electron micrograph of bone lining cells (asterisks). These flat cells have few organelles and form a thin cellular layer on inactive bone surface that is often hard to resolve by light microscopy. (Original magnification: ×3000. Bar: 0.1 μm.)

fails to keep pace with resorptive activity and skeletal mass, including the connectivity of trabecular bone, decreases. This reduces skeletal strength and increases the risk of fracture over time, depending on the magnitude by which resorption and formation are uncoupled. Given the apparent inevitability and universality of an osteoporotic trend with age, therapy has focused on increasing skeletal mass during development and/or slowing resorption after the fifth decade. What is needed is a selective, predictable, locally active anabolic agent. This discovery may be more likely if we focus more on skeletal development than its pathology.

It is clear that the coordination of the activities of skeletal cells is a local event. Local factors recruit specific cells and local factors regulate their activity. Furthermore, multiple factors in a precise sequence and concentration are needed for the full expression of a cell's potential, and these factors and their concentrations differ for bone formation and bone resorption. It is also clear that more than one cell type can produce many of these factors and that normal skeletal development is a collaborative effort of cells from diverse lineages (Marks and Popoff, 1988; Yamazaki and Eyden, 1995; Yoder and Williams, 1995). The complexities of skeletal development and maintenance are now being acknowledged along with the poverty of our understanding of these relationships. This book is an attempt to put these factors and cells in some order that has both theoretical (functional) and practical (therapeutic) significance.

General Regulation of Cellular Activities

Most simply put, the challenges of understanding the complexities of skeletal modeling and remodeling, coupling and uncoupling, are illustrated by the influences that osteoblasts have on osteoclasts and vice versa (Marks and Popoff, 1988; Mundy, 1994). These are illustrated schematically in Fig. 10. Osteoblasts, the progeny of local osteoprogenitor cells, produce factors that influence the differentiation and function of osteoclasts (Martin and Ng,

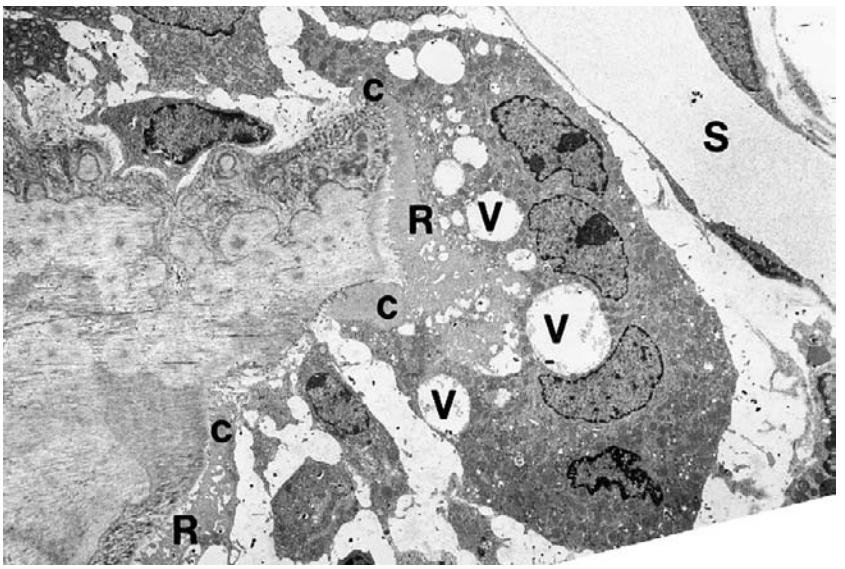

Figure 7 Transmission electron micrograph of parts of two osteoclasts. These multinucleated cells attach to bones at clear zones (C), which create a three-dimensional seal around the ruffled border (R) working area. Active cells have large vacuoles in the cytoplasm next to the ruffled border. S, vascular sinus. (Original magnification: ×2240. Bar: 0.1 μm.)

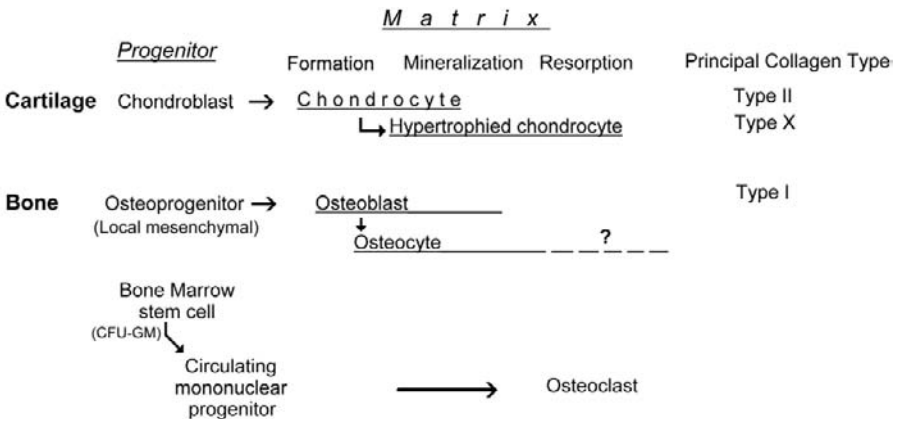

Figure 8 Cellular division of labor in the skeleton. Schematic of the major cells and their functions in cartilage and bone.

1994). Some of these are deposited in bone matrix itself, whereas others appear to be secreted locally in response to hormones or local factors. These conclusions are based on the facts that receptors for most osteolytic factors are found on osteoblasts, not osteoclasts (Rodan and Martin, 1981), that osteoclasts resorb bone in response to factors released into culture media by activated osteoblasts (McSheehy and Chambers, 1986), and that some components of the extracellular matrix of bone can attract and/or activate osteoclasts (Thesingh and Burger, 1983). Osteoclasts, however, are derived from hemopoietic stem cell progeny (monocytes) that use vascular routes to migrate to skeletal sites (Marks, 1983). After exiting the vasculature at specific locations in the skeleton, these mononuclear precursors either fuse with each other or other multinucleated cells to become osteoclasts. Their activation depends in large part on local signals derived from other cells, including but not limited to osteoblasts. However, bone resorption itself produces factors that recruit and activate osteoblasts. Indeed, the ability of supernatants of resorbing bone organ cultures to promote the proliferation and differentiation of osteoblast progenitors began the current interest in identifying the coupling factor(s) (Drivdahl *et al.,* 1981; Farley *et al.,* 1982).

It is clear from the foregoing that the activities of skeletal cells in a particular site change with age, that these changes are controlled by local factors, including weight bearing, and that we have much to learn about the identity and sequence of action of these agents in the changing dynamics of skeletal metabolism (Frost and Jee, 1994; Weryha and Leclere, 1995).

Figure 9 Development, maintenance, and pathology of the skeleton. Summary of the relative levels of skeletal cell activity during the human life cycle.

Formation of the Skeleton

Formation of the skeleton (ossification) occurs by either a direct (intramembranous) or an indirect (endochondral) process. Both require a solid base and a well-developed vascular supply for the elaboration and mineralization of the extracellular matrix. Mobility or low oxygen tension at the site favors the differentiation of chondrocytes or fibroblasts.

Intramembranous ossification occurs during embryonic development by the direct transformation of mesenchymal cells into osteoblasts. This type of ossification for entire bones is restricted to those of the cranial vault, some facial bones, and parts of the mandible and clavicle. The flat bones of the skull grow toward each other from primary ossification centers in each and meet at sutures. Sutures are fibroelastic cellular domains (Fig. 11) composed of the periostea of adjacent bones. The center of a suture contains a proliferating cell population whose progeny differentiate and move toward adjacent bone surfaces, becoming osteoblasts. During this migration these cells produce type III collagen at low levels, types V and XI transiently, and finally type I, the major bone collagen (Wurtz *et al.,* 1998). This mechanism provides a steady source of osteoblasts and allows bones to expand at their edges. When growth is complete, sutures remain as fibrous connections or disappear, depending on the suture site.

Bones that participate in joints and bear weight form by endochondral ossification, a method by which the unique properties of cartilage and bone are exploited to provide a mechanism the for formation and growth of the skeleton during growth of the individual. In such bones the condensed embryonic mesenchyme transforms into cartilage, which reflects in both position and form the eventual bone to be formed at that site. In the central part of such a bone, endochondral ossification provides for a linear, interstitial proliferation of columns of chondrocytes. Their progressive hypertrophy, mineralization of the intercolumnar cartilage matrix in the long axis of the bone, and the persistence of mineralized cartilage after disappearance of its cells acts as an elongating scaffold for the deposition of subchondral

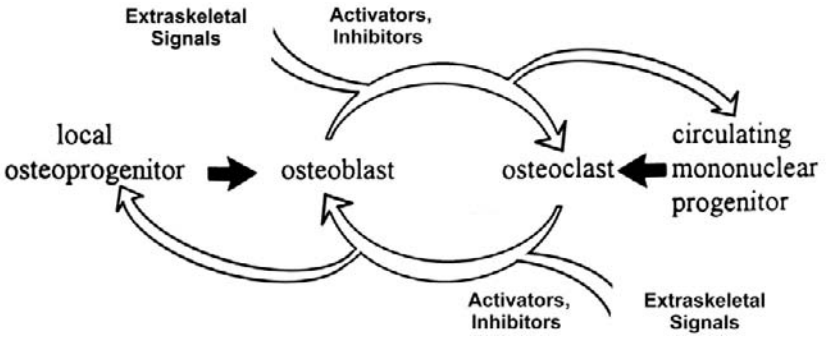

Figure 10 Cellular coordination of skeletal development. Schematic of the divergent origin and interrelated function of the principal bone cells.

(metaphyseal) bone (Hunziker, 1994). In the circumference of such a bone, starting initially at the center and progressing toward the ends, the investing cartilage cells and stroma (perichondrium) transform into osteoblasts that form a periosteal collar after the underlying chondrocytes have hypertrophied and mineralized the matrix. The peripheral osteoblasts (periosteum) arrive with a blood supply whose vessels penetrate the central hypertrophied, mineralized cartilage core and carry to the interior the skeletal cell progenitors for the formation and turnover of bone. Thus, peripherally extension of the periosteum and centrally mineralization of cartilage, hypertrophy, and disappearance of chondrocytes and bone formation on the mineralized cartilagenous scaffold proceed toward the end of each growing long bone.

The cellular events of long bone growth in length by endochondral ossification are illustrated in Figs. 12 and 13. At the top of the figures, chondrocyte proliferation and matrix elaboration in the direction of bone growth and the hypertrophy of these cells are the primary mechanisms for the linear growth of bones (Hunziker, 1994). Chondrocytes mineralize the intercolumnar matrix, producing a rigid scaffold that persists in the metaphysis and becomes the solid base upon which osteoblasts deposit and mineralize bone matrix. The closely packed mineralized cartilage septae at the chondroosseous junction are thinned to about one-third their density (Schenk *et al.,* 1967, 1968) by osteoclasts at this site (Fig. 12), providing space for new bone and a longitudinally oriented vasculature in the metaphysis (Aharinejad *et al.,* 1995). The final component of longitudinal bone growth is resorption of the central (marrow cavity) ends of metaphyseal trabeculae.

The fate of hypertrophied chondrocytes is controversial. Earlier reports of universal cell death conflicted with biochemical data and were perpetuated by poor fixation methods that produced pyknotic cells. Better fixation preserves the morphology of these cells, and it is clear that at least some hypertrophied chondrocytes survive (Farnum *et al.,* 1990; Hunziker and Schenk, 1984; Takechi and Itakura, 1995) after vascular penetration of their lacunae (Figs. 12 and 13) and can differentiate into osteoblasts (Galotto *et al.,* 1994; Roach *et al.,* 1995; Thesingh *et al.,* 1991) at least *in vitro* but that the percentage of such cells may vary among species (Gibson *et al.,* 1995).

Longitudinal bone growth is a precise balance between chondrocyte proliferation, cartilage matrix production and mineralization, and hypertrophy and vascular invasion of the lacuna of the terminal hypertrophied chondrocyte after re-

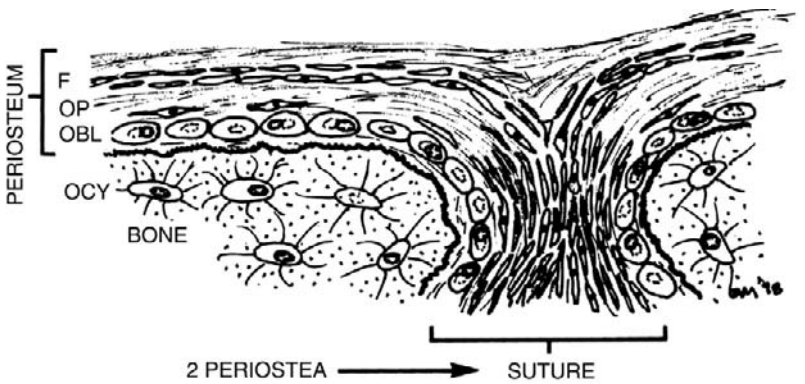

Figure 11 Cellular relationships in a periosteum and a suture. F, fibroblast; OP, osteoprogenitor cell; OBL, osteoblast; OCY, osteocyte. Reprinted from Marks *et al.* (1999), with permission of John Wiley & Sons.

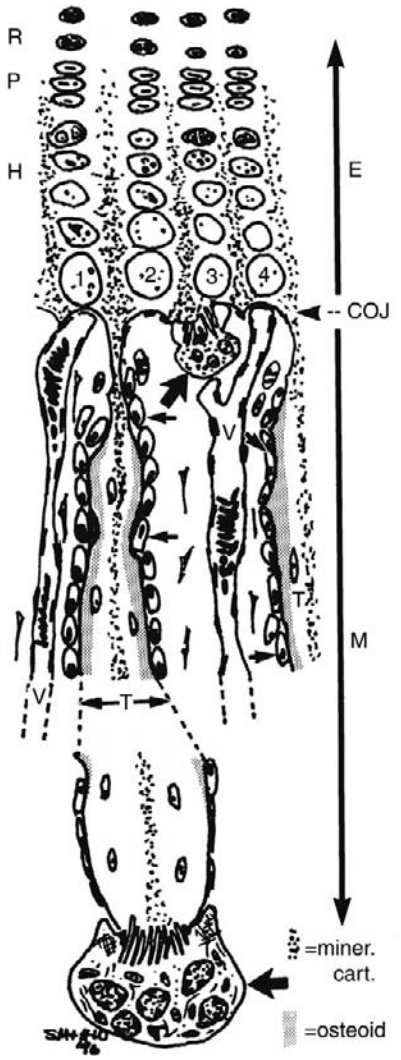

Figure 12 Schematic drawing of cellular locations and activities at the chondroosseous junction (COJ) of growing bone. The physis, or epiphyseal plate (E), consists of resting (R), proliferating (P), and hypertrophied (H) chondrocytes. In the metaphysis (M), trabeculae (T) alternate longitudinally with vascular channels (V). Osteoblasts (small arrows) line trabecular surfaces beginning just below the COJ, and osteoclasts (large arrows) are found in two locations: at the COJ and at the marrow cavity ends of the trabeculae. Chondrocytes are aligned in columns (four are numbered), and their alignments are maintained by mineralization of the longitudinal interterritorial matrix between columns that begins in the zone of proliferating chondrocytes and gets denser in the zone of hypertrophy. These mineralized cartilaginous struts are the surfaces in the metaphysis on which osteoblasts differentiate, produce, and mineralize the extracellular matrix of bone. All trabeculae in the metaphysis have a mineralized cartilage core, which is then resorbed, together with bone, by osteoclasts at the margin of the marrow cavity (bottom). Other osteoclasts at the COJ resorb about two of every three cores of mineralized cartilage that extend from the epiphysis. This provides space in the metaphysis for bone deposition and vascular invasion. The latter is an important regulator of the thickness of the zone of hypertrophied chondrocytes by penetrating the horizontal septum between the oldest such chondrocytes and the metaphysis (illustrated for cells 1 and 4). Reprinted from Marks (1998), with permission of C.V. Mosby.

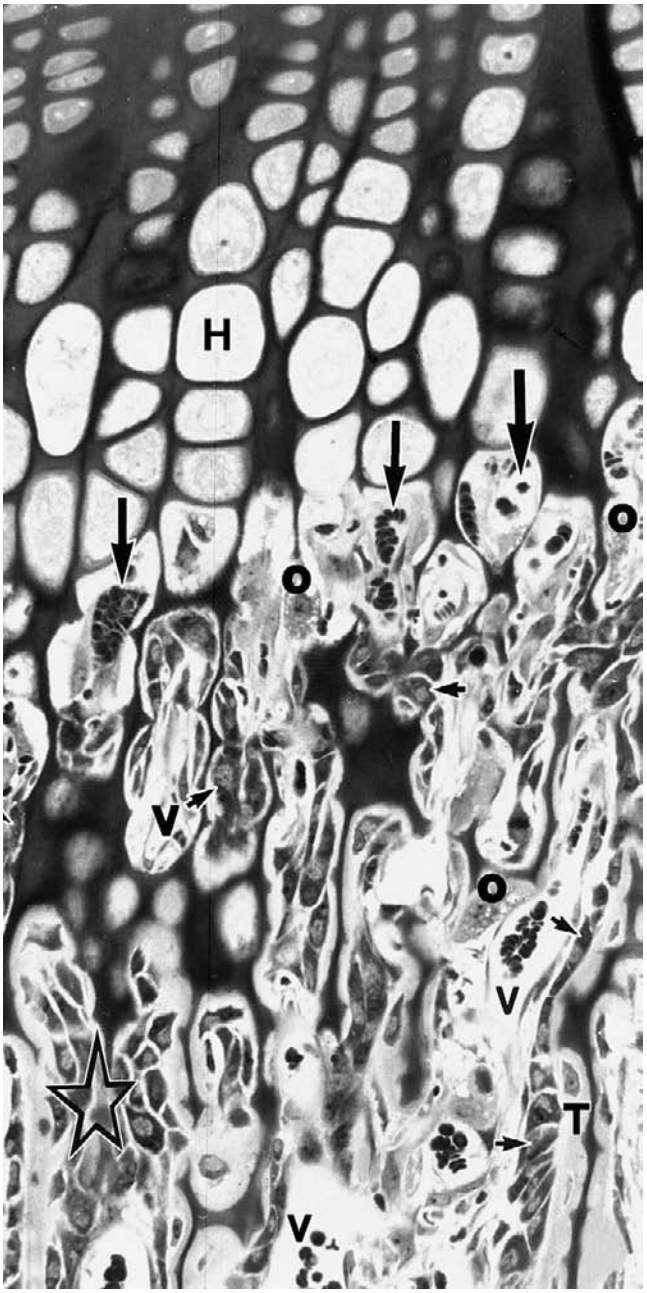

Figure 13 Photomicrograph of the chondroosseous junction in a young rat. The physis is composed primarily of hypertrophied (H) chondrocytes in this field. Vascular invasion of chondrocyte lacunae is occurring at many sites (vertical arrows) along the COJ, and vascular channels (V) are common. Mineralized cartilage in the metaphysis stains darkly. The typical trabecular cross section of a central cartilage core, bone, osteoid, and osteoblasts is clear at the lower right (T) but is obscured in much of the rest of the field due to the obliquity of their planes of section. Osteoblasts (small arrows) can be identified on most of the metaphyseal surfaces, and a large group (star) appears where trabeculae converge just out of the plane of this section. Several osteoclasts (O) can be seen near the COJ. (Toluidine blue stain; ×500.) Reprinted from Marks (1998), with permission of C. V. Mosby.

sorption of the horizontal septum within a column by mononuclear cells (Hunziker, 1994; Price *et al.,* 1994) rich in cathepsin B and with a distinct morphology (Lee *et al.,* 1995). Cartilage proliferation is under the direct influence of a variety of hormones (growth, thyroid, corticosteroids, and parathyroid) and local growth factors (insulin-like growth factors and basic fibroblast growth factor) (Nilsson *et al.,* 1994). Because most studies have been done *in vitro* where three-dimensional relationships of cells and matrices and the complex physiological landscape cannot be duplicated, it is

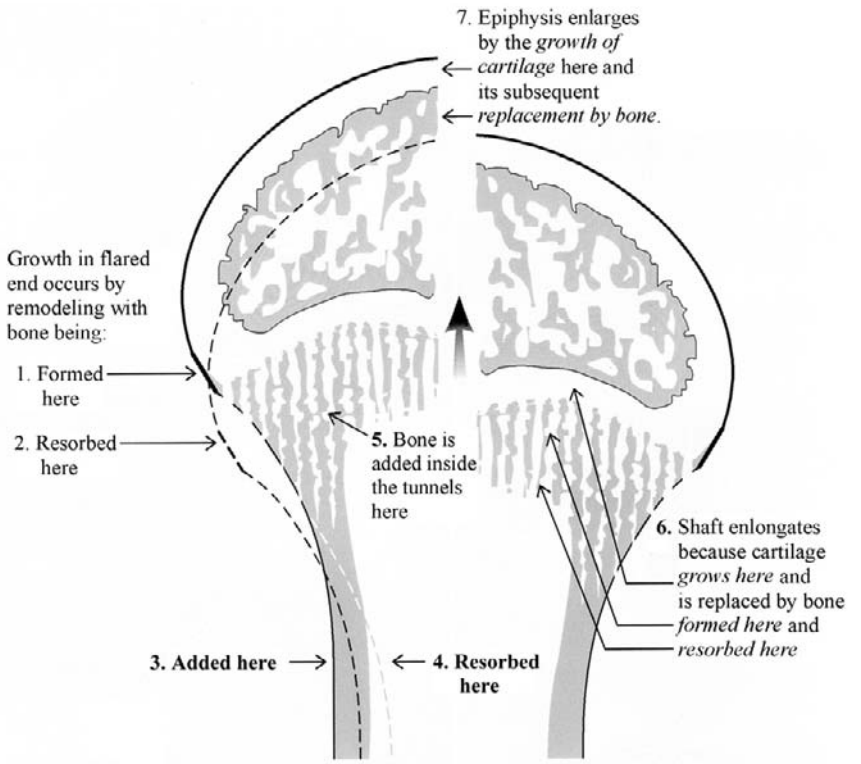

Figure 14 Diagram of regional changes in cartilage and bone that produce growth in the length (large arrow) and width of long bones. Reprinted from Marks (1998), with permission of C. V. Mosby.

not surprising that reports of the effects of individual factors on bone growth conflict and give us incomplete information at best.

Bone growth in diameter (Fig. 14) is accomplished most basically by formation externally (periosteum) and resorption internally (endosteum). This is strictly true only for the central portion of long bones and only if the bone is cylindrical. Because most bones are asymmetrical cylinders centrally and are expanded (flared) unevenly at each end, growth in diameter is more complex than depicted in the process just described and varies by region according to the dynamic changes in bone shape at that site.

At the flared ends of a growing long bone the periosteal collar externally surrounds part of the growth plate cartilage and extends much farther peripherally than the central bone (Fig. 14) of the shaft. Thus, during bone growth, with extension of the new periosteal collar, the old periosteal collar has to be removed and reformed toward the center. This is accomplished by resorption on the periosteal surface and formation on the endosteal surface at this site, a polarization of these activities that is opposite that seen at the center of the shaft. In summary, the succession of metabolic activities on the periosteal surface is (1) formation at the periosteal collar, (2) resorption, and (3) formation toward the center of the shaft. In general, activities in the peripheral endosteum are the opposite. In the metaphysis, bone formation on the mineralized cartilage scaffold takes place after osteoclasts thin the longitudinal mineralized cartilage remnants of the growth plate. This increases the thickness and strength of these trabeculae, which remain until their central ends are resorbed to accommodate longitudinal expansion of the marrow cavity during bone growth.

Bone growth involves the coordination of a variety of cellular activities in specific sites whose onset and rates vary among bones and even within a single bone during its development. These activities are under the influence of a variety of humoral and local factors whose relative concentrations, sites, and sequences of appearance vary during development.

The complexities of skeletal maintenance are unlikely to be substantially less complicated than those of development. Thus, the multiplicity and redundancy of the biological controls of skeletal metabolism need to be appreciated as we seek to interpret all experimental data.

Molecular Regulation of Skeletal Development

The principal physiologic processes of skeletal formation and maintenance might be summarized as pattern formation, transition from cartilage to bone, bone matrix synthesis and secretion, and bone resorption and remodeling. Genes with crucial roles in all these processes have been discovered recently, giving both new depth to our understanding of normal bone biology and hopes for novel clinical strategies and interventions in disease or injury. Some of these discoveries came as surprises in gene knockout or transgenic studies conceived with quite different expected outcomes, demonstrating the critical importance of evaluating gene function in the living organism. Genes essential for bone synthesis,

normal patterning, and bone resorption are discussed in the following brief overview. Subsequent chapters treat these in much greater detail.

Bone Formation

A molecular event crucial for the synthesis and secretion of bone matrix, i.e., for the fully differentiated activity of osteoblasts, is the production by osteoprogenitor cells of the DNA-binding transcription factor cbfa-1. Independent investigations led to its simultaneous discovery by three groups (Ducy *et al.,* 1997; Komori *et al.,* 1997; Mundlos *et al.,* 1997; Otto *et al.,* 1997). People and mice with a haploid insufficiency of the *cbfa-1* gene suffer from skeletal defects that include a ridged skull and lack of clavicles, known clinically as cleidocranial dysplasia. The dramatic, and lethal, phenotypic consequences of diploid defects of *cbfa-1* were seen in knockout mice. Those mice were able to construct a nearly complete cartilage model of the skeleton, but having lost all osteoblastic bone matrix production, failed to mineralize the cartilage model. Clearly, cbfa-1 acts as a master switch in osteoblast differentiation and bone synthesis. In turn, its induction or inhibition by local and systemic factors is central to bone formation. This area has been reviewed by Ducy *et al.,* (2000) and is treated in greater depth in Chapters 3, 4, and 5.

Patterning and Endochondral Ossification: The Changeover from Cartilage to Bone

Growth of the long bones, the spine, and ribs proceeds via the construction of a cartilage model that is then remodeled into bone (see Figs. 12, 13, and 14). This process begins before birth and continues throughout the growth phase. Interestingly, some advances in understanding the complexities of its regulation owe much to basic research done with organisms that have no endoskeleton. The *hedgehog* gene, discovered in *Drosophila melanogaster* as a regulator of body segment polarity, has been conserved through evolution and is present in three versions in mammals, called sonic, desert, and Indian hedgehog. The hedgehog proteins regulate axis polarity and pattern formation in early cartilage modeling. Indian hedgehog, partially through communication with the parathyroid hormone-related protein and its receptor, helps maintain the exquisitely balanced regulation of chondrocyte proliferation and hypertrophy that determines bone growth in the epiphysis (Kronenberg *et al.,* 1997; Philbrick *et al.,* 1996; St-Jacques *et al.,* 1999; van der Eerden *et al.,* 2000; Vortkamp *et al.,* 1998). See Chapter 3 for more information on this process.

Bone Resorption: An Exception to the Redundancy of Critical Functions Rule

The advent of gene knockout technology has necessitated a reevaluation of our thinking about bone resorption. Many genes were knocked out in mice by researchers in various fields who anticipated phenotypic consequences consistent with important gene functions inferred from results of cell culture experiments, only to find that the missing gene's function could be compensated for by other redundant pathway components. While this was not always the case, it did occur with some frequency and produced a general appreciation that evolution has selected for redundancy in many critical functions.

The phenotype of osteopetrosis, however, which results from defective osteoclast development or function, was found unexpectedly in several gene knockout experiments. These include the protooncogenes *c-src* (Soriano *et al.,* 1991) and *c-fos* (Wang *et al.,* 1992); a transcription factor identified in immune system cells, NF-κB (Franzoso *et al.,* 1997; Iotsova *et al.,* 1997); and the hematopoietic transcription factor PU.1 (Tondravi *et al.,* 1997). In addition, genes critical for osteoclast function have been identified in studies of naturally occurring osteopetrotic mutations: the cytokine M-CSF, or CSF-1, in the *op* mouse (Yoshida *et al.,* 1990); and microphthalmia, a transcription factor also active in pigment and mast cells, in the *mi* mouse (Steingrimsson *et al.,* 1994) and the *mib* rat (Weilbaecher *et al.,* 1998). In addition to these, knockouts of osteoclast-specific genes for cathepsin K (Saftig *et al.,* 1998), a cysteine protease, and the vacuolar proton pump Atp6i (Li *et al.,* 1999) also result in osteopetrosis.

The field of immunology contributed another key discovery recently in our understanding of osteoclast formation and activity, the identification of a tumor necrosis factor family member produced by T cells called TRANCE (also known in the literature as RANKL, ODF, and OPGL) (Anderson *et al.,* 1997; Kong *et al.,* 1999; Wong *et al.,* 1997; Yasuda *et al.,* 1998). TRANCE is also produced by osteoblasts, and knockout mice lack both osteoclasts and lymph nodes. The TRANCE receptor (also called RANK) and its intracellular-associated signaling molecule TRAF-6 are both required for osteoclast formation, shown by the severe osteopetrosis in mice in which either of those genes are knocked out (Dougall *et al.,* 1999; Lomaga *et al.,* 1999; Naito *et al.,* 1999). More information about osteoclasts, their formation, and activation is presented in Chapters 7, 8, and 9.

Together, these findings demonstrate that, in contrast to some bodily processes that have redundant means to ensure they take place, bone resorption does not. Bone resorption may in fact be thought of as a highly regulated and specialized form of autoimmunity. It appears that evolution has favored a scenario in which the commitment to resorb bone, which is a unique and potentially debilitating process, requires that many signaling pathways all agree.

Methods for Studying Skeletal Development and Regulation

Mineralization in the skeleton has made cellular access difficult and has impeded progress in understanding bone cell biology. A century ago, studies of the skeleton had to

focus on either the mineral or the cellular components because one had to be destroyed to study the other. Improvements in methods were not sufficient to study both bone cells and their mineralized environment until the advent of electron microscopy, which provided durable embedding media and thin-sectioning procedures. Bone cell cultures were developed later than those for other tissues for similar reasons. As a result, considerable attention was paid to cells outside the skeleton for clues about bone cell function (Kahn *et al.,* 1978). Unfortunately, these data often supported erroneous conclusions because of two facts: cells of a particular family operate differently in different tissues (even the same cells are known to function differently in different site; Cecchini *et al.,* 1994) and no culture conditions *in vitro* can duplicate the complex cell/matrix/humoral interactions that occur in the organism *in vivo*. Detailed discussions of these points have been published (Fox *et al.,* 2000; Marks, 1997; Marks and Hermey, 1996). These principles need to be remembered when trying to reconcile discrepancies between studies of bone cells. The method(s) used will determine or limit the results that are possible.

Fortunately, it is now possible to study the effects of both genes and proteins *in vivo*. Analyses are complex and the results often surprising, but, unlike many *in vitro* studies, the validity of data is unquestioned. The relative ease with which animals can be produced in which a gene has been eliminated, modified, or overexpressed or in which there is cells- or tissue-specific expression has produced a variety of *in vivo* models to study the authentic biological effects of genes and their products. A number of these transgenic and knockout mutations have had surprising skeletal phenotypes. Many of the new developments in bone biology described in this book have been derived from these new discoveries in organismal molecular biology. In short, these targeted gene manipulations, combined with the numerous spontaneous skeletal mutations and an understanding of the predictable, orderly, local events in normal skeletal development, provide a new series of reality checks for bone biologists, replacing the earlier overreliance on *in vitro* methods. Many sites in the body exhibit localized, precisely timed displays of skeletal metabolism, including cell recruitment, activation, function, and senescence and as such are places where the informed investigator can intelligently dissect the crucial elements of these events. Two such sites are the postnatal development of the caudal vertebrae in rodents (unpublished work by Cecchini in Marks and Hermey, 1996) and the skeletal events around erupting teeth (Marks and Schroeder, 1996). We can expect to learn much more about the basic and applied biology of the skeleton using these systems, some of which are reviewed in Chapters 87–96.

Conclusions

The skeleton is a complex association of metabolically active cells attached to, embedded in, or surrounded by a mineralized matrix. The potential activities of each cell type are understood in broad outline, but the complex cellular interactions during development and maturation of the skeleton are under intense scrutiny. These are the new frontiers of skeletal biology and will have required a shift in focus from the isolated *in vitro* cell systems of today to the complex *in vivo* environment. This is accomplished most efficiently by studying the development and progression of reproducible sites of skeletal maturation and the skeletal effects of targeted changes in expression of specific genes. This, in turn, can be facilitated by the application of new molecular and morphologic techniques, such as *in situ* hybridization, polymerase chain reaction, immunocytochemistry, and high-resolution three-dimensional reconstruction.

CHAPTER 2

Biomechanics of Bone

Dennis M. Cullinane and Thomas A. Einhorn
Department of Orthopaedic Surgery, Boston University Medical Center, Boston, Massachusetts 02118

Introduction

Bone is a physiologically dynamic tissue whose primary functions are to provide a mechanical support system for muscular activity, provide for the physical protection of organs and soft tissues, and act as a storage facility for systemic mineral homeostasis. The resulting structure of the skeleton then is influenced heavily by mechanical principles, acting both as constraints and as driving forces in its architecture (Christiansen, 1999; Cullinane, 2000; Galileo, 1638; Thompson, 1946). A form–function relationship exists in the architecture of bone, and this relationship guides the evolution, embryogenesis, and continued ontological adaptation of the skeleton.

Since the observations of Galileo it has been recognized that the inherent architecture of bone is not only organized to accommodate normal loading, but also is influenced during ontogeny by the mechanical stresses associated with daily function. Thus, the skeleton is both evolutionarily adapted and has the capacity to adapt as a result of changes in daily activity (Carter, 2000). A formal description of the dynamic structure–function relationship between bone and mechanical load was established in the late 19th century in what has since become known as Wolff's law (Wolff, 1892). Wolff determined that the trabecular elements of the skeleton were not only designed to perform their specific functions, but also responded to load by altering their structural configuration during the lifetime of an individual. Wolff's law has become widely accepted as the general guiding principle of bone regulation, with some more recent modifications (Bertram and Swartz, 1991; Biewener *et al.,* 1996; Fyhrie and Carter, 1986) and recently proposed mechanisms (Carter, 2000; Martin, 2000; Mullender and Huiskes, 1995; Turner and Pavalko, 1998). The skeleton then is not only genetically programmed for a specific configuration, but a degree of morphological plasticity exists that is influenced heavily by an individual's mechanical loading history. These ontological adaptations modify the skeleton in order to optimize its functional capacity during locomotion or other mechanical duties.

To understand how the skeleton moves or how bone responds to impact, it is necessary to appreciate how the mechanical properties of bone determine skeletal responses to both physiological and mechanical load. If details on the structural configuration and the tissue level properties of bone are provided, this information can be used to predict the risk of fractures associated with normal daily activities, athletic activities, advancing age, or metabolic bone diseases. It is imperative then to apprecial that the mechanical behavior of the skeleton is contingent upon how bone functions as a tissue and a whole organ.

Basic Biomechanics

The mechanical behavior of bone may be studied at two levels: material and structural. The material, or tissue, level properties of bone are evaluated by performing standardized mechanical tests on uniform bone tissue samples. Depending on the level of resolution, tissue level testing is relatively independent of bone structure or geometry. Second, by examining the mechanical behavior of bones as whole anatomical units, the contributions of structural properties can be determined. Mechanical properties may also be estimated *in vivo* using densitometric projections, but these are less accurate than actual mechanical testing. Taken together, these two levels of mechanical properties represent the way bones respond to forces *in vivo* and can be observed by means of experiments on sections of bones

(for material properties) or on fully intact bones with normal geometry (for structural properties).

The assessment of bone mechanical properties can be made using techniques ranging from noninvasive imaging to *in vitro* mechanical tests of excised specimens or whole bones. The accuracy of any assessment, however, is contingent upon its degree of dependence on extrapolation from non-mechanical data and its reflection of actual, *in vivo* physiological stresses. Micro-computed tomography (CT), magnetic resonance imaging (MRI), and peripheral qualitative CT (pQCT) methods of imaging, especially in use with finite element models, continue to improve in their accuracy of mechanical property assessment, (Cody *et al.,* 1999; Moisio *et al.,* 2000), as does simple bone mineral density estimation (Toyras *et al.,* 1999), vibration analysis (Weinhold *et al.,* 1999), ultrasonic wave propagation (van der Perre and Lowet, 1996), and duel-energy absorptiometry (Sievanen *et al.,* 1996). Some of these techniques primarily reflect bone tissue level properties (DEXA, wave propagation, vibration, etc.), whereas others incorporate three-dimensional information from architecture with tissue mechanical property estimates to determine structural level properties (MRI, pQCT, and micro-CT with finite element models).

However, when performing mechanical tests on bone, it is important to bear in mind that the differences between tissue level and structural level properties are not always clear. If one considers a small cube of vertebral trabecular bone as a tissue section, then trabecular element preferred orientation may influence what is assumed to be a material property, when in fact it is largely influenced by structural configuration (Keaveny *et al.,* 2000). Likewise, both material and structural properties of bones can change with the level of resolution. As mentioned earlier, vertebral trabecular bone fails by creep as multiple individual elements fail, yet the failure mode of each individual trabecular element is more elastic. These two levels of mechanical properties in bone are also evident during fractures, when what appears to be a structural failure must be accompanied by a tissue level failure. It is important to realize then that a fracture represents a failure of bone tissue at both the material and the whole bone levels (Hayes, 1983).

Stress–Strain Relationships

Like other objects in nature, bone undergoes acceleration, deformation, or both when a force is applied to it. If the bone is constrained over one portion of its structure so that it cannot move when a force is applied or if equal and opposite forces are applied to it, deformation will occur, resulting in the generation of an internal resistance to the applied force. This internal resistance is known as *stress*. Stress is equal in magnitude but opposite in direction to the applied force and is distributed over the cross-sectional area of the bone (in a long bone example). It is expressed in units of force (Newtons = N) per unit area (meters squared = m^2):

$$\text{Stress} = \delta = \text{force/area}.$$

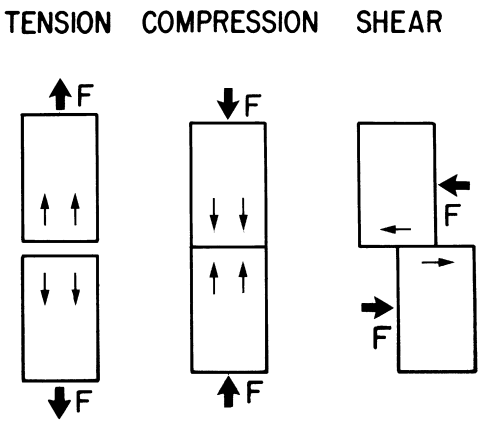

Figure 1 The three basic types of stress into which all complex stress patterns can be resolved: tension, compression, and shear. Reprinted with permission from Craig, R. G. (1989). "Restorative Dental Materials," p. 68. C. V. Mosby, St. Louis.

The standard international unit for stress is the Pascal, which is 1 N of force distributed over 1 m^2, which converts to 1.45×10^{-4} pounds per square inch (psi):

$$1 \text{ Pa} = 1N/m^2 = 1.45 \times 10^{-4} \text{ psi}.$$

Although an externally applied force can be directed at a specimen from any angle, producing complex stress patterns in the material, all stresses can be resolved into three types: tension, compression, and shear (Fig. 1). *Tension* is produced in a material when two forces are directed away from each other along the same line, with resistance to tensile forces coming from the intermolecular attractive forces that resist the material's being torn apart; ultimate tensile strength is a measure of this cohesive force. An example of

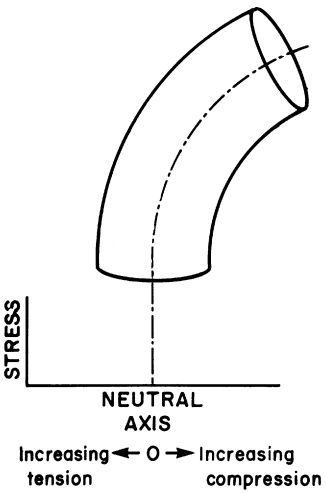

Figure 2 The bending of a simple cylinder results in tensile stresses on the convex side and compressive stresses on the concave side. The magnitude of these stresses increases proportionally to the distance from the neutral axis of bending. Reprinted with permission from Radin, E. L., Simon, S. R., Rose, R. N., and Paul, J. P. (1980). "Practical Biomechanics for the Orthopaedic Surgeon," p. 14. Wiley & Sons, New York.

tension occurs at the tendon–bone interface when a muscle acts via contraction. *Compression* results from two forces, again acting along the same line but directed toward each other; it is resisted by interatomic repulsive forces, which rise sharply at short interatomic distances. An example of compression occurring in the body is when a weight is carried on the head and the compressive load is transduced down the axis of the spine via the vertebral bodies. *Shear* forces occur when two loads act in parallel but in opposite directions from one another and can be linear or rotational. Shear occurs in a vertebral body when the superior end plate surface is loaded anteroposteriorly while the inferior end plate surface experiences a posteroanterior directed load. It must be noted that, *in vivo,* these individual stresses should be looked upon as a predominant rather than a singular stress for they almost always act in concert.

Thus, most stress patterns are complex combinations of these three stress types. Bending, for example, produces a combination of tensile forces on the convex side of a structure or material and compression on the concave side (Fig. 2). *Torsion,* or twisting produces shear stress along the entire length of a structure or material, whereas tensile stresses elongate it and compressive stresses shorten it (Fig. 3). Bending in two directions (X and Y coordinates) simultaneously, even acting on a regularly shaped cantilevered beam, can combine to create more complex

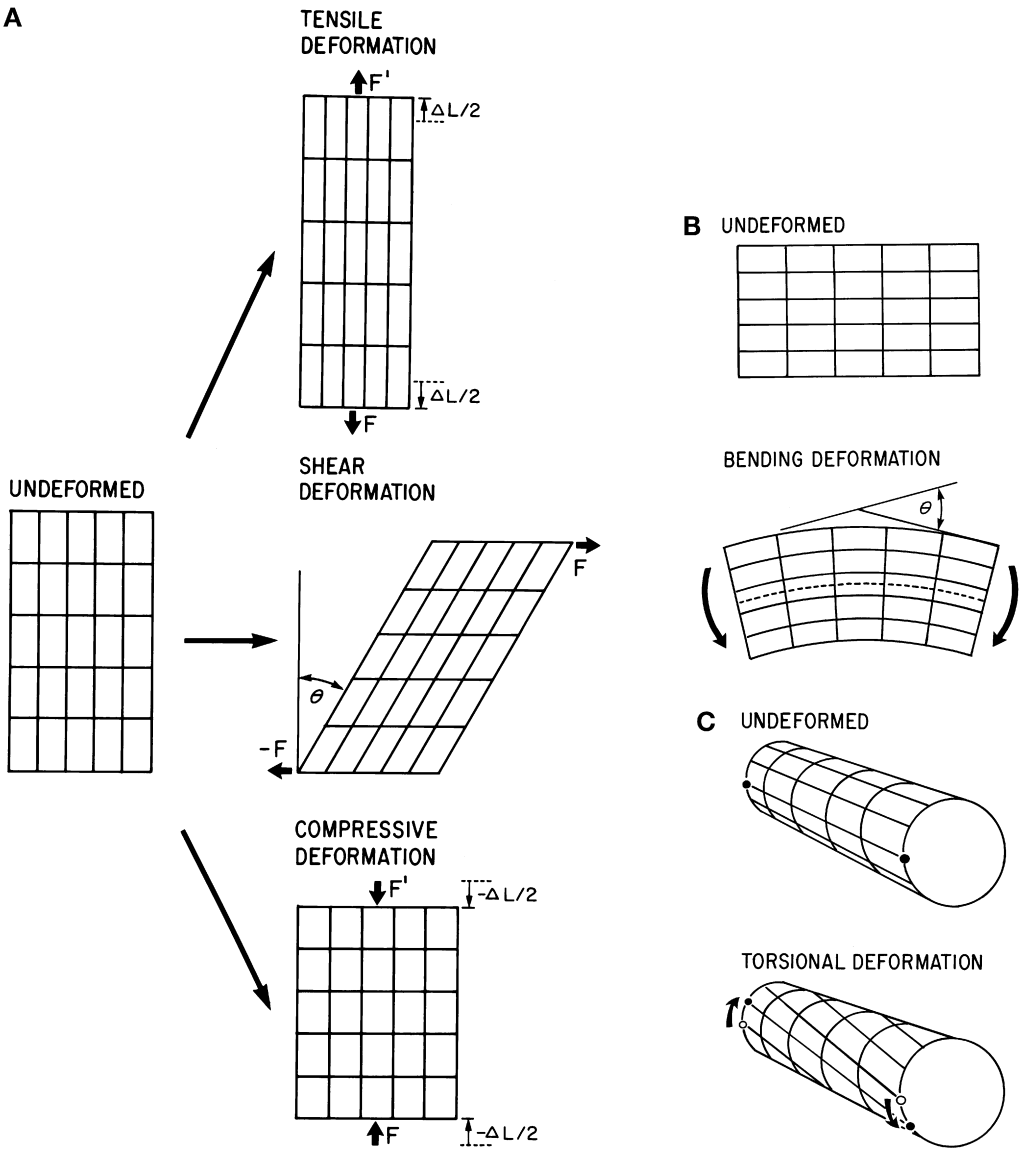

Figure 3 (A) Deformations produced by tensile, shear, and compressive stresses. F' and F are equal and opposite tensile or compressive forces, $-F$ and F are equal and opposite shear forces, θ is the angle of deformation, and Δ is change in length resulting from deformation. (B) Deformation produced by bending stress. θ is the angle of deformation. (C) Deformation produced by torsional stress. Reprinted with permission from Black, J. (1988). "Orthopaedic Biomaterials in Research and Practice." Churchill Livingston, New York.

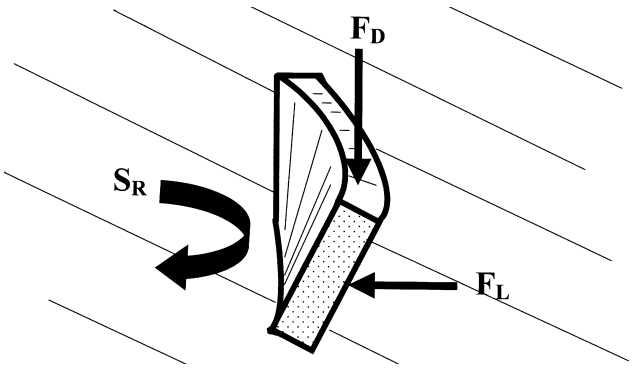

Figure 4 A simple cantilevered beam coming out of the page and with two bending forces applied. A combination of a force downward (F_D) from top and a lateral force from page right to page left (F_L) cause predictable bending in those two planes. However, the resultant strain (S_R) is a combination of bending in those two planes and an additional resultant axial torsion. Thus, even with very regular structures, combinations of even simple loads can induce complex strain behaviors. More complex biological structures like the femur would compound this strain reaction further.

stresses, including torsion along with the initial two simple bending stresses (Fig. 4). This complicating effect is even more apparent in irregularly shaped objects such as a long bone. The measurement of deformation resulting from any of these stresses, when normalized by the original configuration of the specimen, is called *strain:*

$$\begin{aligned}\text{Strain} = \varepsilon &= \text{change in length/original length} \\ &= (\text{deformed length} \\ &\quad - \text{original length})/\text{original length}.\end{aligned}$$

Strain is dimensionless and is therefore expressed as a percentage of change from the original dimensions or angular configuration of the structure. The application of these terms to bone can be made by considering the stresses and strains generated in the diaphysis of the femur (Fig. 5). For this purpose, the assumption must be that a very thin transverse section of bone behaves like a small cube, the top face of which may be designated *A*. Two types of internal forces can act on *A*, a perpendicular force *F* and shear force *S*. The former produces a normal stress gamma (δ), equal to *F/A*, whereas shear force results in a shear stress (*T*), equal to *S/A*. A normal stress might be applied toward the face of the cube, in which case it is called compression, or away from the face of the cube, in which case it is called tension.

The stresses described cause local deformation of the cube (Fig. 6). A normal compressive stress will cause shortening by a distance *L*, and the normal strain in the cube is then defined as the ratio of the change in length of the side of the cube ΔL to the original length *L* (strain = $\Delta L/L$). A shear stress applied to the top face of the cube will cause the front of the face to be deformed, and the resultant shear strain can be defined as the deviation of one side of the cube from its original angle, i.e., strain = $\Delta L/L$.

Considering that the cube represents a section of bone, the normal and shear strains experienced will be influenced

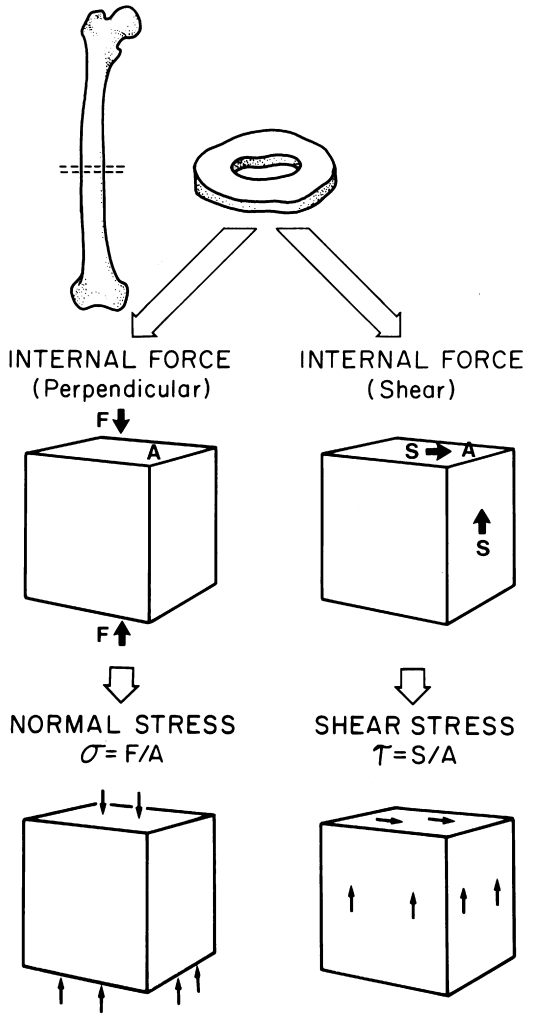

Figure 5 Schematic representation of the stresses acting on the diaphysis of the femur. In this example, a thin transverse section of the femur is considered to behave as if it were a small cube. *F,* perpendicular force; *S,* shear force; *A,* area on which force acts. not only by the magnitude of the stresses applied, but also by the inherent material and structural properties of the bone. Stresses applied to normal, well-mineralized bone tissue will cause small strains, whereas the same stresses applied to poorly mineralized tissue, such as osteomalacic bone, will produce large strains. Likewise, if a bone experiences a bending stress in a direction in which it has a relatively greater areal moment (*I*), it will experience less strain than when loaded in a direction having a lower areal moment. It must be remembered, however, that in nature stresses are applied to bone not only from perpendicular and horizontal directions, but also from oblique angles and combinations of loads, resulting in a variety of complex mechanical relationships. Although strain is given most commonly in length dimensions, it may also be represented by angular deformation as well as other structural alterations such as volumetric changes.

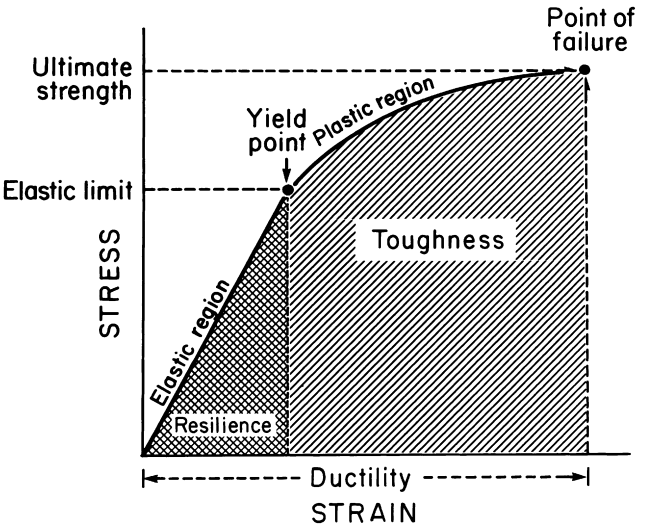

Figure 7 A standard stress–strain curve of bone loaded in bending. The linear portion of the curve represents the elastic region, and the slope of this part of the curve is used to derive the stiffness of the bone. Loading in this region will result in nonpermanent deformation, and the energy returned by the bone when the load is removed is know as its resilience. The nonlinear portion of the curve represents the plastic region in which the bone will be permanently deformed by the load. The junction of these two regions is known as the yield point, and the stress here is known as the elastic limit. The maximum stress at the point of failure is known as the ultimate strength of the bone. The maximum strain at this point is known as the ductility of the bone. The area under the curve is known as the strain energy, and the total energy stored at the point of fracture is known as the toughness of the material. Reprinted with permission from Einhorn, T. A. (1992). Bone strength: The bottom line. *Calcif. Tissue Int.* **51,** 333–339.

Stress–Strain Curve

Under controlled laboratory conditions, the testing of materials involves the application of known forces and measurement of the resulting deformation. For the purposes of this discussion and in order to simplify the mechanical complexities imparted to bone by its geometry, the material properties of bone will first be considered. This involves testing small specimens of uniform geometry under specific loading conditions. Knowing the size of the specimen, the applied force, the area of force application, and the deformation produced, the material properties can be derived from a plot of the stress–strain relationship.

By convention, stress is plotted on the ordinate (*y* axis) and strain on the abscissa (*x* axis; Fig. 7). As three types of stress exist (tension, compression, and shear) and as these stresses are produced by different externally applied forces (tension, compression, bending and torsion), the *y* axis could represent any of these loading conditions and the curve reflect any load versus deformation relationship. Moreover, as in this stress–strain plot for an idealized material the geometric factors are not considered, stress is normalized to unit area, and strain is deformation normalized to unit length. The curve can therefore be applied to a specimen of any size.

The stress–strain curve can be analyzed by breaking it down into different regions and interpolating and extrapolating these points relative to the *x* and *y* axes. Once this is done, it is then possible to derive the material properties of bone. Thus, at physiologic levels of stress there is a linear relationship between the stress applied and the resultant deformation. This proportionality is called the *modulus of elasticity,* or *Young's modulus* (*E*). It is a measure of the slope of the linear portion of the curve and is calculated by dividing the stress by the strain at any point along the linear portion. If this curve were to be generated by testing a whole bone as opposed to an uniform specimen, this measurement of the linear slope would give the *stiffness* or *rigidity* of the bone in that particular loading direction.

The linear portion of the stress–strain curve is known as the *elastic region*. In the elastic region, a material will deform only while the load is being applied to it, returning to its original shape and dimensions when the load is removed. If the slope is straight, the material is said to be linearly elastic. At the point where the curves become nonlinear, the elastic region gives way to the plastic region and the stress at this point is known as the *elastic limit*. The point on the curve where this occurs is known as the *yield*

point. Further loading beyond the yield point will cause permanent deformation of the material. This property is known as plasticity and indicates that a material has undergone some permanent deformation. Up to the elastic limit, energy applied to a material stretches or bends its atomic bonds but does not rearrange its atomic organization. Almost all the energy can be recovered by releasing the applied load (some, for example may, be lost to heat), but once the material has reached its elastic limit, or yield point, removal of the load will no longer cause the material to return to its original dimensions and it will be deformed permanently.

The strength of a bone or specimen of bone tissue is determined by calculating the maximum stress at the point of failure. In tensile loading, this is known as the *ultimate tensile strength* and, similarly, with torsional or compressive loading it is known as the *ultimate torsional* or *ultimate compressive strength.* The strain at the point of failure is known as the *ductility.* Integration of the curve gives the area under the curve and this is a measure of the strain energy. The total strain energy stored at the point of failure is known as the *toughness of the specimen.*

Energy put into deforming an elastic material just prior to reaching the yield point can be recovered by removing the stress. The energy recovered is known as the *resilience* and is a measure of the material's ability to store elastic energy. Although this energy is not always recoverable in a useful form, it will not be lost as long as the material does not undergo permanent deformation. If the area under the stress–strain curve during load removal is smaller than the area during load application, then energy is lost. This energy loss is called *hysteresis.*

Under certain pathological conditions, bone may fail before undergoing permanent deformation, i.e., without exhibiting plasticity. When the yield point and the ultimate failure coincide in this way, bone is said to be *brittle.*

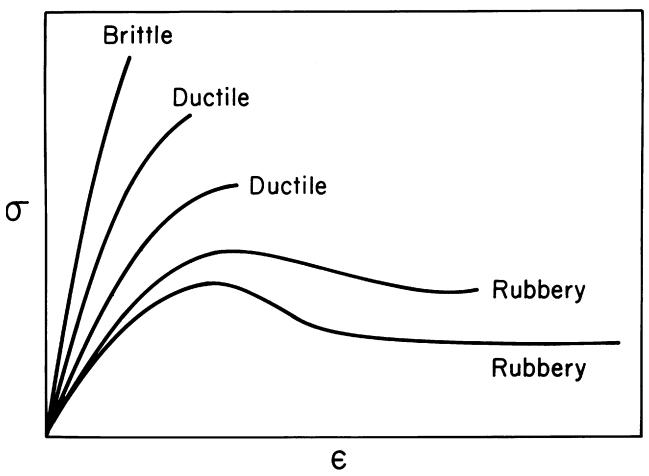

Figure 8 Stress–strain curves for brittle, ductile, and rubbery materials. Reprinted with permission from Einhorn, T. A., Azria, M., and Goldstein, S. A. (1992). "Bone-Fragility: The Biomechanics of Normal and Pathologic Bone." Sandoza Pharma Ltd. Monograph.

However, bones showing normal failure behavior exhibit ductility, which means that some of the energy required to produce the permanent deformation is recoverable and some is not. The molecular structure of the material is reorganized into a new and stable configuration and the external shape of the specimen does not revert to its original configuration. Rubbery materials, such as incompletely healed fracture callus, are capable of withstanding elastic deformation under relatively large strains without yielding: permanent deformation does not occur despite the appearance of the stress–strain curve. The stiffness of this material may be low relative to that of intact bone, but the energy stored prior to failure can in some cases be greater. A brittle material can be tough due to a high modulus and high strength even if it does not show significant deformation prior to failure, while a ductile material can absorb an equal amount of energy by undergoing significant plastic deformation before failing (Fig. 8). Therefore, two materials can have the same toughness with entirely different stiffness, strength, and ductility properties.

Special Properties of Bone

Biological structures generally have orderly structural elements that give them very different material and mechanical properties under different conditions. Thus, the mechanical properties of bone vary not only according to the magnitude of the applied force, but also to its direction and rate of application. Ideal materials are homogeneous and always behave the same way regardless of load orientation. This property is known as *isotropy* and these materials are considered to exhibit isotropic behavior (Turner *et al.,* 1995). Bones, however, have different mechanical properties in different loading directions, a phenomenon known as *anisotropy*. The anisotropy of bone can be illustrated by the application of a load to the femur. As the femur is oriented vertically, it is subjected to a compressive load with every step taken and is therefore capable of resisting high compressive loads (such as jumping from a modest height) without showing permanent deformation. However, the same load applied from a transverse direction, causing bending stresses, will not be as well tolerated by the femur and may result in fracture. Thus, the strength and rigidity of a bone are typically greater in the direction of customary loading. This is particularly true in cortical bone, where osteons are oriented in a longitudinal direction as indicated by the bone's loading history (Hert *et al.,* 1994).

The anisotropic nature of bone is documented by data for the material properties of cortical and trabecular bone in several loading configurations (Table I). Plastic deformation is diminished with transverse loading (Melton *et al.,* 1988), and bone is consequently more brittle in this direction. Cortical bone is stronger in compression than in tension (Burstein *et al.,* 1976), and after maturation the tensile strength and the modulus of elasticity of femoral cortical bone decline by approximately 2% per decade (Burstein

Table I Mean Values for Human Bone Material Parameters

Type of bone	Direction and type of load	Apparent density (g/cm^3)	Ultimate strength	Modulus of elasticity (10^6 MPa)
Cortical (midfemur)	Longitudinal tension	1.85	133	17,000
	Longitudinal compression	1.85	193	17,000
	Longitudinal shear	1.85	68	3,000
	Transverse tension	1.85	51	11,500
	Transverse compression	1.85	33	11,500
Trabecular (vertebral body)	Compression	0.31	6	76

et al., 1976). The ultimate compressive strength of trabecular bone is related to the square of its apparent density so that a decline in the latter due to aging or metabolic bone disease is associated with a reduction in compressive strength. Mathematically, therefore, if the apparent density of a bone were to decline by one-third, there would be a reduction in its compressive strength of the order of one-ninth (Carter and Hayes, 1977).

Trabecular bone also exhibits anisotropy. Compressive strength is greatest along the vertical axis of trabeculae in the lumbar vertebrae (Galante *et al.,* 1970; Mosekilde *et al.,* 1985) but parallel to the trabecular elements in the femoral neck (Brown and Ferguson, 1978). Trabecular bone has a lower modulus of elasticity than cortical bone due to its greater porosity. However, although less stiff, trabecular bone can withstand greater strains, fracturing at deformations of approximately 7%, while cortical bone will fail at strains of only 2% (Nordin and Frankel, 1980).

Creep and Stress Relaxation

Bone, and especially trabecular bone, exhibits phenomena known as *creep* and *stress relaxation* (Bowman *et al.,* 1999). Creep is defined as the change in strain of a mechanically loaded object, over time, whereas stress relaxation is the diminishment of the stress necessary to maintain a given strain over time. This behavior is most evident when bone undergoes a relatively slow rate of load application, which is then maintained statically over time. However, it also contributes to fatigue behavior in cyclically loaded trabecular bone (Bowman *et al.,* 1998). The cause of this behavior can be attributed to several factors, including changes in collagen biochemistry or to trabecular element microcracking. Collagen has been identified as a common denominator in creep behavior in both trabecular and cortical bone (Bowman *et al.,* 1999). Trabecular element microcracking is largely responsible for trabecular bone creep, with up to 94% recovery from the induced strain, and is believed to be a mechanism for energy dissipation (Fyhrie and Schaffler, 1994). Thus, creep can be considered a method by which bone tissue yields to stress without the catastrophic failure of whole-bone fracture.

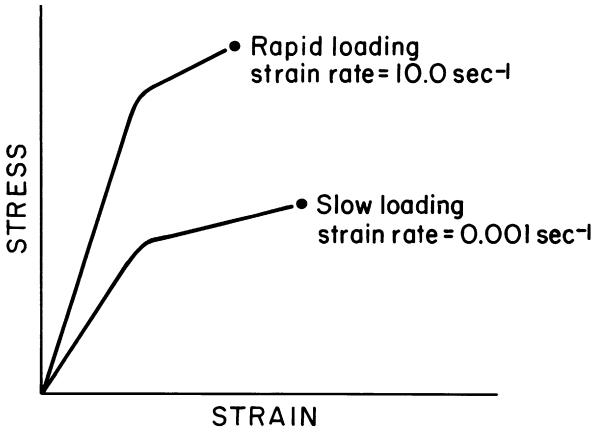

Figure 9 Different stress–strain curve configurations depending on the rate of loading. Reprinted with permission from Einhorn, T. A., Azria, M., and Goldstein, S. A. (1992). "Bone-Fragility: The Biomechanics of Normal and Pathologic Bone." Sandoza Pharma Ltd. Monograph.

Viscoelasticity

Another important mechanical property exhibited by bone is known as *viscoelasticity.* A viscoelastic material is one that undergoes material flow under sustained stress and exhibits different mechanical properties under different rates of loading. If, for example, one slowly places their hand in a tub of water, it will submerge with little resistance, whereas if one slaps their hand down into the tub, it will meet with great resistance. This phenomenon is due to the fact that the material (water in this example) actually flows under an applied load. Thus, an increase in the loading (or strain) rate decreases the time allowed for flow, increasing the modulus of elasticity of the material, while decreasing the ultimate strain (Fig. 9). At low strain rates, bone shows no appreciable elastic deformation but rather flows like a viscous liquid, whereas at high strain rates the same bone can behave like a brittle elastic solid. In normal activities, bone is subjected to strain rates below 0.01/sec, with the modulus of elasticity and the ultimate strength of bone approximately proportional to the strain rate raised to the power of 0.06 (Einhorn *et al.,* 1992). Thus, over a very wide range of strain rates, both the ultimate tensile strength and the modulus of elasticity show a strong linear relationship. Because of these characteristics, the strain rate and the direction of the load applied must be

specified when describing the behavior of bone material (Einhorn *et al.,* 1992).

Bone Structure, Biochemical Composition, and Mechanical Integrity

Bone is comprosed of approximately 70% mineral, 22% protein, and 8% water (Lane, 1979). The viscoelasticity of bone is largely a result of its water content, whereas material properties, such as strength and toughness, come from its solid-phase components. As the major components of bone are mineral and matrix phases, it is possible to describe its material properties as if it were a two-phase composite material (Carter and Hayes, 1977). However, the composition of bone can vary somewhat by species and anatomical location (Currey, 1979; Zioupos *et al.,* 1997), and this variation can influence the mechanical properties of bone. These are important factors to consider when conducting biomechanical research utilizing animal models.

Burstein *et al.* (1977) investigated the individual contributions of collagen and mineral to the elastic and plastic properties of bone. Their findings were consistent with an elastic-perfectly plastic model for the mineral phase of bone tissue in which the mineral contributes the major portion of the tensile yield strength, whereas the slope of the plastic region of the stress–strain curve is solely a function of the matrix. By sequentially demineralizing machined strips of cortical bone and subjecting them to bending loads, these investigators showed that the major determinant of the modulus of elasticity is related to the mineral phase, whereas ultimate yield strength is determined both by the mineral composition and by the integrity of the collagenous matrix (Burstein *et al.,* 1977). Landis (1995) demonstrated that this contribution of the mineral phase to bone strength is a function of the molecular structure and organization of the mineral crystals within the extracellular matrix.

Studies on the contribution of the collagen phase to the mechanical properties of bone have made use of transgenic mice expressing abnormal type I collagen gene products (Bonadio *et al.,* 1993). Because the matrix phase of these bones are rendered biochemically abnormal, the mice represent conditions that might be analogous to human collagen diseases, such as osteogenesis imperfecta. Experiments in young animals have shown that the reduced synthesis of type I collagen leads to a reduction in stiffness and strength properties when static loading tests are performed. Gradual deterioration in the mechanical properties of bones has also been found in conjunction with advancing age where it is suggested that increased bone fragility during aging is accompanied by changes in collagen material properties (Zioupos *et al.,* 1999). Apparent bone density in cancellous bone has likewise been linked to changes in the mechanical properties of aging bone (McCalden *et al.,* 1997). However, with age, adaptive changes in bone geometry leading to cortical expansion, endosteal resorption, and periosteal bone apposition result in the maintenance of structural level mechanical properties due to increases in the areal and polar moment of inertia properties of whole bones (Bonadio *et al.,* 1993). This relationship among structural geometry, bone composition, and biomechanical properties illustrates the importance of the form–function relationship in bone biomechanics.

Approximately 70–80% of the variance in the ultimate strength of bone tissue is accounted for by an age related decrease in bone mineral density (McCalden *et al.,* 1997; Smith and Smith, 1976; Singer *et al.,* 1995), with the remainder possibly due to qualitative changes associated with the altered composition of either the mineral or the matrix phase (Yamada, 1970; Zioupos *et al.,* 1999). Collagen, for example, experiences qualitatives changes with advancing age, but this may only partially affect the ultimate strength of bone and be compensated for by changes in structural properties. Unlike the case with collagen, abnormalities in mineral structure, such as those seen in a variety of metabolic bone diseases, significantly affect both the modulus of elasticity and the ultimate strength. This occurs via factors such as crystal size, crystal structure, and the way in which hormonal changes affect bone resorption and thereby the differential removal of mineral phase components.

Cellular activity plays an important role in determining the mechanical properties of bone. This may account, in part, for the fact that not all patients with low bone mass experience the osteoporotic syndrome (skeletal fragility and a propensity to fracture under minimal load). Although bone has a specific biochemical composition and structural form at any given point in time, the fact that these two properties are in a constant state of dynamic change may affect the ability of bone to respond to an applied load. It is easy to understand how bone, which is constantly undergoing breakdown and repair, may have reduced mechanical properties when compared with bone that exhibits normal homeostasis. The resorptive cavities produced by osteoclastic action may act as stress risers for the initiation of crack propagation, even before osteoblasts have had a chance to fill them in with new bone (Currey, 1962; Goodier, 1993). This is illustrated by the example of two brick walls of identical size and thickness and containing identical quantities of bricks and mortar in exactly the same spatial array. If one wall undergoes continuous degradation and repair (i.e., chipping away of its substance with immediate replacement of any brick or mortar that is lost), it will show reduced mechanical stiffness and strength as compared to the wall that is constantly intact (Fig. 10). Thus, bone that is in a state of high turnover (hyperparathyroidism, high remodeling osteoporosis, Paget's disease) may show a reduction in mechanical properties compared with bone undergoing normal remodeling in response to physiological loads (Einhorn, 1992). It is important to recognize that this phenomenon occurs independent of bone density. Thus, even though bone strength is correlated with density, the remodeling state of bone may be a more important factor with respect to risk of fracture.

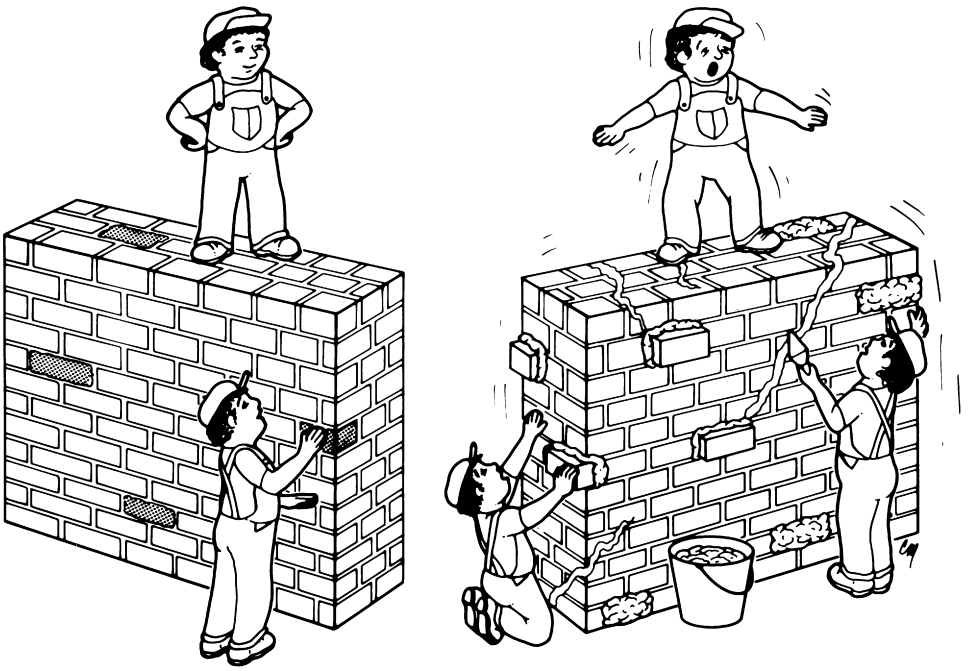

Figure 10 Demonstration that two brick walls of the same mass and dimensions will have different mechanical properties if one is constantly being excavated and patched whereas the other undergoes controlled remodeling. This situation may be analogous to bone that is in a state of high turnover versus bone that experiences normal homeostatic remodeling. Reprinted with permission from Einhorn, T. A. (1992). Bone strength: The bottom line. *Calcif. Tissue Int.* **51,** 333–339.

Mechanisms of Mechanotransduction in Bone

Because bone development, remodeling, and repair are dependent on the cellular responses associated with formation and resorption, it is presumed that mechanical loads applied to bone are transduced through the skeleton and received by a cellular network. That mechanical signal is detected by certain receptor cells, leading to the generation of a secondary, cytogenic signal aimed at target cells that modulate actual bone formation and resorption. However, the mechanisms of mechanotransduction, mechanosensitivity, and response signaling in bone are not completely understood. The currently favored model of mechanotransduction involves osteocytes and their canalicular network (Burger and Klein Nulend, 1999; Cowin *et al.,* 1991; Kufahl and Saha, 1990; Martin, 2000). Readers interested in an excellent review of osteocyte biology should refer to Chapter 6.

Evidence for an osteocyte-mediated mechanotransduction mechanism in bone is growing. Osteocytes are by far the most abundant cell in bone and represent a vast interconnected canalicular network throughout the entire skeleton (Parfitt, 1977). Studies have shown that under mechanical strain, osteocytes increase RNA production and glucose consumption (Pead *et al.,* 1988; Skerry, *et al.,* 1989) as well as produce c-fos, insulin-like growth factor I (IGF-I), and osteocalcin (Mikuni-Takagaki, 1999). The extensive processes of osteocytes, positioned throughout the canalicular network, are linked by gap junctions, which potentially allow a number of cellular signaling mechanisms (Doty, 1981).

This extensive network throughout the skeleton makes osteocytes excellent candidates for mechanical signal reception and transduction, although this is likely not their sole function (Cullinane and Deitz, 2000). Strain derived fluid flow through the canalicular network has been suggested to be the mechanism by which osteocytes receive strain information and then initiate a cellular response to a given load (Burger and Klein-Nulend, 1999; Cowin *et al.,* 1991; Martin, 2000; Owan *et al.,* 2000; Turner *et al.,* 1994). This same canalicular network could then act as a conductance pathway by which osteocyte-generated signal molecules can be distributed throughout the bone network, as well as facilitate the transport of nutritional factors and waste (Burger and Klein-Nulend, 1999). Actual *in vivo* measurements of the efficacy of this canalicular system for molecular transportation demonstrate that a 0.2% strain induced in the forelimb of sheep causes a significant increase in fluid transport (Knothe-Tate and Knothe, 2000). Likewise, Weinbaum *et al*. (1994) suggested that even very small stresses, such as 1 Pa, may be detected by the osteocyte – canalicular network. Microcracking has also been shown to reduce fluid flow downstream of the damage site, increasing osteocyte morbidity (Knothe Tate *et al.,* 2000), and osteocyte morbidity has in turn been linked to the initiation of bone remodeling via osteoclastic activation (Noble *et al.,* 1997; Verborgt *et al.,* 2000). It is even conceivable that osteocyte lacunae act as stress concentration centers within bone, providing a potential mechanism for strain detection (Reilly, 2000). Likewise, osteocyte hypoxia has

been identified as a possible mechanotransduction pathway (Dodd *et al.,* 1999).

Various molecules are potentially involved with this osteocytic signaling system including prostaglandins (Burger and Veldhuijzen, 1993; Noble and Reeve, 2000), nitrous oxide (Noble and Reeve, 2000), and parathyroid hormone (PTH) (Noble and Reeve, 2000; Sekiya *et al.,* 1999), among others. In addition to potential molecular signaling, osteocytes may have the capacity to act as a neural network in bone via a glutamate neural transmission-like mechanism (Noble and Reeve, 2000). Further evidence for a neuroelectric mechanism in osteocyte communication was found in damaged bone where an electrical signal was detected at the site of a fracture (Rubinacci *et al.,* 1998).

The specific nature of the fluid flow to which osteocytes are most likely to respond has been investigated by several authors. Hypothesizing that osteocytes are the mechanosensors in bone, Klein-Nulend *et al*. (1995) tested this hypothesis using intermittent hydrostatic compression and pulsating fluid flow. Osteocytes, but not osteoblasts or periosteal fibroblasts, were shown to react to 1 h of pulsating fluid with the sustained release of prostaglandin E_2. Intermittent hydrostatic compression stimulated prostaglandin production, but to a lesser extent. The investigators concluded that osteocytes are the most mechanosensitive cells in bone and that stress on bone predominantly causes fluid flow in the lacunar–canalicular system, which signals osteocytes to produce factors that stimulate bone metabolism (Klein-Nulend *et al.,* 1995). Evidence also suggests that among steady, pulsing, and oscillating flow, oscillating flow was found to be a much less potent stimulator of osteocytic reaction, and a reduction in responsiveness occurred with increases in dynamic flow frequencies (Jacobs *et al.,* 1998). The authors suggest that a response by bone cells to fluid flow may be dependent on chemotransport effects (Jacobs *et al.,* 1998).

Although not fully investigated in bone cells, an alternate or parallel mechanism for mechanotransduction is directly through the cytoskeleton of cells. Wang *et al*. (1993) have shown that the direct attachment of endothelial cells to their extracellular matrix via integrin interactions with the extracellular matrix provides a mechanism for alterations in cellular responses (Cowin and Weinbaum, 1998; Wang *et al.,* 1993; Zimmerman *et al.,* 2000). These experiments suggested that attachment of cells to their extracellular matrix allows direct mechanical strain in the environment to be transduced across the cell, through its cytoskeleton, and directly to the nucleus.

Fracture Behavior of Bone

When whole bones are subjected to experimental or physiological loads they exhibit structural behavior. This behavior is dependent on the mass of the tissue, its material properties and its geometry, and the magnitude and orientation of the load. A useful way of describing the structural behavior of bone is to consider what happens when a bone fractures. When bones are exposed to severe loads, large stresses are generated. As noted earlier, if the stresses exceed the ultimate strength of the bone tissue (material) in the section being loaded, a fracture will occur. Thus, a fracture is an event initiated at the material level, which ultimately affects the load-bearing capacity of the whole bone at the structural level. To describe these events, a set of biomechanical parameters that specify the behavior of bone is required.

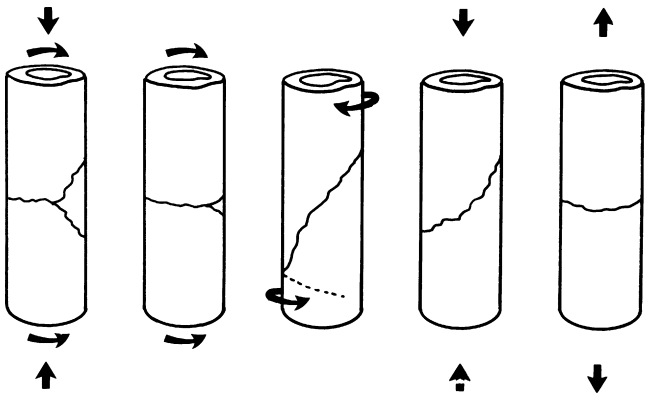

Figure 11 Fracture patterns in a cylindrical section of bone subjected to different complex loading configurations. Bending (a combination of compression and tension) produces an essentially transverse fracture with a small fragment on the concave side; torsion produces a spiral fracture; axial compression causes an oblique fracture; and tension produces a purely transverse fracture. Reprinted with permission from Carter, D. R., and Spengler, D. M. (1982). Biomechanics of fractures. *In* "Bone in Clinical Orthopaedics," pp. 305–334. Saunders, Philadelphia.

As noted previously, four modes of loading occur in whole bones—compression, tension, bending, and torsion—and these modes result in the types of long bone fractures observed clinically (Fig. 11). Axial loading can take place in either tension or compression. Tension is particularly important in the pathogenesis of *avulsion fractures*. These are fractures caused by excessive loads on tendons or ligaments, where the acute tensile force generated actually breaks off a fragment of bone at the point of soft tissue insertion (Fig. 12).

Fractures of the vertebral bodies are of particular interest in metabolic bone diseases. These fractures occur as a result of combinations of compression, bending, and shear. Compression forces arise as loads are transmitted across the spine in the axial direction, but if the cross-sectional area of the vertebral body is reduced due to age-related bone loss, its effective length of vertical trabeculation will be increased. This is a result of the removal of horizontal trabeculae, which act as lateral supports or cross-ties (Mosekilde *et al.,* 1985). The trabeculae then behave like columns and, as such, are subject to critical buckling loads. A 50% reduction in cross-sectional area is associated with a 75% reduction in load-bearing capacity, and a doubling in relative length with a 75% reduction in the critical buckling load (Compston, 1994).

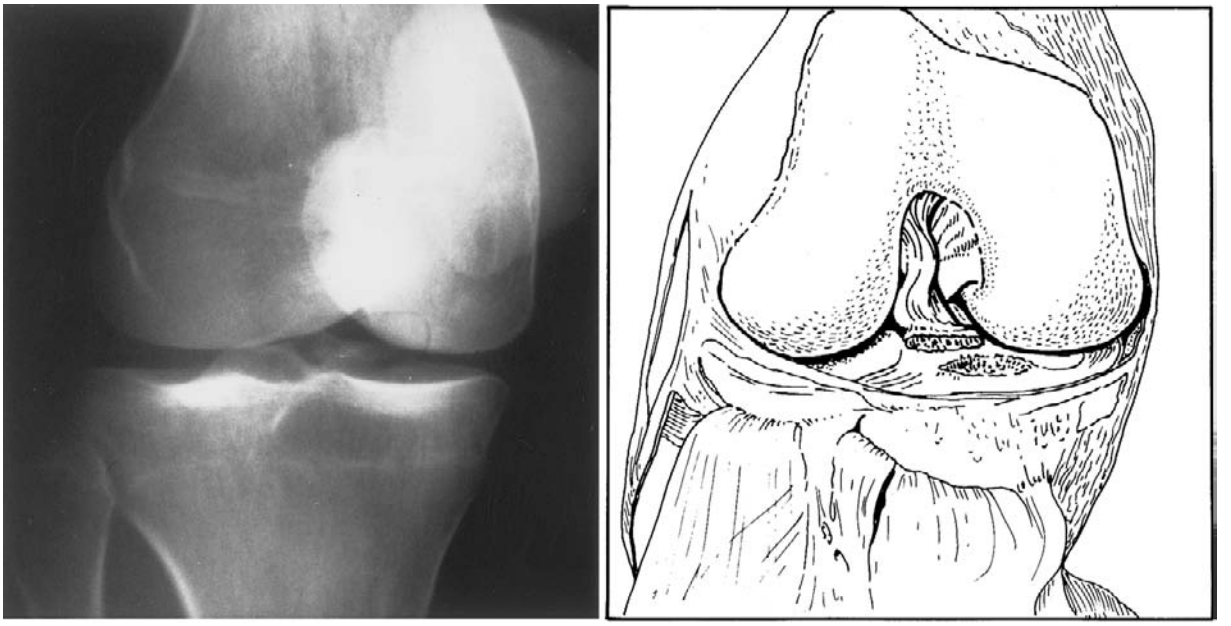

Figure 12 Anterior–posterior radiograph and associated schematic drawing of a fracture produced by a pure tensile force that occurred in a skiing accident. In this patient, an acute tensile force produced by the anterior cruciate ligament caused an avulsion fracture of bone to occur in the tibial plateau. Reprinted with permission from Einhorn, T. A., (1992). Bone strength: The bottom line. *Calcif. Tissue Int.* **51,** 333–339.

Most long bone failures will occur under a combination of axial compression, bending, and torsion, a realistic combination of loads under normal activity. With pure bending, which involves subjecting one side of the cortex to tension and the other to compression, the rigidity of the bone will depend on its cross-sectional shape, its length, and its material properties, as well as on how its ends are fixed. In the case of bending, the cross-sectional area is less important than its distribution with respect to the axis of loading, which, ideally, should be as far from the axis of bending (neutral axis) as possible; the geometric parameter used to describe this is the *areal moment of inertia* (Einhorn *et al.,* 1992; Fig. 13). Similarly, in torsion, deformation is resisted more efficiently the farther bone (or any material) is distributed away from the torsional axis. The geometric parameter used to describe this is the *polar moment of inertia* (Einhorn *et al.,* 1992; Fig. 14).

With aging, the outer cortical diameter of bone increases while the cortical wall thickness declines. This is the result of the combined effects of increased endosteal resorption (due to involutional osteoporosis) and periosteal appositional bone

Figure 13 Moment of inertia properties of bone. Although the cross-sectional areas of bone in each of these three bones are roughly equivalent, their bending strengths are very different due to the differences in moments of inertia. This occurs as a result of the way bone is distributed in relation to the central axis of bending or rotation. The solid bone on the left has the same amount of bone (area) as the one in the center, but the latter has a higher moment of inertia because the bone is farther away from the central axis. Thus its bending strength is 50% greater. Similarly, the bone on the right has only slightly more bone area than the one in the center, but its moment of inertia is again 50% higher, making it 30% stronger under bending stress. Reprinted with permission from Einhorn, T. A., Ariza, M., and Goldstein, S. A. (1992). "Bone-Fragility: The Biomechanics of Normal and Pathologic Bone." Sandoza Pharma Ltd. Monograph.

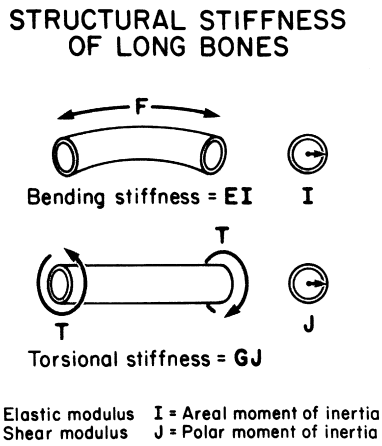

Figure 14 Diagram of the structural stiffness of long bones loaded in bending and torsion. Note that the elastic modulus and the shear modulus, measures of stiffness in bending and torsion, are related to the areal and polar moments of inertia, respectively. These moments of inertia are increased, and thus the structural stiffnesses are increased when bone is distributed farther away from the neutral axis of bending or torsion. Reprinted with permission from Einhorn, T. A. (1992). Bone strength: The bottom line. *Calcif. Tissue Int.* **51,** 333–339.

formation (due to mechanical strain). Although the net effect is cortical thinning, the increased diameter of the bone improves its resistance to bending and torsional loads through its areal and polar moment properties. This may also be sufficient to offset any loss of bone tissue (Melton *et al.,* 1988) and may explain why cortical bone fractures are surprisingly uncommon in osteoporotic patients.

Stress Fractures

By definition, a bone should fail when it is subjected to a load that exceeds its ultimate stress. However, it is not always necessary that the ultimate stress be exceeded in order for a fracture to occur; repeated loading of the bone can cause it to fail even if loads are below this level (Muller *et al.,* 1998; Reilly and Currey, 2000; Yeh and Keaveny, 2000). This phenomenon is known as *fatigue failure,* and fractures that result from this kind of loading are known as *stress fractures* or *fatigue fractures.* Fatigue failure occurs when each loading cycle produces a small amount of microdamage, which accumulates with repetitive loads (Muller *et al.,* 1998; Schaffler *et al.,* 1994). Biological materials such as bone have repair mechanisms for healing the microdamage as it occurs. Under normal conditions, microdamage will occur but will not accumulate because it will be repaired in a timely fashion (Hirano *et al.,* 2000; Tomlin *et al.,* 2000). This process of bone matrix repair has been linked to signals originating via osteocyte apoptosis (Verborgt *et al.,* 2000). However, when the normal repair mechanisms are impaired or attenuated (e.g., in certain metabolic bone diseases or in patients taking certain drugs) or when bones are loaded repetitively over short periods without sufficient time for a reparative process (e.g., during intense basic military training), bones may exhibit fatigue failure after several cycles of loading (Givon *et al.,* 2000; Hirano *et al.,* 2000; Lauder *et al.,* 2000; Stanitski *et al.,* 1978). A high prevalence of stress fractures in patients who are maintained on glucocorticoids is due to the combined effects of osteoporosis and the impaired healing of microfractures. Sodium fluoride may have a similar effect on bone and may account for the increased prevalence of appendicular fractures reported in certain fluoride-treated patients (Boivin *et al.,* 1991).

Stress fractures are most likely to occur when bone is loaded repeatedly in the plastic region (Chamay, 1970). Here, small deformations of the tissue have already occurred and repeated damage will eventually lead to the ultimate point of failure. However, fatigue failure in the elastic region is also possible, particularly in bones that are more brittle. This requires a large number of loading repetitions (Chamay, 1970) or less rest time between loading cycles (Schaffler *et al.,* 1994).

Stress fractures may occur on either the tension side or the compression side of a bone undergoing bending. It should be noted that a stress fracture on the tension side, resulting in a crack in the cortex, is more serious because it may rapidly go on to a complete fracture, as bone is stronger under compression than under tension (Burstein *et al.,* 1976). This phenomenon is especially true if the initial microcracks are created in compression and then subjected to tension, reducing the energy-absorbing capacity of a bone by as much as 40% (Reilly and Currey, 2000). Stress fractures that occur on the compression side of bones may also result from a slower process, in which repair mechanisms may be mobilized more easily, leading to healing before a complete fracture occurs (Baker *et al.,* 1972).

Correlation among Bone Strength, Bone Fragility, and Fracture Risk

Although there is considerable evidence that bone density has an important effect on the risk of fracture, the relationship among bone strength, bone fragility, and fracture risk may depend on several factors. As mentioned previously, the proteinaceous matrix of bone plays an important role in determining its elastic and plastic stiffness. Moreover, the way in which the mineral phase is embedded in the matrix also dictates strength-related properties, as does the spatial distribution of bone tissue.

Bone formation or remodeling can occur in response to conditions such as age (Tanck *et al.,* 2000; Weinans, 1998), mechanical stimulation (Biewener and Bertram, 1994; Fyhrie and Carter, 1986; Hauser *et al.,* 2000), metabolic disorders (Lanyon, 1996), and even as compensation for tumors (Hauser *et al.,* 2000). This adaptive response suggests that reduction in strength due to osteolytic bone defects can be compensated for by adaptive remodeling of

Table II Trabecular Bone Content at Various Skeletal Sites

Vertebrae	66 – 90%
Hip (intertrochanteric)	50%
Hip (femoral neck)	25%
Distal radius	25%
Midradius	1%
Femoral shaft	5%

the cortical bone via thickening of the adjacent cortex, increases in areal moment, or formation of buttress-like septae. Thus, bone is capable of compensating for changes in activity level, age, and disease, and these compensations by the skeleton are an effort to reduce the risk of fracture. However, confounding factors, such as reduction in cell sensitivity due to advancing age, may be difficult to overcome by structural remodeling (Stanford *et al.,* 2000).

Fracture risk is highly site specific, depending on the type of bone involved and the loading to which it is subjected. For example, because the human spine is predominantly under compressive loading and is composed predominantly of trabecular bone, it is the mechanical properties of vertebral trabecular bone that primarily dictate the fracture risk of vertebrae. This is of particular relevance to metabolic bone disease, as turnover in trabecular bone is nearly eight times faster than in cortical bone (Parfitt, 1987). Bones with a high trabecular component are at a much higher risk of fracture in patients with metabolic bone disorders (Table II). Thus, bone loss due to metabolic disorders such as osteoporosis differentially affect the axial skeleton (Grey *et al.,* 1996) leaving it more vulnerable to fracture over the course of the disease.

Consideration of Table II may lead one to wonder why femoral neck fractures are so common in the elderly if trabecular bone content at this site is no higher than the average for the skeleton as a whole. This explanation may lie in the phenomenon of increased periosteal bone apposition leading to age-related cortical expansion and changes in areal and polar moments. Because the femoral neck is an intracapsular structure (within the hip capsule) and is not covered by periosteum (Phemister, 1939; Pankovich, 1975), its external diameter does not increase as the skeleton ages, despite increased mechanical loading. Thus, whereas cortical bone in the rest of the skeleton increases its areal and polar moments of inertia, protecting older persons from sustaining fractures in the diaphysis of their long bones, this biomechanical adaptation is not exhibited by the femoral neck. Endosteal resorption occurs, the cortex becomes thinner, and the femoral neck is then weakened in the absence of a compensatory response via a periosteal increase in bone diameter. Thus, there are peculiarities to location, tissue composition, and systemic metabolic status that must all be incorporated into risk of fracture assessments.

Predicting Fractures

As can be inferred from a discussion of structure – function relationships at hierarchical levels, changes in both material and structural properties of bone may arise from numerous causes. Geometric changes at any structural level will significantly influence the mechanical integrity of the tissue composite. For example, increases in the radius of long-bone diaphyses will increase resistance to torsion or bending loads by a factor raised to the fourth power, as predicted by both polar and bending moments of inertia. Increases in trabecular plate thickness at the microscopic level, however, are more difficult to assess, as the continuum properties of trabecular bone volumes are influenced approximately equally by alterations in bone mass and orientation (Keaveny *et al.,* 2000). Similarly, precise estimates of the effects of other changes in trabecular morphology, such as plate perforations, trabecular reorientation, and increases or decreases in connectivity, cannot be made readily. Use of the statistically based empirical relationships described earlier may provide some insight, but these relationships have not been verified for diseased bone or bone undergoing significant adaptation. Future work should continue to address these relationships.

While current understanding of bone mechanics makes it possible to estimate the effects of geometric changes, as described previously, very little data available for assessing the effects of changes at upper hierarchical levels. At the tissue level, decreases in the mean wall thickness of trabecular packets, as well as potential changes in lamellar thickness, have been reported as a function of age and gender. While it has been suggested that these morphological changes affect global mechanical behavior significantly, no direct evidence of their effects has been presented. Similarly, changes in extracellular matrix ultrastructure, mineralization profiles, and remodeling rate probably have a significant effect on the mechanical integrity of the tissue and its ability to resist or propagate cracks, although properties such as mineral density and tensile strength may not be reflected in fracture toughness (Wang *et al.,* 1998).

The long-term objective of the majority of studies designed to characterize the mechanical behavior of bone is to provide the means for accurate fracture risk prediction. Much of the discussion in this chapter has been devoted to identifying those factors that contribute to the integrity of bone and, more specifically, its resistance to fracture. The complex, anisotropic, heterogeneous properties of bone, its ability to adapt continuously to environmental and metabolic changes, and our limited understanding of specific failure mechanisms associated with crack propagation have severely limited accurate fracture risk prediction. By far the majority of studies to date have tried to relate fracture risk to bone density, but this has only partially succeeded in explaining changes seen *in vivo* (patients) and *in vitro*. More recently, attempts to account for architecture by including density distributions have helped improve estimates of fracture risk, but have not yet been verified in clinical studies.

The use of analytical models, such as finite element analyses, has the advantage of taking both complex geometric and anisotropic tissue properties into account when attempting to predict the occurrence of fractures. These models incorporate specific geometric measures from individual patients but are still dependent on appropriate estimates of material properties. They will continue to increase their predictive capacity as finer resolution, noninvasive imaging techniques become available. In addition, accurate failure analysis is dependent on the selection of loading conditions appropriate to the bony region being modeled, as well as of appropriate failure criteria within the structure. These parameters can be estimated accurately only through careful locomotion analysis and biomechanical testing. These noninvasive fracture assessment methods are currently being investigated and refined for future use.

CHAPTER 3

Embryonic Development of Bone and the Molecular Regulation of Intramembranous and Endochondral Bone Formation

Andrew C. Karaplis

Department of Medicine and Lady Davis Institute for Medical Research, Division of Endocrinology, Sir Mortimer B. Davis–Jewish General Hospital, McGill University, Montréal, Canada H3T 1E2

Introduction

The skeletal system is multifunctional in that it provides the rigid framework and support that gives shape to the body, serves to protect delicate internal organs, endows the body with the capability of movement, acts as the primary storage site for mineral salts, and functions in hematopoiesis. The vertebrate skeleton is composed of two main subdivisions: axial and appendicular components. The axial skeleton encompasses the skull, spine, sternum, and ribs, whereas the appendicular skeleton defines the bones of the extremities. The skull, in turn, is best regarded as consisting of two units: the chondrocranium whose elements first develop in cartilage and includes the cranial base and capsules surrounding the inner ears and nasal organs, and the cranial vault and most of the upper facial skeleton, which arise from the direct conversion of undifferentiated mesenchymal cells into bone.

Skeletal cells are derived from three distinct embryonic cell lineages: neural crest cells contribute to the craniofacial skeleton; sclerotome cells from somites give rise to the axial skeleton; and lateral plate mesoderm cells form the appendicular component. Cells from these lineages participate in the process of skeletogenesis in four distinct phases: (1) the migration of cells to the site of future skeletogenesis, (2) the epithelial–mesenchymal interaction that leads to (3) the formation of condensations, and (4) the overt differentiation of chondroblasts or osteoblasts (Fig. 1, see also color plate) (Hall and Miyake, 2000).

Bone formation arising from a cartilaginous template is referred to as endochondral ossification. This is a complex, multistep process requiring the sequential formation and degradation of cartilaginous structures that serve as templates for the developing bones. Formation of calcified bone on a cartilage scaffold, however, occurs not only during skeletogenesis, but is also an integral part of postnatal growth, bone modeling, and fracture repair. Intramembranous bone differs from the endochondral component in that it is formed in the absence of a cartilaginous blastema. Rather, it arises directly from mesenchymal cells condensing at ossification centers and being transformed directly into osteoblasts.

The organization and morphology of the developing skeleton are established through a series of inductive interactions. The functional elements in these inductive and morphogenetic processes are not individual cells but rather interacting populations that elaborate an extensive extracellular matrix, which in turn feeds back onto these matrix-producing cells and controls their differentiation potential. Since the early 1990s, considerable insight has been gained

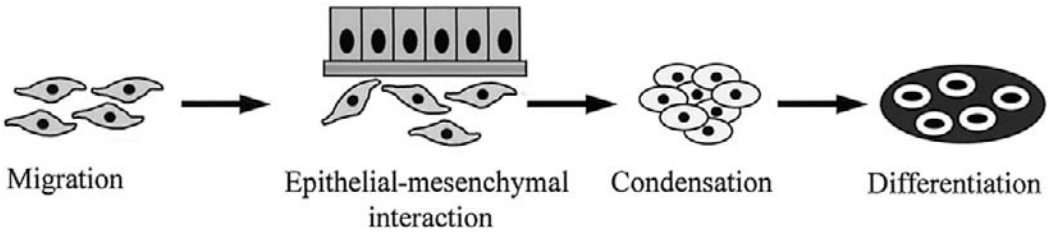

Figure 1 The four phases of skeletal development. Migration of preskeletal cells to sites of future skeletogenesis is followed by these cells interacting with an epithelium. This in turn leads to mesenchymal condensation and subsequent differentiation to chondroblasts or osteoblasts. Adapted from Hall and Miyake (2000). (See also color plate.)

into the molecular mechanisms that control these developmental programs. Genetic and biochemical analyses of human heritable skeletal disorders in concert with the generation of transgenic and knockout mice have provided useful tools for identifying key molecular players in mammalian skeletogenesis. It is the nature and interplay of these signaling cascades controlling skeletal patterning and cellular differentiation that are the focus of this chapter.

Axial Skeleton

Somitogenesis

A defining feature of the vertebrate body plan is metameric segmentation of the musculoskeletal and neuromuscular systems. The origin of this basic anatomic plan during embryogenesis is segmentation of the paraxial mesoderm (for reviews, see Burke, 2000; Christ *et al.,* 1998). Upon gastrulation, paraxial mesoderm cells segregate from axial and lateral mesoderm to form two identical strips of unsegmented tissue (referred to as presomitic mesoderm in the mouse embryo or segmental plate in the avian embryo) on either side of the neural tube. Paraxial mesoderm in vertebrates gives rise to the axial skeleton, as well as all trunk and limb skeletal muscles, and portions of the trunk dermis and vasculature. Through a series of molecular and morphogenetic changes, this unsegmented tissue is converted into a string of paired tissue blocks on either side of the axial organs, called somites (Fig. 2A). The process, referred to as somitogenesis, occurs sequentially by the addition of new somites in a strict craniocaudal (head-to-tail) direction along the body axis with a periodicity that reflects the segmental organization of the embryo. The recruitment of new presometic tissue from the primitive streak into the posterior end of the presometic mesoderm, as well as cell division within it, permits the presomite mesoderm to maintain its longitudinal dimension as somite budding is taking place anteriorly. Somite formation is preceded by epithelialization of the presometic mesoderm so that a new pair of somites is formed when cells are organized into an epithelial sphere of columnar cells en-

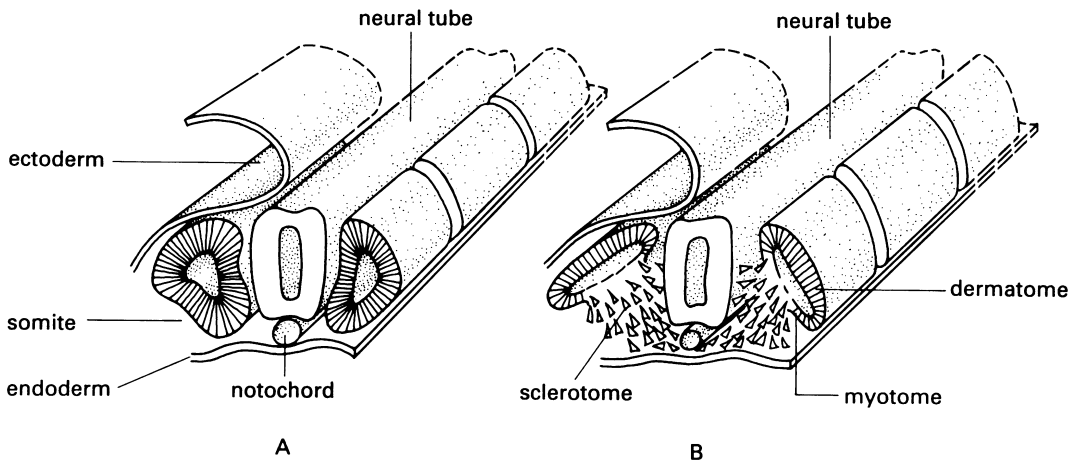

Figure 2 Diagrammatic representation of sclerotome formation. (A) Organization and differentiation of somites in the trunk region of the mouse embryo. (B) Ventral medial somite cells (those further away from the back and closer to the neural tube) undergo mitosis, migrate ventrally, lose their epithelial characteristics, and become mesenchymal cells, which give rise to the sclerotome. They ultimately become the vertebral chondrocytes that are responsible for constructing the axial skeleton (vertebrae and ribs). The notochord provides the inductive signal by secreting SHH. Following formation of the vertebral bodies, the notochordal cells die, except in between the vertebrae where they form the intervertebral discs. Adapted from Hogan *et al.* (1994).

veloping mesenchymal cells within the central cavity, the somitocoel. This epithelial structure, however, is not maintained, as somite maturation is accompanied by a commitment of its cells to different lineages in response to signals that arise from adjacent tissues. Cells on the ventral margin undergo an epitheliomesenchymal transition as they disperse and move toward the notochord, giving rise to the sclerotome, which serves as the precursor of the vertebrae and ribs (Fig. 2B). The dorsal epithelial structure of the somite is maintained in the dermatomyotome, which eventually gives rise to the epaxial muscles of the vertebrae and back (medial myotome), the hypaxial muscles of the body wall and limbs (lateral myotome), and the dermis of the skin of the trunk (dermatome).

Somitogenesis has long been known to be driven by mechanisms intrinsic to the presomitic mesoderm. Two distinct molecular pathways have been implicated in vertebrate segmentation (Fig. 3, see also color plate). The first is referred to as the "segmentation clock" (McGrew *et al.,* 1998; Palmeirim *et al.,* 1997; Pourquie, 1999). This clock corresponds to a molecular oscillator identified on the basis of rhythmic production of mRNAs for *c-hairy1,* the vertebrate homologue of the *Drosophila* pair-rule gene *hairy,* and for *lunatic fringe,* the vertebrate homologue of the fly *fringe* gene. The expression of these genes appears as a wave, which arises caudaly and progressively sweeps anteriorly across the presomitic mesoderm. Although a new wave is initiated once during the formation of each somite, the duration of the progression of each wave equals the time to form two somites. This wave does not result from cell displacement or from signal propagation in the presomitic mesoderm but rather reflects intrinsically coordinated pulses of *c-hairy1* and *lunatic fringe* expression.

The second pathway implicated in somitogenesis is *Notch/Delta* signaling, an essential regulator of paraxial mesoderm segmentation. It centers on a large transmembrane receptor called Notch, which is able to recognize two sets of transmembrane ligands; Delta and Serrate. Upon ligand binding, Notch undergoes a proteolytic cleavage at the membrane level, leading to the translocation of its intracytoplasmic domain into the nucleus, where, together with the transcription factor Su(H)/RBPjk, it activates the expression of downstream genes such as *HES1/HES5* in vertebrates. Many of the genes in this pathway are expressed strongly in the presomitic mesoderm, and mutation studies in the mouse have established their role in the proper formation of rostral–caudal compartment boundaries within somites, pointing to a key role for a *Notch*-signaling pathway in the initiation of patterning of vertebrate paraxial mesoderm (Barrantes *et al.,* 1999; Conlon *et al.,* 1995; Kusumi *et al.,* 1998; Yoon and Wold, 2000). It is now recognized that *lunatic fringe* is the link between the *Notch*-signaling pathway and the segmentation clock, as there is evidence to suggest that it acts downstream of *c-hairy1* and

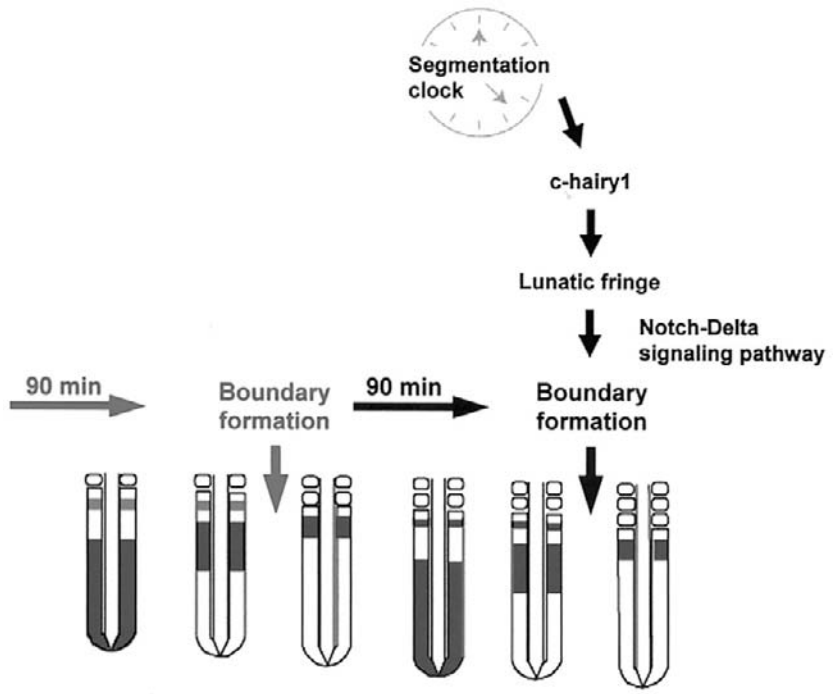

Figure 3 Proposed role of the segmentation clock in somite boundary formation. Waves of *c-hairy* and *Lunatic Fringe* (green) expression arise caudally and get narrower as they move anteriorly. A wave completes this movement in the time required to form two somites. Boundary formation occurs when the wave has reached its most rostral domain of expression where it is associated with rhythmic activation of the Notch signaling pathway that endows cells with setting-of-boundary properties. The purple color indicates a second such wave. Adapted from Pourquié (1999). (See also color plate.)

modifies Notch signaling. Likely, it is *lunatic fringe* that delimits domains of Notch activity, thereby allowing for the formation of the intersomitic boundaries characterized morphologically by the epithelization event (for review, see Pourquie, 1999).

Epithelization and somite formation require the expression of the gene *paraxis*. Paraxis is a basic helix-loop-helix (bHLH) transcription factor expressed in paraxial mesoderm and somites. In mice homozygous for a *paraxis*-null mutation, cells from the paraxial mesoderm are unable to form epithelia and so somite formation is disrupted (Burgess *et al.,* 1996). In the absence of normal somites, the axial skeleton and skeletal muscle form but are patterned improperly. Sosic *et al*. (1997) have shown that *paraxis* is a target for inductive signals that arise from the surface ectoderm, but the nature of these signals remains unknown.

Specifying the Anterior–Posterior Axis

Initially, somites at different axial levels are almost indistinguishable morphologically and eventually give rise to the same cell types such as muscle, bone, and dermis. A great deal of research has therefore focused on identifying factors that dictate the ultimate differentiation fate of somitic cells as well as the overall patterning of the body plan. Burke (2000) has proposed that correct pattern requires two levels of information. At one level, short-range, local signals could dictate to a cell to differentiate into a chondroblast instead of a myoblast. These signals, however, would not contain all the information required to also bestow regional identity to this chondrocyte and ensure that it would, for example, contribute to the development of the appropriate vertebral body, be that cervical, thoracic, or lumbar. In fact, additional information would be needed in order to provide global landmarks and to ensure correct pattern formation.

Patterning of somites extends beyond the formation of distinct epithelial blocks. Early on they acquire cues that dictate anteroposterior as well as dorsoventral position. What signals are important for regional specification of segments along the anterior–posterior dimensions into occipital, cervical, thoracic, lumbar, and sacral domains? This regionalization is, in part, achieved by specific patterns of *Hox* gene expression (for reviews, see Mark *et al.,* 1997; McGinnis and Krumlauf, 1992; Veraksa *et al.,* 2000). All bilateral animals, including humans, have multiple *Hox* genes, but in contrast to the single *Hox* cluster in *Drosophila* and other invertebrates, four clusters of *Hox* genes—*HOXA, HOXB, HOXC,* and *HOXD*—have been identified in vertebrates. Mammalian *HOX* genes are numbered from 1 to 13, starting from the 3′ end of the complex. The equivalent genes in each complex (*HOXA-1, HOXB-1, HOXD-1*) are referred to as a paralogous group. Comprising a total of 39 genes in human, these clusters are arranged such that all the genes in each cluster are oriented in the same 5′ to 3′ direction. Moreover, genes located at the 3′ end of the cluster are expressed prior to and extend more anteriorly in the developing embryo than those at the 5′ end. The high degree of evolutionary conservation of homeotic gene organization and transcriptional expression pattern of these genes in flies and mammals argues strongly for a common scheme in anteroposterior axis formation.

How do *Hox* genes dictate pattern formation? It appears that there is a code of *Hox* gene expression that determines the type of vertebrae along the anterior–posterior axis. For example, in the mouse, the transition between cervical and thoracic vertebrae is between vertebrae 7 and 8, whereas in the chick, it is between vertebrae 13 and 14. In either case, *Hox-5* paralogues are seen in the last cervical vertebra, whereas *Hox-6* paralogues extend up to the first thoracic vertebra, their anterior boundary. Changes in the *Hox* code lead to shifting in the regional borders and axial identities, otherwise known as homeotic transformations. Therefore, *Hox* loss of function results in the affected body structures resembling more anterior ones, whereas gain-of-function mutant phenotypes due to ectopic expression of more posterior *Hox* genes cancel the function of more anterior ones and specify extra posterior structures. The persistent expression of *Hox* genes in discrete zones on the anteroposterior axis is required in order to remind cells of their position identity along the axis.

Hox proteins are all transcription factors that contain a 60 amino acid motif referred to as the homeodomain and exert their effect through the activation and repression of numerous target genes. In mammals, little is known about the upstream mechanisms that initiate *Hox* gene expression (Manzanares *et al.,* 1997; Marshall *et al.,* 1996). More is known about factors involved in the maintenance of *Hox* expression in both flies and mice (see Veraksa *et al.,* 2000 and references therein). Studies with the Trithorax and Polycomb protein groups indicate that the former function as transcriptional activators whereas the latter are transcriptional repressors of the *Hox* genes. In loss-of-function mutants for *Polycomb* genes *Bmi1* and *eed,* the domain of expression of the *Hox* gene is expanded, causing homeotic transformation and, conversely, loss of the *Trithorax* group gene *Mll* results in diminished levels of expression of the *Hox* gene with the phenotype resembling the mutants of the *Hox* gene themselves. Interestingly, axial–skeletal transformations and altered *Hox* expression patterns of *Bmi1*-deficient and *Mll*-deficient mice are normalized when both *Bmi1* and *Mll* are deleted, demonstrating their antagonistic role in determining segmental identity (Hanson *et al.,* 1999). In summary, repeated identical units formed by the action of segmentation genes become different due to *Hox* gene action.

Specifying the Dorsal–Ventral Axis

The newly formed somites are composed of a sphere of columnar epithelial cells and a central cavity, the somatocoel, containing mesenchymal cells. Early somites are characterized by the expression of the *Pax3* gene. Following somite formation, however, expression of the gene is downregulated in the ventral half of the somite epithelium and in

the somatocoel cells whereas as it persists in the dorsal half of the somite. The ventral medial cells of the somite subsequently undergo mitosis, lose their epithelial characteristics, and become mesenchymal cells again. This epitheliomesenchymal transition of the ventral part of the somite is preceded by the expression of *Pax1* in the somitic ventral wall and somatocoel cells as it signals the beginning of sclerotome formation. Mutations in *Pax1* affect sclerotome differentiation, as reported with different mutations in the *undulated* (*un*) locus (Balling *et al.,* 1988). Successful dorsoventral compartmentalization of somites ultimately leads to the development of the sclerotome ventrally and the dorsally located dermomyotome.

In the fourth week of human development, cells from the somites migrate to the most ventral region of the somite in an area surrounding the notochord forming the ventral sclerotome (Fig. 2B). These mesenchymal cells differentiate to prechondrocytes and ultimately form the template of vertebral bodies and ribs. The initiation of sclerotome formation is under control of the notochord. Sonic hedgehog (Shh), a secreted signaling molecule known to play a role in the patterning of the central nervous system and the limb in vertebrates, is expressed in the notochord at that time and has been implicated as the key inductive signal in patterning of the ventral neural tube and initiation of sclerotome formation (Fan and Tessier-Lavigne, 1994; Johnson *et al.,* 1994). Mutations in the gene encoding human SHH are associated with holoprosencephaly 3, an autosomal-dominant disorder characterized by single brain ventricle, cyclopia, ocular hypotelorism, proboscis, and midface hypoplasia (Roessler *et al.,* 1996). In humans, loss of one *SHH* allele is insufficient to cause ventralization defects of sclerotomes. In the mouse, loss of both *Shh* alleles leads to brain abnormalities and a skeletal phenotype typified by a complete absence of the vertebral column and posterior portion of the ribs (Chiang *et al.,* 1996). Formation of the sclerotome, however, does take place, although the sclerotomes are smaller and *Pax1* expression is decreased markedly, suggesting that Shh does not initiate but rather maintains the sclerome program. McMahon and associates (1998) have reported that *Noggin,* which encodes a bone morphogenetic protein (BMP) antagonist expressed in the node, notochord, and dorsal somite, is required for normal Shh-dependent ventral cell fate. In *Noggin*-null mice, somite differentiation is deficient in both muscle and sclerotomal precursors and *Pax1* expression is delayed, whereas the addition of Noggin is sufficient to induce *Pax1*. These findings suggest that different pathways mediate induction and that *Noggin* and *Shh* induce *Pax1* synergistically. Inhibition of BMP signaling by axially secreted Noggin, therefore, is an important requirement for normal induction of the sclerotome.

In contrast to the sclerotome, dorsal signals promote the development of the dermomyotome. These are members of the Wnt family of proteins emanating from the dorsal neural tube and the surface ectoderm necessary for the induction of myogenic precursor cells in the dermomyotome (Wagner *et al.,* 2000). Ectopic *Wnt* expression (*Wnt1, 3a-,* and *4*) is able to override the influence of ventralizing signals arising from the notochord and floor plate. This shift of the border between the two compartments is identified by an increase in the domain of *Pax3* expression and a complete loss of *Pax1* expression in somites close to the ectopic *Wnt* signal. Therefore, Wnts disturb the normal balance of signaling molecules within the somite, resulting in an enhanced recruitment of somitic cells into the myogenic lineage. In contrast, Shh reduces *Wnt* activity in the somitic mesoderm, at least in part, by upregulating *Secreted frizzled-related protein 2 (Sfrp2),* which encodes a potential *Wnt* antagonist (Lee *et al.,* 2000).

In summary, dorsoventral polarity of the somitic mesoderm is established by competitive signals originating from adjacent tissues. Studies suggest that the dorsoventral patterning of somites involves the coordinate action of multiple dorsalizing and ventralizing signals. The ventrally located notochord provides the ventralizing signals to specify the sclerotome, whereas the dorsally located surface ectoderm and dorsal neural tube provide the dorsalizing signals to specify the dermomyotome.

Sclerotome Differentiation

Pax1-expressing cells that arise from the ventromedial end of the sclerotome invade and colonize the perinotochordal space. These cells, expressing additional sclerotome markers such as *twist* and *scleraxis,* proliferate under the influence of *Shh* signaling from the notochord and form the perinotochordal tube from which vertebral bodies and intervertebral discs will develop. Segmentation begins by the condensation of sclerotome cells that represent the intervertebral discs, thereby defining the boundaries of the future vertebral bodies. Notochordal cells die if surrounded by sclerotome cells that form a vertebral body, whereas those that become part of the intervertebral disc form the nucleus pulposus. The ribs, pedicle, and lamina of the neural arch arise from *Pax1*-expressing cells in the lateral sclerotome.

Not all of the sclerotome cells are under the influence of Shh and Noggin emanating from the notochord and consequently express *Pax1*. Cells located in the ventrolateral and dorsomedial angles of the sclerome escape the ventralizing signals. While other sclerotomal cells migrate ventrally to surround the notochord where they form the vertebral body, these cells move dorsomedially to form the dorsal mesenchyme, which is the precursor of the dorsal part of the neural arch and the spinous process. These sclerotome cells express homeobox genes (*Msx1* and *Msx2*) as they are subjected to a different microenvironment, specifically to signals arising from the roof plate of the neural tube and surface ectoderm (Monsoro-Burq *et al.,* 1994). BMP4 is expressed transiently in these structures and likely exerts a positive effect on the induction of dorsalizing gene expression in sclerotome cells (Monsoro-Burq *et al.,* 1996).

The Cranial Vault and Upper Facial Skeleton

In contrast to the obvious segmentation of the axial skeleton, craniofacial development is a poorly understood process. The craniofacial skeleton forms primarily from neural crest cells that migrate from hindbrain rhombomeres into the branchial arches. Neural crest cells are multipotential stem cells that contribute extensively to vertebrate development and give rise to various cell and tissue types, including mammalian craniofacial development. Migrating from the rhombomeric neuroectoderm to the pharyngeal arches, these cephalic neural crest cells proliferate as the ectomesenchyme within the arches, form mesenchymal condensations, and differentiate into cartilage and bone of endochondral and membranous skull, respectively. Little is known about the molecular basis underlying their migration, but it appears that interactions with tissues encountered during migration strongly influence this segmental migratory pattern. Neural crest cells possess integrin receptors that are essential for interacting with extracellular matrix molecules in their surroundings. The aberrant migration of cephalic neural crest cells leads to craniofacial defects, as demonstrated in platelet-derived growth factor-α receptor (Soriano, 1997)-and Shh-deficient mice embryos (Ahlgren and Bronner-Fraser, 1999). Homozygotes die during embryonic development and exhibit incomplete cephalic development. Increased apoptosis is observed on pathways followed by migrating neural crest cells, indicating that these signaling molecules affect their survival.

Interactions between neural crest-derived ectomesenchymal cells and surrounding cells are critical as defects in this process can also lead to craniofacial malformation. The development of the facial primordia is in part mediated by transcription factors that are programmed by an intricate array of intercellular signaling between ectomysenchymal neural crest-derived cells and epithelial and mesodermal cell populations within the arches (Francis-West *et al.,* 1998). *Hox* gene products, including Hoxa1, Hoxa2, and Hoxa3, play a role in the development of craniofacial structures derived from the second and third branchial arches, but they are not involved in the patterning of first arch derivatives. Other homeodomain proteins are expressed in cranial neural crest cells that migrate into the first branchial arch, including *goosecoid* (*Gsc*), *MHox*, and members of the *Dlx* and *Msx* families. A pivotal role in this process has been ascribed to components of the endothelin pathway. The G-protein-coupled endothelin-A receptor (ET_A) is expressed in the ectomesenchyme, whereas the cognate ligand for ET_A, endothelin-1 (ET-1), is expressed in the arch epithelium and the paraxial mesoderm-derived arch core. Absence of either ET-1 (Kurihara *et al.,* 1994) or ET_A (Clouthier *et al.,* 1998) results in numerous craniofacial defects. While neural crest cell migration in the head of ET_A-null embryos appears normal, the expression of transcription factors (*Gsc*, *Dlx-2*, *Dlx-3*, *dHAND*, *eHAND*, and *Barx1*) important in the differentiation of cephalic crest cells in the arches during epithelial–mesenchymal interactions is either absent or reduced significantly in the ectomesenchymal cells (Clouthier *et al.,* 2000). Because *Dlx-1, Hoxa-2,* and *MHox* are normally expressed in these mutants, it would argue that additional pathways work in conjunction with the ET_A pathway in patterning the facial primordia from buds of undifferentiated mesenchyme into the intricate series of bones and cartilage structures that, together with muscle and other tissues, form the adult face.

Limb Initiation and Development

Overview of Limb Development

Not all of the mesoderm is organized into somites. Adjacent to the somitic mesoderm is the intermediate mesodermal region, which gives rise to the kidney, and genital ducts and further laterally on either side is the lateral plate mesoderm. In the second month of human development, the proliferation of mesenchymal cells from the lateral plate mesoderm gives rise to the formation of limb buds (Fig. 4A, see also color plate). *Hox* genes expressed within the lateral plate mesoderm specify the positions at which forelimbs and hindlimbs will be developing (for review, see Ruvinsky and Gibson-Brown, 2000). T-box genes, which encode a family of transcription factors that share a conserved domain with the classical mouse *Brachyury (T)* gene, function as activators or repressors of transcription of downstream target genes involved in the regulation of vertebrate limb development. Specifically, transcripts of two of these genes, *Tbx5* and *Tbx4*, are activated as a result of a "read out" of the *Hox* code for pectoral and pelvic appendages, respectively. This positional information then leads to limb development within the perspective fields.

The vertebrate limb is an extremely complex organ in that its patterning takes place in three distinct axes (for review, see Schwabe *et al.,* 1998): (1) the proximal–distal axis (the line connecting the shoulder and the finger tip), which is defined by the apical ectodermal ridge (AER), a single layer of epidermal cells that caps the limb bud and promotes the proliferation of mesenchymal cells underneath. As the limb elongates, mesenchymal cells condense to form the cartilage anlagen of the limb bones. (2) The posterior–anterior axis (as in the line between the little finger and the thumb), which is specified by the zone of polarizing activity (ZPA), a block of mesodermal tissue near the posterior junction of the limb bud and the body wall. (3) The dorsal–ventral axis (as in the line between the upper and lower surfaces of the hand), which is defined by the dorsal epithelium.

THE PROXIMAL–DISTAL AXIS

A variety of growth factors, patterning morphogens, transcription factors, and adhesion molecules, participate in a highly orchestrated system that dictates the blueprint of the developing mammalian limb. The first step, initiation of the site where the presumptive limb will develop, is critically

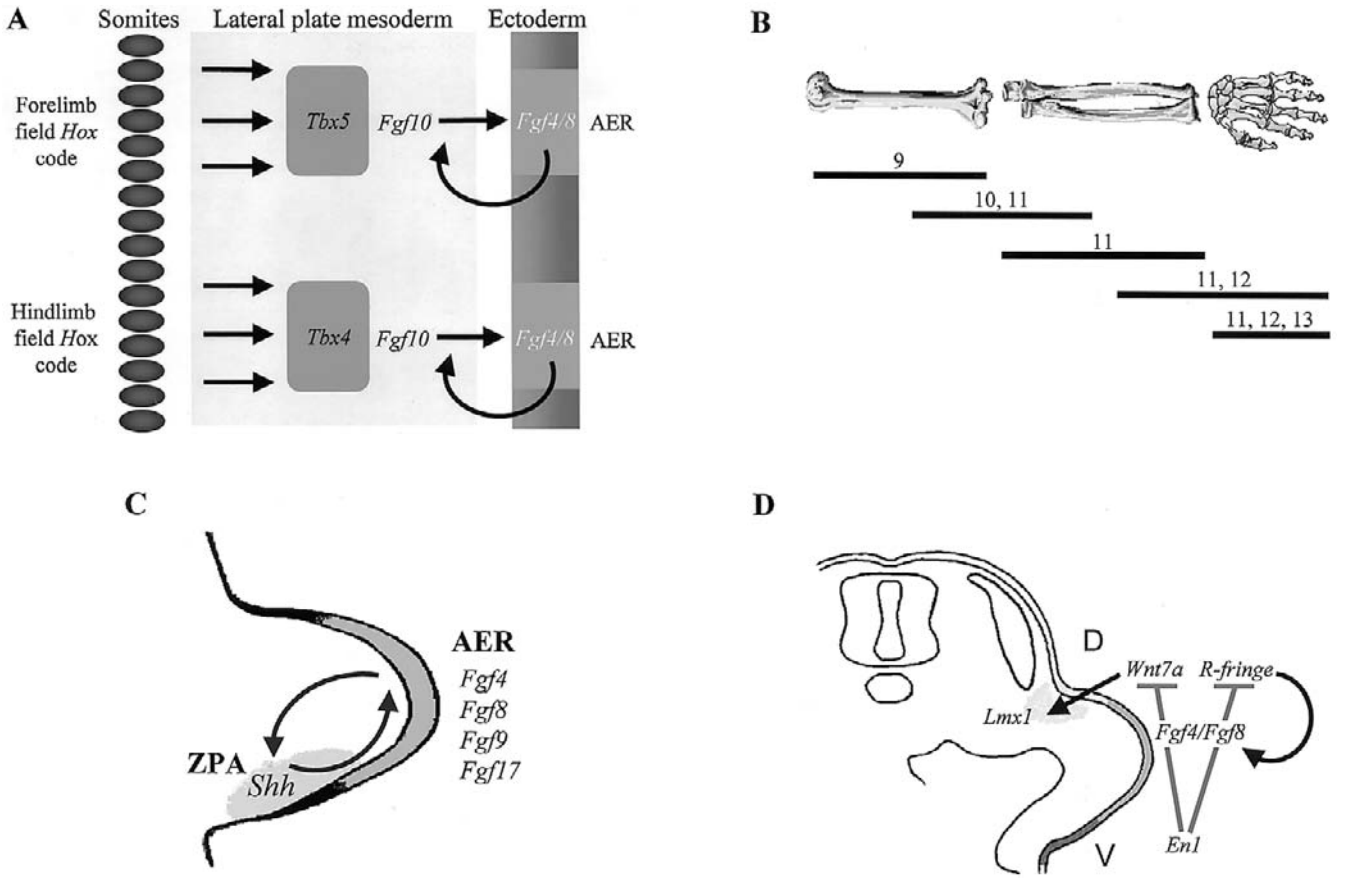

Figure 4 Molecular regulation of limb patterning. (A) Schematic model for specification of limb position. *Hox* genes expressed in the lateral plate mesoderm define the positions where limbs will develop. *Tbx4* and *Tbx5* expression activates the perspective fields and sets up the *Fgf10–Fgf4/8* positive feedback loop implicated in induction of the AER in the overlying ectoderm and initiation of limb bud outgrowth. Adapted and modified from Ruvinsky and Gibson-Brown (2000). (See also color plate.) (B) *HoxA* and *HoxD* genes involved in limb specification. Groups 9 and 10 paralogous genes organize the proximal part of the limb, groups 10, 11, and 12 genes the distal part of the limb, and groups 11, 12, and mostly 13 genes pattern the digits. Adapted and modified form Zakany and Duboule (1999). (C) Specification of the anterior–posterior axis. *Shh* expressed in the ZPA (purple) and *Fgfs* in AER (orange) participate in a positive feedback loop to provide the polarizing signal for anterior–posterior patterning of the limb. (See also color plate.) (D) Specification of the dorsal–ventral axis. *Wnt7a* and *Lmx1* expression correlates with dorsal fate, whereas *En1* expression dictates ventral fate by repressing *Wnt7a* and *R-fhg,* a secreted molecule that directs the formation of the AER (orange) in the boundary between cells that express it in the dorsal ectoderm (yellow) and cells that do not express it in the ventral ectoderm (blue). D, dorsal, V, ventral. Adapted and modified from Niswander (1997). (See also color plate.)

dependent on fibroblast growth factor (FGF) signaling mediated by high-affinity FGF receptors (FGFRs). Expressed in the lateral plate mesoderm, *Fgf10* binds and activates the IIIb splice form of the FGF receptor 2 (FGFR2) in the AER in the overlying ectoderm. This signaling is absolutely crucial for limb bud initiation, as evidenced by the complete absence of limb development in mice homozygous for a null *Fgf10* (Min *et al.,* 1998; Sekine *et al.,* 1999) or *Fgfr2* (Xu *et al.,* 1998) allele. In turn, *Fgf4* and *Fgf8* expressed in the AER act on the underlying mesoderm to maintain *Fgf10* expression, thereby promoting elongation of the limb. As the limb grows, cells directly underneath the AER, in a region termed the progress zone (PZ), maintain their characteristics of undifferentiated mesenchyme while they continue to proliferate. In contrast, the more proximal mesenchymal cells begin to condense and differentiate into the cartilage anlage of the limb. In this scheme, the *Hox* gene expression pattern activates downstream target genes according to the position along the axis. These key signaling pathways control various aspects of limb development, including establishment of the early limb field, determination of limb identity, elongation of the limb bud, specification of digit pattern, and sculpting of the digits. Accumulating evidence indicates that *Hoxa* and *Hoxd* genes are involved in limb specification (for review, see Zakany and Duboule, 1999). In contrast, *Hoxb* and *Hoxc* genes do not participate in limb patterning. Targeted mutations for each gene and compound mutants produced in mice have indicated that genes belonging to groups 9 and 10 determine the length of the upper arm, groups 10, 11, and 12 pattern the lower arm; and groups 11, 12, and mostly 13 organize the digits (Fig. 4B).

THE ANTERIOR–POSTERIOR AXIS

Specification of the anterior–posterior axis is under the control of a small block of mesodermal tissue near the posterior junction of the developing limb bud and the body

wall, referred to as the ZPA. It is now established that *Shh* expressed in the ZPA is the major molecular determinant in the anterior–posterior patterning of the limb (Riddle *et al.,* 1993). The unequivocal requirement for Shh signaling in limb development has been demonstrated by the *Shh* loss-of-function mutation, resulting in the complete absence of distal limb structures (Chiang *et al.,* 1996). The profound truncation of the limbs indicates the existence of a positive feedback loop between the ZPA and the AER. Thus, *Shh* expression in the polarizing region activates *Fgf4* in the AER. The presence of *Formin* (*Fmn*) and *Gremlin* (*Gre*) in the initial mesenchymal response to *Shh* is required to relay this signal to the AER (Zeller *et al.,* 1999; Zuniga *et al.,* 1999). In turn, *Fgf4* maintains *Shh* expression (Niswander *et al.,* 1994), thus providing a molecular mechanism for coordinating the activities of these two signaling centers. This SHH/FGF4 feedback loop model is supported by genetic evidence showing that *Fgf4* expression is not maintained in *Shh*-null mouse limbs. Contradicting this model is the observation that *Shh* expression is maintained and limb formation is normal when *Fgf4* is inactivated in mouse limbs (Moon *et al.,* 2000; Sun *et al.,* 2000). Moreover, expression patterns of *Shh, Bmp2, Fgf8,* and *Fgf10* are normal in the limb buds of the conditional mutants, suggesting that no individual Fgf expressed in the AER is solely necessary to maintain *Shh* expression. Instead, it is the combined activities of two or more AER-Fgfs (*Fgf4, Fgf8, Fgf9,* and *Fgf17*) that function in a positive feedback loop with *Shh* to control limb development (Fig. 4C, see also color plate). *Shh* also regulates BMP gene expression (*Bmp2, Bmp4,* and *Bmp7*) in a gradient through the limb mesoderm. These in turn act to induce *Hox* gene expression in the AER and PZ.

THE DORSAL–VENTRAL AXIS

Dorsoventral patterning is the least understood of the three axes of pattern formation in the limb (for review, see Niswander, 1997). Molecular studies indicate that the signaling molecule *Wnt7a,* a secreted molecule encoded by *Radical fringe* (*R-fng*), and the transcription factor *Engrailed-1* (*En1*) are intimately involved in this process (Fig. 4D, see also color plate). *Wnt7a* is expressed in the dorsal ectoderm and regulates the expression of a LIM homeodomain gene, *Lmx1,* in the dorsal mesenchyme, important for maintaining dorsal structure identity. *R-fng* expression is also localized in the dorsal ectoderm and dictates the location of AER as defined by the boundary between cells that do and cells that do not express *R-fng* (Laufer *et al.,* 1997). However, *En1* expression restricts *R-fng, Wnt7a,* and *Lmx1* to the dorsal ectoderm and mesenchyme and correlates with ventral fate.

The Skeletal Dysplasias

It is implicit from the foregoing discussion that mutations in the genes involved in limb patterning would tend to have profound effects on the final outcome of human limb design. For example, expansion of a polyalanine stretch in the amino-terminal end of the protein product of *HOXD13* is the cause of synpolydactyly, type II, an autosomal dominant disorder characterized by variable syndactyly and insertion of an extra digit between digits III and IV (Muragaki *et al.,* 1996). In homozygous individuals, homeotic transformation of metacarpal and metatarsal bones occurs so that they resemble carpal and tarsal anlages rather than long bones.

Mutations in *GLI3*, a transcription factor involved in the transduction of hedgehog signaling, have been described in four human autosomal dominant disorders: Greig cephalopolysyndactyly syndrome, characterized by a peculiar skull shape, frontal bossing, high forehead, and the presence of (poly)syndactyly (Vortkamp *et al.,* 1991); Pallister–Hall syndrome, a neonatally lethal disorder characterized by hypopituitarism, renal agenesis, cardiac defects, cleft palate, short nose, flat nasal bridge, and short limbs (Kang *et al.,* 1997); postaxial polydactyly type A, a trait typified by the presence of a rather well-formed extra digit, which articulates with the fifth or an extra metacarpal (Radhakrishna *et al.,* 1997); and preaxial polydactyly IV, distinguished by mild thumb duplication, syndactyly of fingers III and IV, first or second toe duplication, and syndactyly of all toes (Radhakrishna *et al.,* 1999).

Heterozygous mutations in the *LMX1B* (LIM homeobox transcription factor 1, β) gene have been described in patients with the nail-patella syndrome, an autosomal dominant disorder encompassing nail dysplasia, hypoplastic patella, decreased pronation and supination, iliac horns, and proteinuria (Dreyer *et al.,* 1998). Functional studies indicate that these mutations either disrupt sequence-specific DNA binding or result in the premature termination of translation. These are the first described mutations in a LIM-homeodomain protein that account for an inherited form of abnormal skeletal patterning.

Mesenchymal Condensation and Skeletal Patterning

Mesenchymal Condensation

The third phase in skeletogenesis, the appearance of mesenchymal condensations that arise as a consequence of epithelial–mesenchymal interactions, originates in areas where cartilage is to appear and where bone is to form by intramembranous ossification. These condensations define not only the position of the skeletal elements they represent, but also their basic shape. Therefore, if a condensation were in the wrong place or of the wrong shape and size, it would be expected to produce a skeletal element that is similarly misplaced or misshapen.

Condensations can be visualized easily *in vivo* as they express cell surface molecules that bind peanut agglutinin lectin (Stringa and Tuan, 1996). Their formation takes place when previously dispersed mesenchymal cells form aggregations and, once again, it is *Shh*, *Bmp* (*Bmp2-5, Bmp7*), *Fgf,* and *Hox* genes that determine the fundamental

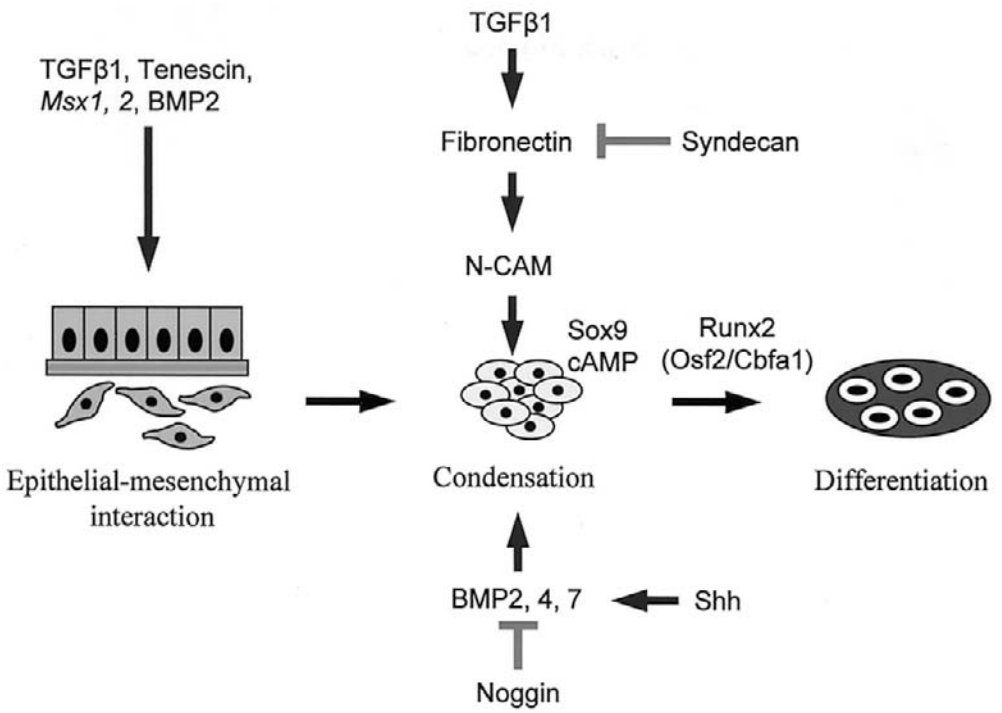

Figure 5 Regulation of mesenchymal condensation. Diagrammatic representation of the network of signaling factors involved in the formation of mesenchymal condensations and their subsequent transition to overt differentiation. Adapted and modified from Hall and Miyake (2000). (See also color plate.)

attributes, such as the timing, position, and shape that they will assume. Mesenchymal condensation can be envisioned as a multistep process involving initiation, setting of boundary, proliferation, adherence, growth, and, finally, differentiation (for review, see Hall and Miyake, 2000) (Fig. 5, see also color plate). Initiation arises as a result of epithelial–mesenchymal interaction upregulating the expression of a number of molecules associated with prechondrogenic and preosteogenic condensations, such as tenascin, fibronectin, N-CAM, and N-cadherin. Transforming growth factor-β (TGFβ) and other members of the TGFβ superfamily that regulate many aspects of growth and differentiation (reviewed in Moses and Serra, 1996) play a pivotal role in this process. This family of signaling molecules, which includes several TGFβ isoforms, the activin and inhibins, growth and differentiation factors (GDFs), and the BMPs, potentiate condensation by promoting the establishment of cell–cell and cell–extracellular matrix interactions (Chimal-Monroy and Diaz de Leon, 1999; Hall and Miyake, 1995). Cell surface adhesion and extracellular matrix proteins contribute to the formation of condensations as they participate in cell attachment, growth, differentiation, and survival. The integrin family of cell surface receptors serves to mediate cell–matrix interactions, thereby providing the link between extracellular matrix and intracellular signaling that can affect gene expression. Integrins that act as receptors for fibronectin ($\alpha5\beta1$), types II and VI collagen ($\alpha1\beta1$, $\alpha2\beta1$, $\alpha10\beta1$), laminin ($\alpha6\beta1$), and vitronectin and osteopontin ($\alpha5\beta3$) are expressed early in the condensation process (Loeser, 2000), although further work is required to precisely define the role of these molecules in the developmental program of the process.

Levels of intracellular cAMP increase during prechondrogenic condensation and, along with the concomitant cell–cell interactions, are thought to mediate the upregulation of chondrogenic genes. The transcription factor Sox9 [SRY (sex-determining region Y)-related HMG box gene 9] is a potent inducer of genes required for cartilage formation, such as type II collagen (*Col2a1*) and aggrecan (*Agc*), and its phosphorylation by protein kinase A (PKA) increases its DNA-binding and transcriptional activity (Huang *et al.,* 2000). *Sox9* expression starts in mesenchymal chondroprogenitor cells and reaches a high level of expression in differentiated chondrocytes. Cells deficient in *Sox9* are excluded from all cartilage but are present as a juxtaposed mesenchyme that does not express the chondrocyte-specific markers (Bi *et al.,* 1999). This exclusion occurs at the condensing mesenchyme stage of chondrogenesis, suggesting that *Sox9* controls the expression of cell surface proteins needed for mesenchymal condensation, thereby identifying *Sox9* as the first transcription factor essential for chondrocyte differentiation and cartilage formation.

Cessation of condensation growth leads to differentiation characterized by the transient expression of the runt-related transcription factor 2, Runx2 (also known as Cbfa1

for core-binding factor, α subunit 1, or Osf2 for osteoblast-specific *cis*-acting element-2), in prechondrogenic as well as preosteogenic condensations. Once overt differentiation takes place, however, its expression is restricted solely to osteogenic cells and is downregulated in chondrogenic lineages (Ducy and Karsenty, 1998). Condensed mesenchymal cells that differentiate into chondroblasts begin to produce a matrix rich in type II collagen, the molecule that best defines the chondroblast/chondrocyte phenotype, and mucopolysaccharides. In contrast, osteogenenic cells produce most notably type I collagen in conjunction with a variety of noncollagenous, extracellular matrix proteins that are deposited along with an inorganic mineral phase. The mineral is in the form of hydroxyapatite, a crystalline lattice composed primarily of calcium and phosphate ions.

The Skeletal Dysplasias

A variety of human skeletal disorders arise as a consequence of gain-of-function and loss-of-function mutations in signaling pathways involved in mesenchymal condensation. *GDF5* (*growth differentiation factor 5*) belongs to the TGFβ superfamily and is expressed predominantly throughout mesenchymal condensations in the developing skeleton. Mutations in *GDF5* are the cause of acromesomelic chondrodysplasia, Hunter–Thompson type (Thomas *et al.,* 1996), an autosomal recessive disorder characterized by short forearms, hands and feet, and very short metacarpals, metatarsals, and phalanges. Mutations in *GDF5* have also been reported in patients with Grebe-type chondrodysplasia, an autosomal recessive disorder characterized by severe limb shortening and dysmorphogenesis with a proximal–distal gradient of severity (Thomas *et al.,* 1997). It is proposed that the mutant GDF5 protein is not secreted and is inactive *in vitro*. It produces a dominant-negative effect by preventing the secretion of other related BMPs, likely through the formation of heterodimers.

Patients with Albright's hereditary osteodystrophy (AHO) have characteristic physical stigmata and skeletal abnormalities consisting of short stature, ectopic calcification and ossification, and short feet and hands, particularly fourth metacarpals. This skeletal disorder has been associated with pseudohypoparathyroidism type Ia (PHP-Ia), which is characterized by parathyroid hormone (PTH)-resistant hypocalcemia and hyperphosphatemia, and other endocrine deficiencies, as well as pseudopseudohypoparathyroidism (pseudoPHP), which encompasses AHO but without the endocrine abnormalities. AHO in PHP-Ia and pseudoPHP arise from heterozygous inactivating mutations in the *GNAS1* gene encoding the α subunit of the stimulatory G protein ($G_s\alpha$) (*Levine et al.,* 1988). Therefore, decreased levels of cAMP arising from a mutated *GNAS1* allele may provide a mechanistic explanation for the impairment in skeletal development associated with this disorder. However, it remains unclear why different parts of the skeleton demonstrate strikingly different phenotypes when the mutant protein is expressed uniformly in all of them.

Defects in *SOX9* are the cause of campomelic dysplasia, a rare, dominantly inherited chondrodysplasia, characterized by craniofacial defects, bowing and angulation of long bones, hypoplastic scapulae, platyspondyly, kyphoscoliosis, 11 pairs of ribs, small thorax, and tracheobronchial hypoplasia (Foster *et al.,* 1994). It is often lethal, soon after birth, due to respiratory distress attributed to the hypoplasia of the tracheobrochial cartilage and restrictive thoracic cage.

Intramembranous Bone Formation

Overview

Intramembranous bone formation is achieved by the direct transformation of mesenchymal cells into osteoblasts, the skeletal cells involved in bone formation. It is the process responsible for the development of the flat bones of the cranial vault, including the cranial suture lines, some facial bones, and parts of the mandible and clavicle. Although the addition of bone within the periosteum on the outer surface of long bones is also described to arise from intramembranous bone formation, current studies suggest that in fact it may be developmentally distinct (see later). With respect to the molecular mechanisms leading to osteoblast differentiation, it can be said that they are rather sketchy. Like cartilage, bone cells are induced initially by specific epithelia (Hall and Miyake, 2000). Here, the cranial sutures will be discussed as intramembranous bone growth sites, which will be followed by a brief description of transcription factors, growth factors, and their receptors associated with normal and abnormal suture development. Intramembranous ossification in the periosteum will be described later on in conjunction with endochondral bone formation.

Cranial Sutures

Cranial vault sutures identify the fibrous tissues uniting bones of the skull and are the major site of bone growth, especially during the rapid growth of the neurocranium. Sutures need to maintain patency while allowing rapid bone formation at the edges of the bone fronts in order to accommodate the rapid, expansile growth of the neurocranium (for review, see Opperman, 2000). The closure of sutures is tightly regulated by growth factors and transcription factors (BMP4, BMP7, FGF9, TWIST, and MSX1 and MSX2) involved in epitheliomesenchymal signaling among the sutural mesenchyme, the underlying dura, and the approaching bone fronts. It is proposed that the approximating bone fronts set up gradients of growth factor signaling between them, which initiates suture formation. For example, a gradient of FGF ligand, from high levels in the differentiated region to low levels in the environment of the osteogenic stem cells, modulates the differential expression of *FGFR1* and *FGFR2*. Signaling through FGFR2 regulates stem cell

proliferation, whereas signaling through FGFR1 promotes osteogenic differentiation (Iseki *et al.,* 1999). As sutures fuse, factors involved in pattern formation (*SHH, MSX1*) are all downregulated, while at the same time *RUNX2* and type I collagen (*COL1A1*) expression is seen at the bone fronts. In the end, the completely fused suture is indistinguishable from bone.

Craniofacial Disorders

As can be inferred from this discussion, the composite structure of the mammalian skull requires precise pre- and postnatal growth regulation of individual calvarial elements. Disturbances of this process frequently cause severe clinical manifestations in humans. The homeobox genes *MSX1* and *MSX2* are of particular interest in that mutated forms are associated with human craniofacial disorders (for review, see Cohen, 2000). An autosomal-dominant form of hypodontia is caused by a mutation in *MSX1* (Vastardis *et al.,* 1996), whereas heterozygous mutations in *MSX2* cause parietal foramina (oval-shaped defects on either side of the sagittal suture arising from deficient ossification around the parietal notch, normally obliterated during the fifth fetal month) (Wilkie *et al.,* 2000). These mutations, which lead to decreased parietal ossification by haploinsufficiency, are in marked contrast to the reported gain-of-function mutation (Pro7His) in *MSX2* associated with premature osseous obliteration of the cranial sutures or craniosynostosis (Boston type) (Jabs *et al.,* 1993). It is likely that *MSX2* normally prevents differentiation and stimulates the proliferation of preosteoblasic cells at the extreme ends of the osteogenic fronts of the calvariae, facilitating expansion of the skull and closure of the suture. Its haploinsufficiency decreases proliferation and accelerates the differentiation of calvarial preosteoblast cells, resulting in delayed suture closure, while its "overexpression" results in enhanced proliferation, favoring suture closure (Dodig *et al.,* 1999).

Osteogenic cell differentiation is influenced by the transcription factor RUNX2. The function of RUNX2 during skeletal development has been elucidated by the generation of mice in which the *Runx2* locus was targeted (Otto *et al.,* 1997). A heterozygous loss of function leads to a phenotype very similar to human cleidocranial dysplasia, an autosomal-dominant inherited disorder characterized by hypoplasia of the clavicles and patent fontanelles that arises from mutations in *RUNX2* (Mundlos *et al.,* 1997). Loss of both alleles leads to a complete absence of bone due to a lack of osteoblast differentiation. *RUNX2,* therefore, controls the differentiation of precursor cells into osteoblasts and is essential for membranous as well as endochondral bone.

Fibroblast growth factor receptors are major players in cranial skeletogenesis, and activating mutations of the human *FGFR1, FGFR2,* and *FGFR3* genes cause craniosynostosis. A C-to-G transversion in exon 5 of *FGFR1*, resulting in a proline-to-arginine substitution (P252R) in the extracellular domain of the receptor, has been reported in affected members of five unrelated families with Pfeiffer syndrome, an autosomal dominant disorder, characterized by mild craniosynostosis, flat facies, shallow orbits, hypertelorism, acrocephaly, broad thumb, broad great toe, polysyndactyly, and interphalangeal ankylosis (Muenke *et al.,* 1994).

Mutations in *FGFR2* (C342Y, C342R, C342S, and a C342W) have been described in patients with Crouzon syndrome (Reardon *et al.,* 1994; Steinberger *et al.,* 1995). This disorder, encompassing craniosynostosis, hypertelorism, hypoplastic maxilla, and mandibular prognathism, is easily distinguishable from Pfeiffer syndrome by the absence of hand abnormalities. Interestingly, the C342Y mutation is also reported in patients with Pfeiffer syndrome and in individuals with Jackson–Weiss syndrome (Tartaglia *et al.,* 1997), an autosomal-dominant disorder characterized by midfacial hypoplasia, craniosynostosis, and cutaneous syndactyly, indicating that the same mutation can give rise to one of several phenotypes. Another conserved cysteine at position 278 is similarly predisposed to missense mutations leading to the same craniosynostotic conditions. However, mutations in S252 and P253 residues have been reported in most cases of Apert syndrome, a condition characterized by craniosynostosis and severe syndactyly (cutaneous and bony fusion of the digits). While the mechanism whereby the same mutation can give rise to distinct phenotypes remains to be clarified, sequence polymorphisms in other parts of the mutant gene may affect its phenotypic expression (Rutland *et al.,* 1995). Finally, mutations within *FGFR2* have also been reported in other rare craniosynostotic conditions (for review, see Passos-Bueno *et al.,* 1999).

In contrast to the propensity of mutations in FGFR1 and FGFR2 affecting craniofacial development, only rarely do mutations in FGFR3 cause craniosynostoses. For the most part, mutations in FGFR3 are associated with dwarfism, suggesting that the primary function of FGFR3 is in endochondral rather than intramembranous ossification. The great majority of FGFR mutations identified to date are inherited dominantly and result in increased signaling by the mutant receptor (Naski and Ornitz, 1999). Altered cellular proliferation and/or differentiation is believed to underlie their pathogenetic effects.

Endochondral Ossification

Overview

The axial and appendicular skeleton develops from cartilaginous blastema, the growth of which arises in a variety of ways (Johnson, 1986). Cartilage is unique among skeletal tissues in that it has the capacity to grow interstitially, i.e., by division of its chondrocytes. This property is what allows cartilage to grow very rapidly. Moreover, cartilage utilizes apposition of cells on its surface, matrix deposition, and enlargement of the cartilage cells as additional means of achieving maximal growth. Appositional growth is the principal function of the perichondrium, which envelops the epiphyses and the cartilaginous diaphysis, serving as

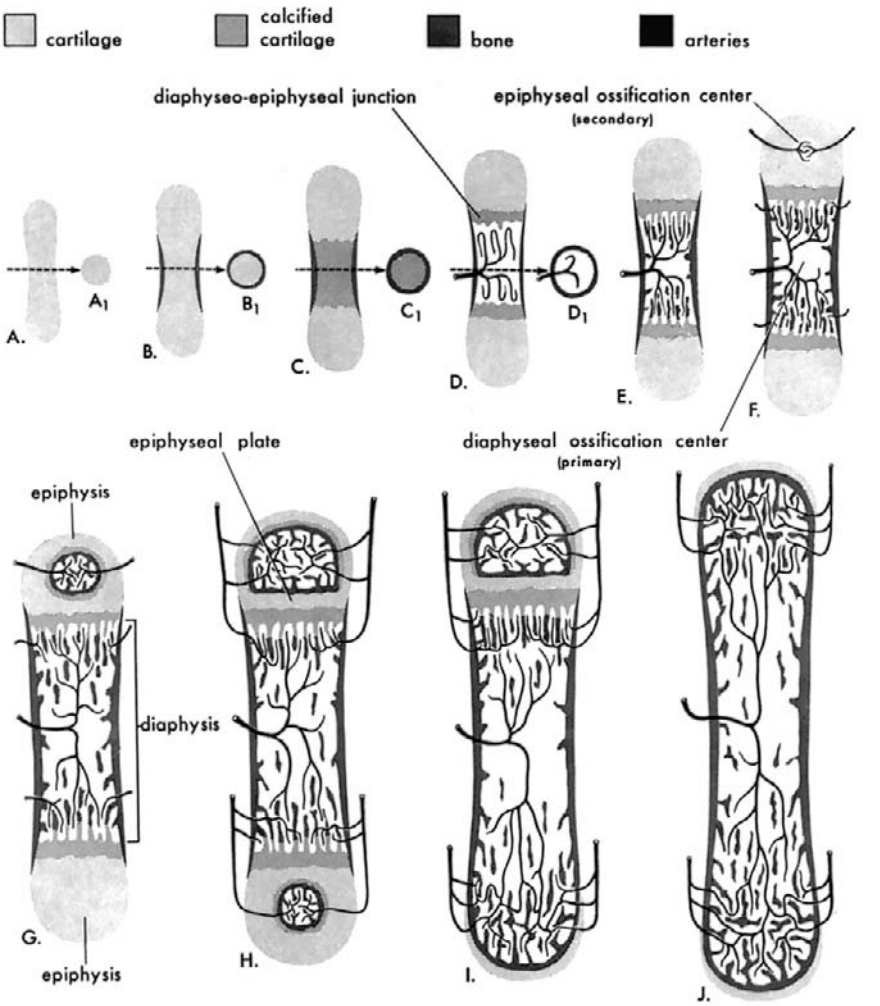

Figure 6 Formation and growth of long bones by endochondral ossification. (A) Mesenchymal condensation leads to the development of a cartilage model. (B) Capillaries invade the perichondrium surrounding the future diaphysis and transform it into the periosteum. (C) Chondrocyte differentiation ensues, just underneath the bone collar, leading to chondrocyte hypertrophy and apoptotic death associated with mineralization of the cartilage matrix. (D and E) Vascular invasion from vessels allows for the migration of osteoblast precursor cells that deposit bone on the degraded matrix scaffold. Chondrogenesis at the ends of the long bone establishes the formation of growth plates. (F) Secondary centers of ossification begin in late fetal life. (G and H) Growth plates serve as a continuous source of cartilage conversion to bone, thereby promoting linear growth. (I and J) Long bones cease growing at the end of puberty, when the growth plates are replaced by bone but articular cartilage persists. Adapted from Recker (1992).

the primary source of chondroblasts. With time, these cells differentiate to chondrocytes that secrete type II collagen, aggrecan, and a variety of other matrix molecules that constitute the extracellular matrix of the hyaline cartilage (Fig. 6). As development proceeds, capillaries invade the perichondrium surrounding the future diaphysis and transform it into the periosteum, while osteoblastic cells differentiate, mature, and secrete type I collagen and other bone-specific molecules, including alkaline phosphatase. This will ultimately mineralize by intramembranous ossification and give rise to the bony collar, the cortical bone.

A predetermined program of chondrocyte differentiation then ensues in the central diaphysis, just underneath the bone collar, leading to chondrocyte hypertrophy, synthesis of type X collagen, and calcification of the cartilage matrix, likely in response to signals emanating from periosteal osteoblasts (Komori *et al.,* 1997; Otto *et al.,* 1997). In turn, matrix mineralization is followed by vascular invasion from vessels originating in the periosteal collar that allows for the migration of osteoblast precursor cells into the cartilaginous blastema (primary ossification center). These cells transform into mature osteoblasts and initiate new bone formation on the degraded matrix scaffolding. The primary growth plates are then established and serve as a continual source of cartilage conversion to bone and linear growth of the long bone during development and postnatally. In late

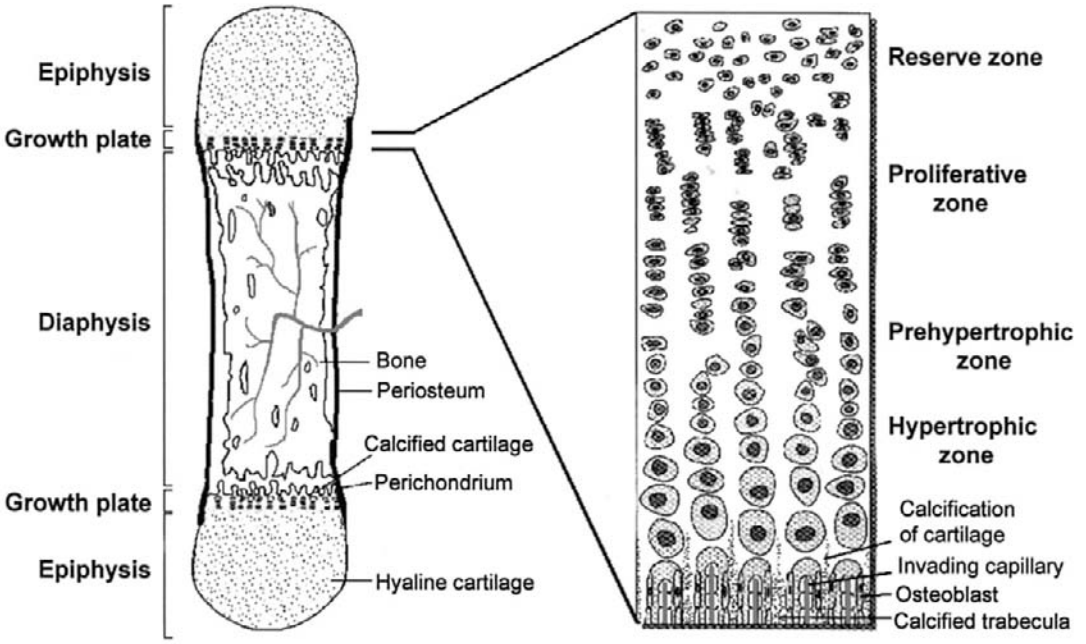

Figure 7 Schematic representation of the organization of the mammalian growth plate. Adapted from Wallis (1996). See text for details. (See also color plate.)

fetal life and early childhood, secondary centers of ossification appear within the cartilaginous epiphyses by a mechanism very similar to that used in the formation of the primary center. Cartilage is retained at the joint surface, giving rise to the articular cartilage, and at the growth plate, extending the full width of the bone and separating epiphysis from diaphysis. Cessation of growth occurs at the end of puberty, when growth plates are replaced by bone.

The Growth Plate

The organization of the mammalian epiphyseal growth plate is represented diagrammatically in Fig.7 (see also color plate). The growth plate conforms to a general basic plan that consists of four zones, which, although distinct, encompass a merging continuum (for reviews, see Johnson, 1986; Stevens and Williams, 1999). In the reserve zone, chondrocytes are nearly spherical in cross section and appear to be arranged randomly, separated by large amounts of matrix consisting largely of type II collagen and proteoglycans. Although parts of this zone are mitotically inert, others function as stem cell sources. Cells from this zone eventually become discoid and are arranged into rather regular columns forming the zone of proliferation. Column formation is in part due to the characteristic division of chondrocytes in that their mitotic axis is perpendicular to the long axis of the bone. Two daughter cells become flattened and are separated by a thin septum of cartilage matrix. Elongation of the blastema occurs mainly at its ends and arises primarily from the division of chondrocytes, as it is here that cell proliferation is maximal. Eventually, chondrocytes from this zone enlarge and lose their characteristic discoidal shape as they enter the zone of maturation (prehypertrophic chondrocytes). Growth here ceases to be due to cell division and continues by increases in the size of the cells. In the midsection, chondrocytes mature, enlarge in size (hypertrophy), and secrete a matrix rich in type X collagen. These cells continue to enlarge to the point that their vertical height has increased nearly five times. Once glycogen stores have been depleted, they undergo programmed cell death or apoptosis (Farnum and Wilsman, 1987), leaving behind longitudinal lacunae separated by septae of cartilaginous matrix that become selectively calcified as well as largely uncalcified transverse septae. In response to these changes, vascular invasion ensues as new blood vessels enter the lower hypertrophic zone from the primary spongiosum and penetrate the transverse septae while calcified cartilage is removed by chondroclasts that accompany this erosive angiogenic process. The remaining longitudinal septae, which now extend into the diaphysis, are used by osteoblasts derived from bone marrow stromal cells to settle on and lay down extracellular matrix (osteoid), which calcifies into woven bone. With time, osteoclasts resorb the woven bone and replace it with mature trabecular bone, thereby completing the process of endochondral ossification.

Mediators of Growth Plate Chondrocyte Proliferation and Differentiation

Proper skeletal formation, growth, and repair are critically dependent on the accurate orchestration of all the processes participating in the formation of endochondral bone at the growth plate. It is only recently, however, that

fundamental insight has emerged into the molecular pathways regulating these processes. This section discusses the major systemic and local influences on growth plate chondrocyte proliferation and differentiation and associated developmental abnormalities arising from their failure to function in the appropriate fashion. In specific situations, the distinction between systemic as opposed to local mediators may not be so apparent, which will be pointed out.

SYSTEMIC MEDIATORS

A variety of systemic hormones, such as the growth hormone (GH)–insulin-like growth factor-1 (IGF1) signaling system, thyroid hormone, estrogens, glucocorticoids, and vitamin D, partake in the regulation of linear growth pre- and postnatally. The importance of these hormones in linear skeletal growth has been highlighted by both genetic studies in animals and "experiments of nature" in humans.

Growth Hormone and Insulin-like Growth Factor 1 GH plays an important role in longitudinal bone growth because bone growth is impaired both in GH-deficient humans (Laron *et al.,* 1966; Rosenfeld *et al.,* 1994) and in the GH receptor-null mouse (Sjogren *et al.,* 2000; Zhou *et al.,* 1997). Homozygous-null mice display severe postnatal growth retardation, disproportionate dwarfism, and markedly decreased bone mineral content. Reduced bone length in GH receptor-negative mice is associated with premature growth plate contraction and reduced chondrocyte proliferation, which is not detectable until 3 weeks of age; before this, bone growth proceeds normally, indicating that GH is not required for normal murine prenatal development or early postnatal growth. While cortical and longitudinal bone growth and bone turnover are all reduced in GH receptor deficiency, many of these effects can be reversed by IGF1 treatment (Sims *et al.,* 2000), suggesting that the main defect relates to reduced IGF1 levels in the absence of GH receptor.

In the original "somatomedin hypothesis," it was proposed that the primary effect of GH was to stimulate IGF1 production by the liver, with circulating IGF1 then stimulating the longitudinal expansion of growth plates in an endocrine fashion. Because longitudinal bone growth is not affected in the liver-specific *Igf1*-knockout mouse (Yakar *et al.,* 1999), locally produced IGF1 and/or direct effects of GH may substitute for deficient systemic IGF1. More recent work suggests that GH acts directly at the growth plate to amplify the production of chondrocytes from germinal zone precursors and then to induce local IGF1 synthesis, proposed to stimulate the clonal expansion of chondrocyte columns in an autocrine/paracrine manner (Ohlsson *et al.,* 1998). Although the actions of GH on a range of cell types are mediated by Stat5 signaling, interestingly, the bone phenotypes in GH receptor- and *Stat5*-knockout animals (Teglund *et al.,* 1998) are different, suggesting that the effects of GH on bone, whether direct or through IGF1, are not mediated by Stat5 transcription factors but by other cytokine or signaling cascades.

IGF1 plays a pivotal role in longitudinal bone growth, as *Igf1* gene deletion results in dwarfism in mice (Liu *et al.,* 1993; Powell-Braxton *et al.,* 1993) and extreme short stature in humans (Woods *et al.,* 1996). In study of longitudinal bone growth in the *Igf1*-null mouse, growth plate chondrocyte proliferation and cell numbers are preserved, despite a 35% reduction in the rate of long bone growth (Wang *et al.,* 1999). The growth defect due to *Igf1* deletion has been traced to an attenuation of chondrocyte hypertrophy, which is associated with *Glut4* glucose transporter expression, glycogen synthesis (GSK3β serine phosphorylation), and ribosomal RNA levels being significantly diminished in *Igf1*-null hypertrophic chondrocytes, resulting in reduced glycogen in these cells. Glycogen stores are normally accumulated by proliferative and early hypertrophic chondrocytes and are depleted during maturation of the hypertrophic chondrocytes. Hypertrophic chondrocytes are highly active metabolically and are dependent on glycolysis to fuel their expansive biosynthetic activity. The decrease in ribosomal RNA in *Igf1*-null hypertrophic chondrocytes may reflect cellular "starvation" for fuel and building blocks for protein synthesis.

Thyroid Hormones Thyroid hormone deprivation has deleterious effects on bone growth. The observed delay in bone development is mediated by a direct effect of thyroid hormone on bone and an indirect effect of the hormone on GH release and IGF1 action (Weiss and Refetoff, 1996). Thyrotoxicosis, however, accelerates growth rate and advances bone age. In euthyroid human (Williams *et al.,* 1998) and rat cartilage (Stevens *et al.,* 2000), thyroid hormone receptor α1 (TRα1), TRα2, and TRβ1 proteins are localized to reserve zone progenitor cells and proliferating chondrocytes. When animals are rendered hypothyroid, growth plates become grossly disorganized and hypertrophic chondrocyte differentiation fails to progress (Fraichard *et al.,* 1997; Stevens *et al.,* 2000). In thyrotoxic growth plates, histology is essentially normal, but mRNA for parathyroid hormone-related protein (*Pthrp*) and its receptor are undetectable. PTHrP signaling exerts potent inhibitory effects on hypertrophic chondrocyte differentiation (see later), suggesting that the dysregulation of local mediators of endochondral ossification may be a key mechanism that underlies growth disorders in childhood thyroid disease. Although thyroid hormone may also act directly on osteoblasts (Abu *et al.,* 2000), these effects have received much less attention.

Estrogens The biosynthesis of estrogens from testosterone in the ovary, adipose tissue, skeletal muscle, skin, hair follicles, and bone is catalyzed by the enzyme aromatase, the product of the *CYP19* gene. In recent years, a number of patients, two men and five women, have been described suffering from aromatase deficiency due to mutations in *CYP19,* resulting in the synthesis of a nonfunctional gene product and the failure to synthesize estrogens (reviewed in Faustini-Fustini *et al.,* 1999). Males with this

condition have sustained linear growth into adulthood as a consequence of failed epiphyseal closure. Reduced bone mineral density and bone age are also characteristic. The women show absence of a growth spurt and delayed bone age at puberty as well as unfused epiphyses later on, despite evidence of virilization.

The biological effects of estrogens are mediated by two estrogen receptors (ER), ERα and ERβ which regulate transcription through direct interaction with specific binding sites on DNA in promoter regions of target genes (for review, see Pettersson and Gustafsson, 2001). Smith and associates (1994) have described a man with a biallelic inactivating mutation of the ERα gene. This patient had normal genitalia but suffered from osteoporosis and was still growing at the age of 28 because the epiphyseal plates were unfused.

These two "experiments of nature" (aromatase and ERα deficiency), supported by the recent identification of ERα and ERβ expression in chondrocytes (Ushiyama *et al.,* 1999) and osteogenic cells of trabecular and cortical bone (Rickard *et al.,* 1999), have firmly established that estrogens exert direct effects on the growth plate and are crucial for peripubertal growth and epiphyseal growth plate fusion at the end of puberty in both women and men. Moreover, they have revealed a greater appreciation for the importance of estrogens in bone mass maintenance in both sexes.

Glucocorticoids Glucocorticoids have well-documented effects on the skeleton, as pharmocological doses cause stunted growth in children (Canalis, 1996). The skeletal actions of glucocorticoids are mediated via specific receptors, which are widely distributed at sites of endochondral bone formation. Studies now indicate that glucocorticoids are involved in chondrocyte proliferation, maturation, and differentiation earlier in life, whereas at puberty they are implicated primarily in chondrocyte differentiation and hypertrophy. Further investigation is required, however, to clarify the physiologic actions of glucocorticoids on cartilage.

Glucocorticoid receptors are also highly expressed in rodent and human osteoblastic cells both on the bone-forming surface and at modeling sites (Abu *et al.,* 2000). Pharmacologic doses of glucocorticoids in mice inhibit osteoblastogenesis and promote apoptosis in osteoblasts and osteocytes, thereby providing a mechanistic explanation for the profound osteoporotic changes arising from their chronic administration (Weinstein *et al.,* 1998).

Vitamin D 1,25$(OH)_2$-vitamin D_3 exerts its effects on growth plate chondrocytes through classical vitamin D (VDR) receptor-dependent mechanisms, promoting mineralization of the extracellular matrix (Boyan *et al.,* 1989). Vitamin D deficiency is the major cause of rickets in children and osteomalacia in adults. Inactivating mutations in the coding sequences of 25-hydroxyvitamin D_3 1α-hydroxylase (*CYP27B1*) (Fu *et al.,* 1997) and *VDR* (reviewed in Hughes *et al.,* 1991) genes are associated with rickets. In both conditions, there is expansion of the hypertrophic zone of the growth plate, coupled with impaired extracellular matrix calcification and angiogenesis. Also, a direct role of vitamin D on bone is suggested, as *VDR* is expressed in osteoblasts and osteoclast precursors (Johnson *et al.,* 1996; Mee *et al.,* 1996).

The 25-hydroxyvitamin D-24-hydroxylase enzyme (24-OHase; *CYP24*) is responsible for the catabolic breakdown of 1,25$(OH)_2$-vitamin D_3. The enzyme can also act on the 25(OH)-vitamin D_3 substrate to generate 24,25$(OH)_2$-vitamin D_3, a metabolite whose physiological importance remains unclear. Although earlier studies in *Cyp24*-knockout mice had suggested that the 24-hydroxylated metabolite of vitamin D, 24R,25$(OH)_2$-vitamin D_3, exerts distinct effects on intramembranous bone mineralization (St-Arnaud, 1999), more recent work has concluded that this metabolite is dispensable during bone development (St-Arnaud *et al.,* 2000).

LOCAL MEDIATORS

TGFβ *TGFβ1*, *2*, and *3* mRNAs are synthesized in the mouse perichondrium and periosteum from 13.5 days *postcoitus* until after birth (Millan *et al.,* 1991). As discussed previously, TGFβ promotes chondrogenesis in early undifferentiated mesenchyme (Leonard *et al.,* 1991), but in high-density chondrocyte pellet cultures or organ cultures it inhibits terminal chondrocyte differentiation (Ballock *et al.,* 1993). TGFβs signal through heteromeric type I and type II receptor serine/threonine kinases. To delineate the role of TGFβs in the development and maintenance of the skeleton *in vivo*, Serra *et al*. (1997) generated transgenic mice that express a cytoplasmically truncated, functionally inactive TGF−type II receptor under the control of a metallothionein-like promoter, which can compete with the endogenous receptors for complex formation, thereby acting as a dominant-negative mutant. Loss of responsiveness to TGFβ promoted chondrocyte hypertrophy, suggesting an *in vivo* role for TGFβ in limiting terminal differentiation. In mouse embryonic metatarsal bone rudiments grown in organ culture, TGFβ inhibited several stages of endochondral bone formation, including chondrocyte proliferation, hypertrophic differentiation, and matrix mineralization (Serra *et al.,* 1999).

Parathyroid Hormone-Related Protein (PTHrP) and Indian Hedgehog (Ihh) Parathyroid hormone-like hormone (PTHLH), or PTH-related protein (PTHrP), as more commonly recognized, is a major determinant of chondrocyte biology and endochondral bone formation. PTHrP was discovered as the mediator of hypercalcemia associated with malignancy but is now known to be expressed by a large number of normal fetal and adult tissues (Philbrick *et al.,* 1996; Wysolmerski and Stewart, 1998). The amino-terminal region of PTHrP reveals limited but significant homology with the parathyroid hormone (PTH), resulting in the interaction of the first 34 to 36 residues of either protein with a single seven transmembrane-spanning G-protein-linked receptor

termed the PTH/PTHrP receptor, or PTH receptor type 1 (PTHR1). Both PTH and PTHrP, through their interaction with this receptor, activate cAMP and calcium second messenger signaling pathways by stimulating adenylate cyclase and/or phospholipase C activity, respectively (Abou-Samra *et al.,* 1992; Juppner *et al.,* 1991). Targeted inactivation of *Pthrp* and *Pthr1* has established a fundamental role for this signaling pathway in chondrocyte proliferation, differentiation, and apoptotic death (Amizuka *et al.,* 1994, 1996; Karaplis *et al.,* 1994; Lanske *et al.,* 1996; Lee *et al.,* 1996). Mice homozygous for *Pthrp*- or *Pthr1*-null alleles display a chondrodysplastic phenotype characterized by reduced chondrocyte proliferation and premature and inappropriate hypertrophic differentiation, resulting in advanced endochondral ossification. Conversely, targeted expression of PTHrP (Weir *et al.,* 1996) or a constitutively active form of PTHR1 (Schipani *et al.,* 1997) to the growth plate leads to delayed mineralization, decelerated conversion of proliferative chondrocytes into hypertrophic cells, and prolonged presence of hypertrophic chondrocytes with delay of vascular invasion.

Correlation of these findings to human chondrodysplasias arose initially from studies in patients with Jansen-type metaphyseal dysplasia. This autosomal-dominant disorder is characterized by short stature, abnormal growth plate maturation, and laboratory findings indistinguishable from primary hyperparathyroidism, despite low normal or undetectable levels of PTH and PTHrP. Schipani and associates (1995, 1996, 1999) reported heterozygous missense mutations in *PTHR1* that promote ligand-independent cAMP accumulation, but with no detectable effect on basal inositol phosphate accumulation. These activating mutations have therefore provided an explanation for the observed biochemical abnormalities and the abnormal endochondral ossification characteristic of Jansen metaphyseal chondrodysplasia. In contrast to *PTHR1*-activating mutations in this disorder, Blomstrand chondrodysplasia arises from the absence of a functional PTHR1 protein (Jobert *et al.,* 1998; Karaplis *et al.,* 1998; Karperien *et al.,* 1999; Zhang *et al.,* 1998). This is a rare autosomal recessive chondrodysplasia characterized by skeletal abnormalities that bear a remarkable resemblance to the phenotypic alterations observed in *Pthr1* knockout mice.

The pivotal role of PTHrP signaling in the growth plate has served as the impetus for subsequent studies aiming to identify and characterize upstream and downstream molecular components regulating chondrocyte proliferation and differentiation. Indian hedgehog (Ihh) is a member of the vertebrate homologs of the *Drosophila* segment polarity gene, hedgehog (*hh*). Although only one *hh* gene has been identified in *Drosophila*, several *hh* genes are present in vertebrates. The mouse Hedgehog (Hh) gene family consists of *Sonic* (*Shh*), *Desert* (*Dhh*), and *Indian* (*Ihh*) *hedgehog*, all encoding secreted proteins implicated in cell–cell interactions. Signaling to target cells is mediated by a receptor that consists of two subunits; Patched (Ptc), a 12 transmembrane protein, which is the binding subunit (Marigo *et al.,* 1996; Stone *et al.,* 1996); and Smoothened (Smo), a 7 transmembrane protein, which is the signaling subunit. In the absence of Hh, Ptc associates with Smo and inhibits its activities. In contrast, binding of Hh to Ptc relieves the Ptc-dependent inhibition of Smo (Nusse, 1996). Signaling then ensues and includes downstream components such as the Gli family of transcriptional factors. The three cloned *Gli* genes (*Gli1, Gli2,* and *Gli3*) encode a family of DNA-binding zinc finger proteins with related target sequence specificities.

Ihh is expressed in prehypertrophic chondrocytes of the mouse embryo. Earlier studies using Ihh overexpression and misexpression in the developing cartilage demonstrated that Ihh delays the hypertrophic differentiation of growth plate chondrocytes (Vortkamp *et al.,* 1996). A number of *in vitro* as well as *in vivo* studies now indicate that the capacity of Ihh to slow chondrocyte differentiation is mediated by PTHrP. Ihh upregulates *Pthrp* expression in the growth plate. This expression, however, is abolished by the targeted disruption of *Ihh* and leads to premature chondrocyte differentiation (St-Jacques *et al.,* 1999), thereby implicating PTHrP as the mediator of Ihh actions on chondrocyte hypertrophy. These observations, among others, have led to the proposal that an Ihh/PTHrP feedback loop regulates the pace of chondrocyte differentiation in the growth plate (Fig. 8, see also color plate) (Chung and Kronenberg, 2000). As chondrocytes differentiate into the prehypertrophic state, they express Ihh, which stimulates the expression of PTHrP. In turn, PTHrP binds and activates PTHR1 in proliferating chondrocytes to delay their differentiation into prehypertrophic chondrocytes, which make Ihh. In so doing, this negative feedback loop serves to regulate the rate of chondrocyte differentiation.

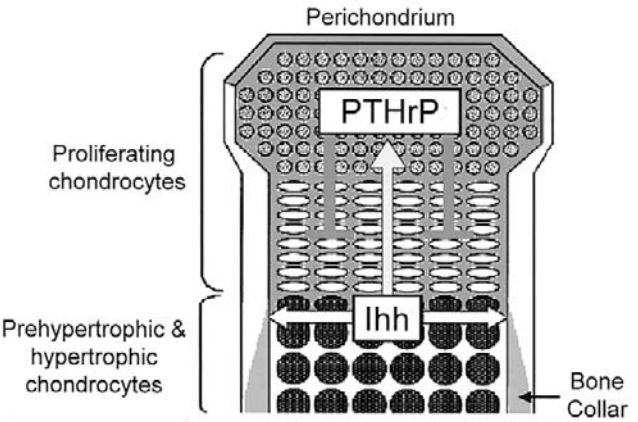

Figure 8 Ihh and PTHrP interaction in the growth plate. Ihh and PTHrP participate in a negative feedback loop to regulate the rate of chondrocyte differentiation. Ihh, expressed in chondrocytes in the prehypertrophic zone, stimulates indirectly (yellow arrow) the synthesis of PTHrP in the growth plate, which in turn acts on proliferating chondrocytes to delay their differentiation (red T bars). Ihh is also implicated in the induction of bone collar formation (white arrows). Adapted from Chung and Kronenberg (2000). (See also color plate.)

What is the mechanism by which Ihh stimulates *Pthrp* expression? Although it is possible that Ihh interacts directly with *Pthrp*-expressing cells in the growth plate, it is more likely, given the number of restrictions imposed on Ihh diffusion (Chuang and McMahon, 1999), that the action is indirect. BMPs have been proposed to serve as a secondary signal downstream of Ihh. For example, viral expression of a constitutively active form of the BMP receptor IA increased *Pthrp* mRNA expression in embryonic chicken limbs and blocked chondrocyte differentiation in a similar manner as misexpression of Ihh without inducing *Ihh* expression (Zou *et al.,* 1997). Further studies have indicated that BMP2 and BMP4 are the likely secondary signals, which act through the BMP receptor IA to mediate the induction of *Pthrp* expression (Pathi *et al.,* 1999). It is of interest to note that TGFβ also stimulates *Pthrp* expression in mouse embryonic metatarsal bone rudiments grown in organ culture (Serra *et al.,* 1999). Furthermore, terminal differentiation is not inhibited by TGFβ in metatarsal rudiments from *Pthrp*-null embryos, supporting the model that TGFβ acts upstream of PTHrP to regulate the rate of hypertrophic differentiation. Whether it is TGFβ or other members of the BMP family of proteins that serve as the intermediary relay that links the Ihh and PTHrP signaling pathways remains to be determined. Other studies, however, have failed to support a role for BMPs in this process (Haaijman *et al.,* 1999). For now, it would be prudent to conclude that the mechanism transmitting Ihh signaling to PTHrP-expressing chondrocytes remains, for the most part, uncertain.

What are the downstream molecular mechanisms that convey the inhibitory action of PTHrP on chondrocyte differentiation? Transgenic studies have attempted to address this question by assessing the significance of the cyclic AMP/PKA and phospholipase C/PKC signal transduction pathways on the cartilage differentiation program. In the first scenario, a PTH receptor with normal phospholipase C signaling, but deficient $G_s\alpha$ signaling was expressed in chimeric mice (Chung *et al*. 2000). Cells with deficient $G_s\alpha$ signaling underwent premature maturation in the growth plate, whereas wild-type cells had a normal rate of differentiation. In the second scenario, mice expressing a mutant PTHrP receptor with normal $G_s\alpha$ signaling, but deficient phospholipase C signaling were shown to be of normal size and did not have reduced rates of chondrocyte differentiation (Guo *et al.,* 2000). These genetic experiments, as well as more recent work using cultured chondrocytes (Ionescu *et al.,* 2001), support the contention that the cyclic AMP/PKA signal transduction pathway is involved intimately with chondrocyte differentiation, whereas PKC signaling appears less relevant for these events both *in vivo* and *in vitro*.

Given that PKA-phosphorylated SOX9 is present in the prehypertrophic zone of the growth plate, the same location where the gene for PTHR1 is expressed, then SOX9 is a likely target for PTHrP signaling (Fig. 9, see also color plate). What is the evidence to support this conclusion? SOX9 phosphorylated at serine 181 (S181), one of two consensus PKA phosphorylation sites, is detected almost

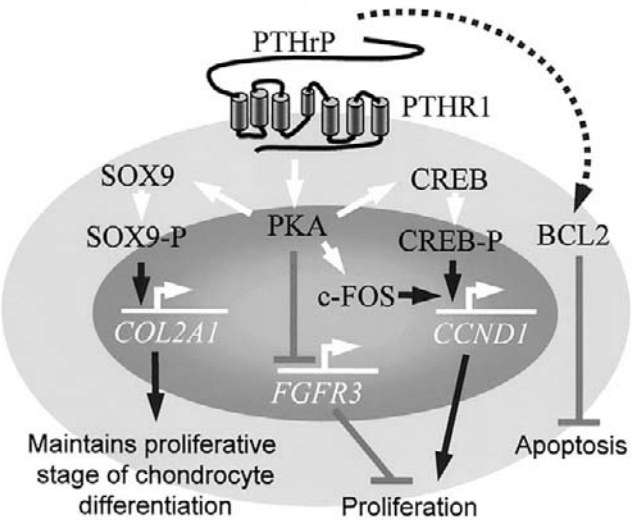

Figure 9 PTHrP and chondrocyte biology. Signaling pathways proposed to mediate the effects of PTHrP on differentiation, proliferation, and apoptotic death of chondrocytes. The dashed line depicts putative PTHrP actions that may not be mediated by PTHR1 (intracrine effects). (See also color plate.)

exclusively in chondrocytes of the prehypertrophic zone in wild-type mouse embryos (Huang *et al.,* 2000). Moreover, no phosphorylation of SOX9 is observed in prehypertrophic chondrocytes of the growth plate or any chondrocytes of *Pthr1*-null mutants. Phosphorylation of SOX9 by PKA enhances its transcriptional and DNA-binding activity (Huang *et al.,* 2000). PTHrP greatly potentiates the phosphorylation of SOX9 (S181) and increases the SOX9-dependent activity of chondrocyte-specific enhancers in *Col2a1,* the gene for type II collagen. These findings indicate that SOX9 is a target of PTHrP signaling in prehypertrophic chondrocytes in the growth plate and that the PTHrP-dependent increased transcriptional activity of SOX9 helps maintain the chondrocyte phenotype of cells in the prehypertrophic zone, thereby delaying their maturation to the hypertrophic state.

While the effects of PTHrP on chondrocyte differentiation are generally considered only in terms of its interaction with the cell surface receptor (PTHR1), studies *in vitro,* as well as *in vivo,* now indicate that the capacity of PTHrP to influence this process must also be assessed in relation to its intracrine actions at the level of the nucleus/nucleolus (Henderson *et al.,* 1995). Nucleolar localization of the protein has been associated with the inhibition of differentiation and delay in the apoptotic death of chondrocytes (Henderson *et al.,* 1996), likely by increasing *Bcl2* gene expression in these cells (Amling *et al.,* 1997). However, the events that determine the timing and degree of PTHrP nucleolar translocation or the role that it may serve in the *in vivo* biology of chondrocytes remain, for the most part, undefined.

Mechanisms underlying the molecular regulation of chondrocyte proliferation have been investigated, notably using transgenic mice that carry either gain- or loss-of-function mutations. From these studies, it has become

evident that one of the most potent inducers of chondrocyte proliferation is Ihh. In support of this contention is the observation that the most striking feature of the *Ihh*-null endochondral skeleton is a profound decrease in limb length arising as a consequence of severe reduction in growth plate chondrocyte proliferation (St-Jacques *et al.,* 1999). Interestingly, this effect, unlike that on differentiation, is for the most part independent of PTHrP (Karp *et al.,* 2000), although PTHrP likely exerts its own unique influence on this process (Amizuka *et al.,* 1994; Karp *et al.,* 2000). What factors, if any, are involved in mediating the proproliferative effect of Ihh, however, remain to be defined.

More is known about the signaling pathways that mediate the role of PTHrP on chondrocyte proliferation. Many of the transcriptional effects of cAMP are mediated by the cAMP response element (CRE)-binding protein CREB, which binds to the CRE element in the upstream region of a variety of genes. CREB is a member of the CREB/activating transcription factor (ATF) family of transcription factors and is phosphorylated by PKA following increases in intracellular cAMP levels. Phosphorylation permits its interaction with p300/CBP and other nuclear coactivators, leading to gene transcription (Montminy, 1997). A role for CREB in skeletal development was not suggested initially by the phenotype of the *Creb*-knockout mice perhaps due in part to the functional compensation by other CREB family members (Rudolph *et al.,* 1998). In keeping with this supposition is the observation that targeted overexpression of a potent dominant-negative inhibitor for all CREB family members to the murine growth plate causes a profound decrease in chondrocyte proliferation, resulting in short-limbed dwarfism and perinatal lethality due to respiratory compromise (Long *et al.,* 2001). Similarly, disruption of the gene encoding the transcription factor ATF2, another member of the CREB/ATF family, also inhibits the proliferation of chondrocytes (Reimold *et al.,* 1996).

Because the genes of the cell cycle machinery execute the intracellular control of proliferation, it is likely that these genes play a pivotal role during endochondral ossification. This view is supported by targeted disruption in mice of the CDK inhibitor p57Kip2 (Yan *et al.,* 1997) and the pRb-related p107 and p130 genes (Cobrinik *et al.,* 1996). In both cases, chondrocytes display delayed exit from the cell cycle and differentiation, leading to severe skeletal defects. A large body of experimental evidence now indicates that the major regulatory decisions controlling cell cycle progression, and hence proliferation, of mammalian cells take place during G_1 (reviewed in Sherr, 1993). Because cell cycle genes play an important role in proliferation, it is reasonable to speculate that they might be involved in the biological responses of chondrocytes to PTHrP. The cyclin D1 gene (*Ccnd1*) is a key regulator of progression through the G_1 phase of the cycle and has been identified as a target for the transcription factor ATF2 (Beier *et al.,* 1999). ATF2 is present in nuclear extracts from chondrogenic cell lines and binds, as a complex with a CRE-binding protein (CREB)/ CRE modulator protein, to the cAMP response element (CRE) in the cyclin D1 promoter. Moreover, site-directed mutagenesis of the cyclin D1 CRE causes a reduction in the activity of the promoter in chondrocytes, whereas overexpression of ATF2 in chondrocytes enhances activity of the cyclin D1 promoter. Inhibition of endogenous ATF2 or CREB by the expression of dominant-negative inhibitors of CREB and ATF2 significantly reduces the activity of the promoter in chondrocytes through the CRE. Finally, levels of cyclin D1 protein are reduced drastically in chondrocytes of ATF2-negative mice. These data identify the cyclin D1 gene as a direct target of ATF2 in chondrocytes and suggest that the reduced expression of cyclin D1 contributes to the defective cartilage development of these mice. Homozygous deletion of *Ccnd1* in mice results primarily in reduced postnatal growth (Sicinski *et al.,* 1995). It is likely that alterations in the proliferation of chondrocytes may have contributed to this phenotype. However, the skeletal defects of these mice are clearly less severe than those of ATF2-null mice, possibly because of the presence of intact cyclins D2 and D3. This advocates that additional target genes of ATF2 are involved in the reduction of chondrocyte proliferation in ATF2-deficient mice. In particular, it will be of interest to determine whether other D-type cyclin genes (cyclin D2 and D3) are regulated by ATF2 in chondrocytes. Finally, it remains to be seen whether PTHrP induces cyclin D1 expression through activation of CREB and how this impacts on chondrocyte proliferation. Alternatively, such a response may be mediated by the transcription factor AP-1, which is also central to the action of PTHrP in chondrocytes (Ionescu *et al.,* 2001). Signaling by PTHR1 activates AP-1, a complex formed through interactions between c-Fos and c-Jun family members, by inducing the expression of c-Fos in chondrocytes. The protein complex binds to the phorbol 12-myristate 13 acetate (PMA) response element (TRE), a specific *cis*-acting DNA consensus sequence in the promoter region of target genes, like cyclin D1.

Fibroblast Growth Factor Receptor 3 (FGFR3) Another major molecular player in growth plate chondrocyte biology is fibroblast growth factor receptor 3 (FGFR3). FGF1, FGF2, and FGF9 bind FGFR3 with relatively high affinity (Ornitz and Leder, 1992); however, the ligands of FGFR3 *in vivo* and their downstream effects in individual tissues have not been defined precisely. Gain-of-function mutations in *FGFR3* have been linked to several dominant skeletal dysplasias in humans, including achondroplasia (Bellus *et al.,* 1995; Rousseau *et al.,* 1994; Shiang *et al.,* 1994), thanatophoric dysplasia (TD) types I (Rousseau *et al.,* 1996; Tavormina *et al.,* 1995) and II (Tavormina *et al.,* 1995), and hypochondroplasia (Bellus *et al.,* 1995). This group of disorders is characterized by a continuum of severity, from hypochondroplasia exhibiting a lesser degree of phenotypic severity, to achondroplasia, and to TDs, two lethal neonatal forms of dwarfism distinguished by subtle

differences in skeletal radiographs. Achondroplasia is the most common genetic form of dwarfism in humans and results from a mutation in the transmembrane domain (G380R) of FGFR3, whereas thanatophoric dysplasia is the most common neonatal lethal skeletal dysplasia in humans and results from any of three independent point mutations in *FGFR3*. Nearly all reported missense mutations in families with TDI were found to cluster in two locations: codon 248 involving the substitution of an arginine for a cysteine residue (R248C) and the adjacent codon 249 causing a serine to a cysteine change (S249C). In all patients with TDII, a lysine to glutamic acid substitution at position 650 (K650E) was described in the tyrosine kinase domain of the FGFR3 receptor. Heterozygous *FGFR3* mutations have also been reported in patients with hypochondroplasia. In 8 out of 14 alleles examined, a single C-to-A transversion causing an asparagine-to-lysine substitution at position 540 (N540K) of the protein was demonstrated.

Clinically, all of these mutations result in a characteristic disruption of growth plate architecture and disproportionate shortening of the proximal limbs. The mechanism by which *FGFR3* mutations disrupt skeletal development has been investigated extensively. Outside of the developing central nervous system, the highest level of *FGFR3* mRNA is found in the cartilage rudiments of all bones, and during endochondral ossification, *FGFR3* is restricted to the resting and proliferating zones of cartilage in the growth plates (Peters *et al.,* 1993). Inactivation of FGFR3 signaling in mice leads to an increase in the size of the hypertrophic zone, as well as a coincident increase in bone length postnatally, suggesting that FGFR3 functions as a negative regulator of bone growth (Colvin *et al.,* 1996; Deng *et al.,* 1996). *In vitro* studies indicate that *FGFR3*-associated mutations confer gain-of-function properties to the receptor by rendering it constitutively active (Naski *et al.,* 1996). Ligand-independent receptor tyrosine phosphorylation then leads to inhibition of cell growth and differentiation in cartilaginous growth plates (Naski *et al.,* 1998; Segev *et al.,* 2000). While the molecular mechanisms that underlie these processes remain sketchy at present, expression of the master chondrogenic factor Sox9 was shown to be upregulated in chondrocytes following FGF treatment (Murakami *et al.,* 2000). FGF stimulation of Sox9 expression was mediated by the mitogen-activated protein kinase (MAPK) cascade, a signal transduction pathway activated by growth factors such as FGF. It would be anticipated, therefore, that in skeletal disorders caused by activating mutations in FGFR3, chondrocyte *SOX9* expression would be abnormally high (de Crombrugghe *et al.,* 2000), thereby helping to maintain the phenotype of cells in the prehypertrophic zone and delaying their maturation to the hypertrophic state.

Interplay of Local Mediators

During the process of proliferation and differentiation, chondrocytes integrate a complex array of signals from both local and systemic factors. Understanding the specific role of one signaling pathway requires an appreciation of how it integrates with other signals participating in bone development. What is known about the interplay among FGFR3, PTHrP, and Ihh signaling in the growth plate? The overlapping expression of FGFR3 and PTHR1 in the growth plate would suggest that these signaling pathways interact. Inactivation of either PTHrP or the PTHR1 in mice results in a marked decrease in the size of the proliferative zone, a phenotype resembling that seen with the constitutive activation of FGFR3 signaling. It is likely therefore that one pathway by which PTHrP can stimulate chondrocyte proliferation may involve downregulation of *Fgfr3* expression. In fact, work by McEwen *et al*. (1999) suggests a model whereby PKA signaling, by effectors such as the PTHR1, attenuates chondrocytic expression of *Fgfr3* and thus serves to regulate endochondral ossification (Fig. 9). Moreover, *in vivo* studies indicate that FGFR3 signaling can repress *Ihh* and *Pthr1* expression in the growth plate (Chen *et al.,* 2001; Naski *et al.,* 1998). This would link Ihh/PTHrP signaling to the FGFR3 pathway in the epiphyseal growth plate and hence complete a potential feedback loop that orchestrates endochondral bone growth.

Articular Cartilage

Little is known about the factors that control the differentiation of chondrocytes located at the epiphyseal tip of long bones to articular cartilage. In contrast to chondrocytes in the shaft, which tend to undergo maturation, hypertrophy, mineralization, and subsequent replacement by bone, these cells resist differentiation and produce abundant extracellular matrix in order to maintain normal joint function throughout life. The mechanisms that drive chondrocytes to this alternative fate are only now beginning to be unveiled. Endogenous TGFβs likely maintain cartilage homeostasis by preventing inappropriate chondrocyte differentiation, as expression of a dominant-negative form of the transforming growth factor type II receptor in skeletal tissue results in increased hypertrophic differentiation in the growth plate as well as articular chondrocytes (Serra *et al.,* 1997).

Studies by Iwamoto *et al.* (2000) have identified C-1–1, a novel variant of the ets transcription factor ch-ERG, which lacks a 27 amino acid segment upstream of the ets DNA-binding domain. C-1–1 expression has been localized in the developing articular chondrocytes, whereas ch-ERG is particularly prominent in prehypertrophic chondrocytes in the growth plate. Virally driven overexpression of C-1–1 in developing chick leg chondrocytes blocks their maturation into hypertrophic cells and prevents the replacement of cartilage by bone. It also induces the synthesis of tenascin-C, an extracellular matrix protein that is unique to developing articular chondrocytes. In contrast, the expression of ch-ERG stimulates chondrocyte maturation. This work identifies C-1–1 as a transcription factor instrumental in the genesis and maintenance of epiphyseal articular

chondrocytes and provides a first glimpse into the mechanisms that dictate alternative chondrocyte developmental pathways.

Coupling Chondrogenesis and Osteogenesis

Formation of Bone Collar

As illustrated in Fig. 6B, the bone collar that forms in the perichondrium is the precursor of the cortical region of long bones. Hypertrophic chondrocytes have been proposed to play a critical role in coordinating growth plate chondrogenesis and perichondrial osteogenesis, although the molecular parameters that regulate these processes remain for the most part undefined. In earlier work, it was noted that *Ihh*-null mice have no bone collar (St-Jacques *et al.,* 1999), whereas overexpression of Ihh induces bone collar formation (Vortkamp *et al.,* 1996). Follow-up observations made in growth plates from genetically altered mice have identified *Ihh* expression by prehypertrophic chondrocytes as the critical determinant in the site of bone collar formation and in the induction of mature osteoblasts in the adjacent perichondrium (Chung Ui *et al.,* 2001). The presence of mature osteoblasts in membranous bones of *Ihh* mutants suggests that the bone collar, which is often referred to as being similar to intramembranous ossification, is in fact developmentally distinct.

Vascular Invasion of the Growth Plate

Ossification begins by the invasion of calcified hypertrophic cartilage. If ossification is to occur successfully, vascular invasion of the growth plate must take place. This process presents a challenge to the system because cartilage, a tissue highly resistant to vascularization, is replaced by bone, one of the most vascular tissues in the body. As such, this process would require the coordination of expression of factors that promote neovascularization and/or removal of factors that inhibit it, along with the proteolysis of the cartilage extracellular matrix that allows for vascular invasion to take place. In support of this concept is the observation that avascular cartilage expresses potent angiogenic inhibitors such as chondromodulin I (Hiraki *et al.,* 1997), whereas a number of factors that promote neovascularization are being produced by hypertrophic chondrocytes.

Matrix metalloproteinases (MMPs), a family of extracellular matrix-degrading enzymes, have been implicated in this process (for review, see Vu and Werb, 2000). MMPs are produced as latent proenzymes and can be inhibited by specific tissue inhibitors of metalloproteinases (TIMPs). Gene-targeting studies have implicated two particular MMPs in bone development: MMP9/gelatinase B (MMP9) and MT1-MMP (MMP14). MMP9 is highly expressed in multinucleated osteoclasts localized along the mineralized longitudinal septae and chondroclasts at the nonmineralized transverse septae of the cartilage–bone junction that lead the vascular invasion front. Endothelial cells, however, which are also abundant at the invasion front of the growth plate, do not express MMP9. Targeted disruption of *Mmp9* in mice leads to the development of abnormal growth plates in the long bones characterized by a nearly doubling in the length of the hypertrophic zone at birth with no changes noted in the reserve or proliferating zones (Vu *et al.,* 1998). By 3 weeks of age, the zone has enlarged to six to eight times the normal length. Because these cells appear normal and the matrix calcifies normally, alterations in the hypertrophic zone are attributed to a delay in the apoptosis of hypertrophic chondrocytes coupled with an impediment in vascular invasion. Because *Mmp9*-null hypertrophic cartilage exhibits a net decrease in angiogenic activity, the model for MMP9 action at the growth plate is attributed to the release of angiogenic factors sequestered in the extracellular matrix.

A variety of angiogenic factors are expressed in the growth plate, including members of the FGF family, IGF1, EGF, PDGF-A, members of the TGF family, Cyr61, and transferrin. However, the importance of these factors in growth plate angiogenesis is still uncertain. Vascular endothelial growth factor (VEGF) is one angiogenic protein that is expressed in hypertrophic chondrocytes and binds to extracellular matrix. When made bioavailable, VEGF binds to its respective tyrosine kinase receptors, Flt-1 (VEGFR1) and Flk-1/KDR (VEGFR2), both of which are expressed on endothelial cells (Ferrara and Davis-Smyth, 1997). Strong experimental evidence now links receptor activation to VEGF-induced mitogenesis, angiogenesis, and endothelial cell survival (Fong *et al.,* 1995; Gerber *et al.,* 1998; Shalaby *et al.,* 1995). Blockade of VEGF action through the systemic administration of a soluble receptor chimeric protein (Flt-(1–3)-IgG) recapitulates the phenotype of the *Mmp9*-null bones by impairing invasion of the growth plate (Gerber *et al.,* 1999). It appears that MMP9 releases VEGF from the extracellular matrix (Bergers *et al.,* 2000), which in turn recruits endothelial cells and thus induces and maintains blood vessels. These blood vessels bring in not only nutrients but also chondroclasts, osteoclasts, and osteoblasts, as well as a proapoptotic signal(s) (Engsig *et al.,* 2000). VEGF-mediated blood vessel invasion is therefore essential for coupling resorption of cartilage with bone formation. In the absence of blood vessel invasion, hypertrophic chondrocytes fail to undergo cell death, resulting in thickening of the growth plate. Therefore, the vasculature conveys the essential signals required for correct growth plate morphogenesis.

Vascular Invasion of the Epiphysis

MT1-MMP (MMP14) is a membrane-bound matrix metalloproteinase capable of mediating the pericellular proteolysis of extracellar matrix components. Its role in skeletal development was also recognized following its targeted inactivation (Holmbeck *et al.,* 1999; Zhou *et al.,* 2000). In contrast to *Mmp9* mice, these animals display craniofacial

dysmorphism and dwarfism, the former arising likely from impaired intramembranous bone formation while the latter reflects defects in endochondral ossification of the epiphyseal (secondary) centers of ossification. In the epiphysis, hypertrophic cartilage is formed in the center, as chondrocyte maturation progresses inward. The formation of vascular canals involves the degradation of uncalcified cartilage to clear a path for invading vessels that bring in osteogenic precursor cells for the ensuing ossification process (Fig. 6F). In *Mmp14*-null mice, invasion of the uncalcified epiphyseal hyaline cartilage by vascular canals, which represents a critical early step in the development of the secondary centers of ossification, fails to occur, leading to a delay in ossification. For reasons that are not exactly clear, this delay has profound consequences on the growth of the epiphyseal plate, including thinning, disorganization, and lack of chondrocyte proliferation. It is speculated that the delay of epiphyseal vascularization results in a shortage of chondrocyte precursors and subsequent growth plate atrophy. In addition to skeletal deformities, these mice display severe osteopenia, arthritis, and generalized soft tissue abnormalities, all of which are speculated to arise from loss of its collagenolytic activity or conceivably from loss of its activity on growth factors that influence the biology of resident cells in these tissues.

Summary

In each phase of skeletal development, it is the appropriate interplay of a number of gene products that will determine the final phenotypic outcome. This chapter, reviewed the developmental biology of the skeleton, the complex array of signals that influence each developmental stage, and finally have touched upon a number of inherited disorders of the skeleton arising from mutant gene products that influence primarily, although not exclusively, one of these specific phases. Knowledge of how specific gene defects contribute to bone pathophysiology will offer insight into the molecular etiology of inherited and metabolic skeletal disorders and will guide further efforts in their treatment.

Introduction

Despite the known close physiological interactions of the two main cellular systems in bone, there are effectively separate and distinct origins of osteoclasts (hemopoietic cell origin) and stromal/osteoblast lineages from the developing fetus onward in mammalian development (Waller *et al.,* 1995). We have little detail of the early phenotypic stages of the osteogenic cells, the basic mechanisms governing the stem cell cycle, or the activation mechanisms relating to their physiological recruitment. We do know, however, that they are present at all bone surfaces. The old suggestion that osteoblast, and related, stem cells circulate systemically has been reincarnated recently with negligible evidence, however, for normal physiological relevance in bone anabolic processes.

There is still no general consensus of nomenclature for the stem cells that give rise to a number of tissues, including bone and cartilage. Such stem cells have been termed connective tissue stem cells, stromal stem cells, stromal fibroblastic stem cells, and mesenchymal stem cells. Current terminology of the stem cell giving rise to the osteoblast and related cell lineages (Fig. 1) appears to have favored the use of "mesenchymal stem cell" (MSC) introduced by Caplan (1991). Just as the term "stromal stem cell" coined earlier (Owen, 1985), MSC may be considered to be an ambiguous term and not a strictly correct usage. Generally, names for stem cells include the resultant end cells of the lineage they spawn (e.g., hemopoietic stem cells, HSCs) and not their embryonic tissue origin. Embryologically, components of the mesenchyme give rise not only to bone but also to the blood and other cells. Considering the functionally separate origins of the hemopoietic and stromal cell types in physiologically relevant systems, from an early distinct point in fetal development (Waller *et al.,* 1995), the term MSC conveys an inaccurate situation, particularly postnatally. Furthermore, cells termed MSC do not give rise to all components of the mesenchyme, as the name "mesenchymal stem cell" suggests, but they are derived developmentally from the mesenchyme. A more accurate definition for such cells would be mesenchyme-derived stem cells (MDSC), but it seems likely given its expanding usage that MSC, with its indication of cellular origins rather than developmental potential, will probably continue to be used extensively. Thus, we will use MSC in the context of MDSC, even though we believe that a more appropriate alternative name would be preferable. Within this system there may be a hierarchy of stem cells (Aubin, 1998), as there is in the hemopoietic system, of which the ones yielding bone and cartilage may be termed osteogenic cells. Their development into osteoblasts is through a sequence of cellular transitions, which have been described using morphological and molecular criteria (Aubin and Liu, 1996).

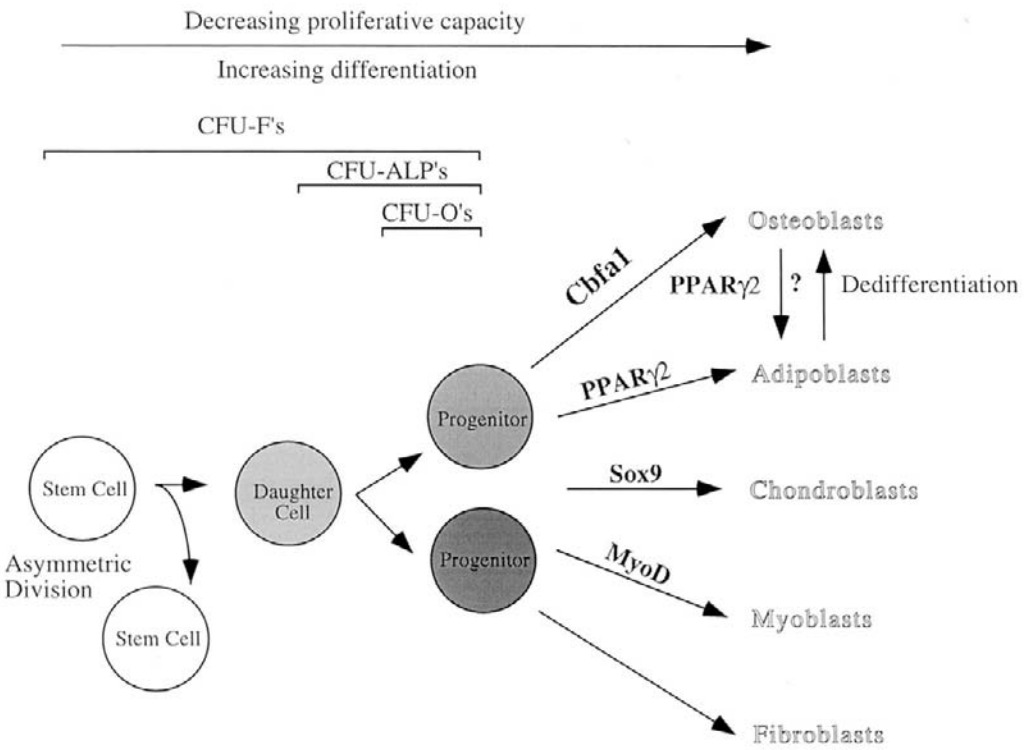

Figure 1 Schematic of stem cell commitment to various end-stage mesenchymal cell types, with known regulatory transcription factors indicated.

Ontogeny of Osteoblasts and Control of Osteoblast Development

CFU-F Assays and Osteogenic Cell Lineage Hierarchies

Friedenstein first showed that bone marrow stroma contains cells that have both significant proliferative capacity and the capacity to form bone when transplanted *in vivo* in diffusion chambers. Subsequently, he and others demonstrated that, in addition to bone, cartilage, marrow adipocytes, and fibrous tissue also formed *in vivo* and that all the tissues could arise from single colonies or CFU-F (Friedenstein, 1990; summarized in Bianco *et al.,* 1999; Owen, 1998; Prockop, 1997). *In vivo* analyses of stromal cells have been augmented by functional assays *in vitro* that show formation of a range of differentiated cell phenotypes and have led many to identify stromal populations as MSCs. However, the kinds of experiments needed to address whether marrow stroma contains a definitive stem cell—by the definition of self-renewal capacity and ability to repopulate all the appropriate differentiated lineages or even by less stringent definitions (Morrison *et al.,* 1997)—are only beginning to be done. For example, while expanded *populations* of human stromal cells are routinely now reported to express capacity to undergo differentiation along multiple mesenchymal lineages, a recent attempt to assess individual colonies showed that, among a small number (only six were reported) of individual colonies, only two appeared to express multilineage capacity and none were tested explicitly for self-renewal capacity (Pittenger *et al.,* 1999). This supports previous and more recent studies that clearly show that CFU-F are heterogeneous in size, morphology, and potential for differentiation (Friedenstein, 1990; Kuznetsov *et al.,* 1997b), consistent with the view that they belong to a lineage hierarchy in which only some of the cells are multipotential stem or primitive progenitors whereas others are more restricted (Aubin, 1998). This is also consistent with studies that show, by limiting dilution or by very low density plating, that only a proportion of CFU-F are CFU alkaline phosphatase (CFU-ALP) and further that only a proportion of these are CFU osteogenic (CFU-O, clonogenic bone colonies or bone nodules) with some variation reported between different species; CFU adipocytic (CFU-A) also comprise a subset of CFU-Fs (Aubin, 1999; Wu *et al.,* 2000) (see later) (Fig. 1). What would help advance the field are assays comparable to those achievable for hemopoietic stem cells, long-term culture-initiating cells (LTC-IC), and HSC/LTC-IC capable of long-term repopulating ability detected by their ability to serially repopulate lethally irradiated mice at limiting dilution (reviewed in Eaves *et al.,* 1999). While such assays may be difficult to achieve for MSCs, especially *in vivo*, clear quantitation of and understanding of the clonality of mesenchymal cell progeny, the ratios of stem to other more restricted progenitors in various stromal populations, the identifiable commitment and restriction points in the stromal cell hierarchy, the self-renewal capacity, and the repopulation capacity of individual precursor cells should be goals. Attempts to combine retrospective assays for specific prog-

enitor cell types with quantitative approaches *in vitro* and *in vivo* [e.g., gene marking, reviewed in Prockop (1997), limiting dilution (Aubin, 1999), and single cell-sorting experiments (Waller *et al.,* 1995)] are beginning to aid in the determination of the frequency and biological properties of various mesenchymal precursor cell populations and concepts where HSC and MSC biology may overlap and diverge. These issues may become increasingly important as work on stromal populations increases based on their proposed utility for tissue regeneration and as vehicles for gene therapy (see later).

Differentiation analyses of clonally derived immortalized (e.g., spontaneously or via large T antigen expression) cell lines derived from stroma, bone-derived cells, or other mesenchymal/mesodermal tissues, such as the mouse embryonic fibroblast line C3H10T1/2, the fetal rat calvaria-derived cell lines RCJ3.1 and ROB-C26, and the mesodermally derived C1 line, have also provided evidence for the existence of multipotential mesenchymal progenitor or stem cells capable of giving rise to multiple differentiated cell phenotypes, including osteoblasts, chondroblasts, myoblasts, and adipocytes (Aubin and Liu, 1996). Studies on these cell lines have led to suggestions of two different kinds of events underlying MSC commitment: a stochastic process with an expanding hierarchy of increasingly restricted progeny [e.g., RCJ3.1 (Aubin, 1998); see also that recent stromal cell clonal analysis (Pittenger *et al.,* 1999) would fit this model] and a nonrandom, single step process in which multipotential progenitors become exclusively restricted to a single lineage by particular culture conditions [an (environment of soluble inducers, substrate, and/or cell density) (e.g., C1 (Poliard *et al.,* 1995)] have been proposed to underlie mesenchymal stem cell restriction (see discussion in Aubin, 1998). These models may be different end points on a single continuum, as particular culture restraints or environmental or local conditions *in vivo* may shift the frequency or probability of what might otherwise be random or stochastic commitment/restriction events to favor particular outcomes.

Committed osteoprogenitors, i.e., progenitor cells restricted to osteoblast development and bone formation, at least under standard conditions, can also be identified by functional assays of their differentiation capacity *in vitro* or, as so-called earlier, the CFU-O assay in not only stromal cell populations but also populations derived from calvaria and other bones. However, under some conditions and from some tissues, mixed colony types can also be seen. A number of studies on human bone-derived cells, both populations derived from human trabecular bone and clonally derived lines of human bone marrow stromal cells, have supported the observations on rodent marrow stromal populations that a bipotential adipocyte–osteoblast precursor cell exists (reviewed in Aubin and Heersche, 1997; Nuttall and Gimble, 2000). It has also been suggested that the inverse relationship sometimes seen between expression of the osteoblast and adipocytic phenotypes in marrow stroma (e.g., in osteoporosis or in some culture manipulations) may reflect the ability of single or combinations of agents to alter the commitment or at least the differentiation pathway these bipotential cells will transit. In many cases, individual colonies are seen in which both osteoblast and adipocyte markers are present simultaneously. However, whether a clearly distinguishable bipotential adipo-osteoprogenitor can be identified or other developmental paradigms, such as transdifferentiation, underlie expression in these two lineages needs to be analyzed further. For example, dedifferentiation has been proposed to account for observations in some cultures of marrow stroma in which highly differentiated adipocytes are thought to revert to a less differentiated, more proliferative fibroblastic precursor phenotype and then to osteogenic phenotype (Park *et al.,* 1999). However, osteoblasts, differentiated to the point of already expressing osteocalcin (OCN), are able to undergo rapid differentiation events that lead to essentially 100% of the formerly osteoblastic cells expressing adipogenesis when they are transfected with the nuclear receptor family member peroxisome proliferator-activated receptor $\gamma 2$ or PPAR$\gamma 2$ (Nuttall *et al.,* 1998) (Fig. 1). Thus, although OCN is a very late marker of osteoblast maturation, data are consistent with osteoblastic cells being able to transdifferentiate into an adipogenic phenotype, an outcome of significant clinical interest in osteoporosis and the aging or immobilized skeleton (summarized in, Aubin and Heersche, 1997; Nuttall and Gimble, 2000).

A variety of observations have suggested that a bipotential osteochondroprogenitor may also exist. However, as raised earlier for adipocyte–osteoblast phenotypes, the ability to transdifferentiate or change expression profiles may also characterize osteoblast–chondroblast lineages (summarized in Aubin, 1998). Such observations and their cellular and molecular basis have led to considerable interest in the concept of "plasticity" of stromal and other cell types (Bianco and Cossu, 1999; Perry and Rudnick, 2000; Williams and Klinken, 1999). The possible presence of undifferentiated/uncommitted stem cells and multi- and bipotential progenitors in cultures that may also contain monopotential but plastic progenitors at higher frequencies often complicates the ability to unambiguously discriminate the nature of the cells being affected. Difficulties in establishing unambiguous evidence for multipotentiality, together with certain discrepancies between results in calvaria versus stromal and other populations, underscore the need for more markers and experiments to distinguish the molecular mechanisms underlying the ability of cells to express multipotentiality, the number and nature of commitment steps to a restricted phenotype(s), and both physiological and pathological mechanisms that may govern plasticity.

Control of Osteoblast Development

Significant strides have been made in identifying the regulatory mechanisms underlying lineage restriction, commitment, and/or differentiation within some of the mesenchymal lineages (Fig. 1). Master genes, exemplified by

the MyoD, myogenin, and Myf-5 helix-loop-helix transcription factors in muscle lineages, are one paradigm in which one transcription factor is induced and starts a cascade that leads to the sequential expression of other transcription factors and of phenotype-specific genes (Perry and Rudnick, 2000). A factor of a different transcription factor family, PPARγ2 mentioned earlier, together with other transcription factors, including the CCAAT/enhancer-binding (C/EBP) protein family, plays a key role in adipocyte differentiation (Rosen and Spiegelman, 2000). Sox9, a member of yet another transcription factor family, is essential for chondrocyte differentiation, expression of various chondrocyte genes, and cartilage formation (de Crombrugghe *et al.,* 2000).

With respect to osteoblasts, Cbfa1 (recently renamed Runx2), a member of the runt homology domain transcription factor family, plays a crucial role in osteoblast development. Cbfa1/Runx2 was identified in part based on its ability to regulate OCN (Banerjee *et al.,* 1997; Ducy *et al.,* 1997), the ectopic expression of Cbfa1 in nonosteoblastic cells leads to the expression of osteoblast-specific genes, including OCN, and, strikingly, deletion of Cbfa1 in mice leads to animals in which the skeleton comprises only chondrocytes and cartilage without any evidence of bone (Komori *et al.,* 1997) and in the amount of bone formed postnatally (Ducy *et al.,* 1999). Haploinsufficiency in mice (Komori *et al.,* 1997) and humans leads to the cleidocranial dysplasia phenotype (Mundlos *et al.,* 1997; Otto *et al.,* 1997; reviewed in Ducy, 2000). Cbfa1/Runx2 is the earliest of osteoblast differentiation markers currently known, its expression during development and after birth is high in osteoblasts, and it is upregulated in cultures treated with bone morphogenetic proteins (BMPs) and other factors that stimulate bone formation (reviewed in Yamaguchi *et al.,* 2000). However, in contrast to MyoD and PPARγ2, Cbfa1 is not a master gene; it is necessary but not sufficient to support differentiation to the mature osteoblast phenotype (Lee *et al.,* 1999; Wang *et al.,* 1999). Interestingly, studies have suggested that at least some hypertrophic chondrocytes express Cbfa1 and that the development/maturation of at least some chondrocytes is aberrant in Cbfa1-deficient mice, although the skeletal site-specific nature of the defects suggests that much more information is needed (reviewed in Ducy, 2000; Komori, 2000). With respect to the issue of plasticity, it is interesting that PPARγ2, which, as discussed earlier, is able to transdifferentiate osteoblastic cells to adipocytes, may do so via its ability to downregulate Cbfa1 (Lecka-Czernik *et al.,* 1999).

Ablation of Indian hedgehog (Ihh), a member of the Hedgehog family of secreted growth factors, leads to mice with a disorganized growth plate, as expected based on data that Ihh regulates chondrocyte differentiation. However, Ihh-null mice also have no osteoblasts in bone formed by endochondral ossification (St-Jacques *et al.,* 1999). Because the aberrant chondrocyte differentiation phenotype can be mimicked by hedgehog interacting protein (HIP) overexpression in transgenic mice that have osteoblasts (Chuang and McMahon, 1999), data suggest that the failure of osteoblast development in endochondral sites is due specifically to lack of Ihh rather than a secondary effect due to aberrant chondrocytes. Interestingly, Cbfa1 expression, which is normally high in osteoblasts in endochondral bones, is absent in Ihh -/- mice. Also, consistent with the fact that Ihh is not normally expressed in intramembranous bones, osteoblast differentiation occurs normally in these bones in Ihh -/- animals. These data support the concept that Ihh may be a regulator of Cbfa1 and osteoblast development, but in a skeletal site-specific manner.

Elucidation of the osteoprotegerin–RANK–RANKL pathway underlying stromal cell–hemopoietic cell interactions regulating osteoclast formation and activity (see elsewhere in this volume) also makes it tempting to speculate that a reciprocal or related pathway may regulate osteoblast formation and activity. The fact that hemopoietic cells influence CFU-O/osteoblast development in the bone marrow stromal cell model *in vitro* (Aubin, 1999) (see also later) lends some support for this hypothesis. Also, the fact that other apparently osteoblast-specific *cis*-acting elements have been found in several genes suggests that there are other important osteoblast-associated or -specific transcription factors to be elucidated. We will address further a variety of other transcription factors and receptor signaling pathways that clearly also influence the rate and amount of bone formed.

Stem Cell Immunophenotyping

In hemopoiesis and immune cell biology, the importance of large panels of stem and progenitor cell antibodies has been invaluable (Herzenberg and De Rosa, 2000). In oncology, it is realized that the characterization of reliable stem cell markers should be an immediate aim (Bach *et al.,* 2000). This has not received as much attention in the MSC system, but some attempts have given us a few monoclonal antibody markers to evaluate, although many recognize the more mature cells in the lineage (Aubin and Turksen, 1996). In addition, however, not enough emphasis has been placed on the rigorous definition of reactivities of MSCs and other related primitive osteogenic cells with the many other existing monoclonal antibody marker molecules developed for use in other cell systems, although some characteristics are now available. With respect to the development of specific markers, it must be realized that no such moiety can be considered to identify solely or unambiguously a cell stage or lineage. This is particularly evident for markers developed by the screening of tissues with normal physiology, as in pathological states, or in *in vitro* culture, the probability for alternative gene activation and expression of other cell phenotypic characteristics is high. This further emphasizes the need, known for many years, for confirmation of all the potentials for cell development and activity seen in culture with normal *in vivo* physiological responses.

Figure 2 Postulated steps in the osteoblast lineage implying recognizable stages of proliferation and differentiation as detectable from *in vitro* and *in vivo* experiments. Superimposed on this scheme are several well-established markers of osteoblastic cells with an indication of when during the differentiation sequence they are expressed, but also denoting heterogeneous expression of many of the markers. The list is not exhaustive, but does show some important categories of molecules in the lineage and their utility to help define transitions in osteoblast differentiation. It should be recognized that little is known about the abruptness of turn on or turn off of these markers, in many cases, expression levels may vary as changes to a continuum. −, no detectable expression; −/+–+++, expression ranging from detectable to very high, → +++, heterogeneous expression in individual cells.

A few interesting monoclonal antibodies that react with surface antigens on human MSCs *in vitro* have been generated by a number of research groups. These include the antibodies STR0-1 (Simmons and Torok-Storb, 1991), SH-2, SH-3, SH-4, SB10 (Bruder *et al.,* 1997, 1998), and HOP-26 (Joyner *et al.,* 1997) (Fig. 2). None of them is absolutely lineage and cell stage specific, as may be expected but sometimes receives too little attention. One of the first antibodies that identified the CFU-F in adult human bone marrow was STRO-1 (Simmons and Torok-Storb, 1991). The cell surface antigen recognized by this antibody is still unknown but its expression is restricted to a minor subpopulation of cells in fresh human bone marrow, including the CFU-F. The STRO-1^+ fraction of adult human bone marrow has been shown to contain the osteogenic precursors (Gronthos *et al.,* 1994).

Bruder and colleagues (1997) raised a series of monoclonal antibodies by immunizing mice with human MSCs that had been directed into the osteogenic lineage *in vitro*. Three hybridoma cell lines referred to as SB-10, SB-20, and SB-21 were isolated by screening against osteogenic cells *in vitro* and human fetal limbs. SB-10 was shown to react with marrow stromal cells and osteoprogenitors, but not with more differentiated cells, i.e., those already

expressing alkaline phosphatase (ALP) (see later). By flow cytometry, culture-expanded human MSCs were all found to express SB-10, and these cells appear homogeneous in this respect. In contrast, SB-20 and SB-21 do not react with the progenitor cells *in vivo*, but bind to a subset of ALP-positive osteoblasts. None of these antibodies stains terminally differentiated osteocytes in sections of developing bone. SB-10 has been identified as an activated leukocyte cell adhesion molecule (ALCAM) (Bruder *et al.,* 1998), and orthologues of ALCAM with 90% identity in peptide sequences have been found in rat, rabbit, and canine MSCs. Clearly, ALCAM is not restricted to MSCs or osteoprogenitor cells: ALCAM is an immunoglobulin (Ig) superfamily ligand for the CD6 antigen (Bowen *et al.,* 2000), which is present in lymphoid tissue and may be involved in the homing of hemopoietic cells (Bowen and Aruffo, 1999). Nevertheless, it may be useful combined with other reagents for cell subfractionation and it is worth considering its role in osteoblast development in more detail, as treating human MSCs *in vitro* with SB-10 accelerated osteogenic differentiation, implicating ALCAM as a regulator of this process (Bruder, *et al.,* 1998).

The SH-2 antibody is reported to immunoprecipitate endoglin (CD105), which is the transforming growth factor-β (TGFβ) receptor III present on connective tissue stromal cells, endothelial cells, syncytiotrophoblasts, and macrophages (Barry *et al.,* 1999). This molecule is potentially involved in TGFβ signaling and control of chondrogenic differentiation of MSCs and in interactions between these cells and hematopoietic cells in the bone marrow, as well as in dermal embryogenesis and angiogenesis (Fleming *et al.,* 1998).

The HOP-26 antibody raised against human bone marrow fibroblasts at an early stage of cell culture has been shown to react with cells close to newly forming bone in the periosteum and in trabeculae of the developing human fetal limb (Joyner *et al.,* 1997). In adult trabecular bone, HOP-26 reactivity is much diminished, and a minor proportion of cells within the bone marrow spaces show reactivity. No similar relatively high levels of activity are seen in a variety of soft tissues by immunocytochemistry. By immunopanning, cells with the highest levels of expression of the HOP-26 epitope were shown to be the majority of the CFU-F, and HOP-26 is thus a useful antibody for selecting these cells to enrich osteoprogenitor populations from marrow (Oreffo, 2001). In addition, the reactivity of this antibody with histological specimens fixed routinely with formaldehyde also indicates its value for histopathology investigation. Further studies with histopathological specimens indicate that high HOP-26 expression is also seen in certain populations of mast cells in samples from mastocytoma and in Paget's disease (Joyner *et al.,* 2000).

HOP-26 (Zannettino *et al.,* 2001) was shown by expression cloning to recognize the cell surface and lysosomal enzyme CD63, identical to the melanoma-associated antigen ME491, associated with early melanoma tumour progression (Metzelaar, 1991). The latter is a member of the superfamily of tetraspan glycoproteins (TM4SF), which also includes CD9, CD37, CD53, and CD151. CD63 is expressed on activated platelets and endothelium and is a lysosomal membrane glycoprotein translocated to the cell surface following activation (Vischer and Wagner, 1993). It is also present on monocytes, macrophages, and, at lower levels, on granulocytes and B and T lymphocytes. The initial report on the distribution of HOP-26 used mainly fixed tissues or paraffin-embedded tissues, but other studies with freshly isolated or viable, cultured cells have shown that HOP-26 identifies a range of cell types in preparations of fresh marrow. Histological fixation appears to render the epitope unreactive with the HOP-26 antibody in most cells, except osteoprogenitor cells, perhaps because of the higher level of expression of the epitope in the latter cell types. Studies with blood cells have shown inhibitory effects of CD63 antibodies on cell adhesion, and CD63 has also been shown to interact specifically with $\alpha_3\beta_1$ and $\alpha_6\beta_1$ integrins in a variety of cell types and therefore may be important in cell signaling pathways (Schwartz and Shattil, 2000). Osteoblastic cells also express many of these integrin heterodimers (reviewed in, Damsky, 1999). Compared with another CD63 antibody, 12F12 (Zannettino *et al.,* 1996), there are subtle differences in reactivities of cells with HOP-26, which may be related to glycosylation, but the preservation of this epitope on osteoprogenitors following fixation, unlike those reacting with other CD63 antibodies, suggests that HOP-26 is a valuable reagent for further studies on bone metabolism.

Combinations of antibodies and flow cytometry procedures have been used to subfractionate marrow stromal cells. Most will react with the CFU-F, which include the progenitors with most stem cell-like characteristics, found by Friedenstein (1990) to constitute about 15% of total colonies. Such methods are likely to be valuable for critical studies on cell developmental potential, but any advantage in superselection of primitive progenitors for practical use in cell therapy regimens must be considered carefully. For example, any specificity gained by selection must be offset against the lower manipulation of cell populations when total CFU-F cell progeny are used and the likelihood that the most primitive cells will mainly contribute eventually to the expanded cell population that develops.

Gronthos *et al*. (2001) used STRO-1 and an antibody directed against vascular cell adhesion molecule 1 (VCAM-1/CD106) with magnetic-activated cell sorting followed by fluorescence-activated cell sorting to isolate a highly enriched population of human marrow stromal precursor cells. These cells were homogeneous in phenotype, being STRO-1 bright and VCAM-1-positive, and were large COLL-I-positive cells lacking the phenotypic characteristics of leukocytes or vascular endothelial cells. Selected cells in the STRO-1 bright fraction were noncycling *in vivo* and with expression of constitutive telomerase activity *in vitro.* Data demonstrate that these cells have stem cell characteristics, as defined by extensive proliferative capacity and retention of differentiation capacity for osteogenesis and adipogenesis.

Expression of the bone/liver/kidney isoform of ALP has been used in a number of different studies with and without combination with other antibodies (Aubin and Turksen, 1996) (Fig. 2). Expression of ALP has been studied in relation to STRO-1 with dual-color fluorescence-activated cell sorting in osteogenic cells (Gronthos *et al.,* 1999). Human trabecular bone-derived cells expressing STRO-1 antigen exclusively with no ALP appeared to be early osteoblast precursors with absence of bone-related proteins bone sialoprotein (BSP), osteopontin (OPN), and parathyroid hormone/parathyroid hormone-related protein receptor (PTH1R) by RT-PCR analysis (see also later). The STRO-1-/ALP+ and STRO-1-/ALP- cell phenotypes were considered to represent differentiated osteoblasts, whereas the STRO-1+/ALP+ subset was an intermediate developmental stage. All STRO-1/ALP subpopulations expressed multiple isoforms of Cbfa1, suggesting the presence of cells committed to osteogenesis. With reculture of the four different STRO-1/ALP-selected subpopulations, only the STRO-1+/ALP- subpopulation yielded all of the four subsets with the same proportions of STRO-1/ALP expression as seen in the original primary cultures. Similar studies were performed by others using human marrow fibroblastic populations (Stewart *et al.,* 1999) in which an inverse association was found between the expression of STRO-1 and ALP. Both studies suggest that these antibody combinations permit the identification of cells of the osteoblast lineage at different stages of differentiation and support previous studies suggesting a hierarchy of marker expression during osteoblastic development *in vitro* (reviewed in Aubin and Liu, 1996) (see also later).

Other combinations of antibodies and cell surface characteristics have also been used (for earlier work, see Aubin and Turksen, 1996). For example, osteogenic cells were sorted from mouse bone marrow based on light scatter characteristics, Sca-1 expression, and their binding to wheat germ agglutinin (WGA) (Van Vlasselaer *et al.,* 1994). Cells from the Sca-1 + WGA(bright) gate, but not from other gates, synthesized bone proteins and formed a mineralized matrix, but lost this capacity when subcultured. Further immunophenotypic characterization showed that FSC(high)SSC(high)Lin-Sca-1 + WGA(bright) cells expressed stromal (KM 16) markers and endothelial (Sab-1 and Sab-2) markers, but not hemopoietic cell markers, such as c-kit and Thy1.2. Sorted FSC(high)SSC(high)Lin-Sca-1+WGA(bright) cells formed bone nodules. Somewhat in contradiction to the absence of OPN expression in the STRO-1+/ALP- population, just defined as comprising stem cells, OPN expression combined with cell size and granularity was used to sort rat calvaria and bone marrow stromal cells to attempt to enrich for cells responsive to BMP-7; these were said to have stem-like properties (Zohar *et al.,* 1997, 1998).

Better understanding of the surface chemistry profiles and their temporal changes with the development of osteogenic cells would advance the field. Further, while all the studies summarized have clearly fractionated populations into subpopulations with different characteristics and differentiation potentials, few attempts have yet been made to quantify the most primitive progenitors or stem cells in these populations and their self-renewal, proliferative, and differentiation potentialities at single cell or colony levels so that clear lineage relationships and hierarchies can be established analogous to those that have been achieved in hemopoietic populations (see, however, Pittenger *et al.,* 1999) (see later). In addition, more of the existing antibodies produced against other cell types need to be used and new ones produced that have specificity to restricted developmental stages during osteogenic differentiation.

Osteoprogenitor Cells and Regulation of Osteoblast Differentiation and Activity

Osteoprogenitor Cells

The morphological and histological criteria by which osteoblastic cells, including osteoprogenitors, preosteoblasts, osteoblasts, and lining cells or osteocytes, are identified have been reviewed extensively and will not be reiterated in detail here (Aubin, 1998). Morphological definitions are now routinely supplemented by the analysis of expression of cell- and tissue-specific macromolecules, including bone matrix molecules [type I collagen (COLL-I), OCN, OPN, and BSP, among others] and transcription factors that regulate them and commitment/differentiation events (e.g., Cbfa1, AP-1 family members, Msx-2, Dlx-5) (see also later). Committed osteoprogenitors, i.e., progenitor cells restricted to osteoblast development and bone formation under default differentiation conditions, can be identified in bone marrow stromal cell populations and populations derived from calvaria and other bones by functional assays of their proliferation and differentiation capacity *in vitro* or, as often designated, the CFU-O assay. As mentioned earlier, CFU-O appear to comprise a subset of CFU-F and CFU-ALP (Aubin, 1999; Herbertson and Aubin, 1995, 1997; Wu *et al.,* 2000). Cells morphologically essentially identical to cells described *in vivo* and subject to many of the same regulatory activities can be identified, and the deposited matrix contains the major bone matrix proteins.

Much has been learned from the *in vitro* bone nodule assay in which both the nature of the osteoprogenitors and their more differentiated progeny have been investigated by functional (the nature of the colonies they form, e.g., mineralized bone nodules), immunological (e.g., immunocytochemistry, Western analysis), and molecular (e.g., Northerns, PCR of various sorts, *in situ* hybridization) assays. CFU-O/bone nodules represent the end product of the proliferation and differentiation of osteoprogenitor cells present in the starting cell population. Estimates by limiting dilution have indicated that these osteoprogenitor cells are relatively rare in cell populations digested from fetal rat calvaria (i.e., $<1\%$) (Bellows and Aubin, 1989) and rat (Aubin, 1999) and mouse (Falla *et al.,* 1993) bone marrow stroma (i.e.,

$0.5 - 1 \times 10^{-5}$ of the nucleated cells of unfractionated marrow or <1% of the stromal layer) under standard isolation and culture conditions. The number of nodules or colonies forming bone can be counted for an assessment of osteoprogenitor numbers recoverable from fetal calvaria or other bones [e.g., vertebrae (Ishida *et al.,* 1997; Lomri *et al.,* 1988) or the primary spongiosa of femur metaphysis (Onyia *et al.,* 1997)] and bone marrow stroma (reviewed in Owen, 1998) under particular assay conditions. However, evidence from rat calvaria cell bone nodule assays suggests the existence of at least two populations of osteoprogenitors. One population appears capable of constitutive or default differentiation *in vitro*, i.e., in standard differentiation conditions (ascorbic acid, β-glycerophosphate, fetal calf serum) differentiation leading to the mature osteoblast phenotype appears to be a default pathway, whereas the other population, apparently more primitive based on cell sorting and immunopanning with ALP antibodies (Turksen and Aubin, 1991), undergoes osteoblastic differentiation only following the addition of specific inductive stimuli (Fig. 2). Thus the addition of glucocorticoids [often dexamethasone but natural corticosteroids have also been used (Bellows *et al.,* 1987)], other steroids [e.g., progesterone (Ishida and Heersche, 1997)], or other kinds of factors [e.g., BMPs (Hughes *et al.,* 1995)] increases the number of bone nodules or bone colonies in calvaria-derived and bone marrow stromal cell cultures, suggesting the presence of "inducible" osteoprogenitor cell populations as well. Whether other precursor stages in addition to the multipotential or committed progenitors discussed already can also be identified by combinations of assays *in vitro* remains to be explicitly tested.

Whether all progenitors that differentiate to osteoblasts and make bone belong to the same unidirectional lineage pathway (i.e., immature progenitors induced by a variety of agents to undergo differentiation to mature osteoblasts), whether osteoprogenitor cells must transit all recognizable differentiation stages (or may skip steps under appropriate conditions) under all developmental situations, or whether recruitment from other parallel lineages and pathways can result in functional osteoblasts remains to be established (see also later). However, as discussed already, plasticity between mature cell phenotypes normally considered indicative of terminal differentiation can contribute to osteoblast pools, at least *in vitro*. It is also worth considering whether the osteoprogenitors in calvaria or other bones and bone marrow stroma or other tissues [e.g., pericytes (Bianco and Cossu, 1999; Doherty and Canfield, 1999; Proudfoot *et al.,* 1998; Shanahan *et al.,* 2000)] are the same. As discussed in more detail later, they do appear to reach *similar* end points with respect to the ability to make and mineralize a bone matrix, but may not be *identical*. Data have also indicated that, in rat stromal populations, as in rat calvaria-derived populations, there are two pools of osteoprogenitors: ones that differentiate in the absence of added glucocorticoids (assumed to be more mature) and ones that do so only in its presence (assumed to be more primitive), although the number of the former type is relatively low and so detectable only at relatively high plating cell densities and the latter comprise the majority in stromal populations (Aubin, 1999). Whether the two sorts or stages of progenitors are identical in other features to the progenitors in calvaria remains to be assessed rigorously, as must their relationship to multilineage CFU-F. It is also worth noting that, in rat stroma, unlike in rat calvaria, limiting dilution analysis indicates that more than one cell type is limiting for nodule formation *in vitro*, suggesting a cell nonautonomous aspect to differentiation of the stromal CFU-O; osteogenic differentiation is enhanced, for example, when the nonadherent fraction of bone marrow or its conditioned medium is added to the adherent stromal layer (Aubin, 1999). A role for accessory cells in the osteogenesis of human bone marrow-derived osteoprogenitors has also been shown (Eipers *et al.,* 2000). The relationship of inducible osteoprogenitors that apparently reside in the nonadherent fraction of bone marrow and are assayable under particular culture conditions, e.g., in the presence of PGE_2 [rat (Scutt and Bertram, 1995)] or as colonies in soft agar or methylcellulose [human (Long *et al.,* 1995)], also remains to be determined. Direct and unambiguous comparisons have not yet been done but should be advanced as more markers for the most primitive progenitors, including stem cells, become available.

Morphologically recognizable osteoblasts associated with bone nodules appear in long-term bone cell cultures at predictable and reproducible periods after plating. Recent time-lapse cinematography of individual progenitors forming colonies in low-density rat calvaria cultures indicated that primitive (glucocorticoid-requiring) osteoprogenitors divide ~8 times prior to overt differentiation, i.e., to achieving cuboidal morphology and matrix deposition (Aubin and Liu, 1996; Malaval *et al.,* 1999). Interestingly, however, the measurement of large numbers of individual bone colonies in low density cultures shows that the size distribution of fully formed bone colonies covers a large range but is unimodal, suggesting that the coupling between proliferation and differentiation of osteoprogenitor cells may be governed by a stochastic element, but distributed around an optimum, corresponding to the peak colony size/division potential (Malaval *et al.,* 1999). Osteoprogenitors measurable in functional bone nodule assays also appear to have a limited capacity for self-renewal in both calvaria (Bellows *et al.,* 1990a) and stromal (McCulloch *et al.,* 1991) populations, consistent with their being true committed progenitors with a finite life span (reviewed in Aubin, 1998). However, in comparison to certain other lineages, most notably hemopoietic cells, relatively little has been done to assess the regulation of self-renewal in different osteogenic populations beyond the effects of glucocorticoids. According to signaling threshold models, the differentiation of hemopoietic stem cells is suppressed when certain receptor–ligand (soluble or matrix-bound) interactions are kept above a particular threshold and is increased or more probable when levels are reduced (Eaves *et al.,* 1999); this regulation is

sometimes a proliferation–differentiation switch, but in some cases it is independent of proliferation (Ramsfjell *et al.,* 1999). Very little has been done in osteoblast lineage to assess comparable pathways, yet the differential expression of a variety of receptors for cytokines, hormones, and growth factors during osteoblast development and in different cohorts of osteoblasts predicts that similar mechanisms may play a role in bone formation (see also later).

Differentiation of Osteoprogenitor Cells to Osteoblasts

One fundamental question of osteoblast development remains how progenitors progress from a stem or primitive state to a fully functional matrix-synthesizing osteoblast. Based on bone nodule formation *in vitro*, the process has been subdivided into three stages: (i) proliferation, (ii) extracellular matrix development and maturation, and (iii) mineralization, with characteristic changes in gene expression at each stage; some apoptosis can also be seen in mature nodules. In many studies, it has been found that genes associated with proliferative stages, e.g., histones and protooncogenes such as c-fos and c-myc, characterize the first phase, whereas certain cyclins, e.g., cyclins B and E, are upregulated postproliferatively (Stein *et al.,* 1996). Expression of the most frequently assayed osteoblast-associated genes COLLI, ALP, OPN, OCN, BSP, and PTH1R is upregulated asynchronously, acquired, and/or lost as the progenitor cells differentiate and the matrix matures and mineralizes (Aubin, 1998; Stein *et al.,* 1996). In general, ALP increases and then decreases when mineralization is well progressed; OPN peaks twice during proliferation and then again later but prior to certain other matrix proteins, including BSP and OCN; BSP is expressed transiently very early and is then upregulated again in differentiated osteoblasts forming bone; and OCN appears approximately concomitantly with mineralization (summarized in Aubin, 1998) (Fig. 2). Notably, however, use of global amplification poly(A) PCR, combined with replica plating and immunolabeling, showed that all these osteoblast-associated markers are upregulated prior to the cessation of proliferation in osteoblast precursors except OCN, which is upregulated only in postproliferative osteoblasts; in other words, differentiation is well progressed before osteoblast precursors leave the proliferative cycle. Based on the simultaneous expression patterns of up to 12 markers, osteoblast differentiation can be categorized into a minimum of seven transitional stages (Aubin and Liu, 1996; Candeliere *et al.,* 1999; Liu and Aubin, 1994), not just the three stages mentioned earlier (Fig. 2). An interesting issue is whether osteoprogenitor cells in all normal circumstances must transit all stages or can "skip over" some steps under the action of particular stimuli or regulatory agents.

While many cell systems have been reported to follow the general proliferation–differentiation just outlined some discrepancies exist that are not always noted in detail. At least some of the variations may reflect inherent differences in the populations being analyzed, e.g., species differences or different mixtures of more or less primitive progenitors and more mature cells. However, there is growing evidence from both *in vitro* and *in vivo* observations that somewhat different gene expression profiles for both proliferation and differentiation and regulatory markers may underlie developmental events in different osteoblasts (Aubin *et al.,* 1999). For example, in a study of ROS cells differentiating and producing mineralizing bone matrix in diffusion chambers *in vivo*, neither proliferation nor most differentiation markers followed the pattern described previously (Onyia *et al.,* 1999). One possible explanation is that different subpopulations of cells within the chambers were undergoing different parts of the proliferation–death–matrix synthesis cycle at different times, such that activities of some subpopulations may have been obscured among larger subpopulations engaged in other activities in the chamber at the same time. At least some data supported this view, which may also account for the discrepancies in some reported observations *in vitro*. It is also possible that protein levels may not match the mRNA levels detected. Another possibility is that there are differences in proliferation–differentiation coupling and/or the nature of the matrix and process of mineralization in osteosarcoma cells versus normal diploid osteoblasts. In addition, however, it is growing clear that high levels of genes typical of some normal osteoblasts may not be required in others, i.e., that some pathways by which mineralized matrix can be formed *in vivo* or *in vitro* are different from others and that there is heterogeneity among osteoblast developmental pathways and/or the resulting osteoblasts.

The possibility that marked intercellular heterogeneity in expressed gene repertoires may characterize osteoblast development and differentiation is an important concept (Aubin *et al.,* 1999) (Fig. 2). As already discussed, Ihh is expressed in and required for the development of osteoblasts associated with endochondral bones but not other osteoblast populations (St-Jacques, *et al.,* 1999). It has been evident for some time that not all osteoblasts associated with bone nodules *in vitro* are identical (Liu *et al.,* 1994; Malaval *et al.,* 1994; Pockwinse *et al.,* 1995). Single cell analysis of the most mature cells in mineralizing bone colonies *in vitro* showed that the heterogeneity of expression of markers by cells classed as mature osteoblasts is extensive and appears not to be related to cell cycle differences (Liu *et al.,* 1997). That this extensive diversity is not a consequence or an artifact of the *in vitro* environment was confirmed by the analysis of osteoblastic cells *in vivo*. When individual osteoblasts in 21-day fetal rat calvaria were analyzed, only two markers of nine sampled, ALP and PTH1R, appeared to be "global" or "ubiquitous" markers expressed by all osteoblasts *in vivo*. Strikingly, all other markers analyzed (including OPN, BSP, OCN, PTHrP, c-fos, Msx-2, and E11) were expressed differentially at both mRNA and protein levels in only subsets of osteoblasts, depending on the maturational state of the bone, the age of the osteoblast, and on the environment

(endocranium, ectocranium) and the microenvironment (adjacent cells in particular zones) in which the osteoblasts reside (Candeliere *et al.,* 2001). The biological or physiological consequences of the observed differences are not known, but they support the notion that not all mature osteoblasts develop via the same regulatory mechanisms nor are they identical molecularly or functionally. They predict that the makeup of different parts of bones may be significantly different, as suggested previously by the observations that the presence of and amounts of extractable noncollagenous bone proteins are different in trabecular versus cortical bone and in different parts of the human skeleton (for discussion, see Aubin *et al.,* 1999; Candeliere *et al.,* 2001). They also suggest that the global or ubiquitously expressed molecules COLL-I, ALP, and PTH1R serve common and nonredundant functions in all osteoblasts and that only small variations in the expression of these molecules may be tolerable; e.g., all bones display mineralization defects in ALP knockout mice (Fedde *et al.,* 1999; Wennberg *et al.,* 2000). Differentially expressed lineage markers, however, e.g., BSP, OCN, and OPN, vary much more, both between osteoblasts in different zones and between adjacent cells in the same zone and may have specific functions associated with only some positionally or maturationally defined osteoblasts. In this regard, it is striking that all of the noncollagenous bone matrix molecules are extremely heterogeneously expressed and that ablation of many of those studied to date, e.g., OCN (Ducy *et al.,* 1996), OPN (Yoshitake *et al.,* 1999), and BSP (Aubin *et al.,* 1996b) does not result in a complete failure of osteoblast differentiation and maturation, although the amount, quality, and remodeling of the bone formed may differ from normal.

The nature of the signals leading to the diversity of osteoblast gene expression profiles is not known (for discussion, see Aubin *et al.,* 1999; Liu *et al.,* 1997); however, the fact that the heterogeneity is apparently controlled both transcriptionally and posttranscriptionally implies that regulation is complex. The observations also suggest that it will be important to analyze the expression of regulatory molecules, including more transcription factors, not only globally but at the individual osteoblast level, e.g., as mentioned earlier for the Ihh regulation of osteoblast development or, for example, for the homeobox transcription factor Dlx-5, whose levels modify bone formation *in vivo* (see later) and which appears more highly expressed in periosteal compared to endosteal osteoblasts (Acampora *et al.,* 1999). Another unanswered question remains whether the striking diversity of marker expression in different osteoblasts is nonreversible or reversible in a stochastic manner, governed by changes in a microenvironmental signal or receipt of hormonal or growth factor cues, or both. Because the heterogeneity observed extends to the expression of regulatory molecules such as cytokines and their receptors, it also suggests that autocrine and paracrine effects may be elicited on or by only a subset of cells at any one time and that the responses to such stimuli could themselves be varied (Aubin *et al.,* 1999). We also cannot rule out the possibility that the heterogeneity can be subdivided further, a scenario that seems likely as new markers for the lineage are identified.

The observed differences in mRNA and protein expression repertoires in different osteoblasts may also contribute to the heterogeneity in trabecular microarchitecture seen at different skeletal sites (Amling *et al.,* 1996), to site-specific differences in disease manifestation such as seen in osteoporosis (reviewed in Byers *et al.,* 1997; Riggs *et al.,* 1998), and to regional variations in the ability of osteoblasts to respond to therapeutic agents. A highly pertinent example of potential site-specific cellular responses concerns the estrogen receptors (ERs). Studies support the notion that ERα and ERβ are expressed differentially in different parts of bones, e.g., ERβ was reported to be highly expressed in the cancellous bone of lumbar vertebrae and distal femoral metaphysis but expressed at much lower levels in the cortical bone of the femur (Onoe *et al.,* 1997). These data offer a possible mechanism by which the estrogen deficiency caused by ovariectomy induces bone resorption preferentially in cancellous bone and in vertebrae. Further analysis of differential expression profiles for a variety of receptors in different skeletal sites, and at different maturational age of the cells and skeleton, should provide further insight into site-specific effects of not only estrogen, but other treatments, including fluoride, calcitonin, PTH, and even calcium. In this regard, the observations of Calvi *et al*. (2001) on transgenic mice overexpressing constitutively active PTH1R are interesting. The opposite effects observed in trabecular and endosteal osteoblast populations versus periosteal osteoblast populations are reminiscent of the differential effects of PTH in trabecular versus cortical bone in primary hyperparathyroidism (Parisien *et al.,* 1990; Calvi *et al.,* 2001). However, consistent with our own observations on the global expression of PTH1R in all osteoblast populations (Candeliere *et al.,* 2001), Calvi *et al*. (2001) found similar levels of transgene mRNA expression in both compartments, suggesting that in this case, differential receptor expression cannot account for the different responses elicited by the ligand/PTH. These data predict exquisite control of a signaling threshold as discussed earlier, other intrinsic differences downstream of the PTH1R in these different osteoblast populations, or that the different bone microenvironments in these sites modulate the osteoblast response.

As summarized previously (Aubin and Liu, 1996), many other molecules are now known to be made by osteoblast lineage cells, often with differentiation stage-specific changes in expression levels, but sometimes without known function yet in bone. Several molecules have been identified to be particularly highly expressed in osteoblasts and osteocytes, suggesting that they may play roles in mechanosensing among other activities in bone. For example, a novel osteocyte factor, termed OF45, has been identified by subtractive hybridization based on its high expression in bone marrow stromal cells (Petersen *et al.,* 2000). Northern blot analysis detected the mRNA in bone, but not other

tissues, and immunohistochemistry revealed that the protein was expressed highly in osteocytes within trabecular and cortical bone. The cDNA was predicted to encode a serine/glycine-rich secreted peptide of 45 kDa containing numerous potential phosphorylation sites and one RGD sequence motif, which may suggest a role for this new protein in integrin binding, and osteoblast (or osteoclast) recruitment, attachment, and differentiation. The mRNA for Phex, a phosphate-regulating gene with homology to endopeptidases on the X chromosome, which is mutated in X-linked hypophosphatemia (XLH), is expressed differentially in osteoblasts as they differentiate (Ecarot and Desbarats, 1999; Guo and Quarles, 1997; Ruchon *et al.,* 1998), and the protein is detectable only in osteoblasts and osteocytes (Ruchon *et al.,* 2000). Two cell surface multifunctional molecules that are regulated by osteotropic hormones and expressed throughout osteoblast differentiation, but most highly in osteoblasts and osteocytes, are galectin-3 (Aubin *et al.,* 1996a) and CD44 (Jamal and Aubin, 1996). Consistent with one of its earlier names, i.e., Mac-2, and role as a macrophage marker, ablation of galectin-3, which is thought to have pleiotropic effects in cells in which it is expressed, with diverse roles in adhesion, apoptosis, and other cellular functions, alters monocyte–macrophage function and survival (Hsu *et al.,* 2000). In addition, growth plate and chondrocyte defects with altered coupling between chondrocyte death and vascular invasion have been reported in galectin-3 null mice (Colnot *et al.,* 2001); notably, most hypertrophic chondrocyte–osteoblast markers studied (PTH1R, OPN, Cbfa1/Runx2) appeared to be distributed relatively normally, although Ihh expression was altered. Further work will be required to determine whether osteoblasts and bone metabolism are changed in these animals. In contrast, simultaneous ablation of all known CD44 isoforms, some of which are known to bind OPN, altered the tissue distribution of myeloid progenitors, with evidence for defective progenitor egress from bone marrow, and highly tumorigenic fibroblasts, but no bone abnormalities have been reported yet (Schmits *et al.,* 1997).

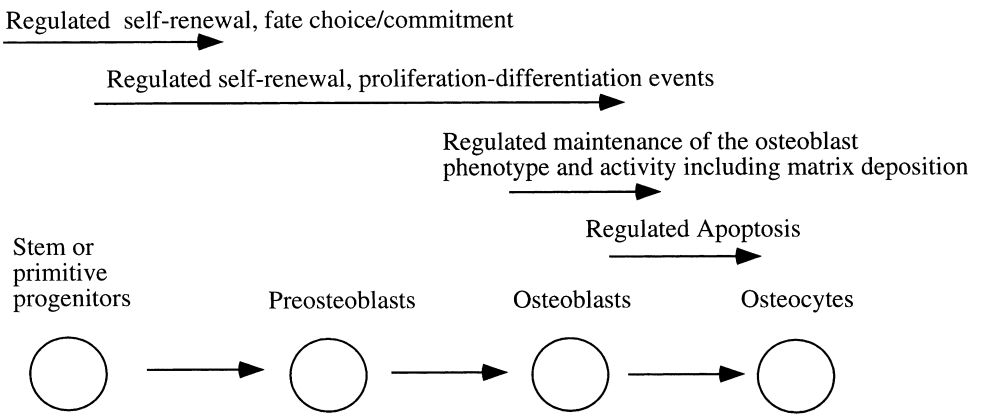
With completion of the human genome sequence project and those of other species and significant progress on the mouse and rat, together with novel new methods for cell-specific gene identification and functional genomics, we can expect to see in a short time a startling increase in known osteoblast gene products (Carulli *et al.,* 1998). For example, in a small-scale cDNA fingerprinting screen from globally PCR-amplified osteoblast colonies, Candeliere *et al*. (1999) identified several new markers with differential expression during osteoblast differentiation, including glycyl tRNA synthetase and cystatin C, among other previously unknown molecules. A high throughput serial analysis of gene expression (SAGE) and microarray hybridization of MC3T3-E1 cells at different times after the induction of osteoblast differentiation yielded a large number of known and novel osteoblast markers (Seth *et al.,* 2000). Rab24, calponin, and calcyclin, among other mRNAs, were coordinately induced, whereas levels of MSY-1, SH3P2, fibronectin, α-collagen, procollagen, and LAMPI mRNAs decreased with differentiation. Among unexpected mRNAs identified was the TGFβ superfamily member Lefty-1, which preliminary blocking studies showed appears to play a role in osteoblast differentiation (Seth *et al.,* 2000).

Transcription Factor, Hormone, Cytokine, and Growth Factor Regulation of CFU-F and Osteoprogenitor Cell Proliferation and Differentation

Transcription factors, hormones, cytokines, growth factors, and their receptors can serve both as markers and as stage-specific regulators of osteoblast development and differentiation (Figs. 2 and 3). It is beyond the scope of this chapter to review every factor known to influence osteoblast differentiation and bone formation at some level, as many will be covered elsewhere in other chapters. However, we have chosen examples that emphasize other issues discussed in this chapter, including heterogeneity of osteoblast response, proliferation–differentiation coupling, and differentiation stage-specific regulatory mechanisms.

Regulation by Transcription Factors

It is already evident from the preceding summary that Cbfa1/Runx2 is necessary for osteoblast development. However, several other issues related to Cbfa1 are of interest. For example, the role of at least three and perhaps more (see, e.g., Gronthos *et al.,* 1999) Cbfa1 isoforms that have been described needs to be clarified (reviewed in Yamaguchi *et al.,* 2000). All three appear to be able to regulate OCN expression (Xiao *et al.,* 1999) and osteoblast differentiation in *in vitro* models (Harada *et al.,* 1999), but with different efficacies/activities. Although it is regulated by BMPs, BMPs are unlikely to be the direct regulators of Cbfa1 expression *in vivo*, and one important area of work is investigation of the regulatory molecules lying upstream of Cbfa1. Cbfa1 regulates itself directly via binding on its own promoter (Drissi *et al.,* 2000; Ducy *et al.,* 1999). As already mentioned earlier, regulation of Cbfa1 by other transcription factors is yielding interesting information on skeletal site-specific regulatory mechanisms for Cbfa1 specifically and bone development generally. For example, downregulation of Cbfa1 expression was observed in both Msx2-deficient (Satokata *et al.,* 2000) and Bapx1-deficient (Tribioli and Lufkin, 1999) mice. A particularly interesting aspect of the phenotypes observed was that Msx-2 deficiency caused delayed growth and ossification of the skull and long bones, whereas the axial skeleton was affected in Bapx-1-deficient mice. In addition, Hoxa-2-deficient mice exhibit ectopic bone formation associated with ectopic expression of Cbfa1 in the second branchial arch (Kanzler *et al.,* 1998), suggesting that Hoxa-2 may normally inhibit the expression of Cbfa1 and bone formation in this area.



Transcription factors altering commitment, proliferation-differentiation choices and/or osteoblast activity

Cbfa-1
Msx-2, Dlx-5
Fra-1, deltaFosB
c-Abl
RORα
PPARγ2

Hormones, growth factors and cytokines or receptors altering self-renewal, commitment, proliferation-differentiation choices, activity and/or apoptosis

Glucocorticoids and other steroids
PTH, PTH1R
TGFβ, TGFβ type II receptor
PGE2, EP receptors
Leptin
BMPs

Antiproliferative proteins altering proliferation-differentiation choices and/or activity

Tob

Matrix proteins altering osteoblast activity

OCN

Figure 3 Regulated events and classes of regulatory molecules in osteoblast development and differentiation. The list is not exhaustive, but highlights some of the known levels of regulation that have been dissected in significant detail in the recent post.

With respect to other mechanisms of Cbfa1 regulation, relatively little is known, but inhibitory cofactors (TLE2/Groucho; HES1), phosphorylation via the MAPK pathway, and cAMP-induced Cbfa1 proteolytic degradation through a ubiquitin/proteosome-dependent mechanism have all been described *in vitro* (reviewed in Ducy, 2000).

Factors that appear to regulate osteoblast recruitment, osteoblast number, and the rate and duration of osteoblast activity are growing in number. Ducy *et al.* (1999) used a dominant-negative strategy in transgenic mice to show that Cbfa1 plays a role beyond osteoblast development in that it appears to regulate the amount of matrix deposited by osteoblasts in postnatal animals. It was also found that mice with leptin or leptin receptor deficiency had increased bone formation, suggesting that leptin may normally be an inhibitor of bone formation acting through the central nervous system (Ducy *et al.,* 2000). While it has been studied most frequently in the context of craniofacial development, Msx-2 appears to play roles in osteoblast differentiation in other bones, as evidenced by the broadly distributed (but not universal, see earlier discussion) bone abnormalities described in Msx-2 -/- mice (Satokata *et al.,* 2000). Msx-2 functional haploinsufficiency also causes defects in skull ossification in humans (Wilkie *et al.,* 2000). However, not only Msx-2 loss-of-function but also gain-of-function studies have been informative. Mutations in Msx-2 that increase its DNA-binding activity (Jabs *et al.,* 1993; Ma *et al.,* 1996) and overexpression of Msx-2 under the control of a segment of the mouse Msx-2 promoter that drives expression in a subpopulation of cells in the skull and the sutures (Liu *et al.,* 1999) result in enhanced calvarial bone growth and craniosynostosis. These latter data, together with findings of Dodig *et al.* (1999) on the effect of forced over- or underexpression of Msx-2 on osteogenic cell differentiation *in vitro*, are consistent with the hypothesis that the enhanced expression of Msx-2 keeps osteoblast precursors transiently in a proliferative state, delaying osteoblast differentiation, resulting in an increase in the osteoblast pool and ultimately in an increase in bone growth. More generally, these studies show that perturbations in the timing of proliferation

and differentiation of osteoprogenitors have profound consequences on the number and activity of osteoblasts and bone morphogenesis.

It was found that osteosclerosis results when either of two different members of the AP-1 subfamily of leucine zipper-containing transcription factors are overexpressed in transgenic mice: Fra-1 (Jochum *et al.,* 2000), a Fos-related protein encoded by the c-Fos target gene *Fosl1* (referred to as *fra-1*), or ΔFosB, a naturally occurring splice variant of FosB (Sabatakos *et al.,* 2000). In both cases, transgenic mice appear normal at birth, but with time, much increased bone formation is evident throughout the skeleton (endochondral and intramembranous bones). The osteosclerotic phenotype derives from a cell autonomous modulation of osteoblast lineage cells that is characterized by accelerated and more osteoblast differentiation and bone nodule formation *in vitro*. Interestingly, the further truncated Δ2ΔFosB isoform, rather than ΔFosB itself, appears to be responsible for the increased bone formation seen in ΔFosB transgenic mice. This suggests that further study of differentiation stage-specific aspects of the mechanism may shed light on the underlying lineage perturbation, as differentiation stage-specific alternative splicing of fosB mRNA and selective initiation site use of ΔFosB appear to be involved in the regulation of osteoblast development and the increased bone formation seen in ΔFosB transgenic mice (Sabatakos *et al.,* 2000). Notably, because neither Fra-1 nor ΔFosB (or Δ2ΔFosB) possesses the typical C-terminal transactivation domain, it seems likely that the transcriptional potential of either resides in or depends on specific heterodimerizing partners or coactivators—either activators or repressors—which remain to be elucidated.

Tob, a member of the emerging family of antiproliferative proteins, has been shown to be a negative regulator of osteoblast production through the regulation of BMP/Smad signaling (Yoshida *et al.,* 2000). Bone histomorphometry showed that the number of osteoclasts in tob -/- mice is equivalent to those in wild-type littermates, but that the osteoblast surface and bone formation rate are increased significantly. These data are consistent with the view that Tob may normally function to inhibit the proliferation of osteoblast precursors and their differentiation into mature ALP-positive osteoblasts, although further studies will be needed to address the possibility that Tob inhibits the function of mature osteoblasts. Mice homozygous for mutations in the gene (AIM) encoding the nonreceptor tyrosine kinase c-Abl also have a bone phenotype, including osteoporotic (both thinner cortical and reduced trabecular) bones and reduced mineral apposition rates (Li *et al.,* 2000), apparently reflecting no change in osteoclast number or activity but an osteoblast defect manifested by delayed maturation *in vitro*. Whether a cell autonomous defect in osteoblasts is responsible for the osteopenia seen in the spontaneous mouse mutant staggerer (sg/sg) (Meyer *et al.,* 2000), which carries a deletion within the retinioic acid receptor-related orphan receptor α (RORα) gene, remains to be determined, but because RORα appears to regulate BSP and OCN transcriptionally, this is clearly one possibility, given the increased bone formation seen earlier in OCN null mice (Ducy *et al.,* 1996). Interestingly, another steroid orphan receptor, estrogen receptor-related receptor α (ERRα), appears to play a positive regulatory role in both proliferation and differentiation of osteoprogenitor cells, at least *in vitro* (Bonnelye *et al.,* 2000).

It is also clear that further analysis of other homeodomain transcription factors expressed in osteoblasts is required. For example, Dlx-5 is expressed differentially as osteoblasts differentiate *in vitro* (Newberry *et al.,* 1998; Ryoo *et al.,* 1997) and in different cohorts of osteoblasts *in vivo* (Acampora *et al.,* 1999). The phenotype of Dlx-5 -/- mice is complex with many tissue abnormalities, but with respect to bone is characterized by craniofacial abnormalities affecting derivatives of the first four branchial arches, delayed ossification of the roof of the skull, and abnormal bone formation in endochondral bones, with the latter perhaps reflecting the differential expression of Dlx-5 at different skeletal sites (Acampora *et al.,* 1999).

It is beyond the scope of this chapter to review all the genes in which mutations or ablations appear to perturb bone patterning or differences in the formation of craniofacial, appendicular, and axial skeletons or differences in the amount of bone formed, but data available already indicate regulatory paradigms of significant complexity and are likely to become more complex as the roles of other related factors are elucidated. Some of these may include a novel Runx1 (Pebp2alphaB/Cbfa2/AML1b) splice variant identified and found to be expressed in bone and the osteoblast-like cell line MC3T3E1 (Tsuji and Noda, 2000); Dlxin-1, which is capable of forming multimers with Dlx-5 and participating in its transactivaton activity (Masuda *et al.,* 2001); and MINT, the Msx-2-binding protein that is expressed differentially as osteoblasts differentiate and modify Msx-2 transcriptional activity on the OCN promoter (Newberry *et al.,* 1999).

Regulation by Hormones, Growth Factors, and Cytokines

In experimental models, bone marrow injury associated with local bleeding, clotting, and neovascularization recapitulates a process similar to callus formation during fracture repair, with the induction of an environment rich in growth factors (e.g., PDGF, FGF, TGFβ, VEGF) followed by a process of very active bone formation (reviewed in Khan *et al.,* 2000; Rodan, 1998). To elucidate the target cells responding (stem cells, mesenchymal precursors, committed progenitors) and the precise nature of the responses in bone and nonbone cells in such an environment, these and a growing list of other systemic or local growth factors, cytokines, and hormones are also being tested in many models *in vitro*. The factors controlling cell lineage development and proliferation of marrow stromal CFU-F and CFU-O from stroma and bone (e.g., calvaria) are under intense study in many laboratories, often with differing

requirements proposed depending on the species studied (Gordon *et al.,* 1997; Kuznetsov *et al.,* 1997a) and opposite results depending on the model cell system under study (e.g., bone marrow stroma versus calvariae-derived populations), whether total CFU-F or specific subpopulations (e.g., CFU-ALP, CFU-O) are quantified, and the presence or absence of other factors. Nevertheless, because of increasingly careful documentation of proliferation and differentiation stages underlying the formation of CFU-F and bone nodules/CFU-O *in vitro*, these models are providing strong support for several concepts proposed earlier and are helping to clarify the nature of perturbations in a normally, carefully orchestrated proliferation–differentiation activity sequence.

VEGFs are suggested to play an important role in the regulation of bone remodeling by attracting endothelial cells and osteoclasts and by stimulating osteoblast differentiation (Deckers *et al.,* 2000). Interferon α has been shown to inhibit human osteoprogenitor cell proliferation, CFU- F formation, HOP-26 expression, and ALP-specific activity and to modulate BMP-2 gene expression, suggesting a role for interferon α in local bone turnover through the modulation of osteoprogenitor proliferation and differentiation (Oreffo *et al.,* 1999). The known anabolic actions of PGE_2 on bone formation may be at least in part via the recruitment of osteoblast precursors from mesenchymal precursor cells (Scutt and Bertram, 1995). While most often considered as osteoclast regulatory factors, interestingly, GM-CSF and IL-3, as well as M-CSF, also appear to stimulate the proliferation and/or differentiation of bone marrow fibroblastic precursors (Yamada *et al.,* 2000).

There is growing evidence that at least some of the actions of growth and differentiation factors are dependent on the relative stage of differentiation (either more or less mature) of the target cells, with stimulatory/mitogenic or inhibitory responses when test factors are added to proliferative/progenitor stages and stimulation or inhibition of differentiation stage-specific precursors and mature osteoblasts when the same factors are added later. This is true, for example, for the inflammatory cytokine IL-1, which is stimulatory to CFU-O formation when calvaria-derived cultures are exposed transiently during proliferative culture stages, and inhibitory when cells are exposed transiently during differentiation stages (Ellies and Aubin, 1990) and able to regulate a variety of osteoblast-associated genes when cells are treated acutely for short (hours) periods of time [e.g., PGHS-2 (Harrison *et al.,* 2000)]; the inhibitory effects dominate when cells are exposed chronically through proliferation and differentiation stages in culture (Ellies and Aubin, 1990). Many other factors of current interest similarly have biphasic or multiphasic effects *in vitro*, including EGF, TGFβ, and PDGF.

Another example of clinical significance is the reported catabolic versus anabolic effects of PTH. PTH1R is expressed throughout osteoblast differentiation, although the levels of expression and activity appear to increase as osteoblasts mature (reviewed in Aubin and Heersche, 2001). Chronic exposure to PTH inhibits osteoblast differentiation in an apparently reversible manner at a relatively late preosteoblast stage (Bellows *et al.,* 1990b). However, when rat calvaria cells were treated for 1-hr versus 6-hr pulses in 48-hr cycles during a 2- to 3-week culture period, either inhibition (1-hr pulse; apparently related to cAMP/PKA pathways) or stimulation (6-hr pulse; apparently related to cAMP/PKA, Ca2+/PKC, and IGF-I) in osteoblast differentiation and bone nodule formation was seen (Ishizuya *et al.,* 1997). In mice deficient in PTH1R, not only is a well-studied defect in chondrocyte differentiation seen (as also seen in PTHrP knockout mice), but also increased osteoblast number and increased bone mass [a phenotype not seen in PTHrP-deficient mice (Lanske *et al.,* 1999)], supporting the view that PTH plays an important role in the regulation of osteoblast number and bone volume. Consistent with this latter view are studies showing that PTH may increase osteoblast lifetime by decreasing osteoblast apoptosis (Jilka *et al.,* 1999). As mentioned, previously, when Calvi *et al.* (2001) expressed constitutively active PTH1R in bone, the osteoblastic function was increased in the trabecular and endosteal compartments, but decreased in the periosteum of both long bones and calvaria; interestingly, an apparent increase in both osteoblast precursors and mature osteoblasts was seen in trabecular bone.

Because of their ability to induce *de novo* bone formation at ectopic sites, BMPs, which are members of the TGFβ superfamily, have been studied extensively *in vivo* and *in vitro* as regulators of osteoblast development (reviewed in Yamaguchi *et al.,* 2000). While many reports document a stimulatory effect of BMPs on osteoblast differentiation, a few show inhibitory effects. Interestingly, while mouse knockout experiments have clearly indicated a role for BMPs in skeletal patterning and joint formation, ablation experiments have not yet provided evidence for a role of BMPs in osteoblast differentiation *in vivo* (for a review, see Ducy and Karsenty, 2000). This may be the result of functional redundancy among members of this family (there are now more than 30), and further experiments will be required to elucidate unequivocally the role of BMP family members in osteoblast differentiation. However, TGFβ has been shown to have biphasic effects on osteoblast development *in vitro*, inhibiting early stage progenitors while stimulating matrix production by more mature cells in the lineage, including osteoblasts (see Chapter 49). These diverse effects may help account for the complex effects seen when TGFβ is overexpressed via the OCN promoter in transgenic mice; these mice have low bone mass, with increased resorption, but increased osteocyte numbers and hypomineralized matrix (Erlebacher and Derynck, 1996). Further studies from Derynck's group showed that when a dominant-negative TGFβ type II receptor was expressed in osteoblasts, osteocyte number, bone mass, and bone remodeling were all influenced in a manner suggesting that TGFβ increases the steady-state rate of osteoblastic differentiation from osteoprogenitor cells to terminally differentiated osteocytes (Erlebacher *et al.,* 1998) while also

regulating bone remodeling, structure, and biomechanical properties (Filvaroff *et al.,* 1999).

Review of all regulatory factors is beyond the scope of this chapter, and indeed, we have not touched on a growing number of reports on matrix and matrix–integrin effects on osteoblast development and/or activity *in vitro* and *in vivo* (see, e.g., Zimmerman *et al.,* 2000). However, given its inclusion in the majority of CFU-F and CFU-O assays *in vitro* reported in this chapter, it is worth considering glucocorticoids (most often dexamethasone in *in vitro* assays) in more detail. Glucocorticoid effects *in vivo* and *in vitro* are complex and often opposite, i.e., stimulating osteoblast differentiation *in vitro* (reviewed in Aubin and Liu, 1996) while resulting in glucocorticoid-induced osteoporosis *in vivo* (Weinstein *et al.,* 1998). An emerging picture of glucocorticoid-induced stimulation of osteoprogenitor cell recruitment, self-renewal, and differentiation (Aubin and Liu, 1996) opposed by the glucocorticoid-induced inhibition of several molecules synthesized by the mature osteoblast (Lukert and Kream, 1996) and a glucocorticoid-induced increase in osteoblast apoptosis (Weinstein *et al.,* 1998) may account for some of the discrepancy.

An area of considerable interest is the stimulatory activity of glucocorticoids on osteoprogenitors (see also Aubin, 1998). One mechanism by which dexamethasone or other glucocorticoids may act is through autocrine or paracrine regulatory feedback loops in which the production of other factors is modulated, including growth factors and cytokines that themselves regulate the differentiation pathway. For example, in rat calvaria cultures, glucocorticoids downregulate the endogenous production of LIF, which is known to be inhibitory to bone nodule formation when cells are treated at a late progenitor/preosteoblast stage (Malaval *et al.,* 1998), and upregulate BMP-6, which is stimulatory possibly through LMP-1, a LIM domain protein (Boden *et al.,* 1998). These are but two of a growing list of examples of dexamethasone regulation of endogenously produced factors with apparently autocrine or paracrine activities on osteoblast lineage cells.

Many factors of interest have effects on gene expression in mature osteoblasts that may correlate with effects on the differentiation process and may be opposite for different osteoblast genes, with glucocorticoids being a case in point. The molecular mechanisms mediating these complex effects are generally poorly understood; however, the ability to form particular transcription factor complexes, localization and levels of endogenous expression of cytokine/hormone/growth factor receptors, and expression of cognate or other regulatory ligands within specific subgroups of osteogenic cells as they progress from a less to a more differentiated state may all play roles. As mentioned earlier, growing evidence shows that the probabilities for self-renewal versus differentiation of hemopoietic stem cells is regulated, at least in part, by the maintenance of required/critical signaling ligands (soluble or matrix or cell-bound) above a threshold level. While there are few explicit data or experiments examining these issues in MSCs or osteoprogenitor populations, it seems likely that similar threshold controls may apply.

Stem Cell/Osteoprogenitor Cell Changes in Disease and Aging

As described previously, the formation of colonies (CFU-F, CFU-O, etc) may give some index of the stem/progenitor cell status of an individual or a tissue site. This colony-counting method was used, together with expression of ALP as an osteogenic marker, in a large study of 99 patients, with an age range from 14 to 97 years who were osteoarthritic, osteoporotic, or showed no evidence of metabolic bone disease (Oreffo *et al.,* 1998a,b). No evidence was found that CFU-F decreased significantly with age or disease in either the total populations or in males or females, but colony size decreased in control, osteoporotic, and osteoarthritic patients with age. Other reports document a decline in total CFU-F in patient groups, but these involve lower sample populations. However, the fact that discrepant results in CFU-F, CFU-O, and CFU-ALP size and number have also been reported in studies done on populations isolated from mice and rats (Bergman *et al.,* 1996; Brockbank *et al.,* 1983; Egrise *et al.,* 1996; Gazit *et al.,* 1998; Schmidt *et al.,* 1987) suggests that many of the issues affecting colony assays *in vitro* remain to be elucidated. Nevertheless, the new results on human cells are interesting because, in osteoporotics, not only was colony size reduced but the number of ALP-positive colonies was also reduced compared to controls. A similar conclusion regarding osteoprogenitor cell number was made by Nishida *et al.* (1999) by studying human CFU-Fs harvested from iliac bone marrow of 49 females aged 4 to 88 years. Numbers of CFU-ALP fell markedly after 10 years of age with a gradual decline with increasing age. This decline is also seen in bone progenitors isolated from human vertebrae (D'Ippolito *et al.,* 1999).

The responsiveness of CFU-F to systemic or locally released osteotropic growth factors has also been reported to decrease with age as suggested earlier (Pfeilschifter *et al.,* 1993). For example, the stimulatory effect of TGFβ on colony number and cells per colony in human osteoprogenitor cells derived from 98 iliac crest biopsies declined significantly with donor age (Erdmann *et al.,* 1999). In BALB/c mice, Gazit, *et al.* (1998) suggested that changes in the osteoprogenitor cell/CFU-F compartment occur with aging because of a reduction in the amount and/or activity of TGFβ1. Ligand concentration-dependent ERα induction and loss of receptor regulation and diminution of ligand–receptor signal transduction with increasing donor age have also been reported (Ankrom *et al.,* 1998). In other studies, PGE_2 was found to exert stimulatory and inhibitory effects on osteoblast differentiation and bone nodule formation through the EP1/IP3 and EP2/EP4-cAMP pathways, respectively, in cells from young rats. However, the EP1/IP3 pathway was reported to be inactive in cells isolated from

aged rats (Fujieda *et al.,* 1999). Thus, the known loss of bone with aging or menopause may be due to a reduced responsiveness of osteoprogenitor cells to biological factors resulting in an alteration in their subsequent differentiation potentials or to local changes in these factors. This has fundamental and strategic implications regarding therapeutic intervention to prevent bone loss and to increase bone mass in postmenopausal women and in aging populations. It also opens up possibilities for experimental studies to test whether the necessary growth factors can be supplied to the deficient site by the transfer of marrow stroma from one bone tissue site to another or by genetically engineered autologous cell therapy.

Relatively little attention has been paid to the interesting issue of telomerase presence and activity and telomere length in osteoblast lineage cells at different developmental ages or differentiation stages. However, in one study, telomere length was compared in cultured human trabecular osteoblasts undergoing cellular aging and in peripheral blood leukocytes (PBL) obtained from women in three different groups [young (aged 20–26 years, $n = 15$), elderly (aged 48–85 years, $n = 15$), and osteoporotic (aged 52–81 years, $n = 14$)] (Kveiborg *et al.,* 1999). Telomere shortening was observed with population doubling increases similar to what has been reported in human fibroblasts, but data from osteoporotic patients and age-matched controls did not support the notion of the occurrence of a generalized premature cellular aging in osteoporotic patients.

Tissue Engineering and Stem Cell Therapy for Skeletal Diseases

There has been enormous interest in the potential of stem cells for therapy in many degenerative disorders of metabolic, environmental, and genetic origins. In particular, the potential for using embryonic stem cells to generate multiple cell types for use in tissue regeneration and repair is receiving much attention (Colman and Kind, 2000). Therapeutic possibilities for use of these and other postnatal, tissue-derived stem cells are apparent for many tissues and organs, not only skeletal tissues (Bach *et al.,* 2000; McCarthy, 2000; Service, 2000). The explosion of interest is documented by the rapid rise in research publications in this area, and MSCs have been noted to have potentials far beyond skeletal reconstruction and augmentation of skeletal mass.

The field of tissue engineering, which combines biomaterials and cell and developmental biology, is a rapidly expanding, new research area of increasing importance. Its main focus is the synthesis of tissues or artificial constructs based on living cells and cell matrix (Caplan, 2000; Reddi, 2000). It is expected that practically all tissues will be capable of being repaired by tissue-engineering principles. Basic requirements are thought to include a scaffold conducive to cell attachment and maintenance of cell function, together with a rich source of progenitor cells. In the latter respect, bone is a special case and there is a vast potential for regeneration from cells with stem cell characteristics (Triffitt, 1996). About 60% of single CFU-F colony-derived marrow stromal cell strains from human donors have been shown to form bone in a model system *in vivo*, although strains differ from each other in osteogenic capacity (Kuznetsov *et al.,* 1997b). It is likely that a lower proportion of these colonies have stem cell characteristics as found by Friedenstein (1990) in other species and predicted based on the observed heterogeneity of individual CFU-F in various assays [e.g., expression of ALP (Herbertson and Aubin, 1997)] or multilineage potential (Pittenger *et al.,* 1999)].

Consistent with data from earlier studies on clonal cell lines (summarized in Aubin, 1998), the development of osteoblasts, chondroblasts, adipoblasts, myoblasts, and fibroblasts results from marrow stromal colonies derived from single cells (Bianco *et al.,* 1999; Krebsbach *et al.,* 1999; Park *et al.,* 1999; Pittenger *et al.,* 1999, 2000; Robey, 2000; Triffitt *et al.,* 1998). They may thus theoretically be useful for the regeneration of all tissues that this variety of cells comprise: bone, cartilage, fat, muscle, and tendons and ligaments. Indeed, as summarized earlier, the recent discoveries of transcription factors such as Cbfa1 and "master genes", which govern tissue development, offer potentials for further tissue engineering involving genetic manipulation that would open additional avenues for skeletal therapy (Nuttall and Gimble, 2000). Fibroblasts with proliferative activity are also present in blood and are inducible with respect to bone formation (Luria *et al.,* 1971), but their origins and relationships to repopulation of skeletal sites are unknown. The hypothesis that osteoprogenitors may circulate systemically and be recruited to bone-forming sites in specific conditions will undoubtedly be tested by numerous laboratories in the near future.

As life expectancy increases, so does the incidence of skeletal diseases such as osteoporosis and osteoarthritis and the resultant requirements for new and more adequate methods of replacing skeletal mass and refurbishing bone and joint structures (Oreffo and Triffitt, 1999). In addition, a number of other genetic and metabolic conditions affecting the skeletal tissues of younger individuals requires even more effective replacement of missing or damaged tissues. Rare genetic conditions such as osteogenesis imperfecta (OI) produce life-long crippling in some patients, and treatment of the skeletal defect is dependent on strengthening and correction by mechanical orthopedic procedures. Any future advances in strengthening the skeleton by other methods in this condition would provide significant improvements in prognosis.

Somatic Cell and Gene Therapy

Relevant to tissue reconstruction is the field of genetic engineering, which as a principal step in gene therapy would be the introduction of a cloned functional specific human DNA into the cells of a patient with a genetic dis-

ease that affects mainly a particular tissue or organ. Such a situation might be OI, for example, where the skeleton is affected with a severity from gross to mild. In certain patients with OI, null allelic mutations result in a 50% reduction in collagen and a mild phenotype (Prockop, 1997). Bone marrow fibroblastic cells could be removed from an affected patient, amplified in culture, genetically manipulated to replace the null allele, and reinserted into the affected individual. Even in severely affected individuals, any improvements in long bone quality would be beneficial to the patient. To this end, even cell culture-expanded allogeneic but tissue-matched normal marrow may be sufficient to effect adequate recovery at particular sites. Unfortunately, no evidence of benefit to OI patients of allogeneic stromal fibroblasts has been demonstrated conclusively to date (Horwitz *et al.,* 1999). Other experimental approaches should be tested thoroughly by investigations of replacement by human marked cells systemically or in intramedullary sites in immunodeficient animals initially before any application to possible human therapy.

Retroviral-mediated gene transfer is not only potentially of value for the correction of defective genes but also for the study of progenitor cell fate. This has been shown to be a reproducible method for infecting large numbers of primitive osteoprogenitors at high efficiency. The Moloney-derived retrovirus containing both LacZ and NeoR genes has been used to transduce human and murine bone marrow stromal cells and the stromal cell phenotype and function not observed to be significantly altered after retroviral-mediated transfer of these marker genes (Bulabois *et al.,* 1998).

With a triple transfection method, a reporter gene (*lacZ*) and a selective marker gene (neo^r) have been transfected retrovirally into the genomes of human bone marrow fibroblasts, and stable persistence of these markers has been shown for at least 8 months in culture (Oreffo, 2001). Such work enables a combination of *in vivo* animal experimentation with human cell populations, as well as with cells from experimental animals, that are marked routinely by these and other marker genes to assess in detail their differentiation into tissues and their extended interactions *in vivo* with other cell systems. It also allows more detailed experimentation on the fate of such marked osteoprogenitor cells from human and experimental animal origins.

Generally, studies on marrow transplants in humans and mice for hematological reconstitutions have concluded that the only donor cells surviving are hemopoietic, with the stromal fibroblasts being of host origin. The concept that marrow fibroblasts never repopulate in radiochimeras or home to the marrow site is rejected by recent experiments, however. A number of reports indicate that donor marrow fibroblasts persist in a variety of tissues following their systemic infusion when assessed by sensitive methods of detection. For example, Pereira *et al*. (1995) showed that 1–5 months after intravenous transplantation into irradiated mice of mouse bone marrow stromal cells enriched by adherence to plastic, expanded in culture, and marked with the human COL1A1 minigene, there was a widespread tissue distribution of connective tissue cells containing and expressing the gene. Among tissues, such as brain, spleen, marrow, and lung, bone also expressed the minigene as detected by PCR. In a very different approach (Nilsson *et al.,* 1999), whole unfractionated uncultured male mouse bone marrow was transplanted intravenously into nonablated female mice. Significant numbers of donor cells were detected by fluorescence *in situ* hybridization (FISH) in whole femoral sections, as both osteocytes encapsulated by mineralized matrix and residing within the bone lacunae and as flattened bone-lining cells in the periosteum, suggesting that donor cells may participate in normal biological turnover (Prockop, 1998). Data support the hypothesis proposed by Horwitz *et al*. (1999) that whole marrow contains enough of these cells to be able to replace sufficient osteoblasts to be clinically useful in diseases such as OI, where marrow ablation is standard preparative treatment. A cloned pluripotent cell line from mouse bone marrow stroma labeled with a genetic marker was traced by fluorescence activated cell sorting (FACS) analysis upon systemic injection into syngeneic mice (Dahir *et al.,* 2000). This manipulation did not affect obviously subsequent differentiation of the cells, the osteogenic characteristics of the cell line were retained in diffusion chamber implantations, and the genetically marked cells were shown to repopulate the marrow in syngeneic animals. It is concluded that differences in views of the transplantability of stromal fibroblastic cells may be explained by the different cell populations and the amounts administered. It could also be dependent on the method of administration and whether and how the medullary site is prepared and these possibilities should be considered.

The potential for therapy in other stromal systems may also be considered feasible as Ferrari *et al*. (1998) have demonstrated that genetically marked bone marrow-derived myogenic progenitors transplanted into immunodeficient mice migrated into areas of induced muscle damage, were able to undergo myogenic differentiation, and contributed, albeit minimally, to muscle regeneration. Genetically modified, marrow-derived myogenic progenitors could thus potentially target therapeutic genes to muscle tissue and provide alternative strategies for the treatment of muscular dystrophies.

A number of species were used to investigate the efficiency of transduction by a variety of viral vectors by Mosca *et al*. (2000). Optimal transduction for human, baboon, canine, and rat MSCs was a effected with amphotropic vectors. However, sheep, goat, and pig MSCs were transduced most effectively by xenotropic retroviral vectors, with rabbit cells requiring gibbon ape-enveloped vectors for best transduction. These authors used a myeloablative canine transplantation model with gene-marked canine mesenchymal stem cells to determine the physiological fate of infused cells. Most marked cells were found in the bone marrow samples.

For xenogeneic implantation of human cells, more strains of immunocompromised mice are now readily available and

their use has revolutionized the possibilities for investigations of human cells in a variety of physiological and regeneration schemes. Severe combined immunodeficient (SCID) mice and a variety of related strains (e.g., SCID/NOD) have been used extensively in studies on development in many xenogeneic and allogeneic cell systems and the persistence and tissue distribution patterns of injected cells determined. Marrow cells and, in a few cases, skeletal cells (Boynton *et al.,* 1996) have been shown to persist and differentiate in these systems. In the hemopoietic field the use of marrow stromal cells has been suggested as a vehicle for cell-mediated gene transfer to replace defective hemopoietic growth factors and deliver the gene product *in situ* to the marrow microenvironment. This also has relevance to the skeletal field particularly as studies (Oreffo, *et al.,* 1998a,b) strongly suggest that local tissue environmental factors rather than decreased stem cell number are basic contributory causes of age and osteoporosis defects in human skeletal quality. In the future, specific gene therapy may be relevant and necessary in certain cases to correct these defects. Model studies on direct cell implantations in animals, however, require assessments of origins of the implanted cells by species-specific antibody methods or by *in situ* hybridization with species-specific nucleic acid probes unless the implanted cells are marked genetically with a distinctive, easily detected marker. The acceptance of these xenografted cells opens new avenues for investigation of how human cells react in neophysiological situations and is an important area of future research, which will extend possibilities for clinical application of basic work on osteogenesis. Requirements for the future include the necessity to show functional relevance of the cells localized in the tissue after injection locally or systemically, and the participation in significant tissue reconstruction. The reticuloendothelial system has long been known to accumulate nonphysiological moieties or "undesirable material" present in the systemic circulation, and the leaky sinusoids of marrow are known to be prime sites for such interactions (Ham, 1969). Even if the "homing" of living cells to marrow in this context is a "nonphysiological" event, some benefit to skeletal reconstruction directly or by expression of growth factors may still be possible.

Acknowledgments

The authors thank many members of their laboratories and other colleagues for valuable input and discussions over many years. This work is supported by CIHR Grant MT-12390 to JEA.

CHAPTER 5

Transcriptional Control of Osteoblast Differentiation and Function

Thorsten Schinke and Gerard Karsenty
Baylor College of Medicine, Houston, Texas 77030

The study of most cellular differentiation processes, such as myogenesis, hematopoiesis, neurogenesis, and adipogenesis, has demonstrated the importance of transcription factors in controlling cell-specific differentiation and gene expression (Arnold and Winter, 1998; Engel and Murre, 1999; Bang and Goulding, 1996; Wu *et al.,* 1999). Compared to other cell lineages, the study of the transcriptional control of osteoblast differentiation has progressed slowly for several reasons. At first, unlike other cell types, osteoblasts in culture do not undergo obvious morphological changes during differentiation that could be used to monitor gene expression. The only morphological feature that distinguishes an osteoblast from a fibroblast lies outside the cell. It is the accumulation of a mineralized matrix, by a process that is still poorly understood and that requires several weeks in culture (Aubin, 1998). Moreover, for a long time, *Osteocalcin* was the only known osteoblast-specific gene whose promoter could serve as a tool to identify osteoblast-specific transcription factors. *Osteocalcin* is expressed late during osteoblast differentiation, thus making it difficult to identify transcription factors acting at earlier stages. The apparent lack of osteoblast-specific markers and morphological features explains why the study of the transcriptional control of osteoblast differentiation has been rather difficult in the past. However, after the identification of Cbfa1 as a lineage-specific transcriptional activator of osteoblast differentiation and with the availability of human and mouse genetics as an experimental tool, we are now beginning to get more insights into this important area of skeletal biology.

Cbfa1: A Master Control Gene of Osteoblast Differentiation and Function

To date, only one transcription factor has been identified that is specifically expressed in cells of the osteoblast lineage, Cbfa1 (core binding factor 1). *Cbfa1* was originally cloned in 1993 as the α subunit of the polyomavirus enhancer binding protein 2 (Ogawa *et al.,* 1993). It represents one of three mammalian homologues (*Cbfa1-3*) of the *Drosophila* transcription factor runt that is required for embryonic segmentation and neurogenesis (Kagoshima *et al.,* 1993). The name given to this gene has changed several times since it was isolated. It was first called *Pebp2a1*, then *Aml3*, and later *Cbfa1* or *Runx2*. For the sake of clarity, we will refer to it as *Cbfa1* in this chapter. Initially, *Cbfa1* was thought to be important for T-cell-specific gene expression as it was found to be expressed in thymus and T-cell lines, albeit at very low levels, but not in B-cell lines (Ogawa *et al.,* 1993; Satake *et al.,* 1995). However, 4 years after the initial cloning of *Cbfa1*, its crucial importance as a transcriptional activator of osteoblast differentiation was demonstrated by several investigators at the same time using different experimental approaches (Ducy *et al.,* 1997; Komori *et al.,* 1997; Otto *et al.,* 1997; Mundlos *et al.,* 1997).

One approach was aiming at the identification of osteoblast-specific transcription factors using the *Osteocalcin* gene as a tool. The analysis of a proximal promoter

fragment of one of the two mouse *Osteocalcin* genes led to the definition of two osteoblast-specific *cis*-acting elements, termed OSE1 and OSE2 (Ducy *et al.,* 1997). Sequence inspection of OSE2 revealed homology to the DNA-binding site of runt family transcription factors, and subsequent analysis demonstrated that the factor binding to OSE2 is related immunologically to Cbfa transcription factors (Geoffroy *et al.,* 1995; Merriman *et al.,* 1995). Eventually, the screening of a mouse primary osteoblast cDNA library revealed that only one of the three mammalian *Cbfa* genes, *Cbfa1*, is expressed in cells of the osteoblast lineage, but not in any other cell types or tissues (Ducy *et al.,* 1997). As such, Cbfa1 is the earliest and most specific marker of osteogenesis identified to date.

During mouse development, *Cbfa1* is first expressed in the lateral plate mesoderm at 10.5 dpc, and later in cells of the mesenchymal condensations. Until 12.5 dpc these cells that prefigure the future skeleton represent common precursors of osteoblasts and chondrocytes. At 14.5 dpc osteoblasts first appear and maintain the expression of *Cbfa1*, whereas in chondrocytes, *Cbfa1* expression is decreased significantly and restricted to prehypertrophic and hypertrophic chondrocytes. After birth, *Cbfa1* expression is strictly restricted to osteoblasts. Taken together, this spatial and temporal expression pattern suggested a critical role for Cbfa1 as a regulator of osteoblast differentiation and function. Such a role was demonstrated by molecular biology and genetic experiments.

First, in addition to the *Osteocalcin* promoter, functional OSE2-like elements were identified in the promoter regions of all genes that are expressed at relatively high levels in osteoblasts such as *α1(I) collagen*, *Osteopontin*, and *Bone sialoprotein* (Ducy *et al.,* 1997). Second, and more importantly, the forced expression of *Cbfa1* in nonosteoblastic cell lines such as C3H10T1/2 mesenchymal cells, primary skin fibroblasts, and even myoblasts induced osteoblast-specific gene expression in these cells, demonstrating that Cbfa1 acts as a transcriptional activator of osteoblast differentiation *in vitro* (Ducy *et al.,* 1997). The ultimate demonstration that Cbfa1 is an indispensable transcriptional activator of osteoblast differentiation came from genetic studies in mice and humans. At the same time, two groups deleted the *Cbfa1* gene from the mouse genome, both expecting an immunological phenotype based on the assumption that *Cbfa1* was a T-cell-specific transcription factor (Komori *et al.,* 1997; Otto *et al.,* 1997). *Cbfa1*-deficient mice die shortly after birth without any detectable immunological defects. Instead, the cause of death is the lack of both endochondral and intramembranous bone formation. The complete absence of bone in *Cbfa1*-deficient mice is a consequence of the maturational arrest in osteoblast differentiation. This was confirmed by *in situ* hybridization analysis showing the absence of osteoblastic markers such as *Osteocalcin* and *Osteopontin* (Komori *et al.,* 1997). Thus, although the skeleton of *Cbfa1*-deficient mice is of normal size and shape, it is entirely cartilaginous. This latter result indicates that *Cbfa1* expression is necessary for osteoblast differentiation.

A more detailed analysis of *Cbfa1*-deficient mice has revealed that some skeletal elements, such as humerus and femur, lack hypertrophic chondrocytes (Inada *et al.,* 1999; Kim *et al.,* 1999), suggesting that Cbfa1 is also required for hypertrophic chondrocyte differentiation, at least in some skeletal elements (Inada *et al.,* 1999; Kim *et al.,* 1999). Such a function was further substantiated by the generation of *Cbfa1*-deficient mice expressing *Cbfa1* in nonhypertrophic chondrocytes under the control of the *α1(II)-collagen* promoter (Takeda *et al.,* 2001). The continuous expression of *Cbfa1* in nonhypertrophic chondrocytes in transgenic *Cbfa1*+/+ mice induces chondrocyte hypertrophy and endochondral ossification in locations where it normally never occurs. This result, consistent with the osteoblast differentiation ability of Cbfa1 indicates that *Cbfa1* expression is sufficient to induce endochondral bone formation ectopically. To test whether Cbfa1 is also a hypertrophic differentation factor, in addition to being an osteoblast differentation factor, these transgenic mice were crossed with *Cbfa1*-deficient mice. The presence of the *α1(II)-Cbfa1* transgene in a *Cbfa1*-deficient background restores chondrocyte hypertrophy and vascular invasion, but does not induce osteoblast differentiation. This latter observation identifies Cbfa1 as a hypertrophic chondrocyte differentiation factor and provides a genetic argument for a common regulation of osteoblast and chondrocyte differentiation mediated, at least in part, by Cbfa1.

The critical importance of Cbfa1 during osteoblast differentiation is demonstrated further by the fact that mice heterozygous for *Cbfa1* display defects in osteoblast, but not in chondrocyte differentiation. *Cbfa1*+/− mice are characterized by hypoplastic clavicles and a delay in the suture of fontanelles, indicating that the dosage of Cbfa1 is critical for osteoblast differentiation in bone structures formed by intramembranous ossification (Otto *et al.,* 1997). The phenotype of *Cbfa1*+/− mice is identical to a classical mouse mutation called *Cleidocranial dysplasia* (*Ccd*) (Selby and Selby, 1978). *Cbfa1* maps to a region on mouse chromosome 17 that is partially deleted in *Ccd* mice (Otto *et al.,* 1997), and two groups at the same time identified mutations of the human *CBFA1* gene in the genome of patients affected with CCD (Lee *et al.,* 1997; Mundlos *et al.,* 1997). Taken together, these lines of evidence demonstrate that Cbfa1 is necessary for osteoblast differentiation *in vivo*, although it remains to be determined if it is by itself sufficient for osteoblast differentiation.

The role of Cbfa1 in osteoblast biology is not limited to osteoblast differentiation. *Cbfa1* expression in osteoblasts is maintained after birth, and the expression of *Osteocalcin*, for instance, a gene only expressed in fully differentiated osteoblasts, is controlled by Cbfa1. This suggested a function for Cbfa1 beyond cellular differentiation. Such a function was confirmed by the generation of transgenic mice expressing a dominant-negative variant of *Cbfa1* (ΔCbfa1) under the control of an *Osteocalcin* promoter fragment (Ducy *et al.,* 1999). This promoter fragment is only active in fully differentiated osteoblasts and only after birth, resembling the specific temporal and spatial expression pat-

tern of the *Osteocalcin* gene. Accordingly, these transgenic mice are born alive because osteoblast differentiation is not affected. However, once the *Osteocalcin* promoter becomes fully active and ΔCbfa1 is expressed, these mice develop an osteoporosis-like phenotype characterized by a decreased bone formation rate, with a normal osteoblast number (Ducy *et al.,* 1999). This phenotype is explained by the fact that the expression of genes encoding bone extracellular matrix proteins, such as *type I collagen*, *Osteocalcin, Bone sialoprotein* and *Osteopontin* is decreased significantly. These findings demonstrate that Cbfa1 not only controls the differentiation of osteoblasts, but is also a regulator of their function, i.e., the production of the bone extracellular matrix.

After the discovery of Cbfa1 as a transcriptional activator of osteoblast differentiation and function, many studies have been performed in several laboratories that further underscored the importance of Cbfa1 in osteoblasts. For example, Cbfa1-binding sites could now be identified in a large number of genes that are expressed in osteoblasts such as *Collagenase 3, TGFβ-type I receptor*, and *RANKL/ODF* (Jimenez *et al.,* 1999; Ji *et al.,* 1998; Kitazawa *et al.,* 1999). Moreover, the identification of Cbfa1 has provided a handle to search for other factors playing a role in osteoblast differentiation. There are especially two equally important future research approaches. (1) the biochemical characterization of Cbfa1 in order to understand the molecular basis of its action and (2) the identification of molecules that regulate the spatial and temporal expression pattern and the level of expression of *Cbfa1*. Both issues are of paramount importance because a positive regulation of Cbfa1 expression or function is likely to be beneficial in bone loss diseases such as osteoporosis.

Like all transcription factors belonging to the Runt family, Cbfa1 contains a DNA-binding region of 128 amino acids, called the runt domain, followed C-terminally by a proline–serine–threonine-rich region, called the PST domain. The PST domain contributes to the transactivation function of Cbfa1 and contains a short sequence at the C terminus that mediates transcriptional repression through interactions with TLE2, a mammalian homologue of the *Drosophila* transcriptional repressor Groucho (Aronson *et al.,* 1997; Thirunavukkarasu *et al.,* 1998). In contrast to other Runt proteins, Cbfa1 has two unique domains located at the N terminus that are also involved in activating transcription. One of them, the so-called QA domain, which is rich in glutamine and alanine, prevents heterodimerization of Cbfa1 with Cbfβ, a known partner of other Runt family transcription factors (Wang *et al.,* 1993; Thirunavukkarasu *et al.,* 1998). Cbfa1 has been shown to be phosphorylated by PKA and MAPK *in vitro* (Selvamurugan *et al.,* 2000; Xiao *et al.,* 2000). Furthermore, physical interactions of Cbfa1 with Smad proteins and with the bHLH protein HES-1 have been shown to modulate Cbfa1 function *in vitro* (Hanai *et al.,* 1999; McLarren *et al.,* 2000). It is likely that the coming years will provide more detailed insights into the signaling pathways controlling Cbfa1 function in osteoblasts. Potentially, this area of research could lead to the identification of compounds that specifically regulate Cbfa1 activity and that may be useful in future therapeutic approaches to treat degenerative bone diseases.

Transcriptional Regulation of *Cbfa1* Expression and the Role of Homeodomain Proteins

The importance of understanding the molecular mechanisms controlling the rate of *Cbfa1* expression in osteoblasts is obvious, as haploinsufficiency at the *Cbfa1* locus leads to severe skeletal dysplasia. Thus, it is conceivable that a moderate increase in the level of Cbfa1 may lead to increased bone formation by activating either, osteoblast differentiation or function. However, given the size and the complex organization of the *Cbfa1* gene (Geoffroy *et al.,* 1998), progress in understanding the regulation of *Cbfa1* expression has been rather slow so far.

One important regulator of *Cbfa1* expression is Cbfa1 itself. Three OSE2-like elements are present in the mouse *Cbfa1* gene, one of them located in the proximal promoter, the others 3′ from the transcriptional start site (Ducy *et al.,* 1999). These elements are high-affinity-binding sites for Cbfa1 and activate transcription *in vitro* in a Cbfa1-dependent manner. The fact that Cbfa1 activates its own expression *in vivo* is clearly demonstrated by the finding that its expression is nearly abolished in transgenic mice expressing a dominant-negative variant of *Cbfa1* in osteoblasts (Ducy *et al.,* 1999). This suggests that once *Cbfa1* expression is turned on in osteoprogenitor cells, it is enhanced by an autoregulatory feedback loop and is maintained during the course of differentiation and thereafter. Thus, the nature of the molecules that are initially activating *Cbfa1* expression becomes even more important. Recently described mouse genetic experiments have given some initial answers to this question. They have shown that certain homeodomain transcription factors are involved in controlling *Cbfa1* expression in specific skeletal elements.

Msx1 and *Msx2* are two mammalian homologues of the *Drosophila* muscle segment homeobox gene *(msh)*. Both factors have been suggested to play roles in osteoblast differentiation, as binding sites were found in the *Osteocalcin* promoters of mouse and rat (Towler *et al.,* 1994; Hoffmann *et al.,* 1994). Msx2 especially gained further attention because it was found to act as a transcriptional repressor of osteoblast-specific gene expression *in vitro* (Towler *et al.,* 1994; Dodig *et al.,* 1999). Several genetic experiments have helped to understand the role of Msx2 as a regulator of osteoblast differentiation *in vivo*. Transgenic mice overexpressing *Msx2* under the control of its own promoter are characterized by enhanced calvarial bone growth resulting from an increased number of 5′-bromo-2′-deoxyuridine (BrdU)-positive osteoblastic cells at the osteogenic fronts (Liu *et al.,* 1999). Likewise, a gain-of-function mutation of *MSX2* in humans causes Boston-type craniosystosis (Jabs *et al.,* 1993). In contrast, *Msx2*-deficient mice display

a defective ossification of the skull resulting from decreased proliferation of osteoblast progenitor cells (Satokata *et al.,* 2000). A similar defect is observed in the skull of patients affected with enlarged parietal foramina, a disease caused by a loss-of-function mutation of *MSX2* (Wilke *et al.,* 2000). Taken together, these data demonstrate that Msx2 is an important regulator of craniofacial bone development and that it acts by maintaining osteoblast precursors in a proliferative stage through inhibition of their terminal differentiation. *Msx2*-deficient mice also display defects in endochondral bone formation. In the tibia and the femur of these mice the numbers of osteoblasts are reduced, thus leading to a decrease in trabecular and cortical thickness. The expression of *Osteocalcin* and *Cbfa1* is strongly reduced in *Msx2*-deficient mice. This suggests that Msx2 is required for osteoblast differentiation in endochondral bones and is a positive regulator of *Cbfa1* expression *in vivo*.

The fact that the expression patterns of *Msx1* and *Msx2* are partially overlapping during craniofacial development suggested a functional redundancy between these two related transcription factors. This has been demonstrated by the generation of mice lacking both *Msx1* and *Msx2*. In these double mutant mice, calvarial ossification is completely absent, leading to perinatal lethality (Satokata *et al.,* 2000). This finding underscores the critical importance of Msx proteins for craniofacial bone formation. However, their relationship to *Cbfa1* expression in both intramembranous and endochondral ossification needs to be investigated further.

Dlx5, a homologue of Distal-less (Dll) in *Drosophila,* is another homeodomain transcription factor that has been suggested to play a role in osteoblast differentiation based on its upregulation in mineralizing calvarial cultures (Ryoo *et al.,* 1997). Transfection of an osteoblastic cell line with a *Dlx5* expression vector results in an increased production of Osteocalcin and in accelerated maturation of a mineralized matrix (Miyama *et al.,* 1999). Importantly, *Cbfa1* expression is not affected in these experiments, suggesting that Dlx5 does not act upstream of Cbfa1 to promote osteoblast differentiation *in vitro* (Miyama *et al.,* 1999). *In vivo, Dlx5* is expressed early during skeletal development in the cranial neural crest and the developing limbs (Simeone *et al.,* 1994; Depew *et al.,* 1999). In adult mice, *Dlx5* expression is detectable in brain, long bones, and calvaria, but not in several other tissues (Ryoo *et al.,* 1997, Miyama *et al.,* 1999). *Dlx5*-deficient mice have been generated (Acampora *et al.,* 1999; Depew *et al.,* 1999). These mice die shortly after birth due to severe defects in craniofacial development. Most of the cranial bones and teeth in *Dlx5*-deficient mice are dysmorphic. It is not clear yet if these abnormalities are the result of patterning defects or if they are a direct consequence of impaired osteoblast differentiation. In contrast, no overt defects are observed in limbs and other appendages. However, upon closer examination Acampora *et al*. (1999) found a mild increase in Osteocalcin-positive periostal cells in femurs of newborn *Dlx5*-deficient mice. This indicates that in long bones, Dlx5 may act as a repressor of *Osteocalcin* expression and possibly osteoblast differentiation. Importantly, *Cbfa1* expression is not affected in *Dlx5*-deficient mice, suggesting that Dlx5 uses a Cbfa1-independent pathway to regulate osteoblast differentiation (Acampora *et al.,* 1999).

The severity of phenotype of *Dlx5*-deficient mice, especially in endochondral bones, may be blunted by a functional redundancy with *Dlx6,* another *Dll*-related gene that is coexpressed with *Dlx5* in developing skeletal structures (Simeone *et al.,* 1994). Thus, the generation of *Dlx5/Dlx6* double mutants may be required to fully uncover the role of Dlx proteins in osteoblast differentiation. One interesting aspect of the *in vitro* experiments is that Dlx5 induces *Osteocalcin* expression in the calvaria-derived cell line MC3T3-E1 (Miyama *et al.,* 1999), whereas it leads to decreased *Osteocalcin* expression in the long bone-derived osteosarcoma cell line ROS 17/2.8 (Ryoo *et al.,* 1997). These findings are in fact consistent with the phenotype of *Dlx5*-deficient mice. They suggest that the role of Dlx5 in osteoblast differentiation may differ in the two types of ossification. The same may be the case for Msx2 where the defects in calvaria and long bones could be caused by different mechanisms.

Another homeodomain protein controlling *Cbfa1* expression at an early stage of osteoblast differentiation is Bapx1, a homologue of the *Drosophila* transcription factor bagpipe. *Bapx1* is expressed early in development in the sclerotome of the somites and later in the cartilaginous condensations prefiguring the future skeleton (Tribioli *et al.,* 1997). *Bapx1*-deficient mice die at birth and display a severe dysplasia of the axial skeleton characterized by malformations or absence of specific skeletal elements in the vertebral column and craniofacial structures. In contrast, the appendicular skeleton is not affected (Tribioli and Lufkin, 1999; Lettice *et al.,* 1999). This phenotype is a consequence of impaired cartilage formation because several markers of chondrocyte differentiation, such as *α1(II) Collagen*, *Indian hedgehog*, and *Sox9* are downregulated in *Bapx1*-deficient mice (Tribioli and Lufkin, 1999). In wild-type mice, *Cbfa1* is coexpressed with these chondrocytic markers at 12.5 dpc in common mesenchymal precursor cells of chondrocytes and osteoblasts. Accordingly, in *Bapx1*-deficient mice, *Cbfa1* is downregulated in these precursor cells (Tribioli and Lufkin, 1999). This indicates that at a very early stage of osteoblast differentiation, Bapx1 acts upstream of Cbfa1 in some skeletal elements. It remains to be determined if Bapx1 regulates *Cbfa1* expression in these elements directly or if this regulation is mediated through other genes downstream of *Bapx1*.

Hoxa-2 is a homeodomain transcription factor that prevents *Cbfa1* expression specifically in skeletal elements of the second branchial arch. This is demonstrated by the fact that *Cbfa1* is upregulated in this region of *Hoxa*-2-deficient mice, resulting in ectopic bone formation (Kanzler *et al.,* 1998). Additionally, transgenic mice expressing *Hoxa-2* in craniofacial bones under the control of the *Msx2* promoter

lack several bones in the craniofacial area, indicating that *Hoxa-2* acts as an inhibitor of intramembranous bone formation (Kanzler *et al.,* 1998). Thus, Hoxa-2 inhibits ectopic bone formation in the second branchial arch by downregulating, directly or indirectly, the expression of *Cbfa1* in this region.

Taken together, these results suggest that in contrast to *Cbfa1,* a determining gene for osteoblast differentiation in all skeletal elements, transcription factors acting upstream of Cbfa1 may act only in specific areas of the skeleton. This is also the case for the growth factor Indian hedgehog required for *Cbfa1* expression and osteoblast differentiation only in bones formed by endochondral ossification (St-Jacques *et al.,* 1999). Although mouse genetic experiments have already revealed some genes that influence *Cbfa1* expression *in vivo,* in all cases molecular biology experiments are required to analyze how these effects are mediated. Additionally, the fact that Dlx5 has an influence on osteoblast differentiation without affecting *Cbfa1* expression suggests that parallel pathways may play a role in differentiation along the osteoblast lineage and may be specific for certain skeletal elements. Thus, the next section focuses on further transcription factors that possibly have important functions during osteoblast differentiation, although their connection to Cbfa1 is still unknown.

Are There Additional Osteoblast-Specific Transcription Factors in Addition to Cbfa1?

Given what we have learned from the study of other cell lineages, where multiple transciption factors are required for differentiation, it is likely that other transcription factors that are specifically expressed in cells of the osteoblast lineage are required to activate osteoblast differentiation throughout the skeleton or in parts of the skeleton. Molecular biology and biochemical experiments have provided evidence for the existence of at least two additional osteoblast-specific transcription factors that remain to be identified.

As was the case for the identification of Cbfa1, one of these factors was initially discovered through the analysis of a short promoter fragment of the mouse *Osteocalcin* gene (Ducy and Karsenty, 1995). On addition to OSE2, the binding site of Cbfa1, this promoter fragment includes another osteoblast-specific *cis*-acting element, termed OSE1, that is equally important as OSE2 for *Osteocalcin* promoter activity *in vitro* and in transgenic mice (Schinke and Karsenty, 1999). Multimers of OSE1 confer osteoblast-specific activity to a heterologous promoter *in vitro*, and an osteoblast-specific nuclear factor, provisionally termed Osf1, binds to the OSE1 oligonucleotide in electrophoretic mobility shift assays (Ducy and Karsenty, 1995; Schinke and Karsenty, 1999). The identification of Osf1 is complicated by the fact that the OSE1 core sequence does not share obvious similarities to binding sites of known transcription factors, suggesting that Osf1 may be a novel protein. Interestingly, Osf1-binding activity declines during the differentiation of mouse primary osteoblasts, being absent in fully mineralized cultures, suggesting that Osf1 is a stage-specific transcription factor that may act early during osteoblast differentiation. The fact that a functional OSE1 site is present in the *Cbfa1* promoter raises the hypothesis that Osf1 may act upstream of Cbfa1 (Schinke and Karsenty, 1999). However, the question of where Osf1 resides in a genetic cascade controlling osteoblast-specific gene expression will need to be addressed once a cDNA becomes available.

Another osteoblast-specific *cis*-acting element has been identified in the promoter of the rat and mouse *pro-α1(I) collagen* genes (Dodig *et al.,* 1996; Rossert *et al.,* 1996). *α1(I) collagen* is not specifically expressed by osteoblasts, but it has been shown that separate *cis*-acting elements control its expression in different cell types (Pavlin *et al.,* 1992; Rossert *et al.,* 1995). After initially identifying a 2.3-kb *α1(I) collagen* promoter fragment that directs bone-specific expression of a reporter gene in transgenic mice, Rossert *et al*. (1996) further narrowed down the critical region to a 117-bp promoter fragment of the mouse *α1(I) collagen* gene. Multimers of this 117-bp fragment cloned upstream of a minimal *α1(I) collagen* promoter led to osteoblast-specific expression of a *lacZ* reporter gene in transgenic mice. An osteoblast-specific factor binds to a sequence within this element in electrophoretic mobility shift assays. Although this sequence is similar to binding sites of homeodomain transcription factors, the molecular nature of the osteoblast-specific factor binding to it is still unknown. At the same time, Dodig *et al*. (1996) described the presence of the same element in the rat *α1(I) collagen* promoter. The authors found that Msx2 can bind to this element in electrophoretic mobility shift assays. However, overexpression of *Msx2* in an osteoblastic cell line led to a reduction of *α1(I) collagen* expression, and the expression pattern of *Msx2* during the course of osteoblast differentiation did not correlate with the observed binding activity. In conclusion, this element may serve as a binding site for an osteoblast-specific transcription factor, also called bone-inducing factor, that remains to be identified. This factor may act at later stages during osteoblast differentiation as the binding activity is only observed in differentiated osteoblast cultures (Dodig *et al.,* 1996).

The Function of AP-1 Family Transcription Factors during Osteoblast Differentiation

Activator protein 1 (AP-1) is a dimeric complex of Fos and Jun proteins that belongs to the bZIP transcription factor family. Known members of the AP-1 family are c-Fos, FosB, and the Fos-related antigens Fra-1 and Fra-2 that heterodimerize with c-Jun, JunB, or JunD (Karin *et al.,* 1997). Several lines of evidence suggest that members of the AP-1 family are involved in the regulation of osteoblast

differentiation. First, functional AP-1-binding sites have been found in the promoter regions of several genes expressed in osteoblasts, including *alkaline phosphatase*, *α1(I) collagen*, and *Osteocalcin* (McCabe *et al.,* 1996). Second, a number of extracellular signaling molecules, such as TGF*β* and PTH, have been shown to induce the expression of AP-1 components in osteoblastic cells (Clohisy *et al.,* 1992; Lee *et al.,* 1994). Third, various members of the AP-1 family have been shown to be expressed in osteoblast cultures and can be detected at sites of active bone formation *in vivo* (Dony and Gruss, 1987). *In vitro*, most of these factors are expressed preferentially in the proliferative stage before the onset of osteoblast differentiation. The exception is Fra-2, which is expressed at later stages (McCabe *et al.,* 1996). The best argument for a role of AP-1 transcription factors in osteoblast differentiation comes from *in vivo* studies where it has been shown that certain AP-1 family members can affect osteoblast proliferation or differentiation, although the underlying mechanisms are not fully understood yet.

One AP-1 family member affecting osteoblast proliferation is c-Fos. The overexpression of *c-Fos* in transgenic mice under the control of the MHC class I H2-K^b promoter leads to osteosarcomas in all mice examined (Grigoriadis *et al.,* 1993). Such a phenotype is not observed in mice overexpressing *FosB* or *cJun*, thus indicating that the impairment of osteoblast proliferation is a specific property of c-Fos. This finding is consistent with the high level of *c-Fos* expression observed in murine und human osteosarcomas (Schon *et al.,* 1986; Wu *et al.,* 1990) and suggests that c-Fos is one regulator of osteoblast proliferation *in vivo*. However, the phenotype of *c-Fos*-deficient mice argues against such a function. These mice display a severe osteopetrosis due to a decreased differentiation of bone-resorbing osteoclasts (Johnson *et al.,* 1992; Wang *et al.,* 1992). Importantly, there are no defects of bone formation in *c-Fos*-/- mice, indicating that osteoblast proliferation and differentiation are not impaired. There are two possibilities to explain this discrepancy between the gain-of-function and the loss-of-function experiment. First, there could be functional redundancies, and other transcription factors belonging to the AP-1 family could fulfill the function of c-Fos in osteoblasts of *c-Fos*-/- mice. Second, the overexpression of *c-Fos* in transgenic mice could perturb the function of yet another unidentified bZIP transcription factor that would be required to regulate osteoblast proliferation in the physiological situation.

Two other AP-1 family members, both lacking a transcriptional activation domain, have been shown to affect the differentiation of osteoblasts *in vivo*. The expression of *Fra-1* in transgenic mice under the control of the MHC class I H2-K^b promoter leads to a severe osteosclerosis due to an increased number of osteoblasts (Jochum *et al.,* 2000). This phenotype is explained by a cell autonomous increase in osteoblast differentiation. Interestingly, *Cbfa1* expression is not altered in primary osteoblast cultures derived from these transgenic mice, although their differentiation is accelerated *ex vivo*. This suggests that the effect of Fra-1 on osteoblast differentiation is independent of the Cbfa1 pathway. This is confirmed by the fact that the overexpression of *Fra-1* on a *Cbfa1*+/− background leads to osteosclerosis without rescuing the CCD phenotype of the *Cbfa1*+/− mice (Jochum *et al.,* 2000). Fra-1 appears to be dispensable for osteoblast differentiation *in vivo*, as newborn *Fra-1*-/- mice derived by injecting *Fra-1*-/- embryonic stem cells into tetraploid wild-type blastocysts show no defects in osteoblastogenesis (Jochum *et al.,* 2000). However, this question will be better addressed by an osteoblast-specific deletion of *Fra-1*, and also of *c-Fos*. Interestingly, transgenic mice expressing Δ*FosB*, a splice variant of *FosB* lacking an apparent transactivation domain, display an osteosclerotic phenotype similar to the one observed in mice overexpressing *Fra-1* (Sabatakos *et al.,* 2000). The only difference between these two mouse models is the fact that the cell autonomous increase of osteoblast differentiation in *ΔFosB* transgenic mice is at the expense of adipogenesis that is reduced significantly in these mice. Again, inducing osteoblast differentiation does not seem to be a physiologic function of ΔFosB because *FosB*-/- mice have normal bone formation (Gruda *et al.,* 1996).

The fact that both Fra-1 and ΔFosB lack a major transcriptional activation domain (Metz *et al.,* 1994) is puzzling and led to the suggestion of two possible mechanisms to explain the osteosclerosis in both transgenic mouse models (Karsenty, 2000). The first possibility is that both factors heterodimerize with an activator of osteoblast differentiation to increase its DNA binding or transactivation ability. In contrast, both factors could heterodimerize with an inhibitor of osteoblast differentiation and therefore act by releasing a brake on osteoblast differentiation that might exist in the physiological situation. Taken together, all these lines of evidence strongly suggest that bZIP transcription factors play a critical role in osteoblast proliferation and differentiation. Although the evidence is only based on overexpression studies so far, c-Fos, Fra-1, and ΔFosB provide excellent handles to elucidate the molecular mechanisms underlying osteoblast differentiation in the normal situation.

Perspectives

Our knowledge about the transcriptional control of osteoblast differentiation and function was almost nonexistent until recently. This has now changed substantially due to the discovery of Cbfa1. There is little doubt that *Cbfa1* is a major player during osteoblast differentiation, although this does not rule out the possibility that other transcription factors may also play important regulatory roles. This premise is supported experimentally by the fact that other osteoblast-specific DNA-binding activities have been described, but also by the severe bone phenotypes of mice overexpressing certain AP-1 transcription factors. The identification of further osteoblast-specific transcription

factors and the elucidation of the molecular mechanisms underlying the AP-1 action on osteoblasts will definitely give a more complete picture of the regulation of osteoblast differentiation in the future. Also, future studies should provide a link between the transcription factors and the extracellular signaling molecules that affect osteoblast differentiation. Additionally, once we know more about the molecules involved, it should be possible to uncover a genetic cascade controlling osteoblast differentiation and function, as it is already known for the bone-resorbing osteoclast (Karsenty, 1999). This would lead to a more complete understanding of bone remodeling, a balanced process mediated by osteoblasts and osteoclasts, and could provide several therapeutic targets for the treatment of degenerative bone diseases, mostly osteoporosis, where bone formation is decreased relative to bone resorption.

CHAPTER 6

The Osteocyte

P. J. Nijweide

E. H. Burger and J. Klein-Nulend
Department of Oral Cell Biology, ACTA-Vrije Universiteit, 1081 BT Amsterdam, The Netherlands

Introduction

The osteocyte is the most abundant cell type of bone. There are approximately 10 times as many osteocytes as osteoblasts in adult human bone (Parfitt, 1977), and the number of osteoclasts is only a fraction of the number of osteoblasts. Our current knowledge of osteocytes, however, lags behind what we know of the properties and functions of both osteoblasts and osteoclasts. However, the striking structural design of bone predicts an important role for osteocytes.

Considering that osteocytes have a very particular location in bone, not on the bone surface but spaced regularly throughout the mineralized matrix, and considering their typical morphology of stellate cells, which are connected with each other via long, slender cell processes, a parallel with the nerve system springs to one's mind. Are the osteocytes the "nerve cells" of the mineralized bone matrix, and if so, what are the stimuli that "excite" the cells? The answers to these questions may very well come from studies in which biomechanical concepts and techniques are applied to bone cell biology. Both theoretical considerations and experimental results have strengthened the notion that osteocytes are the pivotal cells in the biomechanical regulation of bone mass and structure (Cowin *et al.,* 1991; Mullender and Huiskes, 1994, 1995; Klein-Nulend *et al.* 1995b). This idea poses many new questions that have to be answered. By which mechanism(s) are loading stimuli on bone translated into biochemical stimuli that regulate bone (re)modeling and what is the nature of these signaling molecules? How and where do the mechanical and hormonal regulatory systems of bone interact? Are osteocytes mere signaling cells or do they contribute actively to bone metabolic processes such as mineralization, a process that takes place around newly incorporated osteocytes at some distance of the bone matrix formation front?

The development of osteocyte isolation techniques, the use of highly sensitive (immuno)cytochemical and *in situ* hybridization procedures, and the usefulness of molecular biological methods even when only small numbers of cells are available have rapidly increased our knowledge about this least understood cell type of bone in the recent past and will certainly continue to do so in the future. This chapter compiles and analyzes the most recent findings and it is hoped that it contributes to the development of new ideas and thoughts about the role of osteocytes in the physiology of bone.

The Osteocytic Phenotype

The Osteocyte Syncytium

Mature osteocytes are stellate shaped or dendritic cells enclosed within the lacunocanalicular network of bone. The lacunae contain the cell bodies. From these cell bodies, long, slender cytoplasmic processes radiate in all directions, but with the highest density perpendicular to the bone surface (Fig. 1). They pass through the bone matrix via small canals, the canaliculi. Processes and their canaliculi may be branched. They appear generally not to cross the cement lines separating adjacent osteons. The more mature osteocytes are connected by these cell processes to neighboring osteocytes, the most recently incorporated osteocytes to neighboring osteocytes and to the cells lining the bone surface. Some of the processes oriented to the bone surface, however, appear not to connect with the lining

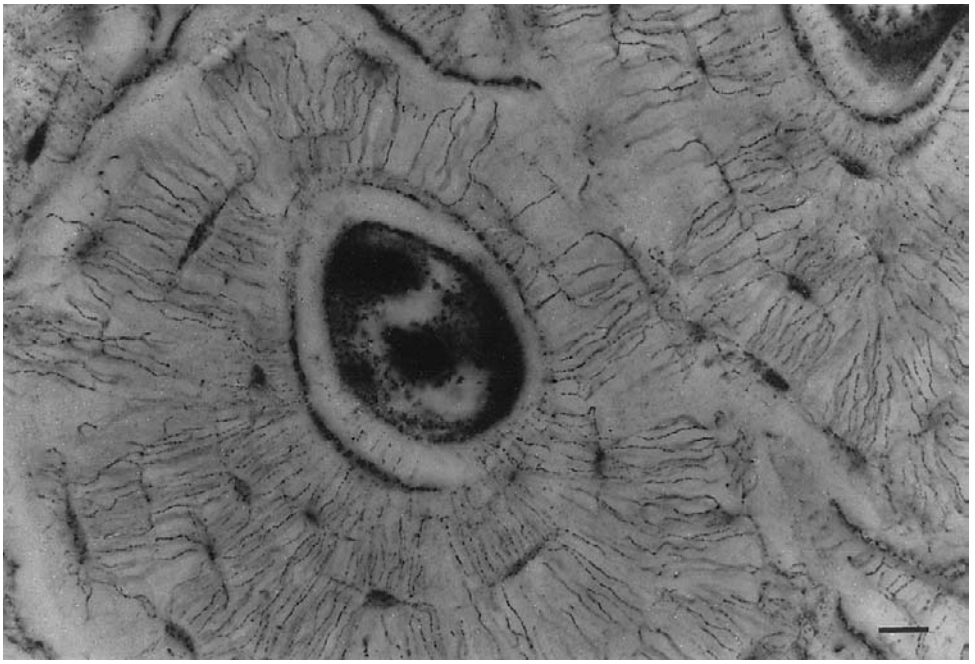

Figure 1 Osteon in mature human bone. Osteocytes are arranged in concentric circles around the central haversian channel. Note the many cell processes, radiating from the osteocyte cell bodies, in particular in the perpendicular directions. Schmorl staining. (Original magnification: ×390; bar: 25μm.)

cells, but pass through this cell layer, thereby establishing a direct contact between the osteocyte syncytium and the extraosseus space. This intriguing observation by Kamioka *et al*. (2001) suggests the existence of a signaling system between the osteocyte and the bone marrow compartment without intervention of the osteoblasts/lining cells.

The typical morphology of the osteocyte was originally thought to be enforced on differentiating osteoblasts during their incorporation in the bone matrix. Osteocytes have to remain in contact with other cells and ultimately with the bone surface to ensure the access of oxygen and nutrients. Culture experiments with isolated osteocytes have shown, however, that although the cells lose their stellate shape in suspension, they reexpress this morphology as soon as they settle on a support (Van der Plas and Nijweide, 1992) (Fig. 2). Apparently, the typical stellate morphology and the need to establish a cellular network are intrinsic characteristics of terminal osteocyte differentiation.

In bone, gap junctions are present between the tips of the cell processes of connecting osteocytes (Doty, 1981). Within each osteon or hemiosteon (on bone surfaces), therefore, osteocytes form a syncytium of gap junction-coupled cells. As the lacunae are connected via the canaliculi, the osteocyte syncytium represents two network systems: an intracellular one and an extracellular one. This feature is probably the key to understanding the function of the osteocyte.

Osteocyte Formation and Death

Osteogenic cells arise from multipotential mesenchymal stem cells (see Chapter 4). These stem cells have the capacity to also differentiate into other lineages, including those of chondroblasts, fibroblasts, adipocytes, and myoblasts (Aubin *et al.,* 1995; Chapter 4). By analogy with hemopoietic differentiation, each of these differentiation lineages is thought to originate from a different committed progenitor, which for the osteogenic lineage is called the osteoprogenitor. Osteodifferentiation progresses via a number of progenitor and precursor stages to the mature osteoblast. Osteoblasts may then differentiate to the ultimate differentiation stage, the osteocyte. The mechanism by which osteoblasts differentiate into osteocytes is, however, still unknown. Marotti (1996) has postulated that a newly formed osteocyte starts to produce an osteoblast inhibitory signal when its cytoplasmic processes connecting the cell with the osteoblast layer have reached their maximal length. The osteoid production of the most adjacent, most intimately connected osteoblast will be relatively more inhibited by that signal than that of its neighbors. The inactivated osteoblast then spreads over a larger bone surface area, thereby even reducing its linear appositional rate of matrix production further. A second consequence of the widening of the cell is that it may intercept more osteocytic processes carrying the inhibitory signal. This positive feedback mechanism results in the embedding of the cell in matrix produced by the neighboring osteoblasts. Ultimately, the cell will acquire the typical osteocyte morphology and the surrounding matrix will become calcified. The theory of Marotti is based entirely on morphological observations. There is no biochemical evidence about the nature or even the existence of the proposed inhibitory factor. Martin (2000) has, however, used the concept successfully in explaining

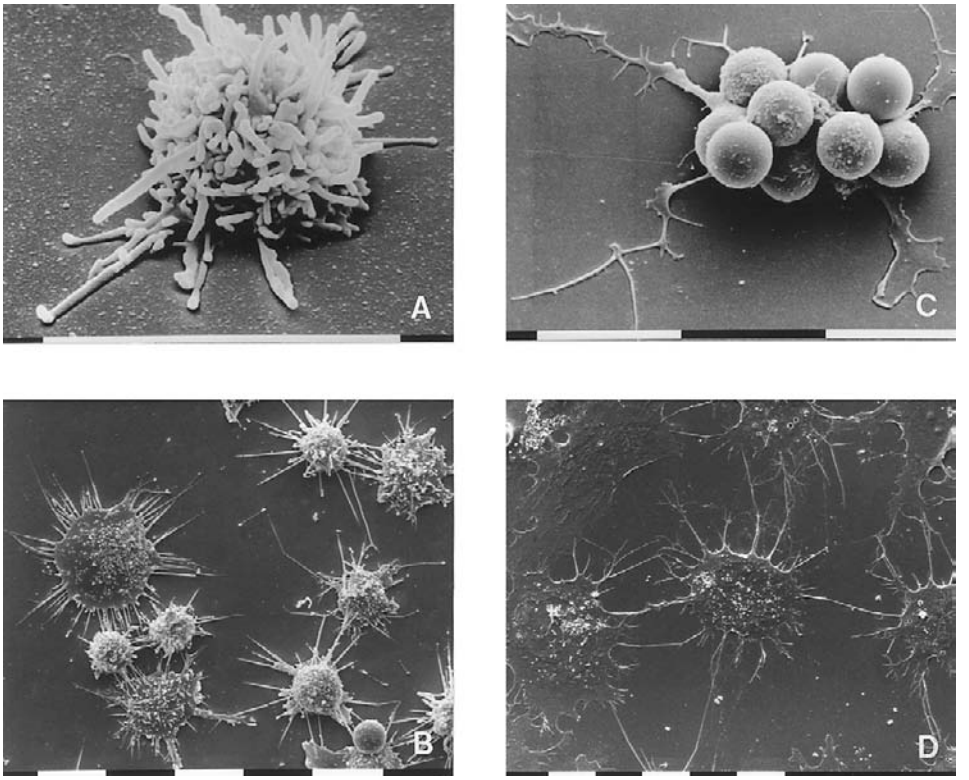

Figure 2 Isolated osteocytes in culture. Osteocytes were isolated by an immunodissection method using MAb OB7.3-coated magnetic beads. After isolation the cells were seeded on a glass support, cultured for 5 min (A), 30 min (B), or 24 hr (C and D) and studied with a scanning electron microscope. Immediately after attachment, osteocytes form cytoplasmic extrusions in all directions (A). During subsequent culture the cell processes perpendicular on the support disappear, while the processes in the plane of the support elongate (B) and ultimately form smooth connections between neighboring cells (D). In A, B, and D the immunobeads were removed from the cells before seeding, in C the beads were left on the cells. (Original magnification: (A) $\times$7200, (B) $\times$1400, (C) $\times$2900, and (D) $\times$940; bar: 10μm).

mathematically the changing rates of matrix formation during bone remodeling.

As described earlier, osteocytes derive from active osteoblasts. Most bone surfaces, particularly in mature bone, are, however, occupied by inactive (in terms of matrix production) bone-lining cells. How then is bone formation and osteocyte differentiation on an inactive bone surface started? Imai *et al*. (1998) found evidence that osteocytes may stimulate osteoblast differentiation and the accompanying matrix and osteocyte formation by expressing osteoblast stimulating factor-1 (OSF-1) (Tezuka *et al.,* 1990). OSF-1 or heparin-binding, growth-associated molecule (HB-GAM) (Rauvala, 1989) accumulates on bone surfaces near by the osteocytes that produce it (Imai *et al.,* 1998) and induces osteoblast formation by coupling to *N*-syndecan, a receptor for OSF-1 (Raulo *et al.,* 1994), present on osteoblast precursor cells. According to Imai *et al*. (1998), the expression of OSF-1 in osteocytes may be activated by local damage to bone or local mechanical stress. The issue of stress-mediated induction of bone formation and the role of osteocytes are discussed in more detail in the second part of this chapter.

The life span of osteocytes is probably largely determined by bone turnover, when osteoclasts resorb bone and "liberate" osteocytes. Osteocytes may have a half-life of decades if the particular bone they reside in has a slow turnover rate. The fate of living osteocytes that are liberated by osteoclast action is presently unknown. There is little evidence that osteocytes may reverse their differentiation back into the osteoblastic state (Van der Plas *et al.,* 1994). Some of them, only half released by osteoclastic activity, may be reembedded during new bone formation that follows the resorption process (Suzuki *et al.,* 2000). These osteocytes are then the cells that cross the cement lines between individual osteons, sometimes seen in cross sections of osteonal bone. Most of the osteocytes, however, will probably die by apoptosis and become phagocytosed. Phagocytosis of osteocytes by osteoclasts as part of the bone resorption process has been documented in several reports (Bronckers *et al.,* 1996; Elmardi *et al.,* 1990). Apoptosis of osteocytes in their lacunae is attracting growing attention because of its expected consequence of decreased bone mechanoregulation, which may lead to osteoporosis. Apoptotic changes in osteocytes were shown to be associated with high bone turnover (Noble *et al.,* 1997). However, fatigue-related microdamage in bone may cause decreased osteocyte accessibility for nutrients and oxygen

inducing osteocyte apoptosis and subsequent bone remodeling (Burger and Klein-Nulend, 1999; Verborgt *et al.,* 2000). Also, loss of estrogen (Tomkinson *et al.,* 1998) and chronic glucocorticoid treatment (Weinstein *et al.,* 1998) were demonstrated to induce osteocyte apoptosis, which may, at least in part, explain the bone-deleterious effects of these conditions.

Osteocyte Isolation

Analysis of osteocyte properties and functions has long been hampered by the fact that they are embedded in a mineralized matrix. Although sensitive methods are now available, such as immunocytochemistry and *in situ* hybridization, by which osteocytes can be studied in the tissue in some detail, osteocyte isolation and culture offer a major step forward. This approach became possible by the development of osteocyte-specific antibodies (Fig. 3) directed to antigenic sites on the outside of the cytoplasmic membrane (Bruder and Caplan, 1990; Nijweide and Mulder, 1986). Using an immunodissection method, Van der Plas and Nijweide (1992) subsequently succeeded in the isolation and purification of chicken osteocytes from mixed bone cell populations isolated from fetal bones by enzymatic digestion. Isolated osteocytes appeared to behave *in vitro* like they do *in vivo* in that they reacquired their stellate morphology and, when seeded sparsely, formed a network of cells coupled to one another by long, slender, often branched cell processes (Fig. 2). The cells retained this morphology in culture throughout the time studied (5–7 days) and even reexpressed it when passaged for a second time (Van der Plas and Nijweide, 1992). As *in vivo* isolated osteocytes were postmitotic (Van der Plas *et al.,* 1994). When seeded on dentin slices, they did not resorb or dissolve the dentin to any extent when observed with a scanning electron microscope. These results therefore do not support the earlier hypothesis of osteocytic osteolysis as a function for osteocytes (Bélanger, 1969).

Mikuni-Takagaki *et al*. (1995) have isolated seven cell fractions from rat calvariae by sequential digestion. They claimed that the last fraction consisted of osteocytic cells. The cells displayed dendritic cell processes, were negative for alkaline phosphatase, had high extracellular activities of casein kinase II and ecto-5'nucleotidase, and produced large amounts of osteocalcin. After a few days of little change in cell number, the cells of fraction VII proliferated, however, equally fast as those of fraction III, the osteoblastic cells, in culture. Because osteocyte-specific antibodies are not yet available for the rat system, the final identification of the cells in fraction VII has to await the development of additional identification methods.

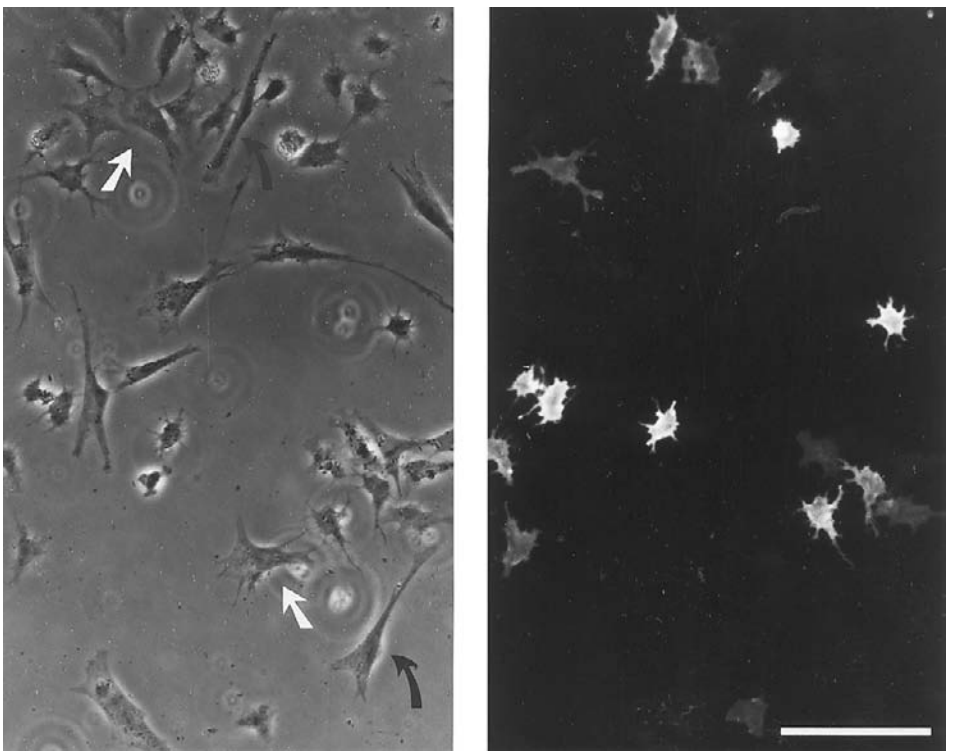

Figure 3 MAb OB7.3 immunostaining of osteocytes. Cells were isolated from periosteum-free 18-day-old chicken calvariae by collagenase digestion, seeded, and cultured for 24 hr. Subsequently the osteocytes in the mixed population were specifically stained with MAb OB7.3 in combination with biotinylated horse–antimouse IgG and streptavidin-Cy3. (Left) Phase contrast. (Right) Immunofluorescence. Black arrows, fibroblast-like cells; white arrows, osteoblast-like cells. (Original magnification: ×300; bar: 100 μm.)

Osteocytic Cell Lines

Because the number of osteocytes that can be isolated each time (Van der Plas and Nijweide, 1992) is limited, several groups have tried to establish osteocytic cell lines. Basically, an osteocytic cell line is a *contradictio in terminis*. Osteocytes are postmitotic. However, a cell line of proliferating precursor cells that would differentiate to osteocytes under specific circumstances, could prove to be very valuable in the study of osteocyte properties and functions. HOB-01-C1 (Bodine *et al.,*1996) may meet these requirements. It is a temperature-sensitive cell line, prepared from immortalized, cloned human adult bone cells. It proliferates at 34°C but stops dividing at 39°C. HOB-01-C1 cells display putative osteocytic markers, such as cellular processes, low alkaline phosphatase activity, high osteocalcin production, and the expression of CD44.

MLO-Y4 (Kato *et al.,* 1997) is another osteocyte-like cell line in that the cells, when seeded at low density, display complex dendritic processes. They produce high amounts of osteocalcin and osteopontin, express CD44, and have low alkaline phosphatase activity. MLO-Y4 cells are, however, strongly proliferative.

The problem of defining these cell lines as really osteocytic lies in the fact that the markers just mentioned are each on their own not osteocyte specific (see later) although the combination of their markers may resemble that of the osteocyte phenotype.

Osteocyte Markers

In bone, osteocytes are fully defined by their location within the bone matrix and their typical stellate morphology. Related to this stellate morphology, osteocytes have a typical cytoskeletal organization. The prominent actin bundles in the osteocytic processes, together with the abundant presence of the actin-bundling protein fimbrin, are exemplary for osteocytes and are retained after isolation (Tanaka-Kamioka *et al.,* 1998). In addition, osteocytes are generally found to express osteocalcin, osteonectin, and osteopontin, but show little alkaline phosphatase activity, particularly the more mature cells (Aarden *et al*. 1996b). As stated previously, these metabolic markers have, however, little discriminating value in mixtures of isolated cells. A promising newly found protein in this class of markers is OF45 (Petersen *et al.,* 2000), a RGD-containing matrix protein particularly expressed by bone-embedded osteocytes. Its degree of mRNA expression appears to correlate with the progressing differentiation of osteoblastic cells *in vitro*. However, whether an antibody generated with the protein can specifically recognize osteocytes in bone cell mixtures is not yet clear. The function of the protein is also not known.

At present the best markers for isolated osteocytes are their typical morphology, which they reacquire in culture (Mikuni-Takagaki *et al.,* 1995; Van der Plas and Nijweide, 1992) in combination with their reaction with monoclonal antibodies, which have been proven to be osteocyte specific in tissue sections. Examples are the monoclonal antibodies MAb OB7.3 (Nijweide and Mulder, 1986) (Fig. 3), MAb OB37.11 (Nijweide *et al.,* 1988), and MAb SB5 (Bruder and Caplan, 1990). All three are specific for avian osteocytes and do not cross-react with mammalian cells. The antigenic sites of OB7.3 and OB37.11 are not identical (Aarden *et al.,* 1996a). Whether SB5 reacts with either or reacts with another, different site is not known. The identities of the three antigens involved have not been reported, although that of OB7.3 has been elucidated (Westbroek *et al.,* submitted). E11 is a monoclonal antibody that reacts specifically with highly mature osteoblasts and with osteocytes in tissue sections of rat bone (Wetterwald *et al.,* 1996). In primary rat osteoblast and ROS 17/2.8 cultures the antibody recognizes a subset of cells (Schulze *et al.,* 1999; Wetterwald *et al.,* 1996). The antigen of the antibody is OTS-8, a transmembrane protein that interacts with the membrane-bound glycoprotein CD44 (Ohizumia *et al.,* 2000). Because CD44 is involved in cell attachment and cell movement and because the E11 antigen is only present in young, recently-embedded osteocytes and is limited in osteoblasts to their basal side (Wetterwald *et al.,* 1996), it is attractive to hypothesize that the CD44–OTS-8 complex is associated with the formation of dendritic processes during osteocyte formation. Osteocytes were indeed found to be strongly immunoreactive to CD44, whereas, again, in osteoblasts attached to the bone surface, CD44 immunoreactivity was restricted to the cytoplasmic processes on the basal side (Nakamura and Ozawa, 1996).

Matrix Synthesis

The subcellular morphology of osteocytes and the fact that they are encased in mineralized matrix do not suggest that osteocytes partake to a large extent in matrix production. Osteocytes, especially the more mature, have relatively few organelles necessary for matrix production and secretion. Nevertheless, a limited secretion of specific matrix proteins may be essential for osteocyte function and survival. Several arguments are in favor of such limited matrix production. First, as the mineralization front lags behind the osteoid formation front in areas of new bone formation, osteocytes may be involved in the maturation and mineralization of the osteoid matrix by secreting specific matrix molecules. It is, however, also possible that osteocytes enable the osteoid matrix to be mineralized by phosphorylating certain matrix constituents, as was suggested by Mikuni-Takagaki *et al*. (1995). However, osteocytes have to inhibit mineralization of the matrix directly surrounding them to ensure the diffusion of oxygen, nutrients, and waste products through the lacunocanalicular system. Osteocalcin, which is expressed to a relative high extent by osteocytes, may play an important role here (Aarden *et al.,* 1996b; Ducy *et al.,* 1996; Mikuni-Takagaki *et al.,* 1995). Finally, if osteocytes are the mechanosensor cells of bone (see later), the attachment of osteocytes to matrix molecules is likely of major importance for the transduction of

stress signals into cellular signals. Production and secretion of specific matrix molecules offer a possibility for the cells to regulate their own adhesion and, thereby, sensitivity for stress signals.

Currently available information about osteocyte capacity to produce certain matrix molecules is based almost entirely on immunocytochemical and *in situ* hybridization studies using sections of bone and isolated osteocytes. Osteocytes have been found positive for osteocalcin and osteonectin (Aarden *et al.,* 1996b), molecules that are probably involved in the regulation of calcification. Osteopontin, fibronectin, and collagen type I (Aarden *et al.,* 1996b) have also been demonstrated in and immediately around (isolated) osteocytes. These proteins may be involved in osteocyte attachment to the bone matrix (see later).

In addition to collagenous and noncollagenous proteins, the bone matrix contains proteoglycans. These macromolecules consist of a core protein to which one or more glycosaminoglycan (GAG) side chains are covalently bound. Early electron microscopical studies (Jande, 1971) already showed that the osteocyte body, as well as its cell processes, is surrounded by a thin layer of unmineralized matrix containing collagen fibrils and proteoglycans. The proteoglycans were shown to consist of chondroitin 4-sulfate, dermatan sulfate, and keratan sulfate with immunocytochemical methods (Maeno *et al.,* 1992; Smith *et al.,* 1997; Takagi *et al.,* 1997). These observations are supported by the findings of Sauren *et al*. (1992), who demonstrated an increased presence of proteoglycans in the pericellular matrix by staining with the cationic dye cuprolinic blue. Of special interest is the reported presence of hyaluronan in osteocyte lacunae (Noonan *et al.,* 1996). CD44, which is highly expressed on the osteocyte membrane, is a hyaluronan-binding protein. CD44 binds, however, also to collagen, fibronectin, and osteopontin (Nakamura and Ozawa, 1996; Yamazaki *et al.,* 1999).

The Osteocyte Cytoskeleton and Cell–Matrix Adhesion

As mentioned earlier, the cell–matrix adhesion of osteocytes is likely of importance for the translation of biomechanical signals produced by loading of bone into chemical signals. Study of the adhesion of osteocytes to extracellular matrix molecules became feasible with the development of osteocyte isolation and culture methods (Van der Plas and Nijweide, 1992). These studies found little difference between the adhesive properties of osteocytes and osteoblasts, although the pattern of adhesion plaques (osteocytes, many small focal contacts, osteoblasts, larger adhesion plaques) was quite different (Aarden *et al.,* 1996a). Both cell types adhered equally well to collagen type I, osteopontin, vitronectin, fibronectin, and thrombospondin. Integrin receptors are involved, as is shown by the inhibiting effects of small peptides containing a RGD sequence on the adhesion to some of these proteins. Adhesion to all aforementioned matrix molecules was blocked by an antibody reacting with the β_1-integrin subunit (Aarden *et al.,* 1996a). The identity of the α units involved is yet unknown.

Deformation of the bone matrix upon loading may cause a physical "twisting" of integrins at sites where osteocytes adhere to the matrix. Integrins are coupled to the cytoskeleton via molecules such as vinculin, talin, and α-actinin. In osteocytes, especially in the osteocytic cell processes, the actin-bundling protein fimbrin appears to play a prominent role (Tanaka-Kamioka *et al.,* 1998). Mechanical twisting of the cell membrane via integrin-bound beads has been demonstrated to induce cytoskeletal rearrangements in cultured endothelial cells (Wang and Ingber, 1994). The integrin–cytoskeleton complex may therefore play a role as an intracellular signal transducer for stress signals. In addition to the integrins, the nonintegrin adhesion receptor CD44 may attribute to the attachment of osteocytes to the surrounding matrix. CD44 is present abundantly on the osteocyte surface (Hughes *et al.,* 1994; Nakamura and Ozawa, 1995) and is also linked to the cytoskeleton.

Hormone Receptors in Osteocytes

Parathyroid hormone (PTH) receptors have been demonstrated on rat osteocytes *in situ* (Fermor and Skerry, 1995) and on isolated chicken osteocytes (Van der Plas *et al.,* 1994). Administered *in vitro*, PTH was reported to increase cAMP levels in isolated chicken osteocytes (Van der Plas *et al.,* 1994; Miyauchi *et al.,* 2000) and, administered *in vivo*, to increase fos protein (Takeda *et al.,* 1999) and the mRNAs of c-fos, c-jun, and Il-6 in rat osteocytes (Liang *et al.,* 1999). Therefore, although the original theory of osteocytic osteolysis and its regulation by calciotropic hormones such as PTH (Bélanger, 1969) has been abandoned, the presence of PTH receptors on osteocytes and their short-term responses to PTH suggest a role for PTH in osteocyte function. As it is now generally accepted that osteocytes are involved in the transduction of mechanical signals into chemical signals regulating bone (re)modeling, PTH might modulate the osteocytic response to mechanical strain. Injection of PTH in rats was shown to augment the osteogenic response of bone to mechanical stimulation *in vivo*, whereas thyroparathyroidectony abrogated the mechanical responsiveness of bone (Chow *et al.,* 1998). However, such an approach cannot separate an effect at the level of osteocyte mechanosensing from one at the level of osteoprogenitor recruitment. One mechanism by which PTH may act on osteocytes is suggested by the reports of Schiller *et al*. (1992) and Donahue *et al*. (1995). These authors found that PTH increases connexin-43 gene expression and gap junctional communication in osteoblastic cells. In osteocytes, where cell-to-cell communication is so important, a similar effect might lead to more efficient communication within the osteocyte syncytium. Activation of receptors for 1,25-dihydroxyvitamin D_3 [$1,25(OH)_2D_3$], which were also shown to be present in osteocytes immunocytochemically (Boivin *et al.,* 1987) and by *in situ* hybridization (Davideau *et al.,* 1996), may have similar effects.

Another important hormone involved in bone metabolism is estrogen. As is demonstrated in many studies, the decrease of blood estrogen levels is accompanied by a loss of bone mass. One explanation for this phenomenon is that estrogen regulates the set point for the mechanical responsiveness of bone (Frost, 1992), i.e, that lowering the ambient estrogen level increases the level of strain in bone necessary for the bone to respond with increased bone formation. If osteocytes are the main mechanosensors of bone, it is reasonable to suppose that osteocytes are the site of set point regulation by estrogen. Estrogen receptors (ERα) were demonstrated in osteocytes with immunocytochemistry and *in situ* hybridization (Braidman *et al.,* 1995; Hoyland *et al.,* 1999) in tissue sections. In addition, Westbroek *et al*. (2000b) found higher levels of ERα in isolated osteocytes than in osteoblast and osteoblast-precursor populations. At this time, no experimental evidence for the estrogen regulation of osteocyte mechanosensitivity is available, but Joldersma *et al*. (2001) reported an increased responsiveness to fluid shear stress by human bone cells as a result of estrogen treatment.

Next to receptors for PTH, $1,25(OH)_2D_3$, and estrogen, the androgen receptor (Abu *et al.,* 1997), the glucocorticoid receptor α (Abu *et al.,* 2000; Silvestrini *et al.,* 1999), and various prostaglandin receptors (Lean *et al.,* 1995; Sabbieti *et al.,* 1999) have been described in osteocytes. The latter may be important for communication within the osteocyte network during mechanotransduction (see later).

Osteocyte Function

Blood–Calcium Homeostasis

The organization of osteocytes as a syncytium of gap junction-coupled cells in each osteon represents such an unique structure that one expects it to have an important function in the metabolism and maintenance of bone. The syncytium offers two advantages that may be exploited by the tissue.

1. A tremendous cell–bone surface contact area, about two orders of magnitude larger than the contact area the osteoblasts and lining cells have (Johnson, 1966).
2. An extensive intracellular and an extracellular communication system between sites within the bone and the bone surface.

The first consideration has led Bélanger (1969) and others to propose the hypothesis that osteocytes are capable of local bone remodeling or osteocytic osteolysis. According to this hypothesis, osteocytes are coresponsible for blood–calcium homeostasis. Later studies (Boyde, 1980; Marotti *et al.,* 1990) supplied alternative explanations for the observations that appeared to support the osteocytic osteolysis theory. The possibility remains, however, that osteocytes are involved in the facilitation of calcium diffusion in and out of the bone (Bonucci, 1990). Although the bulk of calcium transport in and out of the bone is apparently taken care of by osteoblasts and osteoclasts (Boyde, 1980; Marotti *et al.,* 1990), osteocytes may have a function in the fine regulation of blood–calcium homeostasis. The major emphasis of present day thinking is, however, on the role of the osteocyte syncytium as a three-dimensional sensor and communication system in bone.

Functional Adaptation, Wolff's Law

Functional adaptation is the term used to describe the ability of organisms to increase their capacity to accomplish a specific function with increased demand and to decrease this capacity with lesser demand. In the 19th century, the anatomist Julius Wolff proposed that mechanical stress is responsible for determining the architecture of bone and that bone tissue is able to adapt its mass and three-dimensional structure to the prevailing mechanical usage to obtain a higher efficiency of load bearing (Wolff, 1892). For the past century, Wolff's law has become widely accepted. Adaptation will improve an individual animal's survival chance because bone is not only hard but also heavy. Too much of it is probably as bad as too little, leading either to uneconomic energy consumption during movement (for too high bone mass) or to an enhanced fracture risk (for too low bone mass). This readily explains the usefulness of mechanical adaptation as an evolutionary driver, even if we do not understand how it is performed.

Osteocytes as Mechanosensory Cells

In principle, all cells of bone may be involved in mechanosensing, as eukaryotic cells in general are sensitive to mechanical stress (Oster, 1989). However, several features argue in favor of osteocytes as the mechanosensory cells *par excellence* of bone as discussed earlier in this chapter. In virtually all types of bone, osteocytes are dispersed throughout the mineralized matrix and are connected with their neighbor osteocytes via long, slender cell processes that run in slightly wider canaliculi of unmineralized matrix. The cell processes contact each other via gap junctions (Doty, 1981; Donahue *et al.,* 1995), thereby allowing direct cell-to-cell coupling. The superficial osteocytes are connected with the lining cells covering most bone surfaces, as well as the osteoblasts that cover (much-less abundant) surfaces where new bone is formed. From a cell biological viewpoint therefore, bone tissue is a three-dimensional network of cells, most of which are surrounded by a very narrow sheath of unmineralized matrix, followed by a much wider layer of mineralized matrix. The sheath of unmineralized matrix is penetrated easily by macromolecules such as albumin and peroxidase (McKee *et al.,* 1993; Tanaka and Sakano, 1985). Therefore, there is an intracellular as well as an extracellular route for the rapid passage of ions and signal molecules. This allows for several manners of cellular signaling from osteocytes lying

deep within the bone tissue to surface-lining cells and vice versa (Cowin *et al.,* 1995).

Experimental studies indicate that osteocytes are indeed sensitive to stress applied to intact bone tissue. *In vivo* experiments using the functionally isolated turkey ulna have shown that immediately following a 6-min period of intermittent (1 Hz) loading, the number of osteocytes expressing glucose-6-phosphate dehydrogenase (G6PD) activity was increased in relation to local strain magnitude (Skerry *et al.,* 1989). The tissue strain magnitude varied between 0.05 and 0.2% (500–2000 microstrain) in line with *in vivo* peak strains in bone during vigorous exercise. Other models, including strained cores of adult dog cancellous bone, embryonic chicken tibiotarsi, rat caudal vertebrae, and rat tibiae, as well as experimental tooth movement in rats, have demonstrated that osteocytes in intact bone change their enzyme activity and RNA synthesis rapidly after mechanical loading (El Haj *et al.,* 1990; Dallas *et al.,* 1993; Lean *et al.,* 1995; Forwood *et al.,* 1998; Terai *et al.,* 1999). These studies show that intermittent loading produces rapid changes of metabolic activity in osteocytes and suggest that osteocytes may indeed function as mechanosensors in bone. Computer simulation studies of bone remodeling, assuming this to be a self-organizational control process, predict a role for osteocytes, rather than lining cells and osteoblasts, as stress sensors of bone (Mullender and Huiskes, 1995, 1997; Huiskes *et al.,* 2000). A regulating role of strain-sensitive osteocytes in basic multicellular unit (BMU) coupling has been postulated by Smit and Burger (2000). Using finite-element analysis, the subsequent activation of osteoclasts and osteoblasts during coupled bone remodeling was shown to relate to opposite strain distributions in the surrounding bone tissue. In front of the cutting cone of a forming secondary osteon, an area of *decreased* bone strain was demonstrated, whereas a layer of *increased* strain occurs around the closing cone (Smit and Burger, 2000). Osteoclasts therefore attack an area of bone where the osteocytes are underloaded, whereas osteoblasts are recruited in a bone area where the osteocytes are overloaded. Hemiosteonic remodeling of trabecular bone showed a similar strain pattern (Smit and Burger, 2000). Thus, bone remodeling regulated by strain-sensitive osteocytes can explain the maintenance of osteonic and trabecular architecture as an optimal mechanical structure, as well as adaptation to alternative external loads (Huiskes *et al.,* 2000; Smit and Burger, 2000).

If osteocytes are the mechanosensors of bone, how do they sense mechanical loading? This key question is, unfortunately, still open because it has not yet been established unequivocally how the loading of intact bone is transduced into a signal for the osteocytes. The application of force to bone during movement results in several potential cell stimuli. These include changes in hydrostatic pressure, direct cell strain, fluid flow, and electric fields resulting from electrokinetic effects accompanying fluid flow (Pienkowski and Pollack, 1983). Evidence has been increasing steadily for the flow of canalicular interstitial fluid as the likely stress-derived factor that informs the osteocytes about the level of bone loading (Cowin *et al.,* 1991, 1995; Cowin, 1999; Weinbaum *et al.,* 1994; Klein-Nulend *et al.,* 1995b; Knothe-Tate 2000; Burger and Klein-Nulend, 1999; You *et al.,* 2000). In this view, canaliculi are the bone porosity of interest, and the osteocytes the mechanosensor cells.

Canalicular Fluid Flow and Osteocyte Mechanosensing

In healthy, adequately adapted bone, strains as a result of physiological loads (e.g., resulting from normal locomotion) are quite small. Quantitative studies of the strain in bones of performing animals (e.g., galloping horses, fast-flying birds, even a running human volunteer) found a maximal strain not higher than 0.2–0.3% (Rubin, 1984; Burr *et al.,* 1996). This poses a problem in interpreting the results of *in vitro* studies of strained bone cells, where much higher deformations, in the order of 1–10%, were needed to obtain a cellular response (for a review, Burger and Veldhuijzen, 1993). In these studies, isolated bone cells were usually grown on a flexible substratum, which is then strained by stretching or bending. For instance, unidirectional cell stretching of 0.7% was required to activate prostaglandin E_2 production in primary bone cell cultures (Murray and Rushton, 1990). However, in intact bone, a 0.15% bending strain was already sufficient to activate prostaglandin-dependent adaptive bone formation *in vivo* (Turner *et al.,* 1994; Forwood, 1996). If we assume that bone organ strain is somehow involved in bone cell mechanosensing, then bone tissue seems to possess a lever system whereby small matrix strains are transduced into a larger signal that is detected easily by osteocytes. The canalicular flow hypothesis proposes such a lever system. The flow of extracellular tissue fluid through the lacunocanalicular network as a result of bone tissue strains was made plausible by the theoretical study of Piekarski and Munro (1977) and has been shown experimentally by Knothe-Tate and colleagues (1998, 2000). This strain-derived extracellular fluid flow may help keep osteocytes healthy, particularly the deeper ones, by facilitating the exchange of nutrients and waste products between the Haversian channel and the osteocyte network of an osteon (Kufahl and Saha, 1990). However, a second function of this strain-derived interstitial fluid flow could be the transmission of "mechanical information" (Fig. 4). The magnitude of interstitial fluid flow through the lacunocanalicular network is directly related to the amount of strain of the bone organ (Cowin *et al.,* 1991). Because of the narrow diameter of the canaliculi, bulk bone strains of about 0.1% will produce a fluid shear stress in the canaliculi of roughly 1 Pa (Weinbaum *et al.,* 1994), enough to produce a rapid response in endothelial cells (Frangos *et al.,* 1985; Kamiya and Ando, 1996).

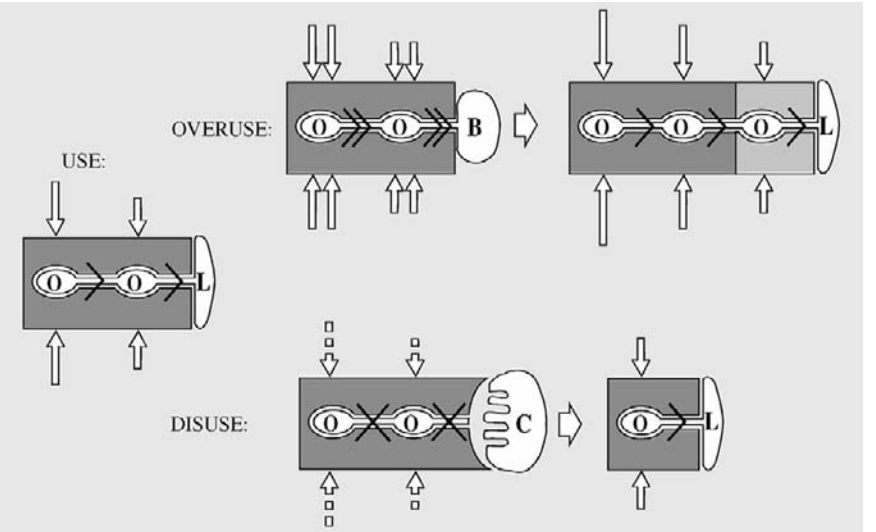

Figure 4 Schematic representation of how the osteocyte network may regulate bone modeling. In the steady state (USE), normal mechanical use ensures a basal level of fluid flow through the lacunocanalicular porosity, indicated by an arrowhead through the canaliculi. This basal flow keeps the osteocytes viable and also ensures basal osteocyte activation and signaling, thereby suppressing osteoblastic activity as well as osteoclastic attack. During (local) overuse (OVERUSE), osteocytes are overactivated by enhanced fluid flow (indicated by double arrowheads), leading to the release of osteoblast-recruiting signals. Subsequent osteoblastic bone formation reduces the overuse until normal mechanical use is reestablished, thereby reestablishing the steady state of basal fluid flow. During (local) disuse (DISUSE), osteocytes are inactivated by lack of fluid flow (indicated by crosses through canaliculi). Inactivation leads to a release of osteoclast-recruiting signals, to a lack of osteoclast-suppressing signals, or both. Subsequent osteoclastic bone resorption reestablishes normal mechanical use (or loading) and basal fluid flow. O, osteocyte; L, lining cell; B, osteoblast; C, osteoclast; dark-gray area, mineralized bone matrix; light-gray area, newly formed bone matrix; white arrows represent direction and magnitude of loading. Adapted from Burger and Klein-Nulend (1999).

Experimental studies *in vitro* have demonstrated that osteocytes are indeed quite sensitive to the fluid shear stress of such a magnitude compared to osteoblasts and osteoprogenitor cells (Klein-Nulend *et al.,* 1995a, b; Ajubi *et al.,* 1996; Westbroek *et al.,* 2000a). These results suggest that the combination of the cellular three-dimensional network of osteocytes and the accompanying porous network of lacunae and canaliculi acts as the mechano sensory organ of bone. The flow of interstitial fluid through the bone canaliculi will have two effects: a mechanical one derived from the fluid shear stress and an electrokinetic one derived from streaming potentials (Pollack *et al.,* 1984; Salzstein and Pollack, 1987). Either of the two, or both in combination, might activate the osteocyte. For instance, streaming potentials might modulate the movement of ions such as calcium across the cell membrane (Hung *et al.,* 1995, 1996), whereas shear stress will pull at the macromolecular attachments between the cell and its surrounding matrix (Wang and Ingber, 1994). Both ion fluxes and cellular attachment are powerful modulators of cell behavior and therefore good conveyors of physical information (Sachs, 1989; Ingber, 1991).

Response of Osteocytes to Fluid Flow *in Vitro*

The technique of immunodissection, as discussed earlier in this chapter, made it possible to test the canalicular flow hypothesis by comparing the responsiveness of osteocytes, osteoblasts, and osteoprogenitor cells to fluid flow. The strength of the immunodissection technique is that three separate cell populations with a high ((90%) degree of homogeneity are prepared, representing (1) osteocytes with the typical "spider-like" osteocyte morphology and little matrix synthesis, (2) osteoblasts with a high synthetic activity of bone matrix-specific proteins, and (3) (from the periosteum) osteoprogenitor cells with a fibroblast-like morphology and very high proliferative capacity (Nijweide *et al.,* 1986). Because the cells are used within 2 days after isolation from the bone tissue, they may well represent the three differentiation steps of osteoprogenitor cell, osteoblast, and osteocyte. In contrast, mixed cell cultures derived from bone that are generally used to represent "osteoblastic" cells likely contain cells in various stages of differentiation. Therefore, changes in mechanosensitivity related to progressive cell differentiation cannot be studied in such cultures.

Using these immunoseparated cell populations, osteocytes were found to respond far stronger to fluid flow than osteoblasts and these stronger than osteoprogenitor cells (Klein-Nulend *et al.,* 1995a,b; Ajubi *et al.,* 1996; Westbroek *et al.,* 2000a). Pulsating fluid flow (PFF) with a mean shear stress of 0.5 Pa (5 dynes/cm^2) with a cyclic variation of plus or minus 0.2 Pa at 5 Hz stimulated the release of nitric oxide (NO) and prostaglandin E_2 and I_2 (PGE_2 and PGI_2) rapidly from osteocytes within minutes (Klein-Nulend *et al.,* 1995a; Ajubi *et al.,* 1996). Osteoblasts showed less response, and osteoprogenitor cells (periosteal fibroblasts) still less. Intermittent hydrostatic compression (IHC) of 13,000 Pa peak pressure at 0.3 Hz (1 sec compression followed by 2 sec relaxation) needed more than 1 hr application before prostaglandin production was increased, again more in osteocytes than in osteoblasts, suggesting that mechanical stimulation via fluid flow is more effective than hydrostatic compression (Klein-Nulend *et al.,* 1995b). A 1-hr treatment with PFF also induced a sustained release of PGE_2 from the osteocytes in the hour following PFF treatment (Klein-Nulend *et al.,* 1995b). This sustained PGE_2 release, continuing after PFF treatment had been stopped, could be ascribed to the induction of prostaglandin G/H synthase-2 (or cyclo-oxygenase 2, COX-2) expression (Westbroek *et al.,* 2000a). Again, osteocytes were much more responsive than osteoblasts and osteoprogenitor cells, as only a 15-min treatment with PFF increased COX-2 mRNA expression by three-fold in osteocytes but not in the other two cell populations (Westbroek *et al.,* 2000). Upregulation of COX-2 but not COX-1 by PFF had been shown earlier in a mixed population of mouse calvarial cells (Klein-Nulend *et al.,* 1997) and was also demonstrated in primary bone cells from elderly women (Joldersma *et al.,* 2000), whereas the expression of COX-1 and -2 in osteocytes and osteoblasts in intact rat bone has been documented (Forwood *et al.,* 1998). These *in vitro* experiments on immunoseparated cells suggest that as bone cells mature, they increase their capacity to produce prostaglandins in response to fluid flow (Burger and Klein-Nulend, 1999). First, their immediate production of PGE_2, PGI_2, and probably $PGF_2\alpha$ (Klein-Nulend *et al.,* 1997) in response to flow increases as they develop from osteoprogenitor cell, via the osteoblastic stage into osteocytes. Second, their capacity to increase expression of COX-2 in response to flow, and thereby to continue to produce PGE_2 even after the shear stress has stopped (Westbroek *et al.,* 2000a), increases as they reach terminal differentiation. Because induction of COX-2 is a crucial step in the induction of bone formation by mechanical loading *in vivo* (Forwood, 1996), these results provide direct experimental support for the concept that osteocytes, the long-living terminal differentiation stage of osteoblasts, function as the "professional" mechanosensors in bone tissue.

Pulsating fluid flow also rapidly induced the release of NO in osteocytes but not osteoprogenitor cells (Klein-Nulend *et al.,* 1995a). Rapid release of NO was also found when whole rat bone rudiments were mechanically strained in organ culture (Pitsillides *et al.,* 1995) and in human bone cells submitted to fluid flow (Sterck *et al.,* 1998). In line with these *in vitro* observations, inhibition of NO production inhibited mechanically induced bone formation in animal studies (Turner *et al.,* 1996; Fox *et al.,* 1996). NO is a ubiquitous messenger molecule for intercellular communication, involved in many tissue reactions where cells must collaborate and communicate with each other (Koprowski and Maeda, 1995). An interesting example is the adaptation of blood vessels to changes in blood flow. In blood vessels, enhanced blood flow, e.g., during exercise, leads to widening of the vessel to ensure a constant blood pressure. This response depends on the endothelial cells, which sense the increased blood flow, and produce intercellular messengers such as NO and prostaglandins. In response to these messengers, the smooth muscle cells around the vessel relax to allow the vessel to increase in diameter (Kamiya and Ando, 1996). The capacity of endothelial cells to produce NO in response to fluid flow is related to a specific enzyme, endothelial NO synthase or ecNOS. Interestingly, this enzyme was found in rat bone lining cells and osteocytes (Helfrich *et al.,* 1997; Zaman *et al.,* 1999) and in cultured bone cells derived from human bone (Klein-Nulend *et al.,* 1998). Treatment with pulsatile fluid flow increased the level of ecNOS RNA transcripts in the bone cell cultures (Klein-Nulend *et al.,* 1998), a response also described in endothelial cells (Busse and Fleming, 1998; Uematsu *et al.,* 1995). Enhanced production of prostaglandins is also a well-described response of endothelial cells to fluid flow (Busse and Fleming, 1998; Kamiya and Ando, 1996). It seems, therefore, that endothelial cells and osteocytes possess a similar sensor system for fluid flow and that both cell types are "professional" sensors of fluid flow. This is an indication that osteocytes sense bone strains via the (canalicular) fluid flow resulting from bone strains.

Mechanotransduction starts by the conversion of physical loading-derived stimuli into cellular signals. Several studies suggest that the attachment complex between intracellular actin cytoskeleton and extracellular matrix macromolecules, via integrins and CD44 receptors in the cell membrane, provides the site of mechanotransduction (Wang *et al.,* 1993; Watson, 1991; Ajubi *et al.,* 1996, 1999; Pavalko *et al.,* 1998). An important early response is the influx of calcium ions through mechanosensitive ion channels in the plasma membrane and the release of calcium from internal stores (Hung *et al.,* 1995, 1996; Ajubi *et al.,* 1999; Chen *et al.,* 2000; You *et al.,* 2000). The signal transduction pathway then involves protein kinase C and phospholipase A_2 to activate arachidonic acid production and PGE_2 release (Ajubi *et al.,* 1999). However, many other steps in the mechanosignaling cascade are still unknown in osteocytes as well as other mechanosensory cells.

Cell Stretch versus Fluid Flow

To mimic the effect of physiological bone loading in monolayer cell cultures, several authors have used cell stretching via deformation of the cell culture substratum (Murray and

Rushton, 1990; Pitsillides *et al.,* 1995; Zaman *et al.,* 1999; Neidlinger-Wilke *et al.,* 1995; Kaspar *et al.,* 2000; Mikuni-Takagaki *et al.,* 1996; Kawata and Mikuni-Takagaki, 1998; for a review of the older literature, see Burger and Veldhuijzen, 1993). Stretchloading by hypoosmotic cell swelling was also used (Miyauchi *et al.,* 2000). The results are generally in agreement with the studies using fluid flow, including the high sensitivity of osteocytes to strain. The advantage of cell straining via the cell culture substratum is that this technique allows to precisely determine the amount of cell strain that is applied, provided that the cell does not modulate its attachment to the substratum during stretching. Cell strain in *vitro* can therefore be adjusted to bone tissue strain *in vivo* during exercise. Using fluid flow *in vitro* means that only the fluid shear *stress* can be well determined, but not the ensuing cell strain (deformation). Attempts to measure cell deformation as a result of fluid flow showed that osteocyte deformation is below the detection limit using phase-contrast microscopy (S. C. Cowin, C. M. Semeins, J. Klein-Nulend, and Burger, E. H. unpublished results). The canalicular fluid shear stress *in vivo*, as predicted by Weinbaum *et al*. (1994) on the basis of a theoretical model validated with respect to the streaming potentials (Cowin *et al.,* 1995), is of the order of 1 Pa (0.8–3 N/m^2). *In vitro,* fluid shear stress between 0.4 and 1.2 Pa dose-dependently stimulated the release of NO and PGE_2 from primary bone cells (Bakker *et al.,* 2001) in good agreement with this figure, but more direct determination of canalicular shear stress is lacking. However, two independent studies concluded that the actual physical cell stimulus during substratum-mediated cell stretching is the *flow* of culture medium over the cell surface (Owan *et al.,* 1997; You *et al.,* 2000). When this medium fluid flow was prevented, 10% cell stretch was needed to induce the increase of cell calcium levels (You *et al.,* 2000). You and co-workers (2000) suggested that bone cell mechanotransduction may involve two distinct pathways relating to two different events. One is the mechanical adaptation of intact bone that occurs throughout life mediated by canalicular loading-induced fluid flow derived from small bone strains of the order of 0.1%. The other relates to fracture healing, when large cell deformations of the order of 10% can be expected. Interestingly, such large cell deformations are also applied during distraction osteogenesis and in orthodontic tooth displacement, where rapid activation of osteoprogenitor cells occurs (Ikegame *et al.,* 2001). It seems therefore that osteoprogenitor cells are activated to express their osteoblastic phenotype when they experience large strains in biological processes related to rapid bone healing. However, the more subtle effects of physiological bone loading seem to be mediated by fluid flow in the osteocyte network in intact bone. Because the flow *in vitro* resulting from substrate stretching or bending is difficult to determine and is probably complicated in pattern, it follows that for the study of physiological strains, the use of a system designed to apply flow is to be preferred. This approach allows at least the determination of the magnitude and pattern of the applied fluid shear stress (Bakker *et al.,* 2001).

Summary and Conclusions

Although we are still at the beginning of understanding the role of osteocytes in bone physiology, important progress has been made. Morphological studies of bone have illustrated the intricate process of osteocyte differentiation and formation of the complex osteocyte network. Studies with isolated osteocytes have shown that the formation of this network is an intrinsic property of osteocytes. Future experiments will have to elucidate the mechanism by which the osteocyte syncytium is formed.

According to the current predominant view, this three-dimensional osteocyte network provides the site for information acquirement underlying Wolff's law of adaptive bone remodeling, in other words, the site where bone is informed about local osteopenia or bone redundancy in relation to its usage. Although deformation of the cells themselves as a result of loading-induced matrix strain cannot yet be excluded as the signaling mechanism, the modulation of canalicular fluid flow resulting from compression/relaxation of the bone matrix seems a more sensitive mechanism of mechanosignaling in bone. This hypothesis does justice to the anatomy of the lacunocanalicular porosity and osteocyte syncytium. The osteocyte, cell body, and processes are surrounded by a thin sheath of unmineralized matrix, which allows a loading-derived flow of interstitial fluid flow over the osteocyte surface, as is demonstrated by the loading–facilitation of macromolecule diffusion. In addition, comparative studies of osteoprogenitor cells, osteoblasts, and osteocytes have shown that bone cells increase their sensitivity for shear stress as they mature, with the highest sensitivity being shown by the terminally differentiated cell stage, the osteocyte. This high sensitivity may be related to the composition of the cytoskeleton of the osteocyte, which in some ways differs from that of the osteoblast. Because the interaction of the cytoskeleton with the surrounding matrix is considered to be one of the possible sites of shear stress transduction, the composition of the matrix seems to be of major importance. Several studies have reported on the specialized matrix of the osteocyte sheath and the presence of receptors on the osteocyte that may interact with molecules in this matrix.

The hypothesis of the osteocyte's three-dimensional cellular network as the mechanosensory organ of bone has spawned several cell-based concepts that explain adaptive bone remodeling at the level of cells, osteons and trabeculae. These models are generally in agreement with Frost's mechanostat hypothesis, but go a step further in explaining the actual cell behavior during adaptive remodeling. As such they are a major step forward in our understanding of bone physiology.

The nature of the signaling molecules produced in the shear-strained osteocyte that modulate the recruitment or activity of the effector cells of loading-related bone remodeling, osteoblasts and osteoclasts, has been a subject of study in many investigations. Generally, authors agree on the importance of NO and prostaglandins. The enzymes

that produce these molecules are thought to be activated directly by changes in the intracellular calcium and the cytoskeletal organization and/or indirectly by the induction of gene expression. Clearly, most of the steps in the signaling cascades that are involved still have to be elucidated.

In sum, the field of molecular and, possibly, electrical signaling during adaptive bone remodeling is still wide open and provides an exciting area of future research. Further analysis of the specific properties of osteocytes, including identification of the antigens of known and newly developed osteocyte-specific antibodies, may help in the understanding of the role of osteocytes in bone physiology.

CHAPTER 7

Cells of Bone

Osteoclast Generation

Naoyuki Takahashi, Nobuyuki Udagawa, Masamichi Takami, and Tatsuo Suda

Department of Biochemistry, Showa University School of Dentistry, Tokyo 142–8555, Japan

Introduction

Osteoclasts, the multinucleated giant cells that resorb bone, develop from hemopoietic cells of the monocyte–macrophage lineage. We have developed a mouse coculture system of osteoblasts/stromal cells and hemopoietic cells in which osteoclasts are formed in response to bone-resorbing factors such as $1\alpha,25$-dihydroxyvitamin D_3 [$1\alpha,25(OH)_2D_3$], parathyroid hormone (PTH), prostaglandin E_2 (PGE_2), and interleukin 11 (IL-11). A series of experiments using this coculture system have established the concept that osteoblasts/stromal cells are crucially involved in osteoclast development. Cell-to-cell contact between osteoblasts/stromal cells and osteoclast progenitors was necessary for the induction of osteoclast differentiation in the coculture system. Studies on macrophage colony-stimulating factor (M-CSF, also called CSF-1)-deficient *op/op* mice have shown that M-CSF produced by osteoblasts/stromal cells is an essential factor for inducing osteoclast differentiation from monocyte–macrophage lineage cells. Subsequently, in 1998, another essential factor for osteoclastogenesis, receptor activator of nuclear factor κB ligand (RANKL) was cloned molecularly. RANKL [also known as osteoclast differentiation factor (ODF)/osteoprotegerin ligand (OPGL)/TNF-related activation-induced cytokine (TRANCE)] is a new member of the tumor necrosis factor (TNF)-ligand family, which is expressed as a membrane-associated protein in osteoblasts/stromal cells in response to many bone-resorbing factors. Osteoclast precursors that possess RANK, a TNF receptor family member, recognize RANKL through cell–cell interaction with osteoblasts/stromal cells and differentiate into osteoclasts in the presence of M-CSF. Mature osteoclasts also express RANK, and RANKL induces their bone-resorbing activity. Osteoprotegerin [OPG, also called osteoclastogenesis inhibitory factor (OCIF)] mainly produced by osteoblasts/stromal cells is a soluble decoy receptor for RANKL. OPG has been shown to function as an inhibitory factor for osteoclastogenesis *in vivo* and *in vitro*. Thus, the rapid advances in osteoclast biology have elucidated the precise mechanism by which osteoblasts/stromal cells regulate osteoclast differentiation and function. Activation of nuclear factor κB (NF-κB) and c-Jun N-terminal protein kinase (JNK) through RANK-mediated signals appears to be involved in the differentiation and activation of osteoclasts. Findings also indicate that TNFα directly induces differentiation of osteoclasts by a mechanism independent of the RANKL–RANK interaction. This chapter describes the current knowledge of the regulatory mechanisms of osteoclast differentiation induced by osteotropic hormones and cytokines.

Role of Osteoblasts/Stromal Cells in Osteoclast Differentiation and Function

Osteoblasts/Stromal Cells Regulate Osteoclast Differentiation

Development of osteoclasts proceeds within a local microenvironment of bone. This process can be reproduced *ex vivo* in a coculture of mouse calvarial osteoblasts and hemopoietic cells (Chambers *et al.,* 1993; Suda *et al.,* 1992; Takahashi *et al.,* 1988). Multinucleated cells formed in the coculture exhibit major characteristics of osteoclasts, including tartrate-resistant acid phosphatase (TRAP) activity, expression of calcitonin receptors, c-Src (p60c-src),

vitronectin receptors ($\alpha v\beta 3$), and the ability to form resorption pits on bone and dentine slices (Suda *et al.,* 1992). Some mouse stromal cell lines, such as MC3T3-G2/PA6 and ST2, are able to support osteoclastogenesis when cultured with mouse spleen cells (Udagawa *et al.,* 1989). In this coculture, osteoclasts were formed in response to various osteotropic factors, including $1\alpha,25(OH)_2D_3$, PTH, PGE_2, and IL-11. Cell-to-cell contact between osteoblasts/stromal cells and osteoclast progenitors is required to induce osteoclastogenesis. Subsequent experiments have established that the target cells of osteotropic factors for inducing osteoclast formation *in vitro* are osteoblasts/stromal cells (Table I).

IL-6 exerts its activity via a cell surface receptor that consists of two components: a ligand-binding IL-6 receptor (IL-6R) and a nonligand-binding but signal-transducing protein gp130 (Taga and Kishimoto, 1997). The genetically engineered soluble IL-6R (sIL-6R), which lacks both transmembrane and cytoplasmic domains, has been shown to mediate IL-6 signals through gp130 in response to IL-6. Neither recombinant IL-6 nor sIL-6R alone induced osteoclast formation in the coculture, but osteoclasts were formed in response to IL-6 in the presence of sIL-6R (Tamura *et al.,* 1993). This suggests that a signal(s) mediated by gp130 is involved in osteoclast development. Using transgenic mice constitutively expressing human IL-6R, it was shown that the expression of human IL-6R in osteoblasts was indispensable for inducing osteoclast recruitment (Udagawa *et al.,* 1995) (Table I). When osteoblasts obtained from human IL-6R transgenic mice were cocultured with normal spleen cells, osteoclast formation was induced in response to human IL-6 without the addition of human sIL-6R. Indeed, cytokines such as IL-11, oncostatin M, and leukemia inhibitory factor (LIF), which transduce their signals through gp130 in osteoblasts/stromal cells, induced osteoclast formation in the coculture. These results established for the first time the concept that bone-resorbing cytokines using gp130 as a common signal transducer act directly on osteoblasts/stromal cells but not on osteoclast progenitors to induce osteoclast formation.

Requirement of PTH/PTHrP receptors (PTHR1) in the osteoblast was confirmed using cocultures of osteoblasts and spleen cells obtained from PTHR1 knockout mice (Liu *et al.,* 1998). Osteoblasts obtained from PTHR1(−/−) mice failed to support osteoclast development in cocultures with normal spleen cells in response to PTH (Table I). Osteoclasts were formed in response to PTH in cocultures of spleen cells obtained from PTHR1(−/−) mice and normal calvarial osteoblasts. This suggests that the expression of PTHR1 in osteoblasts/stromal cells is critical for PTH-induced osteoclast formation *in vitro*.

PGE_2 exerts its effects through PGE receptors (EPs) that consist of four subtypes (EP1, EP2, EP3, and EP4) (Breyer and Breyer, 2000). Intracellular signaling differs among the receptor subtypes: EP1 is coupled to Ca^{2+} mobilization and EP3 inhibits adenylate cyclase activity, whereas both EP2 and EP4 stimulate adenylate cyclase activity. It was reported that 11-deoxy-PGE1 (an EP4 and EP2 agonist) stimulated osteoclast formation more effectively than butaprost (an EP2 agonist) and other EP agonists in the coculture of primary osteoblasts and bone marrow cells, suggesting that EP4 is the main receptor responsible for PGE_2-induced osteoclast formation (Sakuma *et al.,* 2000). Furthermore, the PGE_2-induced osteoclast formation was not observed in the coculture of osteoblasts from EP4(−/−) mice and spleen cells from wild-type mice, whereas osteoclasts were formed in the coculture of wild-type osteoblasts and EP4(−/−) spleen cells (Sakuma *et al.,* 2000) (Table I). These results indicate that PGE_2 enhances osteoclast formation through the EP4 subtype on osteoblasts. Li *et al.* (2000b) used cells from mice in which the EP2 receptor had been disrupted to test the role of EP2 in osteoclast formation. The response to PGE_2 for osteoclast formation was also reduced in cultures of bone marrow cells obtained from EP2(−/−) mice. In mouse calvarial organ cultures, the EP4 agonist stimulated bone resorption markedly, but its maximal stimulation was less

Table I Osteoclast Formation in Cocultures with hIL-6R Transgenic Mice or Mice Carrying the Disrupted Genes of VDR, PTHR1, or EP4

Osteotropic factor	Coculture system[a]		Osteoclast formation	Reference
	Osteoblasts	Hemopoietic cells		
hIL-6	wt	hIL-6R tg	−	Udagawa *et al.* (1995)
	hIL-6R tg	wt	+	
PTH	PTHR1(−/−)	wt	−	Liu *et al*. (1998)
	wt	PTHR1(−/−)	+	
PGE_2	EP4(−/−)	wt	−	Sakuma *et al.* (2000)
	wt	EP4(−/−)	+	
$1\alpha,25(OH)_2D_3$	VDR(−/−)	wt	−	Takeda *et al.* (1999)
	wt	VDR(−/−)	+	

[a] Osteoblasts or hemopoietic cells obtained from human IL-6R (hIL-6R) transgenic (tg) mice, VDR knockout [VDR(−/−)] mice, PTHR1 knockout [PTHR1(−/−)] mice, or EP4 knockout [EP4(−/−)] mice were cocultured with their counterpart (osteoblasts or hemopoietic cells) obtained from wild-type (wt) mice.

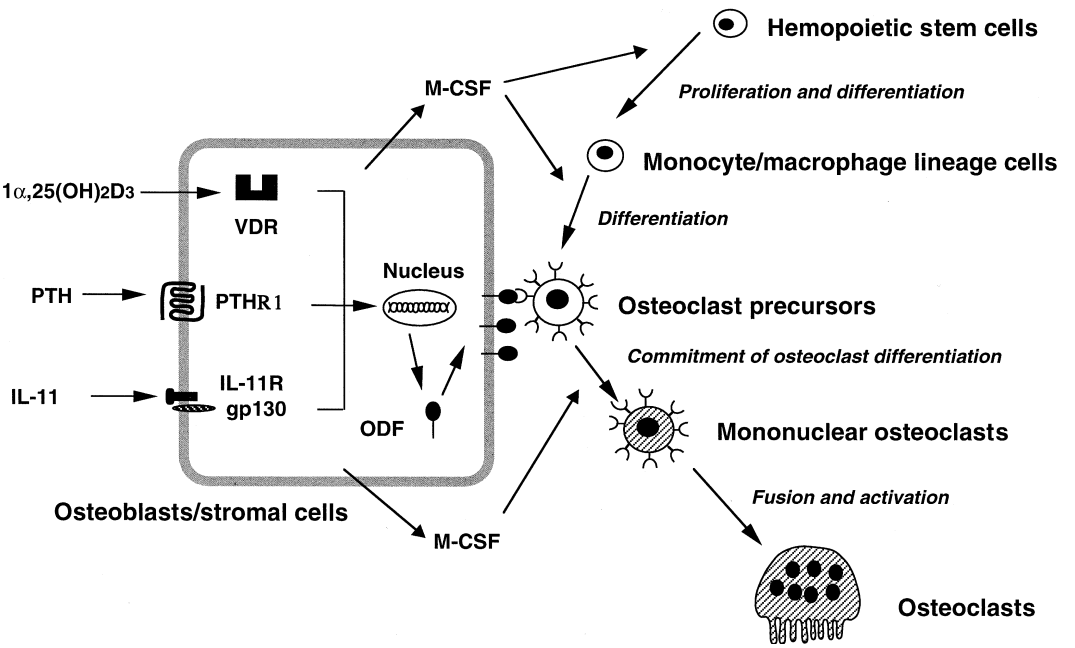

Figure 1 Hypothetical concept of osteoclast differentiation and a proposal for osteoclast differentiation factor (ODF). Osteotropic factors such as $1\alpha,25(OH)_2D_3$, PTH, and IL-11 stimulate osteoclast formation in mouse cocultures of osteoblasts/stromal cells and hemopoietic cells. The target cells of these osteotropic factors are osteoblasts/stromal cells. Three independent signaling pathways mediated by $1\alpha,25(OH)_2D_3$–VDR, PTH–PTHR1, and IL-11–IL-11R/gp130 interactions induce ODF as a membrane-associated factor in osteoblasts/stromal cells in a similar manner. Osteoclast progenitors of the monocyte–macrophage lineage recognize ODF through cell–cell interaction with osteoblasts/stromal cells and differentiate into osteoclasts. M-CSF produced by osteoblasts/stromal cells is a prerequisite for both proliferation and differentiation of osteoclast progenitors. This hypothetical concept has been proven molecularly by the discovery of the RANKL–RANK interaction.

than that induced by PGE_2 (Suzawa *et al.,* 2000). The EP2 agonist also stimulated bone resorption, but only slightly. EP1 and EP3 agonists showed no effect on bone resorption. These findings suggest that PGE_2 stimulates bone resorption by a mechanism involving cAMP production in osteoblasts/stromal cells, mediated mainly by EP4 and partially by EP2.

The other known pathway used for osteoclast formation is that stimulated by $1\alpha,25(OH)_2D_2$. Using $1\alpha,25(OH)_2D_3$ receptor (VDR) knockout mice, Takeda *et al*. (1999) clearly showed that the target cells of $1\alpha,25(OH)_2D_3$ for inducing osteoclasts in the coculture were also osteoblasts/stromal cells but not osteoclast progenitors (Table I). Spleen cells from VDR(−/−) mice differentiated into osteoclasts when cultured with normal osteoblasts in response to $1\alpha,25(OH)_2D_3$. In contrast, osteoblasts obtained from VDR(−/−) mice failed to support osteoclast development in coculture with wild-type spleen cells in response to $1\alpha,25(OH)_2D_3$. These results suggest that the signals mediated by VDR are also transduced into osteoblasts/stromal cells to induce osteoclast formation in the coculture.

Thus, the signals induced by almost all the bone-resorbing factors are transduced into osteoblasts/stromal cells to recruit osteoclasts in the coculture. Therefore, we proposed that osteoblasts/stromal cells express ODF, which is hypothesized to be a membrane-bound factor in promoting the differentiation of osteoclast progenitors into osteoclasts through a mechanism involving cell-to-cell contact (Suda *et al.,* 1992) (Fig. 1).

M-CSF Produced by Osteoblasts/Stromal Cells Is an Essential Factor for Osteoclastogenesis

Experiments with the *op/op* mouse model have established the role for M-CSF in osteoclast formation. Yoshida *et al.* (1990) demonstrated that there is an extra thymidine insertion at base pair 262 in the coding region of the M-CSF gene in *op/op* mice. This insertion generated a stop codon (TGA) 21 bp downstream, suggesting that the M-CSF gene of *op/op* mice cannot code for the functionally active M-CSF protein. In fact, administration of recombinant human M-CSF restored the impaired bone resorption of *op/op* mice *in vivo* (Felix *et al.,* 1990; Kodama *et al.,* 1991). Calvarial osteoblasts obtained from *op/op* mice could not support osteoclast formation in cocultures with normal spleen cells, even in the presence of $1\alpha,25(OH)_2D_3$ (Suda *et al.,* 1997a). The addition of M-CSF to the coculture with *op/op* osteoblastic cells induced osteoclast formation from normal spleen cells in response to $1\alpha,25(OH)_2D_3$. In contrast, spleen cells obtained from *op/op* mice were able to differentiate into osteoclasts when cocultured with normal osteoblasts. It was shown that M-CSF is involved in both proliferation of osteoclast progenitors and differentiation into osteoclasts (Felix *et al.,* 1994; Tanaka *et*

al., 1993). Begg *et al.* (1993) investigated age-related changes in osteoclast activity in *op*/*op* mice. Femurs of newborn *op*/*op* mice were infiltrated heavily with bone, and the marrow hemopoiesis was reduced significantly. However, the femoral marrow cavity of *op*/*op* mice enlarged progressively with the concomitant appearance of TRAP-positive osteoclasts, and by 22 weeks of age the marrow hemopoiesis was comparable to that of controls. Niida *et al*. (1999) reported that a single injection in *op*/*op* mice with recombinant human vascular endothelial growth factor (VEGF) induced osteoclast recruitment. These results suggest that factors other than M-CSF, including VEGF, can substitute for M-CSF to induce osteoclast formation under special occasions.

Osteoblasts/Stromal Cells Regulate Osteoclast Function

One of the major technical difficulties associated with the analysis of mature osteoclasts is their strong adherence to plastic dishes. We have developed a collagen-gel culture using mouse bone marrow cells and osteoblasts/stromal cells to obtain a cell preparation containing functionally active osteoclasts (Akatsu *et al.,* 1992; Suda *et al.,* 1997a). The purity of osteoclasts in this preparation was only 2–3%, contaminated with numerous osteoblasts. However, this crude osteoclast preparation proved to be a useful source to establish a reliable resorption pit assay on dentine slices. Therefore, osteoclasts were purified via centrifugation of the crude osteoclast preparation in a 30% Percoll solution (Jimi *et al.,* 1996b). Interestingly, these highly purified osteoclasts (purity: 50–70%) cultured for 24 h on dentine slices failed to form resorption pits. Resorptive capability of the purified osteoclasts was restored when osteoblasts/stromal cells were added to the purified osteoclast preparation. Similarly, Wesolowski *et al.* (1995) obtained highly purified mononuclear and binuclear prefusion osteoclasts using echistatin from mouse cocultures of bone marrow cells and osteoblastic MB 1.8 cells. These enriched prefusion osteoclasts failed to form resorption pits on bone slices, but their bone-resorbing activity was induced when both MB 1.8 cells and $1\alpha,25(OH)_2D_3$ were added to the prefusion osteoclast cultures. These results suggest that osteoblasts/stromal cells play an essential role not only in the stimulation of osteoclast formation, but also in the activation of mature osteoclasts to resorb bone, which is also a cell-to-cell contact-dependent process (Suda *et al.,* 1997b).

Discovery of the RANKL–RANK Interaction for Osteoclastogenesis

Discovery of OPG

OPG was cloned as a new member of the TNF receptor superfamily in an expressed sequence tag cDNA project (Simonet *et al.,* 1997). Interestingly, OPG lacked a transmembrane domain and presented as a secreted form. Hepatic expression of OPG in transgenic mice resulted in severe osteopetrosis. Osteoclastogenesis inhibitory factor (OCIF), which inhibited osteoclast formation in the coculture of osteoblasts and spleen cells, was isolated as a heparin-binding protein from the conditioned medium of human fibroblast cultures (Tsuda *et al.,* 1997). The cDNA sequence of OCIF was identical to that of OPG (Yasuda *et al.,* 1998a). Tan *et al.* (1997) also identified a new member of the TNF receptor family called TNF receptor-like molecule 1 (TR1) from a search of an expressed sequence tag database. TR1 was also found to be identical to OPG/OCIF.

OPG contains four cysteine-rich domains and two death domain homologous regions (Fig. 2). The death domain homologous regions share structural features with "death domains" of TNF type I receptor (p55) and Fas, both of which mediate apoptotic signals. Analysis of the domain-deletion mutants of OPG revealed that the cysteine-rich domains, but not the death domain homologous regions, are essential for inducing biological activity *in vitro*. When the transmembrane domain of Fas was inserted between the cysteine-rich domains and the death domain homologous regions, and the mutant protein was then expressed in the human kidney cell line 293-EBNA, apoptosis was induced in the transfected cells (Yamaguchi *et al.,* 1998). The biological significance of the death domain homologous regions in the OPG molecule, however, remains largely unknown at present.

OPG strongly inhibited osteoclast formation induced by $1\alpha,25(OH)_2D_3$, PTH, PGE_2, or IL-11 in the cocultures. Analyses of transgenic mice overexpressing OPG and animals injected with OPG have demonstrated that this factor increases bone mass by suppressing bone resorption (Simonet *et al.,* 1997; Yasuda *et al.,* 1998a). Administration of OPG to rats decreased the serum calcium concentration rapidly (Yamamoto *et al.,* 1998). The physiological role of OPG was investigated further in OPG-deficient mice (Bucay *et al.,* 1998; Mizuno *et al.,* 1998). These mutant mice were viable and fertile, but adolescent and adult OPG(−/−) mice exhibited a decrease in bone mineral density (BMD) characterized by severe trabecular and cortical bone porosity, marked thinning of parietal bones of the skull, and a high incidence of fractures. Interestingly, osteoblasts derived from OPG(−/−) mice strongly supported osteoclast formation in the coculture even in the absence of any bone-resorbing agents (Udagawa *et al.,* 2000). Bone-resorbing activity in organ cultures of fetal long bones derived from OPG(−/−) mice was also strikingly higher in the absence of bone-resorbing factors when compared to that of wild-type mice. Osteoblasts prepared from OPG(−/−) mice and wild-type mice expressed comparable levels of RANKL mRNA. These results indicate that OPG produced by osteoblasts/stromal cells functions as an important negative regulator in osteoclast differentiation and activation *in vivo* and *in vitro*.

Discovery of the RANKL–RANK Interaction

The mouse bone marrow-derived stromal cell line ST2 supports osteoclast formation in the coculture with mouse

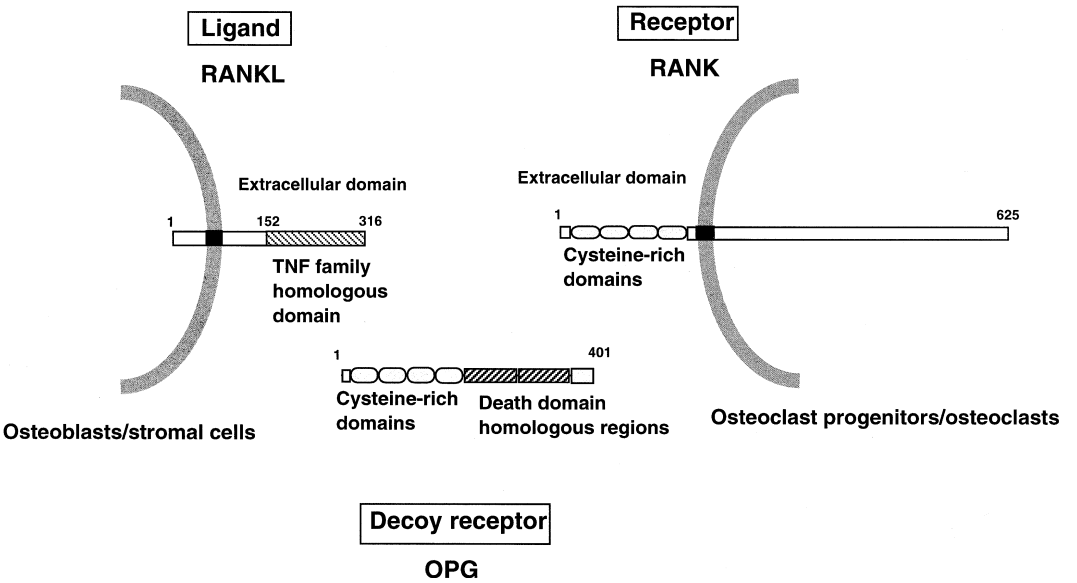

Figure 2 Diagrammatic representation of the ligand, receptor, and decoy receptor of the new TNF receptor–ligand family members essentially involved in osteoclastogenesis. Mouse RANKL is a type II transmembrane protein composed of 316 amino acid residues. The TNF homologous domain exists in Asp_{152}-Asp_{316}. RANK is a type I transmembrane protein of 625 amino acid residues. Four cysteine-rich domains exist in the extracellular region of the RANK protein. OPG, a soluble decoy receptor for RANKL, is composed of 401 amino acid residues without a transmembrane domain. OPG also contains four cysteine-rich domains and two death domain homologous regions. The cysteine-rich domains but not the death domain homologous regions of OPG are essential for inhibiting osteoclast differentiation and function.

spleen cells in the presence of $1\alpha,25(OH)_2D_3$ and dexamethasone (Udagawa *et al.,* 1989). OPG bound to a single class of high-affinity binding sites appearing on ST2 cells treated with $1\alpha,25(OH)_2D_3$ and dexamethasone (Yasuda *et al.,* 1998a). Using OPG as a probe, Yasuda *et al.* (1998b) cloned a cDNA with an open reading frame encoding 316 amino acid residues from an expression library of ST2 cells. The OPG-binding molecule was a type II transmembrane protein of the TNF ligand family (Fig. 2). Because the OPG-binding molecule satisfied major criteria of ODF, this molecule was renamed ODF. Lacey *et al.* (1998) also succeeded in the molecular cloning of the ligand for OPG (OPGL) from an expression library of the murine myelomonocytic cell line 32D. Molecular cloning of ODF/OPGL demonstrated that it was identical to TRANCE (Wong *et al.,* 1997b) and RANKL (Anderson *et al.,* 1997), which had been identified independently by other research groups in the immunology field.

TRANCE was cloned during a search for apoptosis-regulatory genes in murine T cell hybridomas (Wong *et al.,* 1997b). A recombinant soluble form of TRANCE induced activation of JNK in T lymphocytes and inhibited apoptosis of mouse and human dendritic cells. A new member of the TNF receptor family, termed "RANK," was cloned from a cDNA library of human dendritic cells (Anderson *et al.,* 1997). The mouse homologue was also isolated from a fetal mouse liver cDNA library. The mouse RANK cDNA encodes a type I transmembrane protein of 625 amino acid residues with four cycteine-rich domains in the extracellular region (Fig. 2). RANKL was cloned from a cDNA library of murine thymoma EL40.5 cells and was found to be identical to TRANCE. A soluble form of RANKL augmented the capability of dendritic cells to stimulate T cell proliferation in a mixed lymphocyte reaction and increased the survival of RANK-positive T-cells (Wong *et al.,* 1997a). The N-terminal region of RANK has a similar structure to that of OPG, a decoy receptor for RANKL (Fig. 2).

Polyclonal antibodies against the extracellular domains of RANK (anti-RANK Ab) have been shown to induce osteoclast formation in spleen cell cultures in the presence of M-CSF (Hsu *et al.,* 1999; Nakagawa *et al.,* 1998). This suggests that the clustering of RANK is required for the RANK-mediated signaling of osteoclastogenesis. In contrast, the anti-RANK antibody, which lacks the Fc fragment, (the Fab fragment), completely blocked the RANKL-mediated osteoclastogenesis (Nakagawa *et al.,* 1998). A soluble form of RANK, an extracellular domain of RANK, not only inhibited RANKL-mediated osteoclast formation, but also prevented the survival, multinucleation, and pit-forming activity of prefusion osteoclasts treated with RANKL (Jimi *et al.,* 1999a). Transgenic mice expressing a soluble RANK-Fc fusion protein showed osteopetrosis, similar to OPG transgenic mice (Hsu *et al.,* 1999). Taken together, these results suggest that RANK acts as the sole signaling receptor for RANKL in inducing differentiation and subsequent activation of osteoclasts (Fig. 2).

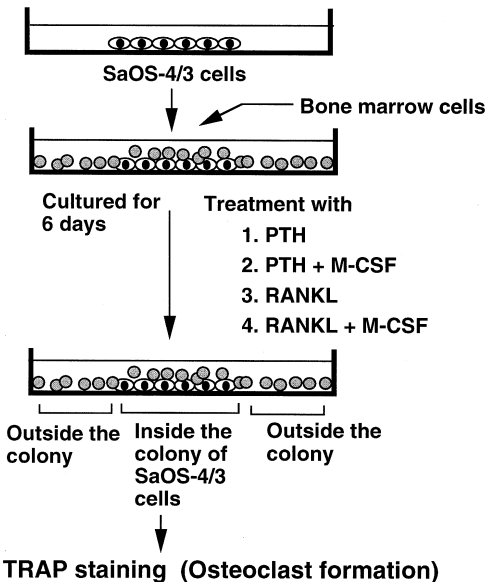
Thus, ODF, OPGL, TRANCE, and RANKL are different names for the same protein, which is important for the development and function of T cells, dendritic cells and osteoclasts. The terms "RANKL," "RANK," and "OPG" are

used in this chapter in accordance with the guideline of the American Society for Bone and Mineral Research President's Committee on Nomenclature (2000).

Role of RANKL in Osteoclast Differentiation and Function

When COS-7 cells transfected with a RANKL expression vector were fixed with paraformaldehyde and cocultured with mouse spleen cells in the presence of M-CSF, osteoclasts were formed on the fixed COS-7 cells (Yasuda *et al.,* 1998b). A genetically engineered soluble form of RANKL, together with M-CSF, induced osteoclast formation from spleen cells in the absence of osteoblasts/stromal cells, which was abolished completely by the simultaneous addition of OPG. Treatment of calvarial osteoblasts with $1\alpha,25(OH)_2D_3$, PTH, PGE_2, or IL-11 upregulated the expression of RANKL mRNA. Human osteoclasts were also formed in cultures of human peripheral blood mononuclear cells in the presence of RANKL and human M-CSF (Matsuzaki *et al.,* 1998). This suggests that the mechanism of human osteoclast formation is essentially the same as that of mouse osteoclast formation. Lum *et al*. (1999) reported that like TNFα, RANKL is synthesized as a membrane-anchored precursor and is detached from the plasma membrane to generate the soluble form of RANKL by a metalloprotease–disintegrin TNFα convertase (TACE). Soluble RANKL demonstrated a potent activity in the induction of dendritic cell survival and osteoclastogenesis. These findings suggest that the ectodomain of RANKL is released from the cells by TACE or a related metalloprotease-disintegrin and that this release is an important component of the function of RANKL in bone and immune homeostasis.

We carefully examined the mechanism of action of RANKL and M-CSF expressed by osteoblasts/stromal cells that support osteoclast formation (Itoh *et al.,* 2000b) (Fig. 3). SaOS-4/3, a subclone of the human osteosarcoma cell line SaOS-2, was established by transfecting the human PTHR1 cDNA. SaOS-4/3 cells supported human and mouse osteoclast formation in response to PTH in cocultures with human peripheral blood mononuclear cells and mouse bone marrow cells, respectively (Matsuzaki *et al.,* 1999). Osteoclast formation supported by SaOS-4/3 cells was completely inhibited by adding either OPG or antibodies against human M-CSF. This suggests that RANKL and M-CSF are both essential factors for inducing osteoclast formation in the coculture with SaOS-4/3 cells. To elucidate the functional form of both RANKL and M-CSF, SaOS-4/3 cells were spot cultured for 2 hr in the center of a culture well and then mouse bone marrow cells were plated uniformly over the well (Fig. 3). When the spot coculture was treated for 6 days with PTH together with or without M-CSF, osteoclast formation was induced exclusively inside the colony of SaOS-4/3 cells irrespective of the exogenous addition of M-CSF. Similarly, when the spot coculture was treated with RANKL, osteoclasts were formed only inside the colony of SaOS-4/3 cells, suggesting that M-CSF acts as a membrane- or matrix-associated form in the coculture. However, the concomitant treatment with RANKL and M-CSF induced osteoclast formation both inside and outside the colony of SaOS-4/3 (Fig. 3). Similar results were obtained in the spot coculture with OPG(−/−) mouse-derived osteoblasts



Treatment with	Osteoclast formation	
	Inside the colony of SaOS-4/3 cells	Outside the colony of SaOS-4/3 cells
1. PTH	+	—
2. PTH + M-CSF	+	—
3. RANKL	+	—
4. RANKL + M-CSF	+	+

Figure 3 Both M-CSF and RANKL act as membrane- or matrix-associated forms in osteoclast formation. SaOS-4/3 cells expressing recombinant human PTHR1 were spot cultured for 2 hr in the center of a culture well; subsequently, mouse bone marrow cells were plated uniformly over the well. Spot cocultures were treated for 6 days with PTH, PTH plus M-CSF, RANKL, or RANKL plus M-CSF. Cells were then fixed and stained for TRAP. The location of TRAP-positive osteoclasts in the culture well was observed under a microscope. Osteoclasts formed outside the colony of SaOS-4/3 cells were observed only when the spot cocultures were treated with both RANKL and M-CSF.

(Udagawa *et al.,* 2000). These results suggest that membrane- or matrix-associated forms of both M-CSF and RANKL are essentially involved in osteoclast formation supported by osteoblasts/stromal cells. Such a mechanism of action of RANKL and M-CSF on osteoclast progenitors may explain the reason why osteoclasts are localized in bone, despite the relatively wide distribution of RANKL (Kartsogiannis *et al*., 1999) and M-CSF (Felix *et al.,* 1994; Wood *et al.,* 1997).

Survival, fusion, and pit-forming activity of osteoclasts are also induced by RANKL (Fig. 4). Treatment of prefusion osteoclasts with OPG suppressed their survival, fusion, and pit-forming activity induced by RANKL (Jimi *et al.,* 1999a). RANKL increased bone resorption by isolated rat authentic osteoclasts (Burgess *et al.,* 1999; Fuller *et al*., 1998). Bone-resorbing factors, such as $1\alpha,25(OH)_2D_3$, PTH, and IL-11, enhanced pit formation by purified osteoclasts only in the presence of osteoblasts (Udagawa *et al.,* 1999). Treatment of prelabeled bone with $1\alpha,25(OH)_2D_3$, PGE_2, and PTH enhanced the release of ^{45}Ca from the bone, which was completely inhibited by the addition of OPG or anti-RANKL antibody (Tsukii *et al.,* 1998). These results suggest that osteoblasts/stromal cells are essentially involved in both differentiation and activation of osteoclasts through the expression of RANKL as a membrane-associated factor (Fig. 4).

RANKL- and RANK-Deficient Mice

The physiological role of RANKL was investigated by generating RANKL-deficient mice (Kong *et al.,* 1999b) (Table II). RANKL(−/−) mice exhibited typical osteopetrosis with total occlusion of bone marrow space within endosteal bone. RANKL(−/−) mice lacked osteoclasts but had normal osteoclast progenitors that can differentiate into functionally active osteoclasts when cocultured with normal osteoblasts/stromal cells. Osteoblasts obtained from RANKL(−/−) mice failed to support osteoclast formation in the coculture with wild-type bone marrow cells even in the presence of $1\alpha,25(OH)_2D_3$ and PGE_2. RANKL(−/−) mice exhibited defects in the early differentiation of T and B lymphocytes. In addition, RANKL(−/−) mice showed normal splenic structure and Peyer's patches, but lacked all lymph nodes. These results suggest that RANKL is an absolute requirement not only for osteoclast development, but it plays an important role in lymphocyte development and lymph node organogenesis.

The physiological role of RANK was also investigated by generating RANK-deficient mice (Dougall *et al.,* 1999) (Table II). The phenotypes of RANK(−/−) mice were essentially the same as those of RANKL(−/−) mice, except for some differences. Like RANKL-deficient mice, RANK(−/−) mice were characterized by severe osteopetrosis resulting from an apparent block in osteoclast differentiation. RANK expression was not required for the commitment, differentiation, and functional maturation of macrophages and dendritic cells from their myeloid precursors, but provided a necessary and specific signal for the differentiation of myeloid-derived osteoclasts. RANK(−/−) mice also exhibited a marked deficiency of B cells in the spleen. RANK(−/−) mice retained mucosal-associated lymphoid tissues, including Peyer's patches, but completely lacked all the other peripheral lymph nodes. These results demonstrate that RANK provides critical signals necessary for lymph node organogenesis and osteoclast differentiation.

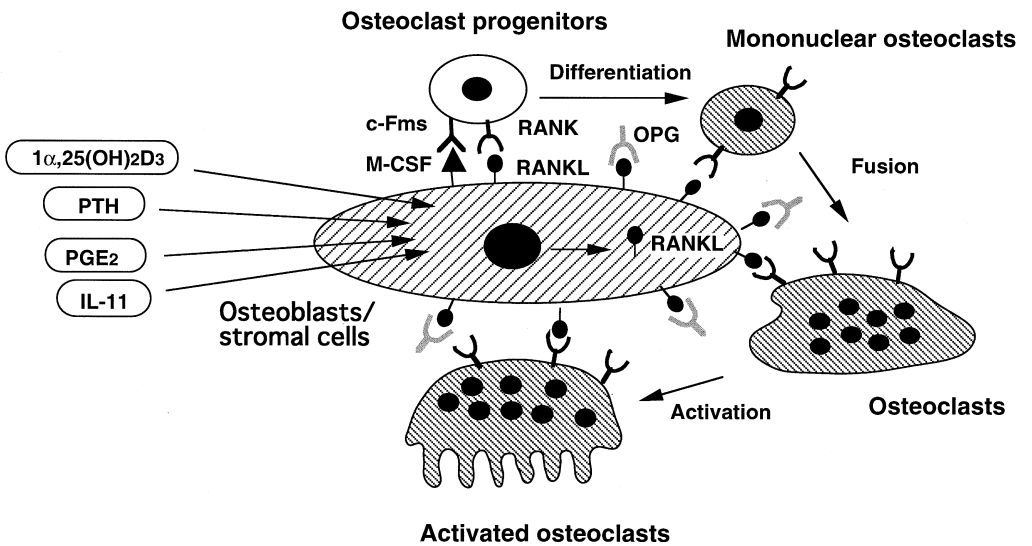


Figure 4 Schematic representation of osteoclast differentiation and function regulated by RANKL and M-CSF. Osteoclast progenitors and mature osteoclasts express RANK, the receptor for RANKL. Osteotropic factors such as $1\alpha,25(OH)_2D_3$, PTH, and IL-11 stimulate expression of RANKL in osteoblasts/stromal cells. Membrane- or matrix-associated forms of both M-CSF and RANKL expressed by osteoblasts/stromal cells are responsible for the induction of osteoclast differentiation in the coculture. RANKL also directly stimulates fusion and activation of osteoclasts. Mainly osteoblasts/stromal cells produce OPG, a soluble decoy receptor of RANKL. OPG strongly inhibits the entire differentiation, fusion, and activation processes of osteoclasts induced by RANKL.

Table II Comparison of Characteristics between RANKL-Deficient Mice and RANK-Deficient Mice

Characteristic	RANKL(−/−) mice	RANK(−/−) mice
Osteopetrosis	Severe	Severe
Osteoclasts in bone	Absence	Absence
Tooth eruption	Impaired	Impaired
Function of macrophages	Normal	Normal
Function of dendritic cells	Normal	Normal
B-cell development	Slightly impaired	Slightly impaired
T-cell development	Slightly impaired	Not impaired
Lymph node formation	Impaired	Impaired
Extramedullary hemopoiesis	Increased	Increased
Bone marrow transplantation	Not curable	Curable

Li *et al.* (2000a) further showed that RANK(−/−) mice lacked osteoclasts and had a profound defect in bone resorption and remodeling and in the development of the cartilaginous growth plates of endochondral bone. Osteopetrosis observed in these mutant mice was rescued by the transplantation of bone marrow from rag1 (recombinase activating gene 1)(−/−) mice, indicating that RANK(−/−) mice have an intrinsic defect in osteoclast lineage cells.

Osteoclastogenesis in RANK(−/−) mice was rescued by the transferring the RANK cDNA back into hematopoietic precursors. These data indicate that RANK is the intrinsic cell surface determinant that mediates RANKL effects on bone resorption.

Activating Mutations of RANK Found in Humans

Familial expansile osteolysis is a rare autosomal dominant disorder of bone characterized by focal areas of increased bone remodeling. The osteolytic lesions, which develop usually in the long bones during early adulthood, show increased osteoblast and osteoclast activity. Hughes *et al.* (2000) reported that the gene responsible for familial expansile osteolysis and familial Paget's disease of bone was mapped to the gene encoding RANK. Two mutations of heterozygous insertion were detected in the first exon of RANK in affected members of four families with familial expansile osteolysis or familial Paget's disease of bone. One mutation was a duplication of 18 bases and the other a duplication of 27 bases, both of which affected the signal peptide region (extracellular domain) of the RANK molecule. Expression of recombinant forms of the mutant RANK proteins revealed perturbations in the expression levels and lack of normal cleavage of the signal peptide. Both mutations caused an increase in RANK-mediated NF-κB signaling *in vitro*, consistent with the presence of an activating mutation. These results further confirm that RANK is involved in osteoclast differentiation and activation in humans as well.

Regulation of RANKL and OPG Expression

Osteoblasts/Stromal Cells

Treatment of calvarial osteoblasts with osteotropic factors such as $1\alpha,25(OH)_2D_3$, PTH, PGE_2 or IL-11, which stimulate osteoclast formation, up regulated the expression of RANKL mRNA. In many cases, expression of OPG mRNA is suppressed by those osteotropic factors. O'Brien *et al.* (1999) reported that the expression of dominant-negative STAT3 or dominant-negative gp130 suppressed RANKL expression in a stromal/osteoblastic cell line (UAMS-32) and osteoclast formation supporting activity stimulated by IL-6 together with soluble IL-6 receptor, oncostatin M, or IL-11 but not by PTH or $1\alpha,25(OH)_2D_3$. This suggests that the gp130/STAT3 signaling pathway induces RANKL expression in osteoblasts. The involvement of PGE receptor subtypes, EP1, EP2, EP3, and EP4, in PGE_2-induced bone resorption was examined using specific agonists for the respective EPs. Both the EP2 agonist and the EP4 agonist induced cAMP production and expression of RANKL mRNA in osteoblastic cells (Suzawa *et al.,* 2000). These results suggest that at least three signals are independently involved in RANKL expression by osteoblasts/stromal cells: VDR-mediated signals by $1\alpha,25(OH)_2D_3$; cAMP/protein kinase A (PKA)-mediated signals by PTH or PGE_2; and gp130-mediated signals by IL-11, IL-6, oncostatin M, and LIF (Fig. 5). Inverted TATA and CAAT boxes, a putative Cbfa1/Osf2/AML3 binding domain, and the repeated half-sites for VDR and the glucocorticoid receptor binding domain are found in the 5'-flanking basic promoter region of the mouse RANKL gene (Kitazawa *et al.,* 1999). Promoter analysis of the RANKL gene may elucidate the precise mechanism of the regulation of RANKL gene expression.

IL-1 stimulates osteoclast formation in the coculture of mouse primary osteoblasts and bone marrow cells, which is completely inhibited by the concomitant addition of indomethacin (Akatsu *et al.,* 1991). A positve correlation was observed between the number of osteoclasts induced by IL-1 and the amount of PGE_2 released into the culture

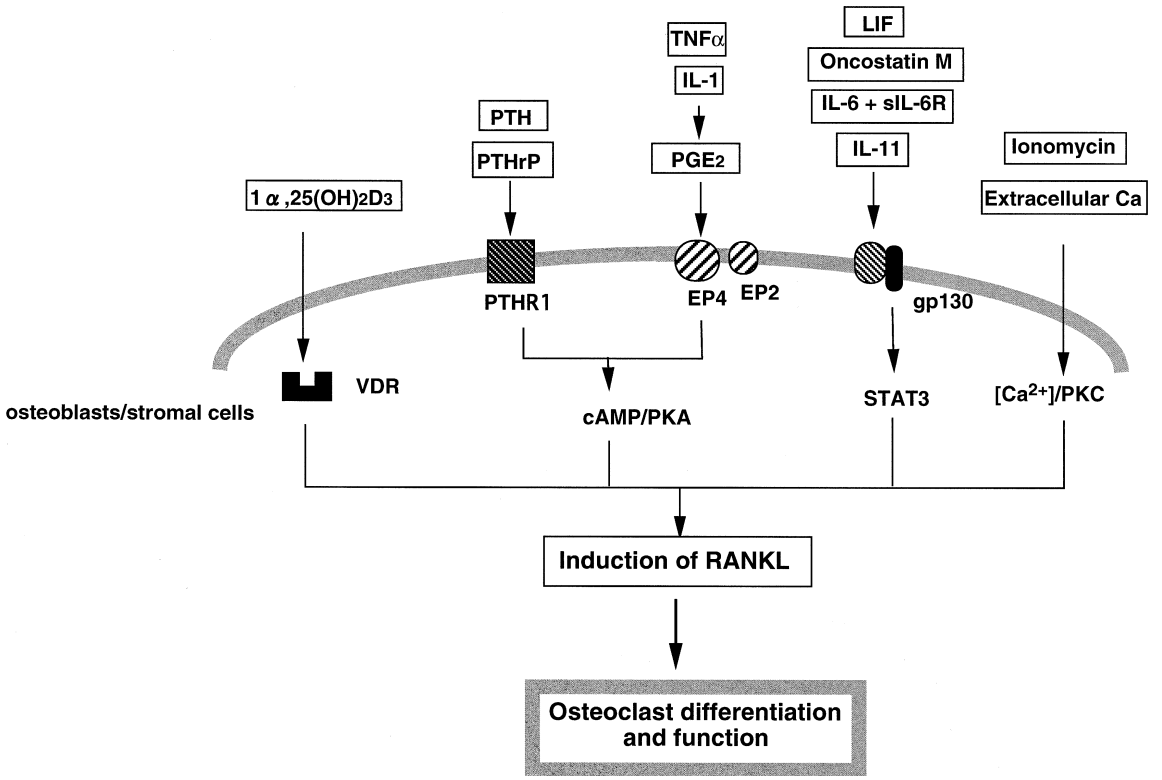

Figure 5 Signaling pathways for the induction of RANKL in osteoblasts/stromal cells. Three independent signals have been proposed to induce RANKL expression in osteoblasts/stromal cells: VDR-mediated signals by $1\alpha,25(OH)_2D_3$, cAMP/PKA-mediated signals by PTH and PGE_2, and gp130-mediated signals by IL-11, IL-6, oncostatin M, and LIF. IL-1 and TNFα also stimulate RANKL expression in osteoblasts/stromal cells through the up regulation of PGE_2 production. The calcium/PKC signal in osteoblasts/stromal cells, which is induced by iomomycin or high calcium concentrations of the culture medium, is now proposed to be the fourth signal involved in the induction of RANKL mRNA expression. RANKL expression induced by these four signals in osteoblasts/stromal cells in turn stimulates osteoclast differentiation and function.

medium. Sakuma *et al.* (2000) reported that osteoclasts were barely induced by IL-1 and TNFα in the coculture of primary osteoblasts and bone marrow cells prepared from EP4(−/−) mice, suggesting the crucial involvement of PGs and the EP4 subtype in osteoclast formation by IL-1 and TNFα (Fig. 5). In contrast, osteoclast formation induced by $1\alpha,25(OH)_2D_3$ was not impaired in the coculture of EP4(−/−) mouse-derived cells. These results suggest that PGE_2 is involved in the mechanism of IL-1- and TNFα-mediated osteoclast formation *in vitro* (Fig. 5).

Compounds, which elevate intracellular calcium, such as ionomycin, cyclopiazonic acid, and thapsigargin, also induced osteoclast formation in mouse cocultures of bone marrow cells and primary osteoblasts (Takami *et al.,* 1997). Similarly, high calcium concentrations of the culture medium induced osteoclast formation in the cocultures. Treatment of primary osteoblasts with these compounds or high medium calcium stimulated the expression of both RANKL and OPG mRNAs (Takami *et al.,* 2000). Phorbol 12-myristate 13-acetate (PMA), an activator of protein kinase C (PKC), also stimulated osteoclast formation in these cocultures and the expression of RANKL and OPG mRNAs in primary osteoblasts. PKC inhibitors, such as calphostin and staurosporin, suppressed ionomycin- and PMA-induced osteoclast formation in the coculture as well as the expression of RANKL and OPG mRNAs in primary osteoblasts. OPG strongly inhibited osteoclast formation induced by calcium-elevating compounds and PMA in the cocultures, suggesting that RANKL expression in osteoblasts is a rate-limiting step for osteoclast formation induced by calcium-elevating compounds. Forskolin , an activator of cAMP/protein kinase A (PKA) signals, also enhanced RANKL mRNA expression but, inversely, suppressed OPG mRNA expression in primary osteoblasts. Thus, calcium/PKC signals stimulate the expression of OPG mRNA whereas cAMP/PKA signals inhibit it, although both signals induce RANKL expression in osteoblasts/stromal cells in a similar manner. Therefore, the calcium/PKC signal is proposed to be the fourth signal pathway involved in the induction of RANKL mRNA expression, which in turn stimulates osteoclast formation (Fig. 5).

During embryonic bone development, osteoclasts appear just after bone mineralization takes place. Implantation of bone morphogenetic proteins (BMPs) into muscle or subcutaneous tissues induces ectopic bone formation at the site of the implantation. In this case, osteoclasts also appear just after bone tissue mineralization is initiated by BMPs. These results suggest that the physiological expression of RANKL in osteoblasts occurs in response to an endogeneous factor(s)

present in mineralized tissues. The calcium/PKC signaling system is one of the candidates that induce osteoclast formation in calcified bone. Further studies are necessary to elucidate the involvement of calcium/PKC signals in the regulation of osteoclast formation.

T LYMPHOCYTES

The RANKL–RANK interaction has been shown to regulate lymph node organogenesis, lymphocyte development, and interactions between T cells and dendritic cells in the immune system. RANKL expression in T cells is induced by antigen receptor engagement. Kong *et al.* (1999a) reported that activated T cells directly triggered osteoclastogenesis through RANKL expression. Using specific inhibitors, it was shown that the induction of RANKL by T cells depends on PKC, phosphoinositide-3 kinase, and calcineurin-mediated signaling pathways. RANKL was detected on the surface of activated T cells. Activated T cells also secreted soluble RANKL into culture medium. Both membrane-bound and soluble RANKL supported osteoclast development *in vitro*. Systemic activation of T cells *in vivo* also induced a RANKL-mediated increase in osteoclastogenesis and bone loss. In a T-cell-dependent model of rat adjuvant arthritis characterized by severe joint inflammation, treatment with OPG at the onset of the disease prevented bone and cartilage destruction but not inflammation. These results suggest that both systemic and local T-cell activation can lead to RANKL production and subsequent bone loss. Horwood *et al.* (1999) also reported that human peripheral blood-derived T cells, prepared with anti-CD3 antibody-coated magnetic beads, supported osteoclast differentiation from mouse spleen cells in the presence of Con A together with IL-1 or transforming growth factor-β (TGF-β) in the coculture. The expression of RANKL mRNA was stimulated in peripheral blood-derived T cells treated with the same factors. In synovial tissue sections with lymphoid infiltrates from patients with rheumatoid arthritis, the expression of RANKL was demonstrated in CD3-positive T cells. The ability of activated T lymphocytes to support osteoclast formation may provide a mechanism for the potentiation of osteoclast formation and bone destruction in diseases such as rheumatoid arthritis and periodontitis.

Teng *et al.* (2000) transplanted human peripheral blood lymphocytes from periodontitis patients into NOD/SCID mice. Human $CD4^{(+)}$ T cells, but not $CD8^{(+)}$ T cells or B cells, were identified as essential mediators of alveolar bone destruction in the transplanted mice. Stimulation of $CD4^{(+)}$ T cells by *Actinobacillus actinomycetemcomitans,* a well-known gram-negative anaerobic microorganism that causes human periodontitis, induced production of RANKL. *In vivo* inhibition of RANKL function with OPG diminished alveolar bone destruction and reduced the number of periodontal osteoclasts after microbial challenge. These data suggest that alveolar bone destruction observed in periodontal infections is mediated by the microorganism-triggered induction of RANKL expression on $CD4^{(+)}$ T cells.

Signal Transduction Mechanism of RANK

TRAFs as Signaling Molecules of RANK

Studies have indicated that the cytoplasmic tail of RANK interacts with TNF receptor-associated factor 1(TRAF1), TRAF2, TRAF3, TRAF5, and TRAF6 (Darnay *et al.,* 1998, 1999; Galibert *et al.,* 1998; Kim *et al.,* 1999; Wong *et al.,* 1998). Mapping of the structural requirements for TRAF/RANK interaction revealed that selective TRAF-binding sites are clustered in two distinct domains of the RANK cytoplasmic tail. In particular, TRAF6 interacts with the membrane-proximal domain of the cytoplasmic tail distinct from binding sites for TRAFs 1, 2, 3, and 5. When the proximal TRAF6 interaction domain was deleted, RANK-mediated NF-κB activation was completely inhibited and JNK activation partially inhibited (Galibert *et al.,* 1998). An N-terminal truncation mutant of TRAF6 (dominant-negative TRAF6) also inhibited RANKL-induced NF-κB activation (Darnay *et al.,* 1999). These results suggest that TRAF6 transduces a signal involved in RANK-mediated differentiation and activation of osteoclasts (Fig. 6).

Lomaga *et al.* (1999) have reported that TRAF6(−/−) mice are osteopetrotic with defects in bone resorption and tooth eruption due to impaired osteoclast function. A similar number of TRAP-positive osteoclasts were observed in bone tissues in wild-type and TRAF6(−/−) mice, but TRAP-positive osteoclasts in TRAF6(−/−) mice failed to form ruffled borders. Using *in vitro* assays, it was demonstrated that TRAF6 is crucial not only for IL-1 and CD40 signalings but also for lipopolysaccharide (LPS) signaling. Naito *et al.* (1999) reported independently that TRAF6(−/−) mice exhibited severe osteopetrosis. However, unlike the report by Lomaga *et al.* (1999), TRAF6(−/−) mice produced by Naito *et al*. (1999) were defective in osteoclast formation as well. *in vitro* experiments revealed that osteoclast precursors derived from TRAF6(−/−) mice are unable to differentiate into functional osteoclasts in response to RANKL and M-CSF. The cause of the difference between the two TRAF6(−/−) mice is not known at present, perhaps it was due to different experimental conditions, but TRAF6 is proposed to be an essential component of the RANK-mediated signaling pathway in bone metabolism and immune/inflammatory systems *in vivo* (Table III).

Takayanagi *et al.* (2000) reported that T-cell production of interferon-γ (IFN-γ) strongly suppresses osteoclastogenesis by interfering with the RANKL–RANK signaling pathway. IFNγ-induced rapid degradation of TRAF6 in osteoclast precursors, which resulted in strong inhibition of the RANKL-induced activation of the transcription factor NF-κB and JNK. These results suggest that there is cross-communication between the TNF and IFN families of cytokines, through which IFNγ provides a negative link between T-cell activation and bone resorption.

Soriano *et al.* (1991) were the first to report that the targeted disruption of the gene encoding c-Src (a member of the tyrosine kinase family) induced an osteopetrotic disorder.

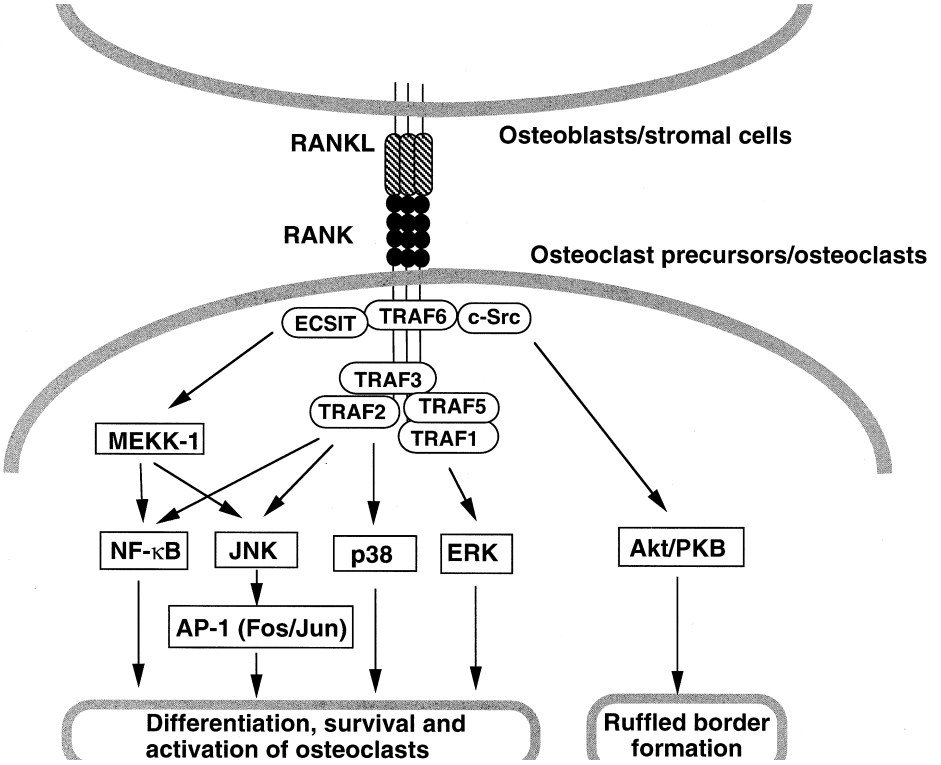

Figure 6 Signal transduction induced by the RANKL–RANK interaction in the target cell. The cytoplasmic tail of RANK interacts with TRAF1, TRAF2, TRAF3, TRAF5, and TRAF6. The RANKL–RANK interaction induces activation of NF-κB, JNK, p38 MAP kinase, and ERK in osteoclast precursors, as well as in mature osteoclasts. In addition, RANKL activates Akt/PKB through a signaling complex involving c-Src and TRAF6. RANK-induced Akt/PKB signals appear to be involved in ruffled border formation. The adapter protein, ECSIT, may be important for TRAF6-mediated osteoclast differentiation and activation.

Local injection of PTH and IL-1 over the calvaria of c-Src-deficient mice increased the number of multinucleated cells with the morphological characteristics of osteoclasts in calvaria, but these multinucleated cells failed to develop ruffled borders (Boyce *et al.,* 1992). Using a mouse coculture system, it was shown that spleen cells obtained from c-Src-deficient mice differentiated into TRAP-positive multinucleated cells, but they did not form resorption pits on dentine slices (Lowe *et al.,* 1993). Transplantation of fetal liver cells into c-Src-deficient mice cured their osteopetrotic disorders. Indeed, osteoclasts have been shown to express high levels of c-Src (Horne *et al.,* 1992; Tanaka *et al.,* 1992). These findings suggest that c-Src expressed in osteoclasts plays a crucial role in ruffled border formation (Table III).

RANKL has been shown to activate the anti apoptotic serine/threonine kinase Akt/PKB (protein kinase B) through a signaling complex involving c-Src and TRAF6 (Wong *et al.,* 1999) (Fig. 6). A deficiency in c-Src or the addition of inhibitors of the Src family kinases blocked RANKL-mediated Akt/PKB activation in osteoclasts. The RANKL–RANK interaction triggered simultaneous binding of c-Src and TRAF6 to the intracellular domain of RANK, resulting in the enhancement of c-Src kinase activity leading to tyrosine phosphorylation of downstream signaling molecules such as c-Cbl (Tanaka *et al.,* 1996) and $p130^{Cas}$ (Nakamura *et al.,* 1998). These results suggest a mechanism by which RANKL activates Src family kinases and Akt/PKB. The results also provide evidence for the presence of cross-communication between TRAF proteins and Src family kinases. Kopp *et al.* (1999) identified a novel intermediate in the signaling pathways that bridges TRAF6 to MEKK-1 [mitogen-activated protein kinase (MAPK)/extracellular signal regulated kinase (ERK) kinase kinase-1]. This adapter protein, named ECSIT (evolutionarily conserved signaling intermediate in Toll pathways), was shown to be specific for the Toll/IL-1 pathways and is a regulator of MEKK-1 processing. Expression of wild-type ECSIT accelerated the processing of MEKK-1 and NF-κB activation, whereas a dominant-negative fragment of ECSIT blocked both MEKK-1 processing and activation of NF-κB. These results indicate that ECSIT plays an important role for TRAF6-meditated osteoclast differentiation and function (Fig. 6).

RANK-Mediated Signals

Franzoso *et al.* (1997) and Iotsova *et al*. (1997) independently generated mice deficient in both p50 and p52 subunits

Table III Characteristics of Mice Carrying Disrupted Genes Involved in Osteoclast Differentiation and Function

Gene disrupted	Phenotype	State of bone resorption	Defective cells	References
c-src	Osteopetrosis	Osteoclasts are present, but fail to form ruffled borders	Osteoclast progenitors	Soriano *et al.* (1991), Boyce *et al.* (1992), Lowe *et al.* (1993)
c-fos	Osteopetrosis	Osteoclasts are absent	Osteoclast progenitors	Wang *et al.* (1992), Grigoriadis *et al.* (1994)
p50/p52 (NF-κB)	Osteopetrosis	Osteoclasts are absent	Osteoblasts progenitors	Franzoso *et al.* (1997), Iotsova *et al.* (1997)
rankl	Osteopetrosis	Osteoclasts are absent	Osteoblasts	Kong *et al.* (1999)
rank	Osteopetrosis	Osteoclasts are absent	Osteoclast progenitors	Dougall *et al.* (1999), Li *et al.* (2000)
opg	Osteoporosis	Osteoclastic bone resorption is enhanced	Osteoblasts	Mizuno *et al.* (1998), Bucay *et al.* (1998)
traf6 (1)	Osteopetrosis	Osteoclasts are present, but fail to form ruffled borders	Not determined	Lomaga *et al.* (1999)
traf6 (2)	Osteopetrosis	The number of osteoclasts are decreased markedly	Osteoclast progenitors	Naito *et al.* (1999)

of NF-κB (Table III). The double knockout mice developed severe osteopetrosis due to a defect in osteoclast differentiation. The osteopetrotic phenotype was rescued by bone marrow transplantation, indicating that the osteoclast progenitors are inactive in the double knockout mice. RANKL has been shown to activate NF-κB in the target cells, including osteoclast precursors and mature osteoclasts. These results suggest that RANKL-induced activation of NF-κB in osteoclast progenitors plays a crucial role in their differentiation into osteoclasts (Fig. 6).

Purified osteoclasts died spontaneously via apoptosis, whereas IL-1 promoted the survival of osteoclasts by preventing their apoptosis. Jimi *et al*. (1996a) reported that the pretreatment of purified osteoclasts with proteasome inhibitors suppressed the IL-1-induced activation of NF-κB and prevented the survival of osteoclasts supported by IL-1. When osteoclasts were pretreated with the antisense oligodeoxynucleotides to the p65 and p50 subunits of NF-κB, the expression of respective mRNAs by osteoclasts was suppressed, together with the concomitant inhibition of IL-1-induced survival of osteoclasts. These results indicate that IL-1 promotes the survival of osteoclasts through the activation of NF-κB. Miyazaki *et al.* (2000) also examined the role of mitogen-activated protein kinase and NF-κB pathways in osteoclast survival and activation, using adenovirus vectors carrying various mutants of signaling molecules. Inhibition of ERK activity by dominant-negative Ras overexpression induced the apoptosis of osteoclasts rapidly, whereas ERK activation by the introduction of constitutively active MEK (MAPK/ERK kinase) prolonged their survival remarkably. Neither inhibition nor activation of ERK affected the pit-forming activity of osteoclasts. In contrast, inhibition of the NF-κB pathway with dominant-negative IκB kinase suppressed the pit-forming activity of osteoclasts. NF-κB activation by constitutively active IκB kinase expression up regulated the pit-forming activity of osteoclasts without affecting their survival. IL-1 strongly induced both ERK and NF-κB activation. Matsumoto *et al.* (2000) found that treatment of bone marrow cells with an inhibitor of p38 MAP kinase (SB203580) suppressed osteoclast differentiation via inhibition of the RANKL-mediated signaling pathway. RAW264, a transformed mouse myeloid cell line, has been shown to differentiate into osteoclasts in response to RANKL (Hsu *et al.,* 1999). Expression of the dominant negative form of p38 MAP kinase in RAW264 cells inhibited their RANKL-induced differentiation into osteoclasts. These results indicate that activation of the p38 MAP kinase pathway also plays an important role in RANKL-induced osteoclast differentiation.

Mice lacking c-Fos have been shown to develop osteopetrosis due to an early differentiation block in the osteoclast lineage (Grigoriadis *et al.,* 1994; Wang *et al.,* 1992) (Table III). The dimeric transcription factor activator protein-1 (AP-1) is composed of mainly Fos proteins (c-Fos, FosB, Fra-1, and Fra-2) and Jun proteins (c-Jun, JunB, and JunD). RANKL activated JNK in the target cells, including purified osteoclasts and osteoclast progenitors. These results suggest that AP-1 appears to be located downstream of RANK-mediated signals. Unlike c-Fos, Fra-1 lacks transactivation domains required for oncogenesis and cellular transformation. Using a retroviral gene transfer, Matsuo *et al.* (2000) showed that all four Fos proteins, but not Jun proteins, rescued the differentiation block of c-Fos-deficient spleen cells into osteoclasts *in vitro*. Structure–function analysis demonstrated that the major carboxy-terminal transactivation domains of c-Fos and FosB are dispensable and that Fra-1 has the highest rescue activity. Moreover, a transgene expressing Fra-1 rescued the osteopetrosis of c-Fos-mutant mice *in vivo*. RANKL induced

transcription of Fra-1 expression in a c-Fos-dependent manner. These results indicate the presence of a link between RANK signaling and the expression of AP-1 proteins in inducing osteoclast differentiation (Fig. 6).

Cross-Communication between RANKL and TGF-β Superfamily Members

Bone is a major storage site for the cytokines of the TGF-β superfamily, such as TGF-β and BMPs. Osteoclastic bone resorption releases these growth factors from bone matrix. Receptors for TGF-β superfamily members are a family of transmembrane serine/threonine kinases and are classified as type I and type II receptors according to their structural and functional characteristics (Miyazono, 2000). Formation of a type I–type II receptor complex is required for the ligand-induced signals. Previous studies have shown that the extracellular domain of type I receptors is sufficient to mediate stable binding to TGF-β superfamily members and subsequent formation of a heteromeric complex with the intact type II receptors. Sells Galvin *et al.* (1999) first reported that TGF-β enhanced osteoclast differentiation in cultures of mouse bone marrow cells stimulated with RANKL and M-CSF. These results support the previous findings (1) that transgenic mice expressing TGF-β2 developed osteoporosis due to enhanced osteoclast formation (Erlebacher and Derynck, 1996) and (2) that osteoclast formation was reduced in transgenic mice expressing a truncated TGF-β type II receptor in the cytoplasmic domain (Filvaroff *et al.,* 1999). Fuller *et al.* (2000) also reported that activin A potentiated RANKL-induced osteoclast formation. Moreover, osteoclast formation induced by RANKL was abolished completely by adding soluble activin receptor type IIA or soluble TGF-β receptor type II, suggesting that activin A and TGF-β are essential factors for osteoclastogenesis. We further found that BMP-2 enhanced the differentiation of osteoclasts and the survival of osteoclasts supported by RANKL (Itoh *et al.,* 2000a). A soluble form of BMP receptor IA, which inhibits the binding of BMP-2 to BMP receptor IA, blocked RANKL-induced osteoclast formation. Thus, BMP-2 is yet another important determinant of osteoclast formation. Although the molecular mechanism by which TGF-β superfamily members potentiate the RANK-mediated signals is not known, cytokines released from bone matrix accompanying osteoclastic bone resorption appear to play an important role in RANKL-induced osteoclast formation. Further studies will elucidate the molecular mechanism of the cross-communication between TGF-β superfamily members and RANKL in osteoclast differentiation and function.

RANK Is Not the Sole Factor Responsible for Osteoclast Differentiation and Function

IL-1 stimulates not only osteoclast differentiation, but also osteoclast function through the IL-1 type 1 receptor (Jimi *et al.,* 1999b). As described earlier, purified osteoclasts placed on dentine slices failed to form resorption pits. When IL-1 or RANKL was added to the purified osteoclast cultures, resorption pits were formed on dentine slices within 24 hr (Jimi *et al.,* 1999b). Osteoclasts express IL-1 type 1 receptors, and IL-1 activated NF-κB rapidly in purified osteoclasts. The pit-forming activity of osteoclasts induced by IL-1 was inhibited completely by adding IL-1 receptor antagonist (IL-1ra) but not by OPG (Jimi *et al.,* 1999a). This suggests that IL-1 directly stimulates osteoclast function through IL-1 type 1 receptors in mature osteoclasts (Fig. 7).

Since the discovery of the RANKL–RANK signaling system, RANKL has been regarded as the sole factor responsible for inducing osteoclast differentiation. Azuma *et al.* (2000) and Kobayashi *et al.,* (2000) independently found that TNFα stimulates osteoclast differentiation in the absence of the RANKL–RANK interaction (Fig. 7). When mouse bone marrow cells were cultured with M-CSF, M-CSF-dependent bone marrow macrophages appeared within 3 days. In addition, TRAP-positive osteoclasts were formed in response to not only RANKL but also mouse TNFα, when bone marrow macrophages were cultured further for another 3 days with either ligand in the presence of M-CSF. Osteoclast formation induced by TNFα was inhibited by the addition of respective antibodies against TNF receptor type I (TNFRI, p55) and TNF receptor type II (TNFRII, p75), but not by OPG. Osteoclasts induced by TNFα formed resorption pits on dentine slices only in the presence of IL-1. These results demonstrate that TNFα stimulates osteoclast differentiation in the presence of M-CSF through a mechanism independent of the RANKL–RANK system (Fig. 7). TNFRI and TNFRII use TRAF2 as a common signal transducer in the target cells, suggesting that TRAF2-mediated signals play important roles in osteoclast differentiation. It has been reported that when osteotropic factors such as $1\alpha,25(OH)_2D_3$, PTHrP, and IL-1 were administered into RANK(−/−) mice, neither TRAP-positive cell formation nor hypercalcemia was induced (Li *et al.,* 2000a). In contrast, administration of TNFα into RANK(−/−) mice induced TRAP-positive cells near the site of injection even though the number of TRAP-positive cells induced by TNFα was not large. This suggests that TNFα somewhat induces osteoclasts in the absence of RANK-mediated signals *in vivo*. These results further strongly delineate that the RANKL–RANK interaction is not the sole pathway for inducing osteoclast differentiation *in vitro* and *in vivo*. It is, therefore, proposed that TNFα, together with IL-1, plays an important role in bone resorption in metabolic bone diseases such as rheumatoid arthritis, periodontitis, and possibly osteoporosis. Lam *et al.* (2000) also reported that a small amount of RANKL strongly enhanced osteoclast differentiation in a pure population of murine precursors in the presence of TNFα. These results suggest that RANKL-induced signals cross-communicate with TNFα-induced ones in the target cells.

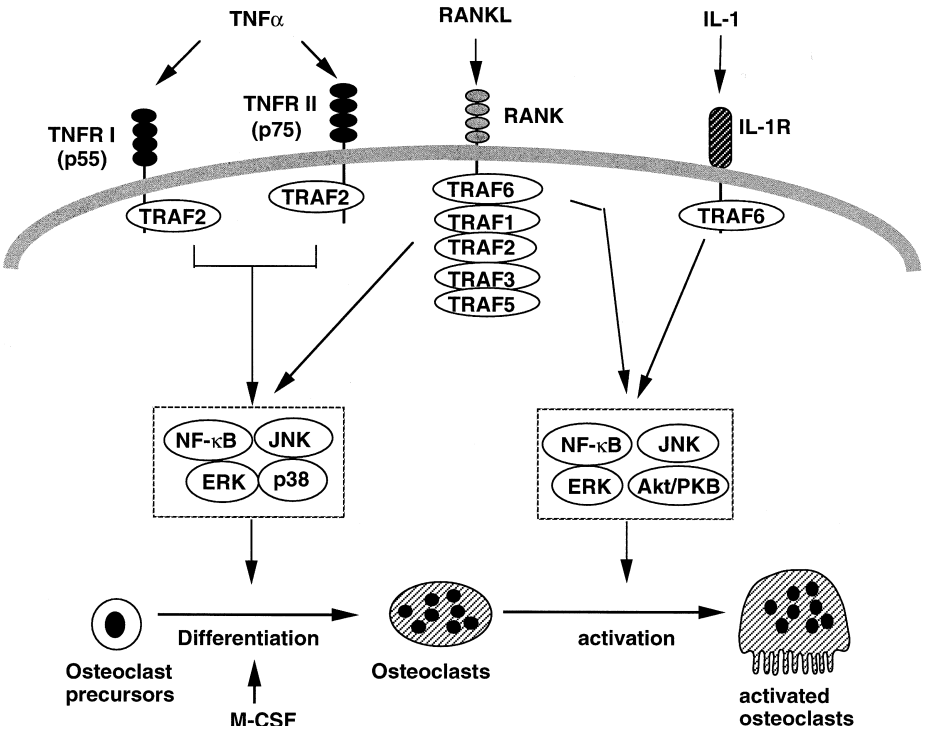

Figure 7 Schematic representation of ligand–receptor systems in osteoclast differentiation and function regulated by TNFα, RANKL, and IL-1. TNFα and RANKL stimulate osteoclast differentiation independently. Osteoclast differentiation induced by TNFα occurs via TNFRI (p55) and TNFRII (p75) expressed by osteoclast precursors. RANKL induces osteoclast differentiation through RANK-mediated signals. M-CSF is a common factor required by both TNFα- and RANKL-induced osteoclast differentiation. Activation of osteoclasts is induced by RANKL and IL-1 through RANK and IL-1 type I receptors, respectively. Common signaling cascades, such as NF-κB, JNK, p38 MAP kinase, and ERK activation, may be involved in the differentiation of osteoclasts induced by TNFα and RANKL. RANKL and IL-1 may activate osteoclast function though signals mediated by NF-κB, JNK, ERK, and Ark/PKB.

Conclusion

The discovery of the RANKL–RANK interaction now opens a wide new area in bone biology focused on the investigation of the molecular mechanism of osteoclast development and function. Osteoblasts/stromal cells, through the expression of RANKL and M-CSF, are involved throughout the osteoclast lifetime in all processes that govern their differentiation, survival, fusion, and activation. OPG produced by osteoblasts/stromal cells is an important negative regulator of osteoclast differentiation and function. Membrane- or matrix-associated forms of both M-CSF and RANKL expressed by osteoblasts/stromal cells appear to be essential for osteoclast formation. Both RANKL(−/−) mice and RANK(−/−) mice show similar features of osteopetrosis with a complete absence of osteoclasts in bone. Gain-of-function mutations of RANK have been found in patients suffering from familial expansile osteolysis and familial Paget's disease of bone. These findings confirm that the RANKL–RANK interaction is indispensable for osteoclastogenesis not only in mice but also in humans. The cytoplasmic tail of RANK interacts with the TRAF family members. TRAF2-mediated signals appear important for inducing osteoclast differentiation, and TRAF6-mediated signals are indispensable for osteoclast activation. Activation of NF-κB, JNK, and ERK, all induced by RANKL in osteoclast precursors and mature osteoclasts, may be involved in their differentiation and function. OPG strongly blocked all processes of osteoclastic bone resorption *in vivo,* suggesting that inhibiting either the RANKL–RANK interaction or RANK-mediated signals are ideal ways to prevent increased bone resorption in metabolic bone diseases such as rheumatoid arthritis, periodontitis, and osteoporosis. Studies have also shown that TNFα and IL-1 can substitute for RANKL in inducing osteoclast differentiation and function *in vitro*. These results suggest that signals other than RANK-induced ones may also play important roles in osteoclastic bone resorption under pathological conditions.

Under physiological conditions, osteoclast formation requires cell-to-cell contact with osteoblasts/stromal cells, which express RANKL as a membrane-bound factor in response to several bone-resorbing factors. In normal bone remodeling, osteoblastic bone formation occurs in a programmed precise and quantitative manner following osteoclastic bone resorption: bone formation is coupled to bone

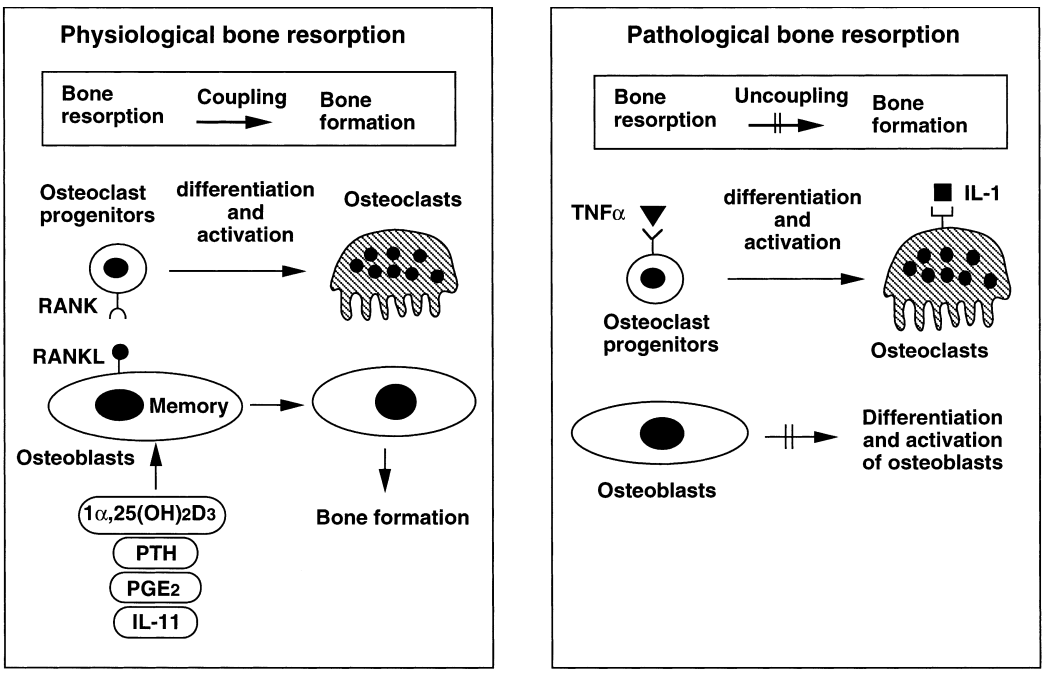

Figure 8 A hypothesis on the regulation of osteoblastic bone formation under physiological and pathological bone resorption. Under physiological conditions, osteoclast formation requires cell-to-cell contact with osteoblasts/stromal cells, which express RANKL as a membrane-associated factor in response to several bone-resorbing factors. In normal bone remodeling, osteoblastic bone formation occurs in a programmed precise and quantitative manner following osteoclastic bone resorption. It is so-called coupling between bone resorption and bone formation. In contrast, in pathological bone resorption, macrophages and/or T cells secrete inflammatory cytokines, such as TNFα and IL-1, as well as a soluble form of RANKL, which act directly on osteoclast progenitors and mature osteoclasts without cell-to-cell contact. This situation is characterized by uncoupling between bone resorption and bone formation. Cell-to-cell contact between osteoclast progenitors and osteoblasts may leave behind some memory for bone formation in osteoblasts.

resorption. In contrast, in pathological bone resorption, as in rheumatoid arthritis, macrophages and/or T cells secrete inflammatory cytokines such as TNFα and IL-1, which act directly on osteoclast progenitors and mature osteoclasts without cell-to-cell contact. This situation is characterized by uncoupling between bone resorption and bone formation. It is, therefore, noteworthy to consider that cell-to-cell contact between osteoclast progenitors and osteoblasts may leave behind in osteoblasts some memory for bone formation (Fig. 8). Further experiments are necessary to verify this hypothesis. Studies on the signal transduction of these TNF-ligand family members in osteoclast progenitors and in mature osteoclasts will provide novel approaches for the treatment of metabolic bone diseases.

CHAPTER 8

Osteoclast Function

Biology and Mechanisms

Kalervo Väänänen and Haibo Zhao
Department of Anatomy, Institute of Biomedicine, University of Turku, 20520 Turku, Finland

Introduction

There is a unanimous consensus among biologists that the main function of osteoclasts is to resorb mineralized bone, dentine, and calcified cartilage. Actually, according to our current knowledge, this seems to be the only function for those large and multinucleated cells that reveal several unique features. Resorption of mineralized tissues is obligatory for normal skeletal maturation, including bone growth and remodeling, as well as tooth eruption.

In evolution the appearance of osteoclasts opened a totally new strategy for skeletal development. However, it is very difficult to know exactly why natural selection during evolution has favored the development of osteoclasts in the first place. Was it because of the obvious advantages they offered for the flexible use of the skeleton? Perhaps the development of osteo (chondro) clast-like cells was favored by natural selection due to the advantages of the effective regulation of calcium homeostasis. The third possibility could be the need and pressure for the development of a safe environment for the hematopoetic tissue. No firm conclusions can be drawn from the current evidence and knowledge. Given the importance of calcium homeostasis and hematopoesis, one might speculate that resorptive cells were originally developed not at all for skeletal purposes, but to support those vital functions.

In the ontogenic development of most vertebrates, cartilage appears before bone. Based on this fact, many biologists, especially bone biologists, have concluded that cartilage is also more primitive than bone. This seems not to be the case, as it is likely that bone actually preceded cartilage during evolution. Thus it is not known yet for sure if functional osteoclasts were originally developed for the resorption of bone or calcified cartilage. It also remains to be clarified at what stage of the evolution resorbing osteoclasts appeared. Most probably this has taken place more than 300 millions years ago.

Is There More Than One Type of Bone-Resorbing Cell?

During skeletal growth, osteoclasts are needed for the resorption of calcified cartilage and modeling of growing bone. In adult bone, resorptive cells are responsible for remodeling. If necessary, they fulfill the requirements of calcium homeostasis via excessive resorption beyond normal remodeling. In addition to osteoclasts tumor cells, monocytes and macrophages have been suggested to have bone-resorbing capacity. However, later studies have not been able to confirm that tumor cells can resorb bone directly. Instead they can induce recruitment, as well as activity of osteoclasts, by secreting a large number of osteoclast regulating factors (Ralston, 1990). Bone resorption by macrophages has been demonstrated only *in vitro* and is probably due to the phagocytosis of bone particles rather than the more specialized mechanisms used by the osteoclasts. It is also possible that mineralized bone per se can induce monocytes and tissue macrophages to differentiate into osteoclasts under culture conditions.

At present it is thus generally accepted that the osteoclast is the only cell that is able to resorb mineralized bone. Both

mononuclear and multinuclear osteoclasts can resorb bone, but larger cells seem to be more effective than smaller ones, although there is no direct relationship between the resorption capacity and the number of nuclei (Piper *et al.,* 1992). The number of nuclei in osteoclasts also varies among species, being higher in birds than in mammals.

Osteoclasts in different types of bone have been thought to be similar. There is now some evidence, however, that osteoclasts are not necessarily similar at all sites. Lee *et al.*(1995) described mononuclear cells with ruffled borders on uncalcified septa of the growth plate cartilage. These cells, named septoclasts by the authors, express high levels of cathepsin B but not ED1, which is present in osteoclasts. Septoclasts probably resorb transversal septa of the growth plate just before chondroclasts start resorption of longitudinal calcified septa. Rice *et al.* (1997) also reported two populations of multinucleated osteoclasts. They observed that in growing calvaria, osteoclasts that were next to sutures expressed MMP-9 but were tartrate-resistant acid phosphatase (TRAP) negative. The majority of multinucleated osteoclasts expressed both enzymes. Everts *et al.* (1999) concluded that osteoclasts in calvarial bones were sensitive to matrix metalloproteinase (MMP) inhibitors, whereas osteoclasts in long bones were not. According to present knowledge, chondroclasts that resorb calcified cartilage are similar to osteoclasts, but there are perhaps also other types of resorbing cells present in specific areas of the growing skeleton.

Life Span of the Osteoclast and the Resorption Cycle

In the adult, stem cells for osteoclasts originate from the hematopoetic tissue (for review, see Chapter 7). They share a common differentiation pathway with macrophages until the final differentiation steps. Differentiation is characterized by the sequential expression of different sets of genes. Several cytokines and growth factors are known to affect the differentiation pathway of the osteoclast, and studies have confirmed the central role of the RANK-RANKL-OPG pathway in this process.

After proliferating in bone marrow, mononuclear preosteoclasts are guided to bone surfaces by mechanisms, that are so far unknown. It is not known in detail where and when fusion of mononuclear precursors to multinuclear osteoclasts actually takes place and what are the molecular mechanisms regulating fusion. There are certainly several types of molecular interactions between the membranes of two cells undergoing fusion. Cadherin-mediated cell–cell interactions might play a role in the early phase of osteoclast fusion (Mbalaviele *et al.,* 1995). Syncytin, a captive retroviral envelope protein, has been described to be important in the fusion of placental syncytiotrophoblasts (Mi *et al.,* 2000). It remains to be seen if similar fusion proteins are also mediating the fusion of precursors into multinucleated osteoclasts.

The fusion of mononuclear precursors into multinucleated osteoclasts in the bone marrow mainly takes place in the vicinity of bone surfaces, as multinuclear osteoclasts are seldom observed far away from the bone surface. Somehow, precursors are guided near to those sites that are determined to be resorbed. How this happens, how these sites are determined, and which cells actually make the decision where and when for instance a new remodeling unit is initiated are not known. Strongest candidates for this role are osteocytes and bone lining cells. Both negative and positive regulation between osteocytes and osteoclasts could exist. We have shown that osteocytes secrete a biological activity that inhibits osteoclasts differentiation (Matikainen *et al.,* 2000). Thus, it is possible that healthy osteocytes secrete a factor(s) that prevents osteoclast differentiation and activation, whereas dying osteocytes promote osteoclast activity. There is indirect evidence, indeed, that such mechanisms are operating *in vivo.* Osteocytes that form an internal network that could sense the whole bone as a single unit (Aarden *et al.,* 1994) are the most obvious cells to act as gatekeepers for the local remodeling processes. Learning the molecular details of this complicated biological event will be the challenge of the next decade for bone biologists.

Although it is not known how resorption sites are determined, it is known that the first sign of a forthcoming resorption place on the endosteal surface is the retraction of bone-lining cells (Jones and Boyde, 1976). This retraction uncovers osteoid and after its removal by osteoblasts the osteoclasts can attach to the mineralized surface. The sequence of cellular events needed for bone resorption is called the resorption cycle (see Figs. 1 and 4). One resorption cycle of any individual osteoclast thus involves complicated multistep processes, which include osteoclast attachment, its polarization, formation of the sealing zone, and

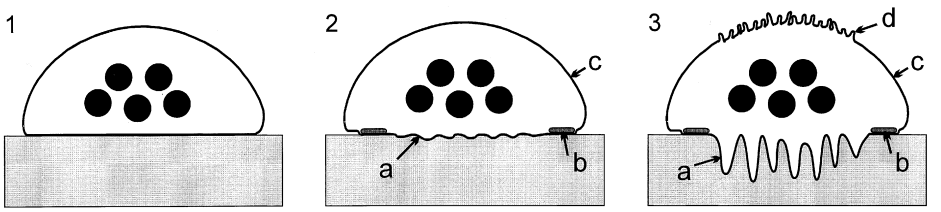

Figure 1 The nonresorbing osteoclast is polarized (1), but immediately after attachment for resorption it shows three different membrane domains (2): ruffled border (a), sealing zone (b), and basal membrane (c). Once matrix degradation has started (3), the fourth membrane domain appears in the basal membrane (d).

resorption itself with final detachment and cell death (Lakkakorpi and Väänänen, 1995; Väänänen *et al.,* 2000). On the basis of *in vitro* studies, one osteoclast can undergo several consecutive resorption cycles before entering the apoptosis pathway (Kanehisa and Heerche, 1988). Following is a short description of each particular phase of the resorption cycle.

Attachment of Osteoclasts to the Bone Surface and Formation of the Sealing Zone

Several lines of evidence have shown that adhesion receptors in osteoclasts play an important functional role in bone resorption. Osteoclasts express at least four integrin extracellular matrix receptors: $\alpha_v\beta_3$ (a classical vitronectin receptor), $\alpha_v\beta_5$ $\alpha_2\beta_1$ (collagen receptor), and $\alpha v\beta 1$, which binds to a variety of extracellular matrix proteins, including vitronectin, collagen, osteopontin, and bone sialoprotein (Nesbit *et al.,* 1993). Antibodies against the vitronectin receptor, Arg-Gly-Asp (RGD) mimetics, and RGD peptides, which block the attachment of the vitronectin receptor to RGD-containing bone matrix proteins, inhibit bone resorption *in vitro* (Sato *et al.,* 1990; Horton *et al.,* 1991; Lakkakorpi *et al.,* 1991) and *in vivo* (Fisher *et al.,* 1993).

Glanzmann's thrombasthenia patients and knock out of the β_3 gene in mice have clarified the importance of the vitronectin receptor in the function of osteoclasts (Djaffar *et al.,* 1993; Hodivala-Dilke *et al.,* 1999; McHugh *et al.,* 2000). β_3 mutants grow normally, indicating that the lack of β_3 does not prevent bone resorption during skeletal growth and modeling. However, in these mice, osteoclasts are morphologically abnormal and do not express normal cytoskeletal organization, including actin ring formation. These observation strongly suggest that the vitronectin receptor, rather than forming a tight cell–matrix contact at the sealing zone, plays a regulatory role in mediating signals between the extracellular matrix and the osteoclast. This function is also supported by observations from echistatin-treated mice (Masarachia *et al.,* 1998; Yamamoto *et al.,* 1998), which did not reveal changes in the sealing zone or ruffled borders. A regulatory role for $\alpha_v\beta_3$ was originally suggested on the basis of its distribution on the plasma membrane of the resorbing osteoclasts (Lakkakorpi *et al.,* 1991). A precise function(s) of $\alpha_v\beta_3$ in osteoclasts remains unknown at the present. The $\alpha_v\beta_3$ integrin could play a role both in the adhesion and migration of osteoclasts (e.g.) by regulation of actin cytoskeleton) and in the endocytosis and transportation of resorption products (Väänänen *et al.,* 2000).

During the mineral dissolution phase, osteoclasts must retain a low pH in the resorption lacuna (see later). The ultrastructure of the resorbing osteoclast (Fig. 2) clearly shows that the plasma membrane of the osteoclast at the sealing zone is tightly attached to the matrix, offering a good structural basis for the isolation of the resorption lacuna from the extracellular fluid. It has also been demonstrated that a pH gradient really exists (Baron *et al.,* 1985), indicating that the sealing around the resorption lacuna is tight enough to maintain the pH gradient. So far the molecular interaction(s) between the plasma membrane and the bone matrix remains unknown. As explained earlier, it is unlikely that $\alpha_v\beta_3$ could mediate this interaction. On the basis of extensive series of morphological and functional studies, Väänänen and Horton (1995) suggested that the osteoclast sealing zone represents a specific type of cell–matrix interaction. Ilvesaro *et al.* (1998) illustrated that the sealing zone might have common features with the epithelial zonula–adherens

type junction, given that tight sealing could be prevented by a hexapeptide containing the cell adhesion recognition sequence of cadherins.

Resorbing Osteoclasts Are Highly Polarized and Show Four Different Membrane Domains

Osteoclasts cycle between resorbing and nonresorbing phases, which are accompanied by drastic changes in their polarization (Figs. 1–4). Resorbing osteoclasts are highly polarized cells containing several different plasma membrane domains, whereas those osteoclasts that are not resorbing do not reveal clear morphological features of polarity. In resorbing cells the sealing zone itself forms one distinctive membrane domain and simultaneously separates two other membrane domains, the ruffled border (RB) and the basolateral domain (Figs. 1 and 2). In addition to these three membrane domains, morphological and functional studies have revealed a distinct membrane domain in the basal membrane, namely a functional secretory domain (FSD) (Salo *et al.,* 1996). This membrane domain has some characteristic features of the apical membrane domain in epithelial cells. Viral proteins that are usually targeted to the apical domain are in osteoclasts targeted to this domain. In addition, FSD is morphologically different from the rest of the membrane, and it has been also shown to be a target for transcytotic vesicles

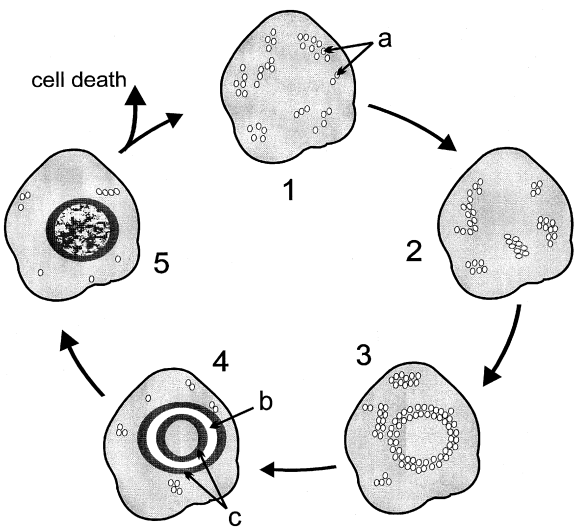

Figure 4 Organization of microfilaments in osteoclasts can be used to recognize different phases of the resorption cycle. When a nonresorbing cell (1) is induced to resorb podosome-type structures (a), gather to certain areas of bone-facing surface (2) and finally form a large circular collection of podosomes (3). In the following step, the individual podosome-type structure diappears (4) and a distinct dense actin ring (b) appears between two broad vinculin rings (c). The vitronectin receptor is tightly colocalized with vinculin in those rings as well as in podosomes. After resorption, cytoskeletal rings disappear in a certain order (5) and the cell can either undergo apoptosis or return to the resting phase.

carrying bone degradation products (Salo *et al.,* 1997; Nesbitt *et al.,* 1997). In resorbing osteoclasts, thick bundles of microtubules connect the RB and the FSD (Mulari *et al.,* manuscript in preparation), and a specific type of exocytotic vesicles, clastosomes, have been described in close association with the FSD (Salo *et al.,* manuscript in preparation). It remains to be seen if these vesicles are associated with the active secretion of resorbed material or if they represent, for instance, a specific type of apoptotic vesicles.

The ruffled border membrane forms the actual "resorbing organ." The characteristics of this unique membrane domain do not perfectly fit any other known plasma membrane domain described so far. The ruffled border membrane is formed by the rapid fusion of acidic intracellular vesicles (Palokangas *et al.,* 1997). Many of the proteins reported to be present at the ruffled border are also found in endosomal and/or lysosomal membranes, including the vacuolar proton pump, mannose-6-phosphate receptor, rab7, and lgp 110 (Baron *et al.,* 1988; Väänänen *et al.,* 1990; Palokangas *et al.,* 1997) (Fig. 5 see also color plate). Functional experiments, for instance, with labeled transferrin and dextran, have further supported the conclusion that the ruffled border represents a plasma membrane domain with typical features of the late endosomal compartment (Palokangas *et al.,* 1997).

Several membrane proteins reveal a nonhomogeneous distribution at the ruffled border. For instance, the vacuolar proton pump (Mattsson *et al.,* 1997), as well as rab7, is concentrated at the lateral edges of the ruffled border (Palokangas *et al.,* 1997). Our functional experiments have also shown that exocytotic vesicles in resorbing osteoclasts are found at the lateral areas of the ruffled border, and endocytotic vesicles mainly bud from the central area of the ruffled border (Zhao *et al.,* 2000). On the basis of these and previous results, we suggest that the ruffled border is composed of two different domains — lateral and central — where exocytosis and endocytosis occur, respectively. This allows for simultaneous proton and enzyme secretion and for the endocytosis of degradation products.

In order to create and maintain specialized membrane domains, as well as to transport products of biosynthetic or secretory machinery, the cell has distinct intracellular trafficking routes, originating from one compartment and reaching another. Intracellular vesicular routes shown to be operating in the resorbing osteoclasts are presented schematically in Fig. 3 (see also color plate). Very little is known at the moment about the molecular mechanisms

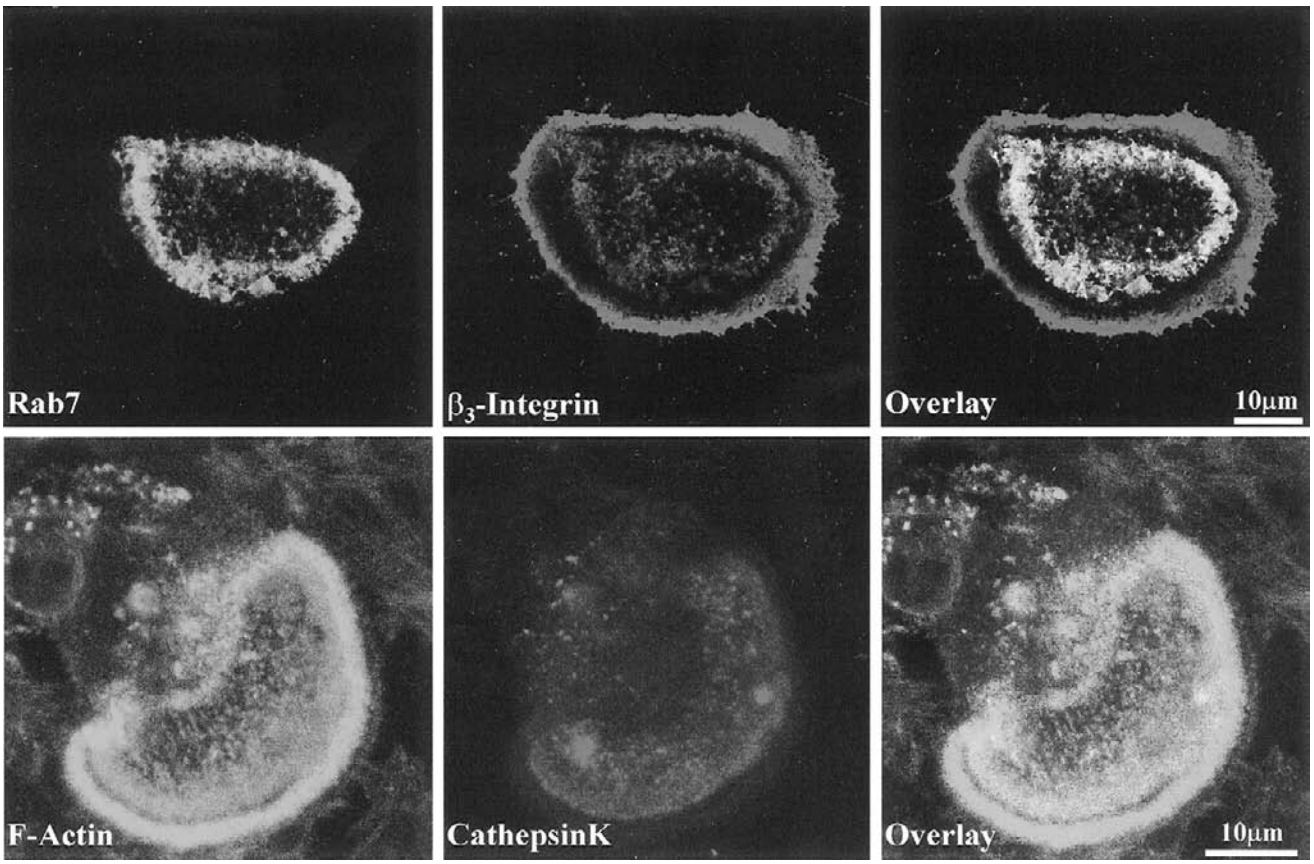

Figure 5 (Top) Laser confocal scanning microscopic images of the localization of rab7 and (β_3, integrin in the resorbing osteoclast. (Bottom) Laser confocal scanning microscopic images of cathepsin K and F-actin in the resorbing osteoclast. (See also color plate.)

regulating these particular vesicular activities in the osteoclasts. It is obvious that these events could be highly specific and may offer new potential targets to inhibit or stimulate bone resorption.

In addition to its role in the organization of membrane domains, the cytoskeleton also undergoes drastic reorganization during cell polarization. In fact, changes in the cytoskeletal organization are the driving force for the formation of different plasma membrane domains. Recent years have clarified to a large degree the connection of cytoskeletal organization to the resorptive activity of osteoclasts.

Cytoskeletal Changes during the Resorption Cycle

Changes in the organization of the cytoskeleton, especially microfilaments and microtubules, are characteristic of the polarization of any cell type. *In vitro* studies of osteoclasts on bone or dentine slices have revealed that the microfilament pattern in osteoclasts undergoes rapid changes when preparing for resorption (Fig. 4) (Kanehisa *et al.,* 1990; Lakkakorpi *et al.,* 1989). In osteoclasts that are not resorbing, polymerized actin is accumulated in podosome-type structures throughout the whole bone-facing surface of the osteoclast (Zambone-Zallone *et al.,* 1988). Thus, at the sites of podosomes, the actin cytoskeleton is anchored via integrins to the extracellular proteins of the matrix. The vitronectin receptor ($\alpha_v\beta_3$ integrin) is the major integrin in the podosomes of osteoclasts (Zambone-Zallone *et al.,* 1988). When resting or moving osteoclasts start preparing for resorption, an intense accumulation of podosomes to the local areas of the bone-facing membrane takes place (Lakkakorpi and Väänänen, 1991). Gradually, podosomes are collected into a large circular structure(s) and simultaneously the density of podosomes increases. Up to this point, vinculin and talin are tightly colocalized with F-actin and with the vitronectin receptor. In the next step, actin forms a dense belt-like structure where individual podosomes cannot be recognized anymore. This actin band (ring) is seen only in cells that are resorbing (Lakkakorpi and Väänänen, 1991). At this point, those proteins, which mediate the association of actin filaments to integrin, form a broad band around the actin band, but still colocalize with vitronectin receptors (Lakkakorpi *et al.,* 1991, 1993). This type of molecular organization at the sealing zone strongly suggests that molecules other than integrins are linking the actin cytoskeleton to the extracellular matrix at the fully developed sealing zone. This is the case not only *in vitro,* osteoclasts in bone also have a similar type of actin ring around the resorption lacuna (Sugiyama and Kusuhara, 1994).

In order to understand the cell biology of the resorption process it is essential to understand in detail how the organization of the cytoskeleton is regulated and how the sealing zone is finally formed. Src-deficient knockout mice (Soriano *et al.,* 1991) offer an interesting model to study the organization of the cytoskeleton and the formation of the sealing zone and ruffled border. These mice, which suffer from osteopetrosis, have a normal number of osteoclasts, which attach to bone but do not form normal ruffled borders (Boyce *et al.,* 1992).

In addition to actin, only a couple of proteins have been localized in the sealing zone. These are PYK2 and $p130^{cas}$ (cas, Crk-associated substrate). PYK2 seems to be a major adhesion-dependent tyrosine kinase in osteoclasts (Duong *et al.,* 1998, Nakamura *et al.,* 1997). When $\alpha_v\beta_3$ is activated by substrate ligation or by some other means, PYK2 is phosphorylated, its kinase activity is increased, and it associates with c-src. Osteoclasts in $src^{-/-}$ mice are not able to form actin rings and, interestingly, the tyrosine phosphorylation of PYK2 is reduced markedly in these cells. $P130^{cas}$ has been shown to be associated with PYK2 and also with actin cytoskeleton. On the basis of these observations, localization of PYK2 and c-src, and the fact that PYK2 is also tightly associated with the cytoskeleton, it has been suggested that the src-dependent tyrosine phosphorylation of PYK2 may be an important regulatory event in formation of the sealing zone (Duong *et al.,* 1999).

Calcitonin and dbcAMP induce a rapid destruction of the actin rings in resorbing osteoclasts (Lakkakorpi and Väänänen, 1990). More recently, Suzuki *et al.* (1996) demonstrated that the effect of calcitonin on the cytoskeleton is mediated by a protein kinase A-dependent pathway. These results suggest that the cytoskeleton could be an important target of the action of calcitonin.

In addition to calcitonin, several other agents, which inhibit osteoclast function, have been shown to cause disruption of the actin rings. These include tyrosine kinase inhibitors such as herbimycin (Tanaka *et al.,* 1995) and an inhibitor of phosphatidylinositol 3-kinase (PI3-kinase), wortmannin (Nakamura *et al.,* 1995). Evidence shows that PI3-kinase is associated with c-src and induces cytoskeletal reorganization in osteoclasts (Grey *et al.,* 2000). Lakkakorpi *et al.* (1997) have also provided evidence on the association of PI3-kinase with the cytoskeleton and $\alpha_v\beta_3$ integrin.

The role of Rho family proteins in cytoskeletal organization has been studied extensively. Zhang *et al.* (1995) demonstrated an important role for Rho p21 protein in regulation of the osteoclast cytoskeleton. Microinjection into osteoclasts of *Clostridium botulinum*-derived ADP-ribosyltransferase, which specifically ADP ribosylates Rho p21, completely disrupted actin rings within 20 min. These studies show that actin ring formation or disruption in osteoclasts is regulated by tyrosine kinase-mediated and PI3-kinase-mediated signals. They also suggest that a Rho p21-mediated pathway is involved in the regulation of the actin cytoskeleton in osteoclasts. More recently, members of the Rho-GTPase subfamily, Rac 1 and Rac 2, were shown to be involved in the organization of the actin cytoskeleton in osteoclasts (Razzouk *et al.,* 1999). Chellaiah *et al.,* (2000) also demonstrated the importance of Rho-A for cytoskeletal organization in osteoclasts.

Burgess *et al.* (1999) offered interesting new information on the resorption cycle of osteoclasts. The authors show that in the presence of RANKL (OPGL), osteoclasts in culture can go through more resorption cycles than in control cultures. Thus, in addition to osteoclast-recruiting activity, RANKL also directly stimulates bone resorption by extending their activity period, at least *in vitro.* Incubation of isolated rat osteoclasts with RANKL stimulated actin ring formation and further resorption markedly after only 30 min of exposure. This study strongly suggests that RANKL could be an important regulator of osteoclast activity. It would be interesting to identify the signal transduction pathways of this biological response downstream of RANK.

Only very few of the proteins participating in the organization of the cytoskeleton during the resorption cycle are known at the moment. We should know many additional details before we can completely understand the regulation of the cytoskeletal changes during the resorption cycle. This would be an important field of osteoclast research during the coming years, especially because it will uncover several new molecular targets for inhibiting bone resorption.

Much less is known about the changes in the organization of microtubules and intermediate filaments during the resorption cycle. In osteoclasts cultured on glass, each nucleus preserves its own microtubule-organizing center during fusion, whereas in myotubes, individual centrioles are eliminated (Moudjou *et al.,* 1989). In resorbing osteoclasts, microtubules form thick bundles in the middle of the cell, originating from the top of the cell and converging toward the ruffled border (Lakkakorpi and Väänänen, 1995). Data suggest that these microtubules actually extend from the ruffled border to the functional secretory domain and are most probably mediating transcytotic trafficking (Mulari *et al.,* 1998). Even less is known about the organization of intermediate filaments and their possible changes during the polarization of osteoclasts.

How Osteoclasts Dissolve Bone Mineral

Bone mineral is mainly crystalline hydroxyapatite, and there are not many biological processes that could be responsible for the solubilization of crystals. In fact, the only process that has been suggested to be able to solubilize hydroxyapatite crystals in the biological environment is low pH. Thus the idea that bone resorption is facilitated by local acidification has been discussed among bone biologists for a long time, and Fallon *et al.* (1984) demonstrated that the resorption lacuna is really acidic. This observation was also confirmed later by other investigators who used the accumulation of acridine orange in acidic compartments as an indicator of low pH (Baron *et al.,* 1985).

First experiments to explain the molecular mechanism of lacunar acidification suggested the presence of gastric-type proton pumps in osteoclasts (Baron *et al.,* 1985; Tuukkanen and Väänänen, 1986). However, it soon became clear that the main type of proton pump in the ruffled border of osteoclasts is a V-type ATPase (Bekker and Gay 1990a; Blair *et al.,* 1989; Väänänen *et al.,* 1990).

V-type ATPases are electrogenic proton pumps that contain several different subunits that form two independently assembled complexes: cytoplasmic and membranebound (for a review, see Stevens and Forgac, 1997). V-type ATPases are found in all mammalian cells and are responsible for the acidification of different intracellular compartments, including endosomes, lysosomes, secretory vesicles, and synaptic vesicles. The membrane-bound complex is composed of at least five different subunits, and the soluble catalytic complex contains at least eight different subunits. In addition, each pump contains several copies of each subunit. Thus the V-type ATPase and mitochondrial F-type ATPase share a common structural architecture.

The level of expression of V-type ATPase is very different among tissues, being very high in adrenal, kidney, and brain. In osteoclasts, it is exceptionally high. In contrast to many other cells, it is found both in various intracellular compartments and in the plasma membrane, namely the ruffled border. In addition to the marked differences in expression level in different cells and tissues, further functional specificity is obtained by slight structural differences of certain subunits. Different isoforms of at least three subunits have been described so far (van Hille *et al.,* 1994; Bartkiewicz *et al.,* 1995; Hernando *et al.,* 1995; Toyomura *et al.,* 2000), and these isoforms are specifically expressed in certain cells giving, at least in theory, a good possibility for remarkable cell and tissue specificity.

Heterogeneity of the 116-kDa subunit has turned out to be of special importance. Three different isoforms of this subunit that stabilize the soluble complex to the membrane complex by as yet unknown mechanisms have been characterized and one of these shows substantial specificity for osteoclasts (Li *et al.,* 1996; Toyomura *et al.,* 2000).

Yamamoto *et al.* (1993) described a patient suffering from craniometaphyseal dysplasia and reported a lack of expression of V-type ATPase in this patient's osteoclasts. Although the specific gene mutation in this patient has not been characterized, studies in other laboratories have shown that a certain number of patients suffering from malignant osteopetrosis have a mutation in the 116-kDa subunit of vacuolar type ATPase (Kornak *et al.,* 2000; Frattini *et al.,* 2000). Further evidence for the importance of this particular subunit is provided by the severe osteopetrotic phenotype in knockout mice of this specific subunit (Li *et al.,* 1999) and also by the fact that oc/oc osteopetrotic mice have a deletion in this subunit (Scimeca *et al.,* 2000).

The low pH in the resorption lacuna is achieved by the action of the proton pump both at the ruffled border and in intracellular vacuoles. Cytoplasmic acidic vacuoles disappear at the time when the ruffled border appears, during the polarization of the cell. It is thus highly likely that the initial acidification of the subcellular space is achieved by the direct exocytosis of acid during the fusion of intracellular

vesicles to form the ruffled border. This ensures rapid initiation of mineral dissolution, and further acidification may be obtained by the direct pumping of protons from the cytoplasm to the resorption lacuna.

In vitro studies with isolated osteoclasts were first used to show the functional importance of the proton pump for mineral dissolution. Sundquist *et al.* (1990) studied the effect of bafilomycin A1 on osteoclast function and observed that it effectively blocked bone resorption without affecting cell adhesion or viability. Antisense oligonucleotides against different subunits of the proton pump complex were then used to confirm the role of the proton pump in osteoclast function (Laitala and Väänänen, 1994). *In situ* hybridization studies using nonradioactive probes and laser confocal microscopy revealed a polarized distribution of mRNAs of vacuolar proton pumps in resorbing osteoclasts (Laitala-Leinonen *et al.,* 1996). Thus osteoclasts seem to offer an excellent dynamic model for studies of mRNA polarization.

An elegant *in vivo* study using local administration of bafilomycin A1 confirmed that inhibition of the vacuolar proton pump can potentially be used to inhibit bone resorption (Sundquist and Marks, 1995). The development of new types of vacuolar proton pump inhibitors with improved specificity and selectivity (Keeling *et al.,* 1998; Visentin *et al.,* 2000) has opened a whole new opportunity for treating osteoporosis and other bone metabolic bone diseases.

In addition to the proton pump, several other molecules have critical functions in the acidification of the resorption lacuna. Minkin *et al.* (1972) showed that bone resorption in mouse calvarial cultures could be inhibited by carbonic anhydrase inhibitors and decrease of CA II expression by using antisense technology leads to the inhibition of bone resorption in cultured rat osteoclasts (Laitala and Väänänen, 1994). In humans, CA II deficiency causes nonfunctional osteoclasts and osteopetrosis (Sly and Hu, 1995), and aging CA II deficient mice also show mild osteopetrosis (Peng *et al.,* 2000). To date, only one isoenzyme of the large carbonic anhydrase family containing at least 14 different members has been found in the osteoclast, namely CA II. It is likely, however, that other members of this gene family are also present in osteoclasts.

Pumping of protons through the ruffled border is balanced by the secretion of anions (see Fig. 3). The presence of a high number of chloride channels in the ruffled border membrane of osteoclasts has been shown (Blair and Schlesinger, 1990). The outflow of chloride anions through the ruffled border is most likely compensated by the action of a HCO_3/Cl exchanger in the basal membrane.

It has been suggested that there is also another mechanism for proton extrusion, besides V-ATPase, in resorbing osteoclasts (Nordström *et al.,* 1995). This could be the Na/H antiporter, as its inhibition blocks bone resorption *in vitro* (Hall *et al.,* 1992). It is not yet known how this antiporter is distributed in resorbing and polarized osteoclasts and what is its specific role in the acidification of resorption lacunae as such. Information now available supports the conclusion that it has a role in the early phases of the resorption cycle (Hall *et al.,* 1992). The basolateral membrane of resorbing osteoclasts also contains a high concentration of Na/K-ATPase (Baron *et al.,* 1986) and Ca-ATPase (Bekker and Gay, 1990b).

How Osteoclasts Degrade Organic Matrix

After solubilization of the mineral phase, the organic matrix is degraded. Roles of two major classes of proteolytic enzymes—lysosomal cysteine proteinases and MMPs—have been studied most extensively. The question of the role of proteolytic enzymes in bone resorption can be divided into at least three subquestions. First, what are the proteolytic enzymes, which are needed to remove unmineralized osteoid from the site of future resorption? Second, what are the proteolytic enzymes, which take part in the degradation of organic matrix in the resorption lacuna? Third, is there intracellular matrix degradation in osteoclasts and what proteolytic enzymes, if any, are responsible for this final degradation process?

Sakamoto *et al.* (1982) and Chambers *et al.* (1985) suggested that osteoblast-derived collagenase (MMP-1) plays a major role in the degradation of bone covering osteoid. Removal of the osteoid layer seems to be a necessary or even obligatory step for the future action of osteoclasts. Although the role of osteoblasts seems to be essential in this early phase of bone resorption, it has not been shown definitively that osteoblasts *in situ* are responsible for the production of all proteolytic enzymes necessary for osteoid degradation. It has not been possible to rule out the possibility that some proteinases necessary for matrix degradation have been produced and stored in the matrix already during bone formation. The stimulus for bone resorption may lead to activation of a local population of osteoblasts, which then secrete the factors that are needed to activate matrix-buried proteinases.

In addition to MMP-1, a membrane-bound matrix metalloproteinase (MT1-MMP) clearly has a role in bone turnover. MT1-MMP-deficient mice develop dwarfism and osteopenia among other connective tissue disorders (Holmbeck *et al.,* 1999). The analysis of deficient mice, however, suggests that the primary defects are in bone-forming cells rather than in osteoclasts. However some studies have indicated a high expression of MT1-MMP in osteoclasts (Sato *et al.,* 1997; Pap *et al.,* 1999). It appears to be localized in specific areas of cell attachment, but at the moment there are no direct data pointing to the specific function of MT1-MMP in the resorption processes. In conclusion, it seems evident that proteinases in osteoblastic cells play an important role in the regulation of bone turnover, but specific mechanisms remain to be elucidated.

It is obvious that a substantial degradation of collagen and other bone matrix proteins during bone resorption takes place in the extracellular resorption lacuna. Two enzymes,

cathepsin K and MMP-9, have been suggested to be important in this process. Data that cathepsin K is a major proteinase in the degradation of bone matrix in the resorption lacuna are now very convincing. First of all, it is highly expressed in osteoclasts and is also secreted into the resorption lacuna (Inaoka *et al.,* 1995; Drake *et al.,* 1996; Tezuka *et al.,* 1994b; Littlewood-Evans *et al.,*1997). Second, it has been shown that it can degrade insoluble type I collagen, and inhibition of its enzymatic activity in *in vitro* and *in vivo* models prevents matrix degradation (Bossard *et al.,* 1996; Votta *et al.,* 1997). Third, deletion of the cathepsin K gene in mice leads to osteopetrosis (Saftig *et al.,* 1998; Gowen *et al.,* 1999). Finally, human gene mutations of cathepsin K lead to pycnodysostosis (Gelb *et al.,* 1996; Johnson *et al.,* 1996).

These data have encouraged several researchers and pharmaceutical companies to try to develop specific inhibitors of cathepsin K to be used in the treatment of osteoporosis. Because mineral dissolution is not prevented by such inhibitors, it is possible that inhibition of this enzyme could lead to the accumulation of an unmineralized matrix. This may be an important contraindication to the long-term use of cathepsin K inhibitors in the treatment of bone diseases.

A number of other lysosomal cysteine proteinases—cathepsins B, D, L, and S—have been suggested to play a role in osteoclasts, and data exist showing that at least B and L are also secreted into the resorption lacuna (Goto *et al.,* 1994). However, extracellular localization of cathepsin B was not observed in the inhibitor studies of Kakegawa (1993) and Hill *et al.* (1994). Taken together, these results suggest that cathepsin L has a role in extracellular matrix digestion, whereas cathepsin B acts only intracellularly. If this is the case, one may find it difficult to explain why a major part of cathepsin B is secreted into the resorption lacunae. It is possible that many of the earlier inhibitor studies were actually complicated by the inhibition of cathepsin K, which was discovered later. Thus, many of the earlier studies on the role of different cathepsins in bone must now be reevaluated.

Several studies have shown a high expression of MMP-9 in osteoclasts, both at the mRNA and at the protein level (Wucherpfennig *et al.,* 1994; Reponen *et al.,* 1994; Tezuka *et al.,* 1994a; Okada *et al.,* 1995). Although there is no direct evidence for the secretion of MMP-9 into resorption lacunae, it is likely to occur. When demineralized bone particles were incubated with MMP-9, the degradation of collagen fragments was observed by electron microscopy (Okada *et al.,* 1995). This suggests that under conditions present in bone matrix, it is possible that MMP-9 could digest collagen even without the presence of collagenase. MMP-9 knockout mice show an interesting phenotype of transient osteopetrosis (Vu *et al.,* 1998). This and some other studies suggest that the role of MMP-9 in different populations of osteoclasts could be different, and furthermore that osteoclasts may be a more herogeneous cell population than previously thought (Everts *et al.,* 1999).

In conclusion, evidence indicates that several MMPs and lysosomal and nonlysosomal proteinases, especially cathepsin K (and perhaps other cysteine proteinases), play a major role in matrix degradation (Everts *et al.,* 1998; Xia *et al.,* 1999). The coordinated action of several proteinases may be needed to solubilize completely fibrillar type I collagen and other bone matrix proteins. Some of these proteinases obviously act mainly extracellularly and some intracellularly or both. Extracellular matrix degradation may be enhanced further by the production of free oxygen radicals directly into resorption lacunae.

How Bone Degradation Products Are Removed from the Resorption Lacuna

During bone resorption the ruffled border membrane is continuously in very close contact with the bone matrix. Thus, it is somewhat misleading to speak about a resorption lacuna, which is only a very narrow space between the cell membrane and the matrix components. This tentatively suggests that degradation products must be somehow removed continuously from the resorption space in order to allow the resorption process to continue. Theoretically, there are two different routes for resorption products. They can either be released continuously from the resorption lacuna beneath the sealing zone or be transcytosed through the resorbing cell.

Salo *et al.* (1994) provided first evidence for the transcytosis of bone degradation products in vesicles through the resorbing osteoclasts from the ruffled border to the functional secretory domain of the basal membrane. This finding has now been confirmed by demonstrating fragments of collagen and other matrix proteins in the transcytotic vesicles (Salo *et al.,* 1997; Nesbit *et al.,* 1997). We have described new vesicle-like structures, called clastosomes, that appear in polarized cells on the FSD area (Salo *et al.,* manuscript in preparation). It is of interest that the number of these structures is tightly linked to the resorption activity of osteoclasts.

When matrix degradation products are endocytosed, it is possible that further degradation of matrix molecules takes place during the transcytosis. Results have shown that TRAP is localized in transcytotic vesicles in resorbing osteoclasts. They also showed that TRAP can generate highly destructive reactive oxygen species able to destroy collagen and other proteins (Halleen *et al.,* 1999). This suggests a new function for TRAP in the final destruction of matrix degradation products during transcytosis. The observed phenotype of mild osteopetrosis in TRAP knockout mice (Hayman *et al.,* 1996) is in good agreement with this type of new role for TRAP in bone resorption.

Stenbeck and Horton (2000) suggested that the sealing zone is a more dynamic structure than previously thought and could be loose enough to allow the diffusion of molecules from the extracellular fluid into the resorption lacuna.

On the basis of their findings, the authors concluded that the sealing zone may also allow diffusion of the resorption products out from the lacuna. However, there is no direct evidence for this at the moment. It also remains to be seen if inorganic ions and degradation products of matrix proteins follow the same pathway or if parallel routes exist.

What Happens to Osteoclasts after Resorption

In vitro studies have shown that an osteoclast can go through more than one resorption cycle (Kanehisa and Heersche, 1988; Lakkakorpi and Väänänen, 1991). Unfortunately, we do not yet know if this also happens *in vivo* or if the osteoclast continues its original resorption cycle as long as it is functional. Regardless, there must be a mechanism that destroys multinucleated osteoclasts *in situ.* There are at least two different routes that the multinucleated osteoclast can take after it has fulfilled its resorption task. It can undergo fission into mononuclear cells or it can die.

Very little evidence exists to support the idea that multinucleated cells are able to undergo fission back to mononuclear cells. Solari *et al.* (1995) have provided some *in vitro* evidence that mononuclear cells can be formed from multinucleated giant cells, but this study remains to be confirmed. Most likely these postmitotic cells are removed by apoptosis after stopping resorption, and in fact there is now a lot of evidence that supports this conclusion. At present, little is known about the molecular mechanisms that regulate osteoclast apoptosis *in vivo.* However, the induction of apoptosis in osteoclasts can be used to inhibit bone resorption and prevent bone loss. It is well established that both aminobisphosphonates and clodronate induce apoptosis in osteoclasts (Hughes *et al.,* 1995; Selander *et al.,* 1996b), but their mechanisms of action are different. Their kinetics are also quite different (Selander *et al.,* 1996a). Aminobisphosphonates inhibit protein prenylation, which leads to disturbances in intracellular vesicular trafficking (Luckman *et al.,* 1998). Apoptosis is most probably secondary to this effect and is observed clearly after the inhibition of bone resorption. In contrast, with clodronate, apoptosis in osteoclasts seems to be the primary reason for the inhibition of bone resorption (Selander *et al.,* 1996ba).

In addition to bisphosphonates, estrogen and calcitonin have been suggested to regulate osteoclast apoptosis (Hughes *et al.,* 1996; Selander *et al.,* 1996a). It is quite evident that cell–matrix interactions are also important signals for osteoclast survival. The importance of the right extracellular milieu for the osteoclast phenotype and for survival is seen clearly when one compares their sensitivity to extracellular calcium. A moderate concentration of extracellular calcium has been shown to promote apoptosis in osteoclasts cultured on an artificial substrate (Lorget *et al.,* 2000), whereas if cultured on bone, the cells can tolerate high concentrations of extracellular calcium (Lakkakorpi *et al.,* 1996).

It is most likely that the molecular pathways leading to apoptosis in osteoclasts are similar to those described in other cells. It is possible, however, that the highly specific phenotype of the osteoclast also includes cell-specific features of cell survival and death.

CHAPTER 9

Integrin and Calcitonin Receptor Signaling in the Regulation of the Cytoskeleton and Function of Osteoclasts

Introduction

The maintenance of normal bone mass during adult life depends on a balance between osteoblastic bone formation and osteoclastic bone destruction. Bone resorption is primarily carried out by osteoclasts, which are multinucleated, terminally differentiated cells derived from the monocyte/macrophage lineage (Roodman, 1999; Suda *et al.,* 1997; Teitelbaum, 2000). The rate of osteoclastic bone resorption is regulated by osteoclast number and function. Osteoclastogenesis is controlled by the proliferation and homing of the progenitors to bone, their differentiation and fusion to form multinucleated cells. A comprehensive review on the regulation of osteoclast generation has been discussed in a previous chapter. Osteoclast function starts with adhesion to the bone matrix, leading to cytoskeletal reorganization that is important for the migration of these cells to and between the resorption sites and their polarization during the resorption process (Duong *et al.,* 2000a). Cell polarization is initiated by cell attachment to the bone surface and forms a tight sealing zone (or "clear zone") enclosing the resorption lacunae. This sealing attachment structure is highly enriched in filamentous actin and is organized as a ring surrounding a convoluted membrane area, called ruffled border, which is formed as a result of directional insertion of vesicles for the active secretion of protons and lysosomal enzymes toward the bone surface (Baron *et al.,* 1985, 1988; Väänänen *et al.,* 2000). During active resorption, the degraded bone matrix is either processed extracellularly or in part endocytosed into the osteoclast and degraded within secondary lysosomes and in part transported through the cell by transcytosis and secreted at the basal membrane (Nesbitt and Horton, 1997; Salo *et al.,* 1997). Detailed description on the cytoskeletal organization associated with osteoclastic bone resorption is also discussed in another chapter.

This chapter focuses on information regarding the signaling pathways that mediate cytoskeletal organization during osteoclast migration and polarization. Spontaneous mutations and gene knockouts in mice have identified many genes that regulate various stages of osteoclast development. The myeloid and B lymphoid transcription factor PU.1, macrophage colony-stimulating factor (M-CSF or CSF-1), c-fos, p50/p52 subunits of NF-κB, RANK, and its soluble receptor, osteprotegerin (OPG), were shown to be essential for osteoclast differentiation (Suda *et al.,* 1997;

Teitelbaum, 2000). However, pharmacological or genetic methods used to disrupt osteoclast function (Rodan and Martin, 2000; Teitelbaum, 2000) identified many molecules that are involved either in the degradation of bone matrix proteins, such as cathepsin K or metalloproteinases (MMPs), or in the regulation of acidification, including carbonic anhydrase type II, tartrate resistant acid phosphatase (TRAP), the a3 subunit of the vacuolar H^+-ATPase (Li *et al.,* 1999; Scimeca *et al.,* 2000; Frattini *et al.,* 2000), and, very recently, the CIC-7 chloride channel (Kornak *et al.,* 2000). Another class of molecules appeared to be important in modulating osteoclastic cytoskeletal organization, including the calcitonin receptor and the adhesion receptor $\alpha_v\beta_3$. Calcitonin has been considered as an important therapeutic agent to acutely block bone resorption in osteoporosis therapy (Rodan and Martin, 2000). More recently, small molecular weight inhibitors of $\alpha_v\beta_3$ integrin have emerged as attractive orally available agents for antiosteoporosis therapy (Hartman and Duggan, 2000; Lark *et al.,* 1999). This chapter discusses the signal transduction pathways mediated by these two receptors in the context of their regulation of cytoskeletal reorganization during osteoclastic bone resorption.

Adhesion and Cytoskeletal Organization in Osteclasts—$\alpha_v\beta_3$ Integrins

Integrins, a superfamily of heterodimeric transmembrane receptors, mediate cell–matrix and cell–cell interactions. Integrin-mediated adhesion and signaling regulate a variety of cell functions, including bone resorption, platelet aggregation, leukocyte homing and activation, tumor cell growth and metastases, cell survival and apoptosis, and cellular responses to mechanical stress (Clark and Brugge, 1995; Schlaepfer *et al.,* 1999). In addition to cell adhesion, the assembly of these receptors also organizes extracellular matrices, modulates cell shape changes, and participates in cell spreading and motility (Wennerberg *et al.,* 1996; Wu *et al.,* 1996).

Upon ligand binding, integrins usually undergo receptor clustering, leading to the formation of focal adhesion contacts, where these receptors are linked to intracellular cytoskeletal complexes and bundles of actin filaments. It has long been recognized that the short cytoplasmic domains of the α and β integrin subunits can recruit a variety of cytoskeletal and signaling molecules. Integrin-mediated signaling has been shown to change phosphoinositide metabolism, raise intracellular calcium, and induce tyrosine or serine phosphorylation of signaling molecules (Giancotti and Ruoslahti, 1999). Models of integrin-stimulated tyrosine phosphorylation and signaling pathways have been discussed extensively elsewhere (Giancotti and Ruoslahti, 1999; Schlaepfer *et al.,* 1999). The involvement of several signaling and adapter molecules, such as c-Src, PYK2, $p130^{Cas}$, and c-Cbl in integrin function in osteoclasts, is discussed in the following sections.

Bone consists largely of type I collagen (>90%) and of noncollagenous proteins interacting with a mineral phase of hydroxylapatite. Adhesion of osteoclasts to the bone surface involves the interaction of integrins with extracellular matrix proteins within the bone matrix. Osteoclasts express very high levels of the vitronectin receptor $\alpha_v\beta_3$ (Duong *et al.,* 2000a; Horton, 1997; Rodan and Martin, 2000). Mammalian osteoclasts also lower levels of the collagen/laminin receptor $\alpha_2\beta_1$ and the vitronectin/fibronectin receptor $\alpha_v\beta_1$. Rat osteoclasts adhere in an $\alpha_v\beta_3$ dependent manner to extracellular matrix (ECM) proteins containing RGD sequences, including vitronectin, osteopontin, bone sialoprotein, and a cryptic RGD site in denatured collagen type I (Flores *et al.,* 1996). More recently, it was reported that rat osteoclasts adhere to native collagen type I using $\alpha_2\beta_1$ integrin, surprisingly in an RGD-dependent manner (Helfrich *et al.,* 1996). Moreover, osteoclastic bone resorption is partially inhibited by both anti-α_2 and anti-β_1 antibodies (Nakamura *et al.,* 1996). To date, it is still unclear the physiological ECM substrate of $\alpha_v\beta_3$ integrins in bone.

$\alpha_v\beta_3$-Mediated Osteoclast Function

The first evidence that $\alpha_v\beta_3$ may play an important role in osteoclast function was obtained when a monoclonal antibody raised against osteoclasts inhibited bone resorption *in vitro* (Chambers *et al.,* 1986), whose antigen was later identified to be the $\alpha_v\beta_3$ integrin (Davies *et al.,* 1989). Furthermore, osteoclastic bone resorption *in vitro* can be inhibited by RGD-containing peptides and disintegrins or by blocking antibodies to $\alpha_v\beta_3$ (Horton *et al.,* 1991; King *et al.,* 1994; Sato *et al.,* 1990).

Inhibition of $\alpha_v\beta_3$ integrins can also block bone resorption *in vivo.* In the thyro-parathyroidectomized (TPTX) model, coinfusion of disintegrins such as echistatin or kinstrin and parathyroid hormone (PTH) completely blocked the PTH-induced increase in serum calcium (Fisher *et al.,* 1993; King *et al.,* 1994). Echistatin was also shown to inhibit bone loss in hyperparathyroid mice maintained on a low calcium diet. In the bones of these animals, echistatin colocalizes with $\alpha_v\beta_3$ integrins in osteoclasts (Masarachia *et al.,* 1998). Additional *in vivo* studies demonstrated that echistatin or RGD peptidomimetics inhibit bone resorption in ovariectomized rodents by blocking the function of $\alpha_v\beta_3$ integrins (Engleman *et al.,* 1997; Yamamoto *et al.,* 1998). Moreover, infusion of the anti-rat β_3 integrin subunit antibody blocked the effect of PTH on serum calcium in TPTX rats (Crippes *et al.,* 1996). Further compelling evidence for the role of $\alpha_v\beta_3$ integrin in osteoclast function has been provided by the targeted disruption of the β_3 integrin subunit in mice, which induces late onset osteopetrosis, 3 to 6 months after birth (McHugh *et al.,* 2000).

Although these findings indicate that the $\alpha_v\beta_3$ integrin has an important rate-limiting function in bone resorption, its mechanism of action in the osteoclast is far from being fully understood. Recognition of extracellular matrix components by osteoclasts is an important step in initiating

osteoclast function. Several studies have demonstrated that integrin-mediated cell adhesion to vitronectin, fibronectin, or collagen was reported to induce cell spreading and actin rearrangement in osteoclasts. The $\alpha_v\beta_3$ integrin plays a role in the adhesion and spreading of osteoclasts on bone (Lakkakorpi and Väänänen, 1991; Nesbitt *et al.,* 1993). Expression of the $\alpha_v\beta_3$ integrin could also be detected in mononucleated osteoclast precursors, and $\alpha_v\beta_3$ was found to mediate the migration of the precursors, necessary for their fusion, during osteoclast differentiation in culture (Nakamura *et al.,* 1998b). Furthermore, the $\alpha_v\beta_3$ integrin plays a role in the regulation of two processes required for effective osteoclastic bone resorption: cell migration and maintenance of the sealing zone (Nakamura *et al.,* 1999).

The presence of the RGD sequence in osteopontin, a bone matrix protein produced by osteoblasts and osteoclasts, led to the suggestion that attachment at the sealing zone may be mediated by integrins. It was reported that $\alpha_v\beta_3$ is found in the sealing zone of resorbing osteoclasts (Hultenby *et al.,* 1993; Reinholt *et al.,* 1990) and in the podosomes (Zambonin Zallone *et al.,* 1989). Other investigators, using different antibodies, could not detect $\alpha_v\beta_3$ in the sealing zone by confocal and electron microscopy (Lakkakorpi *et al.,* 1993; Nakamura *et al.,* 1999). These discrepant results suggest the need for further studies. All investigators, however, agree that the receptor is found in basolateral membranes, in a few intracellular vesicles, and at a much lower level in the ruffled border region of the resorbing osteoclasts.

In echistatin-treated mice, where bone resorption was inhibited, the number of osteoclasts on the bone surface was unchanged rather than decreased, suggesting that osteoclast inhibition by $\alpha_v\beta_3$ integrin antagonists is not due to the detachment of osteoclasts from the bone surface (Masarachia *et al.,* 1998; Yamamoto *et al.,* 1998). Consistent with this observation, the osteoclast number was not reduced in the bones of $\beta_3^{-/-}$ mice (McHugh *et al.,* 2000). These data suggest, as indicated by the analysis of the integrin repertoire of osteoclasts, that in the absence of functional $\alpha_v\beta_3$ receptors, adhesion per se is not compromised and that other integrins, or different attachment proteins, participate in this process. However, $\alpha_v\beta_3$ may well be critical for cell motility via its signaling ability (Nakamura *et al.,* 2001; Sanjay *et al.,* 2001). Ligands (antagonists) of $\alpha_v\beta_3$ may therefore inhibit osteoclastic bone resorption *in vivo* by a different mechanism, such as interfering with the integrin-dependent cytoskeletal organization, required for osteoclast migration and efficient resorption (Nakamura *et al.,* 1999).

Adhesion-Dependent Signal Transduction in Osteoclasts

Target disruption of the β_3 integrin subunit results in an osteopetrotic phenotype (McHugh *et al.,* 2000). Osteoclasts isolated from these mice fail to spread, do not form actin rings, have abnormal ruffled membranes, and exhibit reduced bone resorption activity *in vitro.* Thus, $\alpha_v\beta_3$ plays a pivotal in the resorptive process, through its functions in cell adhesion-dependent signal transduction and in cell motility. Indeed, $\alpha_v\beta_3$ transmits bone matrix-derived signals, ultimately activating intracellular events, which regulate cytoskeletal organization essential for osteoclast migration and polarization. Research interests have been focused on identifying the hierarchy of the $\alpha_v\beta_3$-regulated cascade of signaling and structural proteins required for this cytoskeletal organization. One of the earliest events initiated by integrin–ligand engagement is the elevation of intracellular calcium. In rat, mouse, and human osteoclasts, RGD-containing peptides trigger a transient increase in intracellular calcium apparently mobilized from intracellular stores (Paniccia *et al.,* 1995; Zimolo *et al.,* 1994), and this event is independent of the presence or activation of c-Src (Sanjay *et al.,* 2001). Studies using both genetic and biochemical approaches, such as immunolocalization and -coprecipitation, have partially elucidated the $\alpha_v\beta_3$-associated molecular complex in osteoclasts. Schematic illustration of the recruitment of these signaling molecules to $\alpha_v\beta_3$ integrins in resting and activated osteoclasts is shown in Fig. 1, (see also color plate), although the exact relationship between these proteins and α_v and β_3 subunits is still not firmly established.

c-Src Regulates $\alpha_v\beta_3$ Integrin-Mediated Cytoskeletal Organization and Cell Motility

Src kinases play an important role in cell adhesion and migration, in cell cycle control, and in cell proliferation and differentiation (Thomas and Brugge, 1997). Moreover, novel roles for Src kinases in the control of cell survival and angiogenesis have emerged (Schlessinger, 2000). In bone, the tyrosine kinase c-Src was found to be essential for osteoclast-resorbing activity and/or motility. Targeted disruption of c-Src in mice induces osteopetrosis due to a loss of osteoclast function, without a reduction in osteoclast number (Soriano *et al.,* 1991). Morphologically, osteoclasts in *Src*$^{-/-}$ mice are not able to form a ruffled border, but appear to form sealing zones on bone surfaces (Boyce *et al.,* 1992). Src is highly expressed in osteoclasts, along with at least four other Src family members (Hck, Fyn, Lyn, and Yes) (Horne *et al.,* 1992; Lowell *et al.,* 1996). Hck partly compensates for the absence of Src, as the double mutant *Src*$^{-/-}$*/Hck*$^{-/-}$ mouse is more severely osteopetrotic than the *Src*$^{-/-}$ mouse, despite the fact that the single mutant *hck*$^{-/-}$ mouse is apparently not osteopetrotic (Lowell *et al.,* 1996). However, the transgenic expression of kinase-deficient Src in *Src*$^{-/-}$ mice partially rescued osteoclast function, indicating that full Src tyrosine kinase activity is not absolutely required for mediating osteoclast function, with its role as an adaptor protein to recruit downstream signaling molecules (Schwartzberg *et al.,* 1997) being also essential in its function in osteoclasts (Sanjay *et al.,* 2001).

c-Src is associated with the plasma membrane and multiple intracellular organelles (Horne *et al.,* 1992; Tanaka *et al.,* 1996). It is also concentrated in the actin ring and the cell periphery (Sanjay *et al.,* 2001), regions that are involved in osteoclast attachment and migration. This suggests that the absence of Src might compromise these aspects of os-

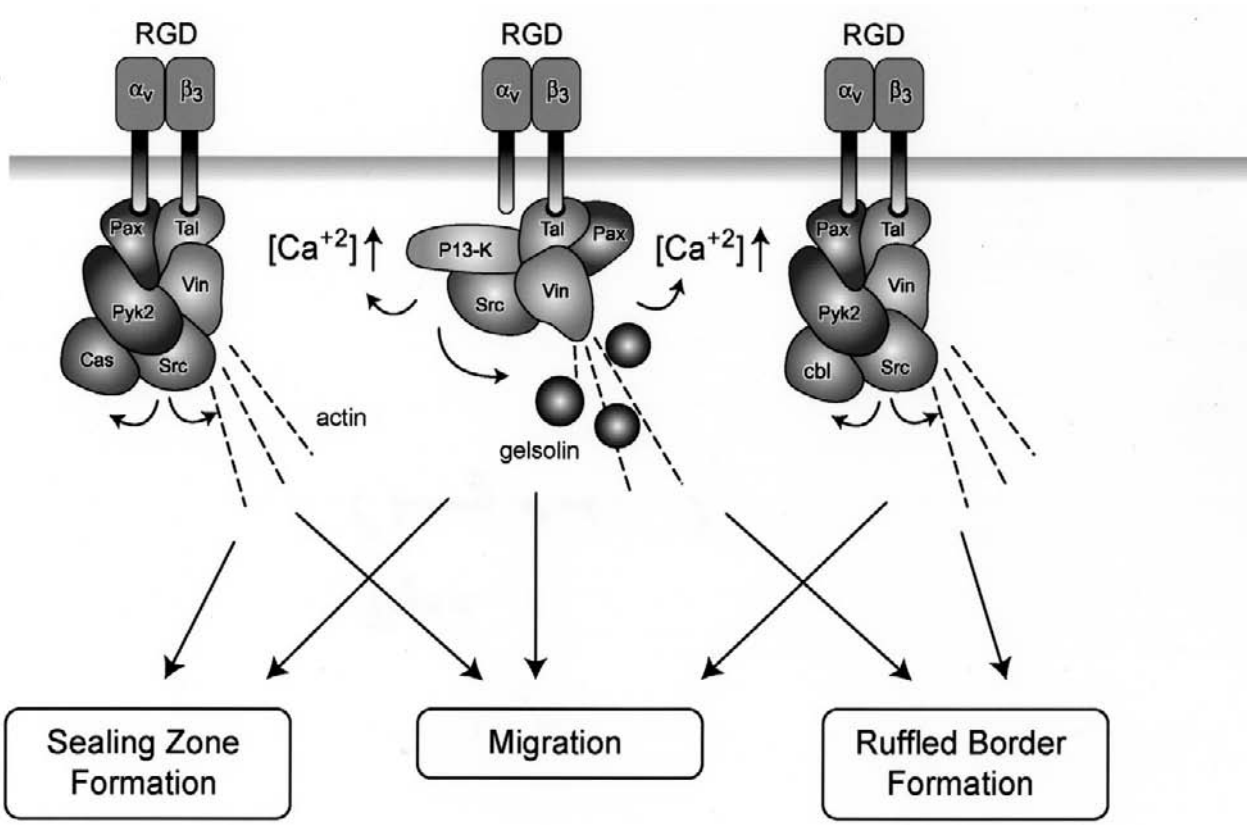

Figure 1 Schematic summary of the current hypothesis regarding the role of the $\alpha_v\beta_3$ integrin-mediated signaling pathway(s) involved in osteoclast cytoskeletal organization during migration and polarization. (See also color plate.)

teoclast function. Indeed, *Src*$^{-/-}$ osteoclasts generated *in vitro* do not resorb bone and exhibit a profound defect in cell adhesion and spreading on vitronectin, suggesting that c-Src plays an important role in adhesion-dependent cytoskeletal organization in osteoclasts (Lakkakorpi *et al.,* 2001; Nakamura *et al.,* 2001). Although $\alpha_v\beta_3$ integrin expression and ligand-binding affinity are not altered in *Src*$^{-/-}$ osteoclasts, the lack of c-Src results in the pronounced aggregation of $\alpha_v\beta_3$ integrins (Fig. 2, see also color plate) and their downstream effectors, such as Pyk2, p130^{Cas}, and paxillin, in the basal surface of resorbing osteoclasts (Lakkakorpi *et al.,* 2001). This thus suggests that c-Src might not be important for the initial recruitment of $\alpha_v\beta_3$-dependent downstream effectors, but it seems to mediate the turnover of the integrin-associated complex of signaling and cytoskeletal molecules. This hypothesis has been supported strongly by the finding that Src$^{-/-}$ osteoclasts do indeed demonstrate significant decreases in their ability to migrate over a substrate, at least *in vitro* (Sanjay *et al.,* 2001). It is therefore conceivable that the decreased bone resorption in *Src*$^{-/-}$ osteoclasts is due in part to low motility of the cells.

Pyk2 and c-Src Coregulate $\alpha_v\beta_3$ Integrin-Mediated Signals

Pyk2 has been identified as a major adhesion-dependent tyrosine kinase in osteoclasts, both *in vivo* and *in vitro* (Duong *et al.,* 1998). Pyk2 is a member of the focal adhesion kinase (FAK) family, highly expressed in cells of the central nervous system and cells of hematopoietic lineage (Schlaepfer *et al.,* 1999). Pyk2 and FAK share about 45% overall amino acid identity and have a high degree of sequence conservation surrounding binding sites of SH2 and SH3 domain-containing proteins. Although the presence of FAK has been reported in osteoclasts (Berry *et al.,* 1994; Tanaka *et al.,* 1995), Pyk2 is expressed at much higher levels than FAK in osteoclasts (Duong *et al.,* 1998). Ligation of $\alpha_v\beta_3$ integrins either by ligand binding or by antibody-mediated clustering results in an increase in Pyk2 tyrosine phosphorylation (Duong *et al.,* 1998). Moreover, Pyk2 colocalizes with F-actin (Fig. 3, see also color plate), paxillin, and vinculin in podosomes and in sealing zones of resorbing osteoclasts on bone (Duong *et al.,* 1998). These observations strongly implicate Pyk2 as a downstream effector in $\alpha_v\beta_3$-dependent signaling in mediating cytoskeletal organization associated with osteoclast adhesion, spreading, migration, and sealing zone formation.

More recently, osteoclasts infected with adenovirus expressing Pyk2 antisense have a significant reduction in Pyk2 expression (Duong *et al.,* 2000b). Similar to *Src*$^{-/-}$ osteoclasts, these cells do not resorb bone accompanied with defects in cell adhesion, spreading, and sealing zone organization, suggesting that Pyk2 is also important for cytoskeletal organization in osteoclasts (Duong *et al.,* 2000b). Consistent with the observation just mentioned,

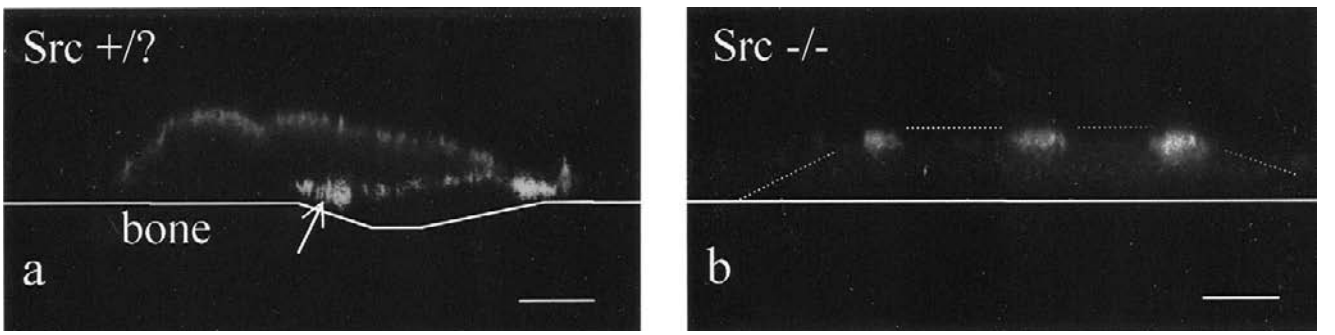

Figure 2 Pronounced aggregation of $\alpha_v\beta_3$ integrin (in red) and F-actin (in green) in the basal membrane of Src-deficient osteoclasts (b) as compared to the normal distribution of the receptor in wild-type osteoclasts on bone (a) (Lakkakorpi *et al.,* 2001). (See also color plate.)

mice that lack Pyk2 were shown to develop osteopetrosis with age similar to that of $\beta_3^{-/-}$ mice (Sims *et al.,* 1999). Furthermore, a double knockout of Src and Pyk2 in mice is more severely osteopetrotic than either of the single mutants (Sims *et al.,* 1999), suggesting that these two proteins might interact during normal osteoclast functioning.

Indeed, tyrosine phosphorylation and kinase activity of Pyk2 are reduced markedly in preosteoclasts derived from *Src*$^{-/-}$ mice (Duong *et al.,* 1998). This is in contrast with the findings of Sanjay *et al.* (2001), who reported that, upon adhesion, *Src*$^{-/-}$ osteoclasts demonstrated levels of Pyk2 phosphorylation comparable to those found in wild-type osteoclasts. Reasons for this discrepancy are not known, but it should be noted that the cells used in these two studies were at different stages of differentiation. Moreover, in adherent osteoclasts, Pyk2 is tightly associated with c-Src via its SH2 domain. An increase in intracellular calcium that results from the engagement or cross-linking of the $\alpha_v\beta_3$ integrin is suggested to activate Pyk2 by inducing the autophosphorylation of Tyr402. This phosphorylated residue binds to the Src SH2 domain (Dikic *et al.,* 1996), displacing the inhibitory Src phosphotyrosine 527 and activating Src, leading to further recruitment and activation of Src-mediated downstream signals. At the same time, activation of Pyk2 following integrin–ligand engagement results in the recruitment of cytoskeletal proteins in a similar manner as FAK (Schlaepfer *et al.,* 1999). The N-terminal domain of FAK was shown to interact with the cytoplasmic domain of the β integrin subunit. On addition to binding to Src, the autophosphorylation sites in FAK and Pyk2 are capable of binding to SH2 domains of phospholipase C-γ (Nakamura *et al.,* 2001; Schlaepfer *et al.,* 1999; Zhang *et al.,* 1999a). Furthermore, the C-terminal domain of FAK and Pyk2 contains binding sites for Grb-2, p130^{Cas}, and paxillin (Schlaepfer *et al.,* 1999). Together, the association and activation of c-Src and Pyk2 could initiate a cascade of activation and recruitment of additional signaling and structural molecules to the $\alpha_v\beta_3$ integrin-associated protein complex, which are important for modulating the actin cytoskeleton in osteoclasts.

ASSOCIATION OF PYK2 WITH SRC AND C-CBL DOWNSTREAM OF INTEGRINS

Engagement of the $\alpha_v\beta_3$ integrin induces the formation of a signaling complex that contains not only c-Src and Pyk2, but also c-Cbl (Sanjay *et al.,* 2001). The product of the protooncogene cCbl is a 120-kDa adaptor protein that gets tyrosine phosphorylated in response to the activation of various signaling pathways, including M-CSF stimulation in monocytes and v-Src transformation and EGF or PDGF

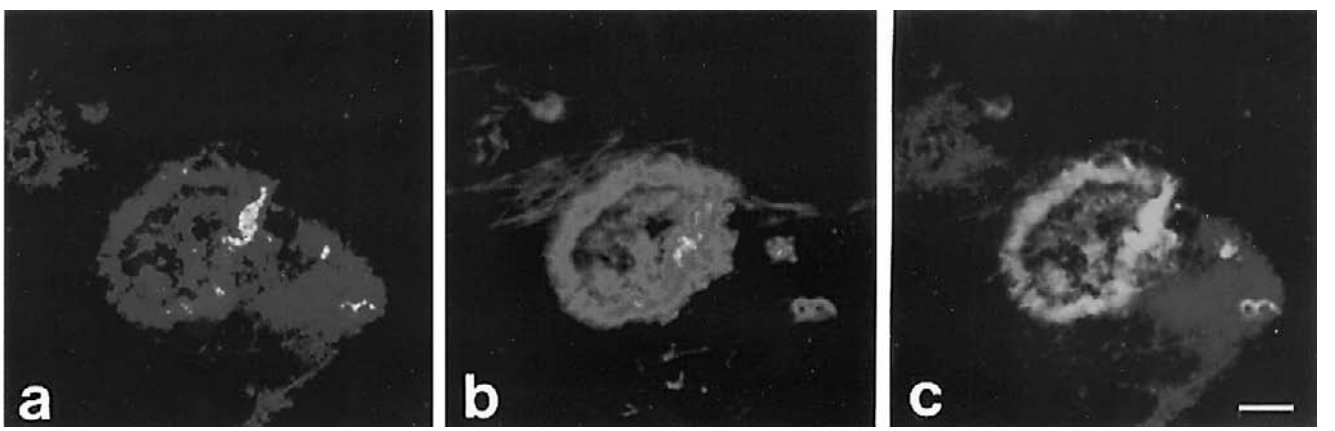

Figure 3 Localization of Pyk2 in the sealing zone of osteoclasts on bone. Confocal images of double immunostaining for Pyk2 (a, in red) and F-actin (b, in green) and their overlay image (c, in yellow) in an osteoclast during resorption (Duong *et al.,* 1998) (See also color plate.)

activation in fibroblasts (Tanaka *et al.,* 1995). Tanaka *et al.* (1996) reported that the level of tyrosine phosphorylation of c-Cbl immunoprecipitated from *Src*$^{-/-}$ osteoclasts is reduced markedly, compared with that found in wild-type osteoclasts (Tanaka *et al.,* 1996). Furthermore, c-Src is found to associate and colocalize with c-Cbl in the membranes of intracellular vesicles in osteoclasts (Tanaka *et al.,* 1996). c-Cbl is a negative regulator of several receptor and nonreceptor tyrosine kinases (Miyake *et al.,* 1997). Consistent with this function, overexpression of Cbl results in decreased Src kinase activity. Interestingly, equivalent inhibitory effects are seen with any fragment of Cbl that contains the N-terminal phosphotyrosine-binding (PTB) domain, regardless of the presence of the Src-binding, proline-rich region (Sanjay *et al.,* 2001). The inhibition of Src kinase activity and the binding to Src of v-Cbl (which lacks the proline-rich domain of Cbl and therefore will not bind to the Src SH3 domain) require the presence of phosphorylated Src Tyr416, the autophosphorylation site of Src on the activation loop of the kinase domain (Sanjay *et al.,* 2001).

In HEK293 cells, overexpression of the Cbl constructs also causes decreases in cell adhesion in parallel with their effects on Src kinase activity. Thus, c-Cbl and fragments of Cbl that contain the PTB domain reduce cell adhesion, whereas the C-terminal half of Cbl, which contains the Src SH3-binding, proline-rich region but not the PTB domain, does not (Sanjay *et al.,* 2001). Interestingly, the absence of either c-Src or c-Cbl causes a decrease in both cell motility (the rapid extension and retraction of lamellipodia) and directional migration of authentic osteoclasts isolated from Src$^{-/-}$ or Cbl$^{-/-}$ mice (Sanjay *et al.,* 2001), and freshly plated osteoclasts from Src$^{-/-}$ mice fail to disassemble podosomes efficiently as the cell spreads (Sanjay *et al.,* 2001), suggesting that the Pyk2/Src/Cbl complex may be required for the disassembly of attachment structures. The increased stability of podosomes could well explain the decreased motility of the Src$^{-/-}$ and Cbl$^{-/-}$ osteoclasts.

Another recently described function of c-Cbl could contribute to the regulation and stability of podosomes in osteoclasts. It has been shown that Cbl acts as a ubiquitin ligase, targeting ubiquitin-conjugating enzymes to the kinases that Cbl binds to and downregulates, with the result that the kinases are ubiquitinated and degraded by the proteosome (Yokouchi *et al.,* 1999; Joazeiro *et al.,* 1999; Levkovitz *et al.,* 1999). Because active, but not inactive, Src is ubiquitinated and degraded via the proteosome (Hakak and Martin, 1999), it could therefore be that once Cbl is bound to the Pyk2/Src complex, it recruits the ubiquitinating system to the podosome, leading to the ubiquitination and degradation of the other components of the complex, thereby participating in the turnover of podosome components that is required to ensure cell motility.

$\alpha_v\beta_3$ Integrin-Mediated Association of Pyk2 with Src and p130^{Cas}

Another integrin-dependent signaling adaptor characterized in osteoclasts is p130^{Cas} (Cas, Crk associated substrate). In a number of different cell types, p130^{Cas} has been shown to be substrates for FAK, Pyk2, Src kinase, or Abl (Schlaepfer *et al.,* 1999). In osteoclasts, p130^{Cas}, via its SH3 domain, can directly associate with the proline-rich motifs in the C-terminal domains of FAK and Pyk2. Similar to Pyk2, p130^{Cas} was shown to be highly tyrosine phosphorylated upon osteoclast adhesion to extracellular matrix substrates of $\alpha_v\beta_v$ integrins (Lakkakorpi *et al.,* 1999; Nakamura *et al.,* 1998a). In addition, p130^{Cas} localizes to the actin ring formed in osteoclasts on glass and to the sealing zone on bone (Lakkakorpi *et al.,* 1999; Nakamura *et al.,* 1998a). In adhering osteoclasts, p130^{Cas} is found to be constitutively associated with Pyk2, suggesting that this adapter molecule participates in the integrin-PYK2 signaling pathway (Lakkakorpi *et al.,* 1999).

Much less is known about what signals are generated by phosphorylation of the p130^{Cas} adaptor protein. In fibroblasts, integrin-stimulated tyrosine phosphorylation of p130^{Cas} has been shown to promote binding to the SH2 domain of either Crk (Vuori *et al.,* 1996) or Nck (Schlaepfer *et al.,* 1997). More recently, expression of the SH3 domain of p130^{Cas} can inhibit FAK-mediated cell motility (Cary *et al.,* 1998), whereas overexpression of Crk has been shown to promote cell migration in a Rac- and Ras-independent manner (Klemke *et al.,* 1998). Moreover, the downstream components of this Rac-mediated migration pathway appear to involve phosphatidyl inositol 3-kinase (PI3-kinase) (Shaw *et al.,* 1997). In osteoclasts, the PI3-kinase-dependent target was found to be the cytoskeletal-associated protein gelsolin (Chellaiah *et al.,* 1998).

$\alpha_v\beta_3$ Integrin-Dependent Activation of PI3-kinase

In avian osteoclasts, $\alpha_v\beta_3$ is associated with the signaling molecule PI3-kinase and c-Src (Hruska *et al.,* 1995). Interaction of $\alpha_v\beta_3$ with osteopontin resulted in increased PI3-kinase activity and association with Triton-insoluble gelsolin (Chellaiah *et al.,* 1998). In murine osteoclasts formed in culture, PI3-kinase was found to translocate into the cytoskeleton upon osteoclast attachment to the bone surface (Lakkakorpi *et al.,* 1997). In addition, potent inhibitors of PI3-kinase, such as wortmannin, inhibit mammalian osteoclastic bone resorption *in vitro* and *in vivo* (Nakamura *et al.,* 1995).

Gelsolin, an actin-binding protein, is known to regulate the length of F-actin *in vitro,* and thus cell shape and motility (Cunningham *et al.,* 1991). More recently, gelsolin-deficient mice were generated that express mild defects during hemostasis, inflammation, and possibly skin remodeling (Witke *et al.,* 1995). Gelsolin$^{-/-}$ mice have normal tooth eruption and bone development, with only modest thickened calcified cartilage trabeculae due to delayed cartilage resorption and very mild and progressive osteopetrosis (Chellaiah *et al.,* 2000). However, osteoclasts isolated from gelsolin$^{-/-}$ mice lack podosomes and actin rings and have reduced cell motility (Chellaiah *et al.,* 2000).

In conclusion, there is little doubt today that integrins present in the osteoclast membrane, and particularly the

$\alpha_v\beta_3$ integrin, play a critical role in osteoclast biology. This involves not only the adhesion itself, but also the regulation of outside-in signaling, which ensures the proper organization of the cytoskeleton, and of inside-out signaling, which modulates the affinity of the receptors for their substrates. These two regulatory modes are essential in ensuring the assembly and disassembly of the attachment structures (podosomes), a cyclic process necessary for efficient cell motility

Calcitonin and the Cytoskeleton

Because of its potent inhibitory effects on osteoclast activity, calcitonin has long been recognized as a potential therapeutic agent for the treatment of diseases that are characterized by increased bone resorption, such as osteoporosis, Paget's disease, and late-stage malignancies. Signaling mechanisms downstream of the calcitonin receptor have therefore been of great interest. A comprehensive discussion of calcitonin-induced signaling appears elsewhere in this volume, and this section focuses on what is known of the interaction of calcitonin-activated signaling events with attachment-related signaling.

In situ, calcitonin causes reduced contact of osteoclasts with the bone surface and altered osteoclast morphology (Holtrop *et al.,* 1974; Kallio *et al.,* 1972). While *in vitro,* calcitonin-treated osteoclasts retract and become less mobile (Chambers and Magnus, 1982; Chambers *et al.,* 1984; Zaidi *et al.,* 1990). These effects suggest that some of the key targets of calcitonin signaling are involved in cell attachment and cytoskeletal function, possibly in relation with integrins and/or their signaling function.

The calcitonin receptor, a G protein-coupled receptor that has been cloned from several species and cell types, couples to multiple heterotrimeric G proteins (G_s, $G_{i/o}$, and G_q)(Chabre *et al.,* 1992; Chen *et al.,* 1998; Force *et al.,* 1992; Shyu *et al.,* 1996; 1999). For technical reasons, much of the recent characterization of signaling downstream of the calcitonin receptor has been conducted in cells other than osteoclasts, particularly cell lines that express recombinant calcitonin receptor. Because it couples to multiple G proteins, the proximal signaling mechanisms that are activated by calcitonin include many classical GPCR-activated effectors, such as adenylyl cyclase and protein kinase A (PKA), phospholipases C, D, and A2, and protein kinase C (PKC). In HEK 293 cells that express the rabbit calcitonin receptor, calcitonin induces phosphorylation and activation of the extracellular signal-regulated kinases, Erk1 and Erk2 (Chen *et al.,* 1998; Naro *et al.,* 1998), via mechanisms that involve the $\beta\gamma$ subunits of pertussis tox-insensitive G_i as well as pertussis toxin-insensitive signaling via phospholipase C, PKC, and elevated intracellular calcium ($[Ca^{2+}]_i$)

It has been shown in the same cell line that calcitonin induces tyrosine phosphorylation and association of FAK, paxillin, and HEF1, a member of the $p130^{Cas}$ family (Zhang *et al.,* 1999b), which are components of cellular adhesion complexes. Interestingly, while these cells express both HEF1 and $p130^{Cas}$, only HEF1 is phosphorylated and associates with FAK and paxillin. This response to calcitonin is independent of adenylyl cyclase/PKA and of pertussis toxin-sensitive mechanisms and appears to be mediated by the pertussis toxin-insensitive PKC/$[Ca^{2+}]_i$ signaling pathway. The relevance of the FAK/paxillin/HEF1 phosphorylation to integrins and the actin cytoskeleton is demonstrated by its requirement for integrin attachment to the substratum and its sensitivity to agents (cytochalasin D, latrunculin A) that disrupt actin filaments (Zhang *et al.,* 2000). The calcitonin-induced tyrosine phosphorylation of paxillin and HEF1 is enhanced by the overexpression of c-Src and is strongly inhibited by the overexpression of a dominant negative kinase-dead Src, indicating that c-Src is required at some point in the coupling mechanism. Interestingly, the dominant-negative Src has little effect on the calcitonin-induced phosphorylation of Erk1/2, in contrast to what has been reported for some other G protein coupled receptors (Della Rocca *et al.,* 1997,1999), indicating that some aspects of calcitonin-induced signaling may be significantly different from other better studied G protein-coupled receptors. These or similar events could well play important roles in mediating the calcitonin-induced changes in cell adhesion and motility in osteoclasts.

Therapeutic Implications

Although the mechanism and action of calcitonin in blocking osteoclast function are not fully understood, the relative selective expression of the calcitonin receptor in osteoclasts and its well accepted role in regulating osteoclastic cytoskeleton have made calcitonin an attractive therapeutic agent for many years. Calcitonin of human, pig, salmon, and eel has been used in both injected and intranasal form in the treatment of osteoporosis and Paget's disease. However, calcitonin-induced downregulation of the receptors in osteoclasts has been observed, resulting in the hormone-induced resistance of osteoclasts in bone resorption. It therefore remains to be seen whether this problem can be overcome for therapeutic application of this class of receptor. Identification of the downstream signaling pathway of calcitonin receptor would further our understanding on how calcitonin blocks bone resorption and regulates calcium hemostasis. As discussed here, it is possible that much of the effects of calcitonin on the osteoclast are due to its ability to generate intracellular signals that interfere with the normal regulation of the cytoskeleton, adhesion, and/or cell motility, thereby converging on similar functional targets as the integrin signaling pathways.

The findings that gene deletion of $\alpha_v\beta_3$ integrin and its downstream effectors, as well as the use of inhibitors of this integrin, results in inhibition of bone resorption *in vivo* in rodent models point to these molecules as potential therapeutic targets for osteoporosis therapy. $\alpha_v\beta_3$ integrin is highly and somewhat selectively expressed in osteoclasts across species. β_3 knockout mice appear to have normal development and growth, besides the defects

related to $\alpha_v\beta_3$ integrin associated osteopetrosis and $\alpha_{IIb}\beta_3$ integrin-associated bleeding. Orally active RGD mimetics have been reported to successfully block bone resorption in rodents without notable adverse effects. This raises the possibilities of developing safe and effective therapeutic agents for osteoporosis based on interfering with the interaction of the osteoclast $\alpha_v\beta_3$ integrin with its physiological ligands.

Introduction

Apoptosis is a form of individual cell suicide that was originally defined by a series of morphological changes in nuclear chromatin and cytoplasm (Kerr *et al.,* 1972; Wyllie *et al.,* 1980). Cells undergoing apoptosis contract, lose attachment to their neighbors, and break up into fragments, apoptotic bodies, which get phagocytosed quickly by surrounding cells. The Greek derivation of apoptosis depicts petals falling from flowers or leaves falling from trees. Thus, the "apo" (as in apocrine) describes the apparent extrusion of dying cells into spaces around them (see later) and the "ptosis" (as in drooping of the upper eyelid) describes them falling out or disappearing from the tissue.

Apoptosis is an important regulatory program in which activation or suppression of many factors, including oncogenes, tumor suppressor genes, growth factors, cytokines, and integrins, can determine a cell's fate (see Chao and Korsmeyer, 1998; Earnshaw *et al.,* 1999; Desagher and Martinou, 2000; Green, 2000; Strasser *et al.,* 2000; Hengartner, 2000). It controls cell numbers in populations of neural, mesenchymal, and epithelial cells during embryonic development; facilitates deletion of superfluous tissue, such as soft tissue between developing fingers; and accounts for some of the cell loss from regenerating epithelial surfaces in adult tissues, such as the skin and alimentary tract.

Since the first version of this chapter was published in 1996, there has been an explosion of information on the significance and molecular regulation of apoptosis in bone (Manolagas, 2000; Weinstein and Manolagas, 2000). It is now evident that apoptosis is as important as its functional opposite, mitosis, for the growth and maintenance of the skeleton. This second edition of the chapter reflects these new developments and is an amalgam of the efforts of two groups of investigators: one (Drs. Boyce and Xing) working on osteoclast apoptosis and one (Drs. Jilka, Bellido, Weinstein, Parfitt, and Manolagas) studying the apoptosis of osteoblasts and osteocytes and its role in the pathophysiology and therapeutic management of osteoporosis. After briefly sketching the features and molecular regulation of apoptosis, we will review its occurrence and regulation in bone cells, its significance for bone development and maintenance, and its importance in the etiology and treatment of bone diseases.

General Features and Regulation of Apoptosis

Morphologic Features and Detection Techniques

The most dramatic changes during apoptosis are seen in the nucleus and begin with clumping of chromatin into dense aggregates around the nuclear membrane (Fig. 1A, see also color plate), rather than the even dispersal seen typically in viable cells (Fig. 1B, see also color plate). This is followed by further chromatin condensation, disintegration of the nucleus, and the formation of numerous balls of condensed chromatin within the cytoplasm (Fig. 1C, see

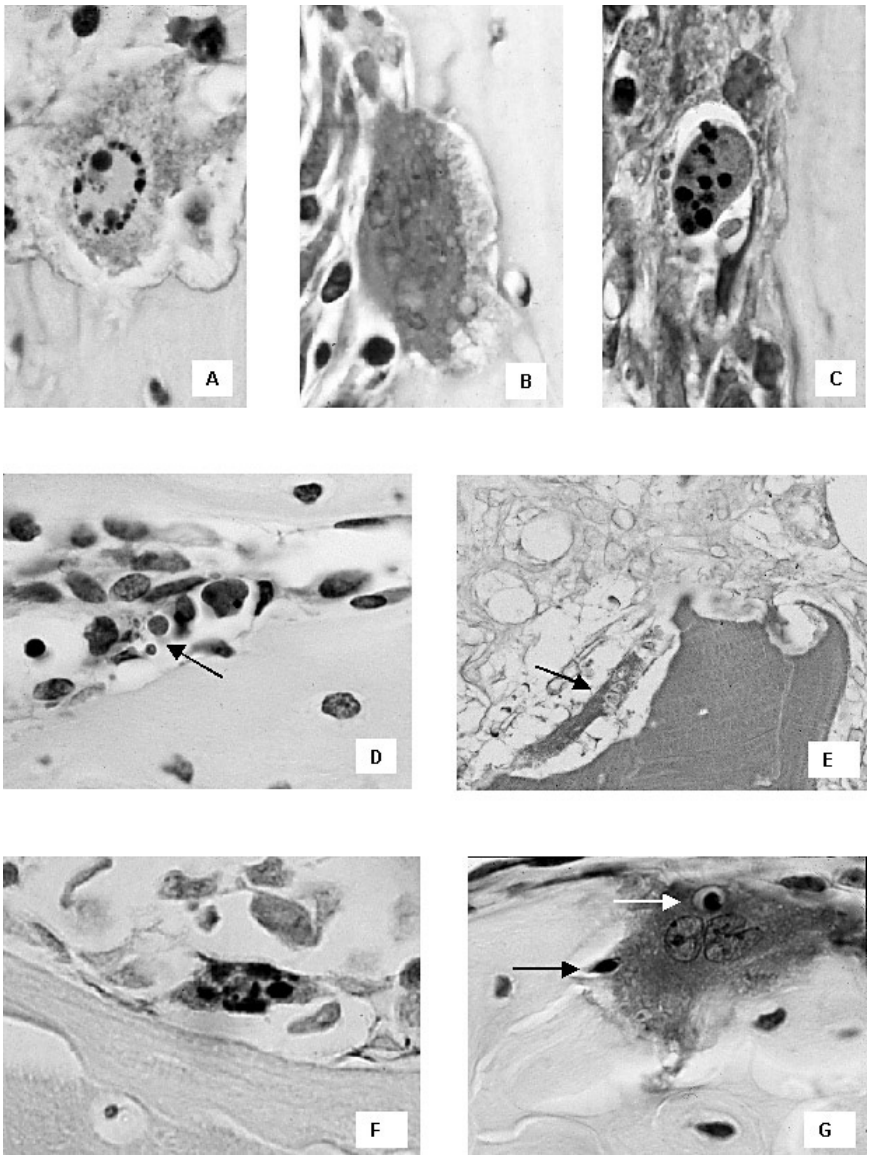

Figure 1 Apoptosis of osteoclasts. (A) Peripheral clumping of chromatin around the nuclear membrane of an osteoclast from a TRAP SV40 Tag transgenic mouse (Boyce *et al.,* 1995). H&E, orange G and phloxine. (B) Actively resorbing osteoclast with normal nuclear and cytoplasmic morphology and ruffled border. TRAP staining, normal mouse following treatment with IL-1. (C) Osteoclast showing classical nuclear and cytoplasmic morphologic features of apoptosis. Note that the cell has withdrawn from the bone surface, contracted, has more intense TRAP staining than the osteoclast in B, and that all of its nuclei have condensed and fragmented simultaneously. TRAP staining. Normal mouse following treatment with IL-1. (D) TRAP-positive apoptotic bodies adjacent to the bone surface (arrow). Note that some do not have fragments of nuclei in them and thus would not be recognized as parts of an osteoclast in an H&E-stained section. TRAP staining, ovariectomized mouse following treatment with estrogen. (E) Necrotic osteoclast in a resorption lacuna (arrow). Note that the nuclei and cytoplasm have not contracted. H&E, orange G and phloxine. Human bone, ischemic necrosis. (F) TUNEL staining of an apoptotic osteoclast. Note the strong positive dark brown signal in all of the contracted nuclei of the cell and no signal in adjacent viable cells. Methyl green counterstain. TRAP SV40 Tag transgenic mouse (Boyce *et al.,* 1995). (G) Osteoclast containing the nucleus of an engulfed apoptotic osteocyte (top arrow). Note the condensed nuclear chromatin of this cell and of the osteocyte about to be engulfed (lower arrow) in comparison with the normal evenly dispersed nuclear chromatin of the viable osteocytes below and to the right of the osteoclast. TRAP staining. Ovariectomized mouse. (See also color plate.)

also color plate). These nuclear changes are accompanied by cell shrinkage due to fluid movement out of the cell and loss of contact with neighboring cells or matrix (Fig. 1C)—a feature that has been used to collect apoptotic cells for analysis in *in vitro* assays (Wyllie *et al.,* 1980; Arends *et al.,* 1990; Hughes *et al.,* 1995b; Hughes *et al.,* 1996; Jilka *et al.,* 1998). As apoptosis progresses, numerous cell surface convolutions form and the cell disintegrates into multiple membrane-bound, condensed apoptotic bodies (Fig. 1D, see also color plate) that typically are phagocytosed rapidly by neighboring cells. The whole process can take a few minutes in some cells (e.g., cytotoxic T-cell-induced apoptosis) to several hours; but in others, DNA fragmentation can begin 2 days prior to cellular disintegration (Pompeiano *et al.,* 1998). Apoptosis differs from ischemic necrosis in that it typically affects single cells rather than groups of cells and, unlike in necrosis (Fig. 1E, see also color plate), apoptotic cells and their nuclei do not swell nor does their destruction attract inflammatory cells.

Caspase-activated DNases (CAD) (Nagata, 2000) are activated early in the apoptosis process and they split genomic DNA at nucleosomes into fragments of varying sizes, giving rise to characteristic "ladders" that are seen on gel electrophoresis (Wyllie *et al.,* 1980; Arends *et al.,* 1990; Kaufmann *et al.,* 2000). The subsequent nuclear fragmentation and condensation can be visualized using acridine orange, Höescht dyes, and propidium iodide by their bright fluorescence upon binding to DNA (Fig. 2A, see also color plate) (Arndt-Jovin and Jovin, 1977; Arends *et al.,* 1990) and in cells transfected with green fluorescent protein containing a nuclear localization sequence (Fig. 2B, see also color plate)—a useful tool for studying apoptosis in cells cotransfected with genes of interest (Bellido *et al.,* 2000; Kousteni *et al.,* 2001).

Degraded DNA can also be detected enzymatically and quantified (Stadelmann and Lassmann, 2000) using TUNEL (TdT-mediated dUTP-biotin nick end labeling) (Gavrieli *et al.,* 1992), ISNT (*in situ* nick translation) (Gold *et al.,* 1993) and ISEL (*in situ* nick end labeling) (Wijsman *et al.,* 1993; Ansari *et al.,* 1993) (Fig. 1F, Fig. 2C-H, see also color plate). The latter is 10-fold more sensitive than TUNEL and can even detect cells undergoing DNA repair; thus it can less specific (Gold *et al.,* 1994). These DNA labeling methods can also identify cells dying by necrosis (Grasl-Kraupp *et al.,* 1995), but unlike apoptosis, necrosis is rarely focal.

Regulation of Apoptosis

Two main pathways appear to initiate apoptosis. One signals cells to die as a consequence of ligand interaction with so-called death receptors on the cell surface, many of which are members of the tumor necrosis factor (TNF) receptor superfamily. The second is activated by a set of molecules from the mitochondria following a variety of stimuli, including oxidative stress and loss of survival signals generated by growth factors and cytokines, as well as loss of attachment to the extracellular matrix—a process called anoikis (Frisch and Ruoslahti, 1997). Both pathways activate a family of proteolytic enzymes called caspases that, by cleaving specific substrates, cause the morphological changes described earlier. The events underlying the regulation of caspase activation are depicted in Fig. 3 (see also color plate).

Death Receptors (DR)

DR have been studied most thoroughly in cells of the immune system and include CD95 (Fas/APO-1), and the TNF receptors (Krammer, 2000). The cytoplasmic tail of CD95 contains a death domain that binds adapter proteins, such as FADD (Fas-associated death domain protein) following receptor activation. FADD has a death effector domain (DED) that recruits DED-containing proteins, such as procaspase-8. TNF and TRAIL (TNF-related apoptosis inducing ligand), which binds to DR5, induce a similar reaction following binding to their receptor in susceptible cells, except that an additional adaptor, TRADD, links the tail of the receptor with FADD. Although the predominant effect of Fas ligand/CD95 and TRAIL/DR5 binding is to trigger cell death, binding of TNF to its receptors can result in additional diverse effects, including NF-κB activation, which can inhibit, rather than stimulate apoptosis (Van Antwerp *et al.,* 1996) in some cell types, including osteoclasts.

Caspases

These are highly conserved cysteine proteases that cleave substrates at aspartate residues (Earnshaw *et al.,* 1999). The focal point of apoptosis control is the proteolytic conversion of inactive procaspases, primarily procaspase-8 and -9 (Hengartner, 2000), to the proteolytically active form. This conversion may be a direct result of death receptor activation or the release of caspase-activating factors such as cytochrome c from mitochondria. Cytochrome c binds to Apaf-1 complexed to procaspase-9, resulting in its activation. Caspases-8 and -9 cleave and activate the effector caspases-3, -6, and-7, which cleave substrates in the nucleus and cytoplasm. For example, effector caspases activate CAD to initiate DNA fragmentation; they also cleave cytoskeletal proteins, such as fodrin and gelsolin (Kothakota *et al.,* 1997; Janicke *et al.,* 1998), to change cell shape.

Regulation of Caspase Activity

Members of the Bcl-2 family of proteins control the release of caspase-activating proteins from the mitochondria. Proapoptotic members of the family include Bad, Bax, and Bid; antiapoptotic members include Bcl-2 and Bcl-x_L (Chao and Korsmeyer, 1998; Kelekar and Thompson, 1998). Because members of the Bcl-2 family can form either homodimers or heterodimers, changes in their biosynthesis and/or activity can shift the balance of the cell between an anti- and a proapoptotic state. Thus, dimers of antiapoptotic members, e.g., Bcl-2, bind to the outer membrane of the

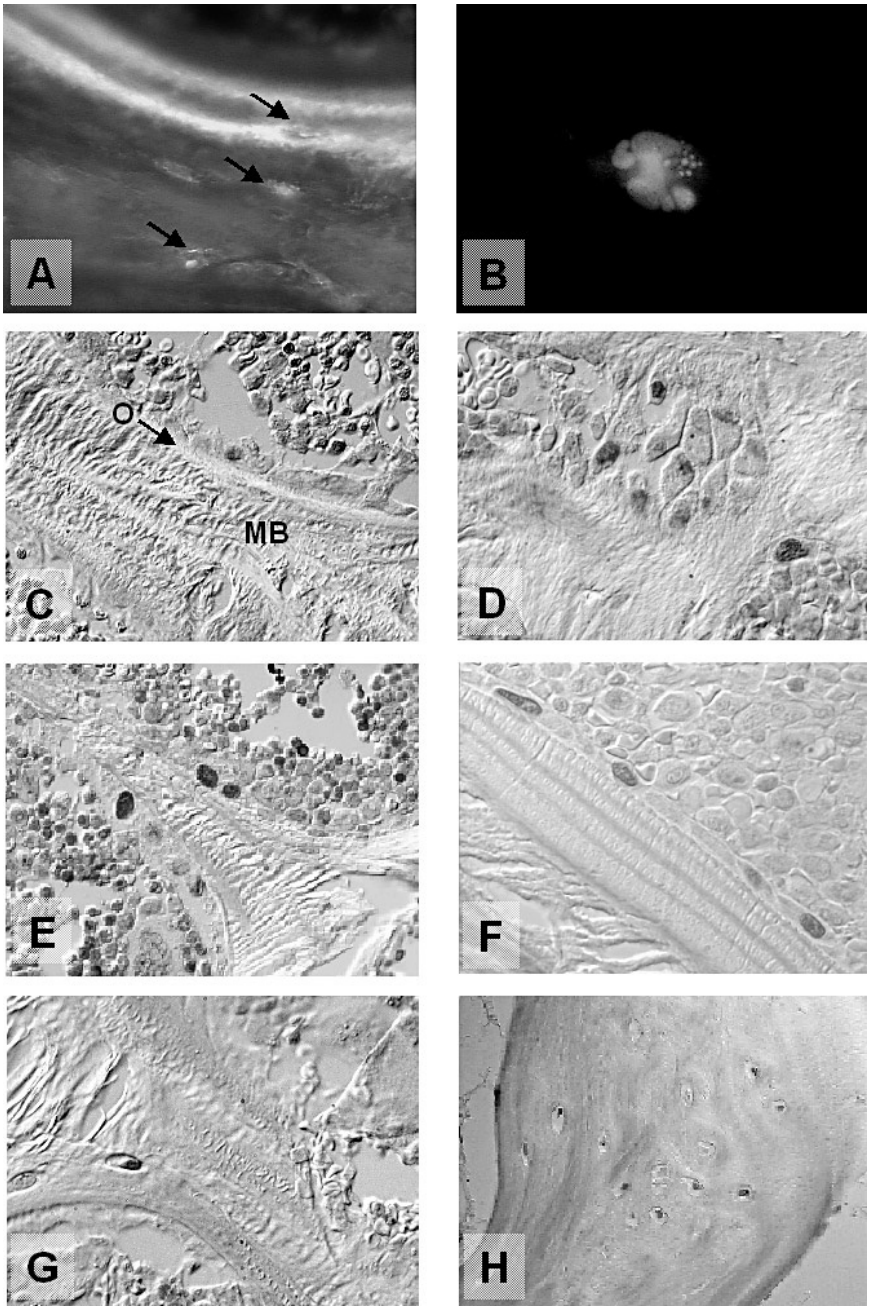

Figure 2 Apoptosis osteoblasts and osteocytes. (A) Transiliac biopsy from a patient with glucocorticoid-induced osteoporosis stained with Höescht dye. Note the apoptotic osteocytes (arrows) recently buried in a new packet of bone outlined by yellow tetracycline labeling. (B) Nuclear fragmentation in osteoblastic OB-6 cells transfected with green fluorescent protein containing a nuclear localization sequence, treated with etoposide for 6 hr, and observed under epifluorescence illumination. (C–H) Apoptotic osteoblasts and osteocytes detected by ISEL staining of nondecalcified sections of vertebral bone of a normal 4-month-old mouse (C) an ovariectomized mouse (D) a prednisolone-treated mouse (E and G) a transiliac bone biopsy from a patient with glucocorticoid-induced osteoporosis (F) and a femoral head obtained during total hip replacement because of glucocorticoid-induced osteonecrosis (H) (C) Note the juxtaposition of labeled osteoblasts (brown) to osteoid ("O") interspersed with unaffected viable (blue) members of the osteoblast team. Mineralized bone is indicated by "MB." (See also color plate.)

mitochondria and prevent the release of caspase activators, whereas dimers of proapoptotic members (e.g., Bax) or, in some cases, heterodimers (e.g., Bad • Bcl-2) promote an increase in membrane permeability. Interaction of Bad with 14–3–3 protein, in cooperation with the phosphorylation of Bad, inactivates the proapoptotic function of Bad by causing its release from Bcl-2 and preventing its interaction with the mitochondrial membrane (Datta *et al.,* 2000). Apoptosis

SR, steroid hormone receptors; P'ase, protein phosphatase; ERK, extracellular signal-regulated kinases; Rsks, MAPK-activated ribosomal S6 kinases; PI3K, phosphatidyl inositol-3-kinase; PKA, protein kinase A; SpK, sphingosine kinase; Stats, signal transducers and activators of transcription. (See also color plate.)

stimulation, however, can be mediated by the dephosphorylation of phospho-Bad via the activation of specific phosphatases (Desagher and Martinou, 2000).

Inhibitors of apoptosis proteins (IAPs), including XIAP, c-IAP1, c-IAP2, and survivin, specifically bind to and inhibit caspases (Roy *et al.,* 1997; Deveraux *et al.,* 1998), thus providing a second mechanism of negative control of apoptosis. They also function as ligases to ubiquinate interacting proteins, thereby facilitating their degradation by proteosomes (Yang *et al.,* 2000), and their action is overcome during apoptosis via the release of Smac/DIABLO from mitochondria, which binds to and inactivates IAPs (Green, 2000).

Survival Signaling via Integrins and Growth Factor Receptors

Binding of integrins with extracellular matrix proteins fosters the assembly of the focal adhesion complex comprising cytoskeletal and catalytic proteins (Giancotti and Ruoslahti, 1999). The most important of the latter are focal adhesion kinase (FAK) and Src-family kinases. Assembly of focal adhesion complexes results in the autophosphorylation of FAK, which in turn activates phosphatidyl inositol-3-kinase (PI3-kinase) and/or the MAP kinase cascade to provide a constant inhibitory brake on the execution of apoptosis (Ilic *et al.,* 1998), perhaps via Bad phosphorylation. FAK signaling may also inhibit apoptosis by the induction of IAP synthesis (Sonoda *et al.,* 2000). Growth factor/cytokine receptor activation also generates survival signals via the activation of intracellular kinase cascades, including Stats, ERK, Akt, and PI3-kinase, as illustrated in Fig. 3.

Chondrocyte Apoptosis

Apoptosis has a major role in three areas of chondrocyte biology: the shaping of long bones during development, endochondral ossification, and the loss of articular cartilage in degenerative and inflammatory bone diseases.

Limb Development

Long bones form from limb buds under the control of genes expressed by primitive mesenchymal cells that interact with overlying ectodermal cells (Rowe and Fallon, 1982; Shubin *et al.,* 1997; Panganiban *et al.,* 1997). They are first formed of a cartilage analag, which is sculpted to determine the shape and length of developing limb elements relative to one another. This sculpting involves both proliferation and apoptosis of chondrocytes in a tightly regulated process in which FGFs, BMPs, sonic hedgehog, and *Hox* genes play major regulatory roles (Macias *et al.,* 1997; Chen and Zhao, 1998; Buckland *et al.,* 1998). The list of genes involved in the regulation of limb development is growing rapidly and consequently the genetic basis of many human skeletal anomalies is being revealed (Mundlos

and Olsen, 1997a; Innis and Mortlock, 1998). These are described in detail in Chapter 3.

Endothelial cells invade the perichondrium near the middle of these elementary bone structures, inducing apoptosis of chondrocytes adjacent to them in the perichondrium. Osteoblasts form from mesenchymal cells behind the advancing endothelial cells laying down bone matrix and forming a primary center of ossification in the central parts of limbs into which circulating hematopoietic precursors cells migrate and form the bone marrow of the medullary cavity. Osteoclasts are not required for this process because it occurs in their absence in RANKL and RANK knockout mice (Hofbauer *et al.,* 2000), but the signaling molecules released by endothelial and other mesenchymal cells that mediate the massive chondrocyte apoptosis that takes place have yet to be determined.

Endochondral Ossification

An epiphyseal growth plate forms from the physis near the ends of long bones and maintains endochondral bone formation until epiphyses close at varying times after puberty in humans. A secondary center of ossification forms in the physis adjacent to the growth plate following massive chondrocyte apoptosis, leaving a rim of articular cartilage at the end of the bone. Proliferating chondroblasts in growth plates give rise to the hypertrophic chondrocytes around which the cartilage calcifies. Some of these hypertrophic chondrocytes undergo apoptosis before they removed by chondroclasts (Lewinson and Silbermann, 1992) and some survive to be covered by new bone laid down by osteoblasts at the primary spongiosa.

Parathyroid hormone related peptide (PTHrP) and Indian hedgehog (Ihh) play central roles in the regulation of endochondral ossification (Vortkamp *et al.,* 1996; Lanske *et al.,* 1996). PTHrP appears to control the life span of hypertrophic chondrocytes, at least during the early stages of endochondral ossification before the formation of the secondary ossification center when it is involved in direct signaling between perichondrial cells at the ends of long bones and underlying proliferating chondroblasts and prehypertrophic and hypertrophic chondrocytes. It prevents premature apoptosis of hypertrophic chondrocytes in a complex autocrine and paracrine signaling mechanism involving Ihh upstream and Bcl-2 downstream (Weir *et al.,* 1996; Zerega *et al.,* 1999). This action of PTHrP was discovered following the analysis of bones from mice with loss or gain of function. PTHrP knockout mice have thinner than normal growth plates with reduced numbers of hypertrophic chondrocytes and growth retardation (Karaplis *et al.,* 1994; Lee *et al.,* 1996), whereas transgenic mice overexpressing PTHrP have thick growth plates and increased numbers of hypertrophic chondrocytes (Weir *et al.,* 1996). Thickened growth plates and delayed apoptosis of hypertrophic chondrocytes were also observed in mice lacking matrix metalloproteinase-9 (MMP-9)/gelatinase B, a defect that was rescued by the transplantation of chondroclast precursors and which also healed spontaneously beginning 3 weeks after birth (Vu *et al.,* 1998).

Degenerative and Inflammatory Joint Disease

Chondrocyte viability is sustained in healthy cartilage through integrin-mediated survival signaling. *In vitro* studies indicate that chondrocytes require continuous contact with one another for their survival (Ishizaki *et al.,* 1994), which can be maintained by cytokines, such as IL-1, TNF and interferon-γ (Blanco *et al.,* 1995; Kuhn *et al.,* 2000). However, in other *in vitro* studies, IL-1 and TNF, induced apoptosis of chondrocytes (Nuttall *et al.,* 2000; Fischer *et al.,* 2000), an effect also seen with nitric oxide (Blanco *et al.,* 1995; Amin and Abramson, 1998) and prostaglandin E_2 (PGE_2) (Miwa *et al.,* 2000). All of these agents are released by activated immune cells and synoviocytes in joints of patients with a variety of inflammatory joint diseases. Finally, IL-1 promotes the release of matrix-degrading enzymes, such as hexosaminidase, by chondrocytes, which could promote their apoptosis (Shikhman *et al.,* 2000).

In rheumatoid arthritis, activated synoviocytes produce degradative enzymes, as well as inflammatory cytokines. Destruction of the cartilage matrix results in anoikis (Nuttall *et al.,* 2000). Specific inhibitors of caspase-3 and-7, but not caspase-1 (Lee *et al.,* 2000), prevent apoptosis of chondrocytes *in vitro,* raising the possibility that such inhibitors might be efficacious in the prevention of degenerative or inflammatory joint diseases. Activated synoviocytes also have a greatly increased expression of the death factor, Fas/Apo-1, but unlike many other cell types, these hyperplastic cells do not die, presumably because the levels of Fas ligand in synovial fluid are extremely low. Delivery of Fas ligand (Yao *et al.,* 2000) or Fas-associated death domain (FADD) protein (Kobayashi *et al.,* 2000) to inflamed joints of arthritic animals induced synoviocyte apoptosis and amelioration of the arthritis. Chondrocyte apoptosis was unaffected, suggesting a new approach to treatment of this disease.

Several studies have documented increased chondrocyte apoptosis in the articular cartilage of osteoarthritic patients compared to normal subjects (Hashimoto *et al.,* 1998; Kirsch *et al.,* 2000; Kobayashi *et al.,* 2000; Kim *et al.,* 2000), a change that is associated with the expression of annexin V (Kirsch *et al.,* 2000) and Fas (Kim *et al.,* 2000). However, further studies are required to determine if chondrocyte apoptosis is the cause of cartilage erosion or a consequence of the matrix degeneration that characterizes osteoarthritis.

Apoptosis of Osteoclasts

Apoptosis of osteoclasts was first recognized following targeting of the simian virus 40 large T antigen to the osteoclast in transgenic mice using the TRAP promoter, and following withdrawal of M-CSF from osteoclasts in culture (Boyce *et al.,* 1995; Fuller *et al.,* 1993). Morphologic

changes consistent with osteoclast apoptosis had been described previously in several publications on the effects of bisphosphonates and estrogen on osteoclasts, but the cellular changes were not recognized as apoptosis at the time (Rowe and Hausmann, 1976; Liu *et al.,* 1982; Flanagan and Chambers, 1989; Sato and Grasser, 1990; Liu and Howard, 1991).

Morphology of Apoptotic Osteoclasts

Osteoclasts undergoing apoptosis have two striking features: stronger cytoplasmic TRAP staining than viable osteoclasts (Figs. 1B and 1C) and simultaneous apoptosis of all their nuclei (Fig. 1C) (Boyce *et al.,* 1995; Hughes *et al.,* 1995b). Retention of cytoplasmic organelle function and enzyme activity is typical of cells undergoing apoptosis. The intense TRAP staining may reflect cytoplasmic contraction and concentration of TRAP within the cells or decreased secretion of TRAP or a combination of both. It facilitates recognition not only of intact apoptotic osteoclasts in tissue sections, but also of fragments of osteoclasts following disintegration of the dead cells (Fig. 1D). It may account for the relatively high percentage (0.3%) of osteoclasts with classic morphologic features of apoptotic cells seen in sections of normal mouse bone (Hughes *et al.,* 1995b) compared with the low percentage of cells with such morphologic features in regenerating tissues, such as large intestine [0.05% in enterocytes (Lee and Bernstein, 1993)] and liver [0.01% in hepatocytes (Bursch *et al.,* 1990)].

Simultaneous death of nuclei contrasts with their progressive accumulation in osteoclasts as mononuclear cells are incorporated into formed osteoclasts by cytoplasmic fusion. It suggests that the theoretical survival of osteoclasts for very long periods through continuous recruitment of new nuclei and shedding of older nuclei is unlikely and that the intracellular signaling controlling osteoclast apoptosis is a highly coordinated process that leads to the demise of the whole cell. Individual nuclei of phagocytosed apoptotic osteocytes are observed frequently in actively resorbing osteoclasts (Fig. 1G, see also color plate).

Osteoclast Apoptosis in Bone-Remodeling Units

The osteoclast number increases dramatically following daily injections of high doses of IL-1 over the calvarial bones of 2- to 3-week-old mice (Boyce *et al.,* 1989), and resorption is followed by the deposition of abundant new bone matrix in a sequence similar to that seen in normal bone remodeling. Thirteen percent of the osteoclasts are apoptotic (Wright *et al.,* 1994), with most of them being at the reversal site between the advancing resorption front (where apoptotic osteoclasts were not seen) and the ensuing new bone formation. Osteoclast apoptosis has been confirmed at the reversal site in bone remodeling units in other animal models and in patients with increased bone turnover (Wright *et al.,* 1994), with the number being close to that seen in long bones of normal mice (0.3%) (Hughes *et al.,* 1995b).

The high percentage of apoptotic osteoclasts observed in mouse calvariae 4–6 days after cessation of IL-1 injections may be due to abrupt reduction in the local concentration of prostaglandins or other antiapoptotic factors. This mechanism might be similar to that seen following the reintroduction of calcium to the diet of calcium-deficient rats (Liu *et al.,* 1982; Wright *et al.,* 1995) and mice when there is a sharp fall in the blood concentrations of 1,25(OH)2 vitamin D3 and parathyroid hormone (PTH) (Liu *et al.,* 1982), both of which prevent osteoclast apoptosis. On the basis of these findings, Parfitt *et al.* (1996) proposed that osteoclast precursors are recruited to the advancing resorption front to maintain the youngest and presumably most active osteoclasts for forward progression of the basic multicellular unit (BMU) of bone remodeling. Older osteoclasts are left behind to complete lateral and downward progression, and these ultimately undergo apoptosis. The depth to which they resorb, and thus the removal or survival of trabeculae, is dependent on the timing of their apoptosis, which can be hastened pharmacologically (e.g., by bisphosphonates or estrogen) or delayed by sex steroid deficiency. Delayed apoptosis could also explain not only the deep resorption lacunae seen typically in Paget's disease, but also the large number of osteoclast nuclei, which might be related to increased Bcl-2 expression (Mee, 1999).

The regulation of osteoclast viability in remodeling units remains poorly understood, but it is possible that the resorptive process itself activates proapoptotic pathways. For example, exposure to the millimolar calcium ion concentrations found in resorption lacunae could induce osteoclast apoptosis (Lorget *et al.,* 2000), an effect that may be attenuated by IL-6 (Adebanjo *et al.,* 1998). Release of chloride and hydrogen ions, the latter through a proton pump on the ruffled border membrane, is required for this release of calcium, and although failure of ruffled border formation is not associated with increased osteoclast apoptosis, specific inhibition of the vacuolar H(+)-ATPase involved in proton release is (Okahashi *et al.,* 1997).

Regulation of Osteoclast Apoptosis.

Like many other factors that stimulate bone resorption, PTH and $1,25(OH)_2$ vitamin D3, prevent osteoclast apoptosis most likely by stimulating expression of RANKL and decreasing expression of osteoprotegerin (OPG) by stromal cells, and the relative local concentrations of these two recently described regulators of most aspects of osteoclast function are likely to be important determinants of osteoclast survival.

RANKL AND M-CSF

Since the initial observations of osteoclast apoptosis, several positive and negative regulators of osteoclast life span have been identified. These include factors such as

M-CSF (Fuller *et al.,* 1993) and RANKL (Lacey *et al.,* 2000), which are also required for osteoclast formation, and OPG, the most potent negative regulator of osteoclasts identified to date. The precise mechanisms whereby M-CSF and RANKL mediate osteoclast survival remain unclear, but studies suggest that the PI3-kinase/Akt signaling pathway may be involved (Wong *et al.,* 1999), and results in increased expression of the antiapoptotic genes, Bcl-2, Bcl-xL (Lacey *et al.,* 2000), and XIAP (Kanaoka *et al.,* 2000).

Following binding of RANKL to RANK on the surface of osteoclasts, TRAF 6, a member of the TNF receptor activator family, binds to the cytoplasmic domain of RANK; *c-src* expression is increased and Src binds to TRAF 6 (Lacey *et al.,* 2000). PI3-kinase binds to Src and Akt binds to PI3-kinase. Akt subsequently phosphorylates Bad and caspase-9 (Wong *et al.,* 1999), thus preventing activation of the apoptosis cascade. A similar signaling cascade is activated when IL-1 binds to its receptor on osteoclasts (Wong *et al.,* 1999). In contrast to M-CSF, RANKL does not appear to induce expression of XIAP (Kanaoka *et al.,* 2000) or Bcl-x_L (Jimi *et al.,* 1999). In addition to activating the PI-3- kinase pathway, RANKL also activates NF-κB (Jimi *et al.,* 1998) to promote osteoclast survival, consistent with findings that inhibitors of NF-κB induce osteoclast apoptosis (Ozaki *et al.,* 1997). This signaling pathway is essential for RANKL-mediated osteoclast formation (Xing *et al.,* 1998) and requires expression of the p50 and p52 subunits of NF-κB (Iotsova *et al.,* 1997; Franzoso *et al.,* 1997).

Src plays an important role in the antiapoptotic action of RANKL because withdrawal of RANKL causes significantly more apoptosis of osteoclasts generated from *src* knockout mice than those from wild-type mice (Wong *et al.,* 1999). The role of Src in RANKL-mediated osteoclast survival, however, is not essential because *src* mutant mice have no increase in osteoclast apoptosis *in vivo* (Xing *et al.,* 2001) and their osteoclast numbers are actually increased (Boyce *et al.,* 1992). However, overexpression of a truncated *src* transgene lacking the kinase domain in *src* knockout mice caused a marked increase in osteoclast apoptosis and more severe osteopetrosis (Xing *et al.,* 2001). This increased osteoclast apoptosis may be due to a dominant-negative action of the truncated protein via interference with survival-related functions of other Src family members that likely substitute for Src in this role in *src* mutant mice. M-CSF-mediated osteoclast survival, however, involves C-jun/AP-1 signaling rather than Src (Wong *et al.,* 1999).

The antiapoptotic effects of RANKL are opposed by OPG (Lacey *et al.,* 2000), a product of stromal/osteoblastic cells that prevents RANKL–RANK interaction. Thus, when OPG is in excess, osteoclasts will die due to loss of antiapoptotic RANKL signaling. Studies suggest that as stromal/osteoblastic cells differentiate into osteoblasts, the OPG/RANKL ratio increases, suggesting that mature osteoblasts might have a negative regulatory role in the survival of osteoclasts (Gori *et al.,* 2000).

Integrin Binding

The PI3-kinase antiapoptotic pathway is also activated as a consequence of integrin-mediated signaling when osteoclasts bind to bone matrix (Rani *et al.,* 1997). This pathway also initiates and maintains signals that reorganize the osteoclast cytoskeleton for ruffled border formation, for which Src is essential (Boyce *et al.,* 1992). However, it is not known if Src, which is also activated after integrin binding, is involved in this antiapoptotic mechanism, but it is worth noting that reorganization of the cytoskeleton and contraction of cells without leakage of their contents are major features of apoptosis that prevent the initiation of an acute inflammatory reaction.

The vitronectin receptor, integrin $\alpha_v\beta3$, mediates osteoclast adhesion to bone matrix (Horton, 1997). Because osteoclasts require tight adhesion to bone matrix to resorb effectively, interruption of adhesion could lead to initiation of the death pathway in a manner similar to that reported in other cell types (Frisch and Ruoslahti, 1997). Treatment with antisense oligonucleotides to the α_v gene not only inhibits osteoclast adhesion and bone resorption, it also promotes osteoclast apoptosis that is associated with reduced expression of Bcl-2 (Villanova *et al.,* 1999). Loss of adhesion, inhibition of resorption, and induction of osteoclast apoptosis have also been reported with nonspecific matrix receptor-inhibiting proteins containing RGD sequences (Rani *et al.,* 1997; Rodan and Rodan, 1997). Although the suspension of osteoclasts in culture medium is associated with a twofold increase in their apoptosis (Sakai *et al.,* 2000), loss of adhesion does not inevitably trigger an apoptosis signal. For example, the antivitronectin receptor agents echistatin and $\alpha_v\beta3$ monoclonal antibody do not induce osteoclast apoptosis (Wesolowski *et al.,* 1995; Villanova *et al.,* 1999).

Cytokines and Other Proinflammatory Agents

The production of cytokines and other proinflammatory agents, such as prostaglandins and nitric oxide, is increased in a variety of conditions associated with increased bone resorption, including estrogen deficiency and chronic inflammatory bone diseases. Most of these agents stimulate stromal cell RANKL expression and promote bone resorption indirectly by multiple mechanisms, including prevention of osteoclast apoptosis. IL-1 also appears to have direct effects on osteoclasts to prevent their apoptosis, although it is not clear whether this is mediated by NF-κB (Jimi *et al.,* 1998) or ERK (Miyazaki *et al.,* 2000) activation. Intracellular domains of the receptors for IL-1 and TNF on osteoclasts (similar to RANKL), bind TRAF 6, which leads to activation of NF-κB and prevention of osteoclast apoptosis (Jimi *et al.,* 1998). The Src/PI3-kinase/AKT pathway is activated in osteoclasts in response to IL-1 (Wong *et al.,* 1999), but it has not been determined if it is also involved in TNF prevention of apoptosis. IL-6 mediates its antiapoptotic signaling through gp130, but the mechanism of this effect in osteoclasts remains unknown. The effects of nitric oxide on osteoclasts are controversial and are discussed in Chapter 55.

Even though it can stimulate bone resorption, nitric oxide appears to promote apoptosis of osteoclasts (Kanaoka *et al.,* 2000) and their precursors (van't Hof and Ralston, 1997).

Calcitonin causes osteoclasts to lose attachment to substrates (Kallio *et al.,* 1972) and inhibit their resorptive activity, which can be resumed upon withdrawal of the hormone (Chambers and Moore, 1983). However, it does not induce osteoclasts to die (Selander *et al.,* 1996; Kanaoka *et al.,* 2000). Indeed, calcitonin protects them from nitric oxide-induced apoptosis, an effect that involves protein kinase A and is associated with the inhibition of caspase-3-like protease activity (Kanaoka *et al.,* 2000). Thus, apoptosis is not an obligatory sequel of inhibition of osteoclastic resorption.

Vitamin K_2, but not vitamin K_1 (Kameda *et al.,* 1996), induces osteoclast apoptosis. Vitamin K_2 has a geranylgeranyl side chain and its effect is associated with increased superoxide and peroxide free radical production (Sakagami *et al.,* 2000), but given that osteoclasts produce and respond positively to free radicals (Garrett *et al.,* 1990), the mechanism of action of vitamin K_2 will require further study.

Apoptosis of Osteoblasts and Osteocytes

Osteoblasts with the condensed chromatin and/or nuclear fragmentation that characterizes the late stages of apoptosis have been reported in murine calvariae and rat fracture callus, but such cells are rare (Furtwangler *et al.,* 1985; Landry *et al.,* 1997). Using TUNEL, however, apoptotic osteoblasts were demonstrated in fracture callus (Landry *et al.,* 1997; Olmedo *et al.,* 1999; Olmedo *et al.,* 2000) and in the osteogenic front of developing sutures in murine calvaria (Rice *et al.,* 1999; Opperman *et al.,* 2000).

Unambiguous identification of apoptotic osteoblasts in remodeling cancellous bone is more difficult because of the proximity of the bone surface to the complex cellular architecture of the marrow. Therefore, specific criteria must be used when enumerating apoptotic osteoblasts in cancellous bone. They must be juxtaposed to osteoid and to other osteoblasts because bone formation is carried out by teams of osteoblasts and they should have a cuboidal morphology to distinguish them from nearby marrow cells and lining cells (Figs. 2C–2F). When analyzed with the TUNEL method, 0.5 to 1.0% of osteoblasts in vertebral cancellous bone of adult mice exhibit DNA strand breaks (Weinstein *et al.,* 1998; Jilka *et al.,* 1998; Silvestrini *et al.,* 1998) and 2–10% are labeled using the highly sensitive ISEL procedure (Plotkin *et al.,* 1999; Jilka *et al.,* 1999b). DNA labeling is highly specific, as evidenced by the lack of any staining in the nuclei of nearby osteoblasts. Most of the labeled osteoblast nuclei are round and only a few have evidence of chromatin condensation (Figs. 2C–2F). Thus, they likely represent cells in the early stage of apoptosis. The demonstration of apoptotic osteoblasts supports Parfitt's earlier contention that the majority of these cells die during bone remodeling, with less than 50% of the originally recruited team of osteoblasts surviving as lining cells or osteocytes

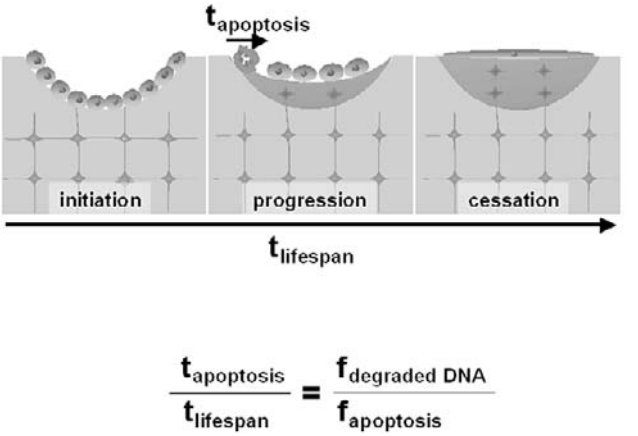

Figure 4 Osteoblast fate and apoptosis. A team of osteoblasts assembles at the floor of the resorption cavity at the beginning of the process ("initiation"). During matrix synthesis ("progression"), some osteoblasts become entombed as osteocytes and some die by apoptosis. When matrix synthesis ceases ("cessation"), all that remain of the original team of osteoblasts are osteocytes and lining cells. The equation shown can be used to calculate the fraction of osteoblasts that die by apoptosis ($f_{apoptosis}$) based on the observed prevalence of osteoblasts exhibiting ISEL labeling ($f_{degraded\ DNA} \sim 0.05$), osteoblast life span [$t_{life\ span}$ = wall width divided by mineral appositional rate = 200–400 hr in vertebral bone of adult mice (Jilka *et al.,* 1999b)], and the number of hours that apoptotic osteoblasts exhibit ISEL labeling, $t_{apoptosis}$. In other cells the latter can be as high as 40–50 hr (Pompeiano *et al.,* 1998), but is likely to be significantly less for osteoblasts because they cannot be recognized after they detach from the extracellular matrix. (See also color plate.)

(Parfitt, 1990) (Fig. 4, see also color plate). Thus, unlike osteoclasts, osteoblasts have three possible fates. Only a small number of osteoblasts exhibit signs of apoptosis because the process is fleeting. Using the equation shown in Fig. 4 (Jilka *et al.,* 1998), it can be shown that the observed prevalence of apoptotic osteoblasts (2–10%) means that 50–80% of them die between the initiation and the completion of bone formation, consistent with Parfitt's estimate (Parfitt, 1990).

Condensed chromatin and degraded DNA (Figs. 2A, 2G, and 2H) have been demonstrated in osteocytes (Noble *et al.,* 1997; Rice *et al.,* 1999; Shibahara *et al.,* 2000; Stevens *et al.,* 2000; Verborgt *et al.,* 2000; Silvestrini *et al.,* 2000). Like osteoblasts, the number of osteocytes undergoing apoptosis is increased by the loss of sex steroids (Tomkinson *et al.,* 1997, 1998; Kousteni *et al.,* 2001), as well as glucocorticoid excess (Weinstein *et al.,* 1998, 2000b) (Figs. 2G and 2H). In distinction to osteoblasts, osteocyte apoptosis represents cumulative death because the cellular debris is not accessible to phagocytic scavenger cells. Indeed, degraded DNA can be detected in osteocyte lacunae of necrotic human bone long after the initial insult of glucocorticoid excess (Weinstein *et al.,* 2000b). The existence of empty osteocyte lacunae has been taken previously as evidence of osteocyte death (Frost, 1960), but in some circumstances this may be an artifact due to loss of the loosely adherent pyknotic cells and cellular debris during processing for histological examination (Wong *et al.,* 1987).

Regulation of Osteoblast and Osteocyte Apoptosis

Activation of death receptors with TNF or CD95 ligand stimulates osteoblast apoptosis *in vitro* (Kitajima *et al.,* 1996; Jilka *et al.,* 1998; Tsuboi *et al.,* 1999; Urayama *et al.,* 2000). Although CD95 and its ligand are expressed by osteoblasts and osteocytes *in vivo* (Hatakeyama *et al.,* 2000), their role in physiologic apoptosis of these cells is unknown.

INTEGRINS

Intracellular antiapoptosis signals are generated in osteoblasts upon integrin binding to extracellular matrix, as evidenced by the induction of apoptosis when binding to fibronectin or collagen is prevented *in vitro* (Globus *et al.,* 1998; Jilka *et al.,* 1999a). A periodic loss of integrin signaling may occur *in vivo* due to dynamic alterations in integrin adhesion migration and matrix assembly as osteoblasts rise above the cement line, as during bone formation (Fig. 4). Thus, it is tempting to suggest that the very process of bone formation is responsible for the induction of apoptosis (Jilka *et al.,* 1999a).

GROWTH FACTORS AND CYTOKINES

Most growth factors and cytokines produced in the bone microenvironment inhibit osteoblast apoptosis, including IGFs (Hill *et al.,* 1997), TGFβ, and IL-6- type cytokines (Jilka *et al.,* 1998). Interestingly, FGF inhibits apoptosis in primary cultures of dividing preosteoblastic cells (Hill *et al.,* 1997), but stimulates the apoptosis of mature osteoblasts (Mansukhani *et al.,* 2000), suggesting differentiation- or cell cycle-dependent effects of this factor. Activation of CD40 by its ligand CD154 (expressed by monocytes and T cells) also inhibits the apoptosis of osteoblasts and osteocytes (Ahuja *et al.,* 1999).

The antiapoptotic effect of IL-6 type cytokines on osteoblastic cells requires cyclin kinase inhibitor $p21^{WAF1,CIP1,SDI1}$, the synthesis of which is stimulated by STAT phosphorylation (Bellido *et al.,* 1998). Although not yet demonstrated in osteoblastic cells, the antiapoptotic effects of IGFs and FGF in other cells involve PI3-kinase and Akt–mediated phosphorylation of Bad (Lizcano *et al.,* 2000; Zhou *et al.,* 2000). IGFs also stimulate the synthesis of $p21^{WAF1,CIP1,SDI1}$ and Bcl-2 (Pugazhenthi *et al.,* 1999; Martelli *et al.,* 2000). Finally, IGFs and FGF may upregulate calbindin-D_{28k} (Wernyj *et al.,* 1999), which binds to and inhibits caspase-3 and blocks TNF-induced apoptosis in osteoblastic cells (Bellido *et al.,* 2000).

MATRIX METALLOPROTEINASES

Increased osteocyte and osteoblast apoptosis was observed in mice bearing a targeted mutation of the Col1a1 gene ($col1A1^{r/r}$ mice) that made collagen resistant to proteolytic attack by MMPs (Zhao *et al.,* 2000). This finding suggests that tonic MMP-mediated pericellular degradation of type I collagen provides survival signals to osteoblasts and osteocytes, perhaps via exposure of cryptic integrin-binding sites following cleavage of collagen (Messent *et al.,* 1998) or release of growth factors associated with the collagenous matrix.

Because of their location, osteocytes and their canalicular system provide the most likely means by which the skeleton detects sustained changes in mechanical forces. Perception of these changes in turn leads to adaptive changes in bone strength. Likewise, osteocytes likely perceive fatigue-induced bone microdamage (Parfitt *et al.,* 1996; Parfitt, 1996), and their apoptosis might provide site-specific signals its repair (Verborgt *et al.,* 2000). Induction of microcracks in rat ulnae by fatigue loading induced apoptosis of osteocytes adjacent to microcracks, but not in distant osteocytes. More importantly, resorption of the affected sites followed. Very high strains also increased osteocyte apoptosis in rat ulnae (Noble *et al.,* 1998).

Regulation of Bone Cell Apoptosis by Sex Steroids

Loss of estrogens leads to an increased rate of remodeling. This alone accounts for the initial decrease in bone mineral density due to expansion of the remodeling space, but it cannot explain the imbalance between formation and resorption that leads to progressive bone loss. A potential explanation for this imbalance is that estrogen promotes osteoclast apoptosis (Hughes *et al.,* 1996; Kameda *et al.,* 1997), but prevents apoptosis of osteoblasts (Kousteni *et al.,* 2001). Loss of these complementary actions in estrogen deficiency could account for the deeper than normal erosion cavities created by osteoclasts (Parfitt *et al.,* 1996; Eriksen *et al.,* 1999) and the reduction in wall thickness. Moreover, estrogen deficiency increases the prevalence of osteocyte apoptosis (Tomkinson *et al.,* 1997, 1998; Kousteni *et al.,* 2001), which might impair the ability of the osteocyte/canalicular mechanosensory network to repair microdamage, thus contributing further to bone fragility.

Estrogen promotes the apoptosis of osteoclasts (Hughes *et al.,* 1996) and their precursors (Shevde and Pike, 1996; Hughes *et al.,* 1996) in mixed cell cultures, as well as in cultures of isolated osteoclasts (Kameda *et al.,* 1997; Bellido *et al.,* 1999) or preosteoclastic cells, in some (Zecchi-Orlandini *et al.,* 1999; Sunyer *et al.,* 1999), but not all studies (Arnett *et al.,* 1996). The proapoptotic effect is associated with a reduced expression of IL-1R1 mRNA, and increased IL-1 decoy receptor expression (Sunyer *et al.,* 1999). However, in murine bone marrow cocultures, the proapoptotic effect of 17β-estradiol, as well as tamoxifen, seems to be mediated by TGFβ (Hughes *et al.,* 1996). Increased TGFβ, whether produced by stromal cells (Oursler *et al.,* 1991) or B lymphocytes (Weitzmann *et al.,* 2000), can directly stimulate the apoptosis of osteoclasts and osteoclast progenitors. It may also act indirectly via the stimulation of OPG synthesis (Takai *et al.,* 1998, Murakami *et al.,* 1998), which would reduce RANKL-mediated antiapoptotic signaling. The effects of TGFβ on osteoclasts,

however, are not straightforward, and further study is required to determine its role in normal and disease states. For example, in the absence of stromal cells, TGFβ (Fuller *et al.,* 2000b), activin (Fuller *et al.,* 2000a), and BMP-2 (Koide *et al.,* 1999) act directly on osteoclast precursors to promote their differentiation, and transgenic mice overexpressing TGFβ have an osteoporotic phenotype (Erlebacher and Derynck, 1996).

Testosterone, like estrogen, indirectly promotes osteoclast apoptosis *in vitro* and *in vivo* (Hughes *et al.,* 1995a). Its effect is also prevented by the anti-TGFβ antibody, but the proapoptotic effect of testosterone is observed approximately 4 hr later than that of estrogen (Dai and Boyce, 1997). In these cultures, testosterone is converted to estradiol within 4 hr, which presumably then promotes the formation of TGFβ, thus accounting for the delay. Dihydrotestosterone, which cannot be converted to estrogen, did not promote osteoclast apoptosis in mixed cultures (B. F. Boyce, unpublished observations); however, it did in osteoclast cultures devoid of stromal/osteoblastic cells (S. C. Manolagas *et al.,* unpublished observations).

The increase in osteoblast and osteocyte apoptosis following loss of sex steroids is due to loss of survival signals induced directly by estrogens and androgens via a newly discovered nongenotropic activity of the estrogen receptor (ER) and AR (Kousteni *et al.,* 2001). Upon activation with ligand, ER and AR stimulate a Src/Shc/ERK signaling pathway that prevents apoptosis induced by TNF, dexamethasone, etoposide, or anoikis. Strikingly, either estrogens or androgens activate the antiapoptotic activity of both ER and AR with similar efficiency. This activity could be eliminated by nuclear, but not by membrane, targeting of the ER. More important, it can be dissociated from its transcriptional activity with peptide antagonists of ER activity and by synthetic ER ligands.

Induction of Bone Cell Apoptosis by Glucocorticoids

High dose glucocorticoid treatment causes rapid bone loss via transiently increased resorption and reduced osteoblast number and bone formation rate (Dempster, 1989; Weinstein *et al.,* 1998). The rapid bone loss is due to increased osteoclast activity and/or life span, which may be caused by suppression of OPG synthesis and increase in RANKL (Hofbauer *et al.,* 1999). Increased osteoclastogenesis, however, is not involved because bone marrow of glucocorticoid-treated mice exhibits a decline in osteoclast progenitors even after brief glucocorticoid exposure (Weinstein *et al.,* 2000a). In rats, glucocorticoids increase bone mass, in contrast to humans and mice. This atypical situation has been attributed to the glucocorticoid-induced apoptosis of rat osteoclasts (Dempster *et al.,* 1997).

The decrease in osteoblast number and bone formation rate in glucocorticoid excess may be explained in part by the increased prevalence of osteoblast apoptosis observed in murine vertebral bone and human iliac bone (Weinstein *et al.,* 1998; Gohel *et al.,* 1999) (Figs. 2E and 2F). A decrease in osteoblast progenitors may also contribute (Weinstein *et al.,* 1998). Increased osteocyte apoptosis has also been documented in bone of mice and humans receiving glucocorticoids (Figs. 2A, 2G, and 2H). In fact, osteocytes with condensed chromatin have been observed in between the tetracycline labeling that demarcates sites of bone formation, indicating that these cells died immediately after entombment in the bone matrix (Fig. 2A).

Glucocorticoid-induced osteoporosis is often complicated by the *in situ* death of portions of bone, a process called osteonecrosis (Mankin, 1992). Studies of femoral heads from patients with glucocorticoid excess, but not with alcoholic, traumatic, or sickle cell osteonecrosis, revealed abundant apoptotic osteocytes and cells lining cancellous bone juxtaposed to the subchondral fracture crescent—a ribbon-like zone of collapsed trabeculae (Weinstein *et al.,* 2000b). In these five patients, signs of marrow inflammation and necrosis, such as hyperemia, round cell infiltration, or lipid cyst formation, were absent in contrast to the high frequency of these features in patients with sickle cell disease and femoral osteonecrosis. Therefore, in femoral head osteonecrosis due exclusively to glucocorticoid excess, marrow and bone necrosis are not inextricably linked to collapse of the joint. Thus, glucocorticoid-induced "osteonecrosis" may actually be osteocyte apoptosis, a cumulative and unrepairable defect that would disrupt the mechanosensory osteocyte–canalicular network. This situation would promote collapse of the femoral head and explain the correlation between total steroid dose and the incidence of avascular necrosis of bone (Felson and Anderson, 1987), as well as the occurrence of osteonecrosis after cessation of steroid therapy.

Glucocorticoids induce apoptosis of murine and rat calvarial cells and murine MLOY4 osteocyte-like cells (Plotkin *et al.,* 1999; Gohel *et al.,* 1999) via the glucocorticoid receptor. This effect was prevented by the receptor antagonist RU486, as well as overexpression of 11β-hydroxysteroid dehydrogenase type 2, which inactivates glucocorticoids (O'Brien *et al.,* 2000), suggesting that it is due to direct actions on osteoblasts/osteocytes rather than indirect actions of the steroid on the gastrointestinal tract, kidneys, parathyroid glands, or gonads. The molecular mechanism of glucocorticoid-induced apoptosis of osteoblasts and osteocytes is unknown. It may involve the suppression of survival factors such as IGFs (Cheng *et al.,* 1998), IL-6 type cytokines (Tobler *et al.,* 1992), integrins, and MMPs (Meikle *et al.,* 1992; Partridge *et al.,* 1996).

Regulation of Osteoblast and Osteocyte Apoptosis by PTH

Intermittent administration of PTH increases bone mass due to an increase in osteoblast number and bone formation rate (Dempster *et al.,* 1993). The precise mechanism is unclear but possibilities include increased osteoblast

precursor proliferation, increased osteoblast life span, and reactivation of lining cells. Studies in mice have revealed that it may be due to an approximately 10-fold reduction in osteoblast, as well as osteocyte, apoptosis (Jilka *et al.,* 1999b). Increased bone formation and osteoblast apoptosis suppression were also noted in mice expressing a constitutively active PTH/PTHrP receptor in osteoblastic cells (Calvi *et al.,* 2001). The ability to inhibit apoptosis provides a rational explanation for the efficacy of intermittent PTH administration in the prevention of glucocorticoid-induced bone loss and increased fragility (Lane *et al.,* 1998).

In vitro studies indicate that the antiapoptotic effect of PTH is due to G_s-activated cAMP production, and protein kinase A-mediated Bad phosphorylation (Jilka, unpublished observations). Although the PTH/PTHrP receptor delivers proapoptotic signals when coupled to G_q in human embryonic kidney cells (Turner *et al.,* 1998), PTH fails to activate G_q in osteoblastic cells expressing both G_s and G_q (Schwindinger *et al.,* 1998). The anabolic effects of other cAMP-inducing agents, such as PGE, may likewise be due to decreased osteoblast apoptosis (Jee and Ma, 1997; Machwate *et al.,* 1998a, 1999). Indeed, cell-permeable analogs of cAMP, as well as agents that stimulate cAMP production such as PGE and calcitonin (CT), inhibit the apoptosis of cultured osteoblastic and osteocytic cells (Machwate *et al.,* 1998b; Plotkin *et al.,* 1999). However, unlike PTH, PGE-stimulated cAMP activates sphingosine kinase to suppress apoptosis in periosteal osteoblastic cells (Machwate *et al.,* 1998b). The CT-mediated suppression of MLOY4 osteocytic cells involves ERK activation, most likely via a cAMP-activated pathway as reported in other cells (Gutkind, 1998). Besides activation of intracellular antiapoptotic pathways, PTH may exert its antiapoptotic effects via stimulation of synthesis of MMPs and/or IGFs that exert their own survival effects (Meikle *et al.,* 1992; Watson *et al.,* 1995; Pfeilschifter *et al.,* 1995; Partridge *et al.,* 1996; Hill *et al.,* 1997). Indeed, IGF-1 is required for the anabolic effect of PTH (Bikle *et al.,* 2000; Miyakoshi *et al.,* 2000).

A PTH receptor (CPTHR) that recognizes a sequence in the C-terminal portion of PTH(1–84) has been shown to stimulate the apoptosis of osteocytic cells (Divieti *et al.,* 2001). Because of the high level of circulating carboxy-terminal fragments of PTH in renal osteodystrophy, activation of this receptor could be responsible for the loss of osteocyte viability seen in this condition (Bonucci and Gherardi, 1977).

Effects of Bisphosphonates on Bone Cell Apoptosis

Bisphosphonates have been used since the mid-1970s to inhibit pathologic bone resorption. It has been shown that the induction of apoptosis, rather than death by necrosis, is the characteristic morphologic effect of bisphosphonates on osteoclasts *in vitro* and *in vivo* (Hughes *et al.,* 1995b), which could account for much of their inhibitory action. The number of osteoclasts with morphologic features of apoptosis seen in bone sections of mice treated in short-term experiments with bisphosphonates are high (up to 26% of osteoclasts) (Hughes *et al.,* 1995b). In most circumstances, macrophages or other adjacent cells remove apoptotic cells rapidly. The high number of apoptotic and nonapoptotic osteoclasts seen in these experiments may reflect bisphosphonate-induced impairment of macrophage phagocytic function and short-term stimulation of osteoclast formation (Fisher *et al.,* 2000).

The proapoptotic effect of aminobisphosphonates on osteoclasts is due to inhibition of the function of enzymes that mediate cholesterol synthesis in the mevalonic acid pathway (Luckman *et al.,* 1998; Coxon *et al.,* 2000). A final step in this pathway is prenylation of small proteins, such as ras and rho, which are involved in cell survival. In contrast, nonaminobisphosphonates, such as clodronate and etidronate, are metabolized to toxic ATP-like molecules whose precise mechanism of induction of osteoclast apoptosis remains unclear. These studies and the description of other possible mechanism of action of bisphosphonates are described in detail in Chapter 78. However, it is worth noting that statins also inhibit enzymes in the mevalonate pathway, and not only induce osteoclast apoptosis (Coxon *et al.,* 1998), but also prevent glucocorticoid-induced osteonecrosis (Cui *et al.,* 1997), presumably by a mechanism similar to that of bisphosphonates. The concentrations of these drugs that induce osteoclast apoptosis are higher than those shown to stimulate osteoblasts *in vitro* and increase bone formation *in vivo* (Mundy *et al.,* 1999).

Bisphosphonates may do more than kill osteoclasts and prevent further bone erosion. They may also possess anabolic activity as evidenced by an increase in wall thickness after long-term treatment (Storm *et al.,* 1993; Balena *et al.,* 1993; Chavassieux *et al.,* 1997). In addition, they appear to decrease fracture incidence disproportional to their effect on bone mass, suggesting another effect on bone strength unrelated to effects on bone resorption or formation (Weinstein, 2000). Bisphosphonates such as alendronate are an effective therapy for glucocorticoid-induced osteoporosis (Reid, 1997; Gonnelli *et al.,* 1997), an effect that may be due in part to the prevention of increased apoptosis of osteoblasts and osteocytes (Plotkin *et al.,* 1999). Thus, part of the antifracture efficacy of bisphosphonates may be due to the inhibition of osteocyte apoptosis via preservation of the integrity of the canalicular mechanosensory network.

The antiapoptotic activity of bisphosphonates is exerted at concentrations 3–4 orders of magnitude lower than required for stimulating osteoclast apoptosis (Hughes *et al.,* 1995b; Plotkin *et al.,* 1999). Moreover, a bisphosphonate that lacks antiresorptive activity (IG9402) (Van Beek *et al.,* 1996; Brown *et al.,* 1998) also suppresses osteocyte/osteoblast apoptosis (Plotkin *et al.,* 1999), indicating that bisphosphonates modulate different apoptosis regulating pathways in osteoblasts/osteocytes and osteoclasts. Indeed, like sex steroids, the antiapoptotic effect of bisphosphonates is trig-

gered by the stimulation of ERK phosphorylation (Plotkin *et al.,* 1999). Importantly, activation of this pathway appears to be mediated by the opening of connexin-43 hemichannels in the plasma membrane (Plotkin *et al.,* 2000).

Summary

Apoptosis of chondrocytes, osteoclasts, osteoblasts, and osteocytes plays a critical role in the development and maintenance of the skeleton. Alterations in bone cell life span contribute to the pathogenesis of limb development and growth plate defects, erosive joint disease, and the bone loss that results from sex steroid deficiency and glucocorticoid excess. Moreover, the ability of PTH to influence osteoblast life span may account for at least part of its anabolic effect on the skeleton—an action that may also extend to bisphosphonates. Further work is needed to identify the factors controlling bone cell survival and death during bone remodeling. It may then be possible to develop pharmacologic agents to modulate apoptosis so as to preserve, or even enhance, bone mass and strength.

CHAPTER 11

Involvement of Nuclear Architecture in Regulating Gene Expression in Bone Cells

Introduction

Skeletal development and bone remodeling require stringent control of gene activation and suppression in response to physiological cues. The fidelity of skeletal gene expression necessitates integrating a broad spectrum of regulatory signals that govern the commitment of osteoprogenitor stem cells to the bone cell lineage and proliferation and differentiation of osteoblasts, as well as maintenance of the bone phenotype in osteocytes residing in a mineralized bone extracellular matrix. To accommodate the requirements for short-term developmental and sustained phenotypic expression of cell growth and bone-related genes, it is necessary to identify and functionally characterize the promoter regulatory elements as well as cognate protein/DNA and protein/protein interactions that determine the extent to which genes are transcribed. However, it is becoming increasingly evident that the catalogue of regulatory elements and proteins is insufficient to support transcriptional control in the nucleus of intact cells and tissues. Rather, gene regulatory mechanisms must be understood within the context of the subnuclear organization of nucleic acids and regulatory proteins.

There is growing appreciation that transcriptional control, as it is operative *in vivo,* requires multiple levels of nuclear organization (Figs. 1 and 2). It is essential to package 2.5 yards of DNA as chromatin within the limited confines of the nucleus (Fig. 1, see also color plate). Gene promoter elements must be rendered competent for protein/DNA and protein/protein interactions in a manner that permits binding and functional activities of primary transcription factors as well as coactivators and corepressors. Less understood but pivotally relevant to physiological control is the localization of the regulatory machinery for gene expression and replication at subcellular sites where the macromolecular complexes that support DNA and RNA synthesis are localized (Fig. 2, see also color plate).

This chapter focuses on contributions by several indices of nuclear architecture to the control of gene expression in bone cells. This chapter presents cellular, biochemical, molecular, and genetic evidence for linkages of developmental and tissue-specific gene expression with the organization of transcriptional regulatory machinery in subnuclear compartments. Using the promoter of the bone-specific osteocalcin gene and the skeletal-specific core binding factor alpha (CBFA; also known as runt-related transcription factor, Runx) transcription factor as paradigms, this chapter addresses mechanisms that functionally organize the regulatory machinery for transcriptional activation and suppression during skeletal development and remodeling. It also provides evidence for consequences that result from perturbations in nuclear structure: gene expression interrelationships in skeletal disease.

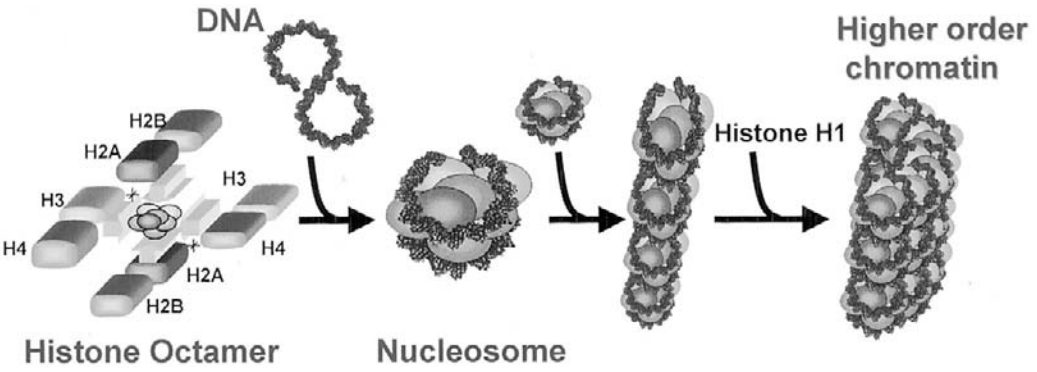

Figure 1 Levels of chromatin organization. DNA (blue coil) is packaged by histone octamers (ovals in gold tones) to form nucleosomes. Histone octamers form by the assembly of two histone H3 and two histone H4 proteins to organize a central H3/H4 tetramer, while two heterodimers of histone H2A and H2B interact with, respectively, the top and bottom of the tetramer. Multiple nucleosomes form a beads on a string structure (10 nm fiber) and, in the presence of histone H1, nucleosomes will form higher order chromatin structures (30 nm fiber) presumably by interdigitation and/or coiling of nucleosomal DNA. (See also color plate.)

Gene Expression within the Three-Dimensional Context of Nuclear Architecture: Multiple Levels of Nuclear Organization Support Fidelity of Gene Regulation

While the mechanisms that control gene expression remain to be formally defined, there is growing awareness that the fidelity of gene regulation necessitates the coordination of transcription factor metabolism and the spatial organization of genes and regulatory proteins within the three-dimensional context of nuclear architecture. The parameters of nuclear architecture include the sequence of gene regulatory elements, chromatin structure, and higher order organization of the transcriptional regulatory machinery into subnuclear domains. All of these parameters involve mechanisms that include transcription factor synthesis, nuclear import and retention, posttranslational modifications of factors, and directing factors to subnuclear sites that support gene expression (Figs. 2 and 3). Remodeling of chromatin and nucleosome organization to accommodate requirements for protein–DNA and protein–protein interactions at promoter elements are essential modifications for both activation of genes and physiological control of transcription. The reconfiguration of gene promoters and assembly of specialized subnuclear domains reflect the orchestration of both regulated and regulatory mechanisms (Fig. 4, see also color plate). There are analogous and complex regulatory requirements for processing of gene transcripts. Here it has been similarly demonstrated that the regulatory components of splicing and export of messenger RNA to the cytoplasm are dependent on the architectural organization of nucleic acids and regulatory proteins.

From a biological perspective, each parameter of factor metabolism requires stringent control and must be linked to structure–function interrelationships that mediate transcription and processing of gene transcripts. However, rather than representing regulatory obstacles, the complexities of nuclear biochemistry and morphology provide the required specificity for physiological responsiveness to a broad spectrum of signaling pathways to modulate transcription under diverse circumstances. Equally important, evidence is accruing that modifications in nuclear architecture and nuclear structure–function interrelationships accompany and appear to be causally related to compromised gene expression under pathological conditions.

Multiple levels of genomic organization that contribute to transcription are illustrated schematically in Fig. 4. Additional levels of nuclear organization are reflected by the subnuclear localization of factors that mediate transcription, processing of gene transcripts, DNA replication, and DNA repair at discrete domains (Fig. 2).

Sequence Organization: A Blueprint for Responsiveness to Regulatory Cues

Appreciation is accruing for the high density of information in both regulatory and mRNA-coding sequences of cell growth and phenotypic genes. The modular organizations of promoter elements provide blueprints for responsiveness to a broad spectrum of regulatory cues that support competency for transient developmental and homeostatic control as well as sustained commitments to tissue-specific gene expression. Overlapping recognition elements expand the options for responsiveness to signaling cascades that mediate mutually exclusive protein/DNA and protein/protein interactions. Splice variants for gene transcripts further enhance the specificity of gene expression. However, it must be acknowledged that the linear order of genes and flanking regulatory elements is necessary but insufficient to support expression in a biological context. There is a requirement to integrate the regulatory information at independent promoter elements and selectively utilize subsets of promoter regulatory information to control the extent to which genes are activated and/or suppressed.

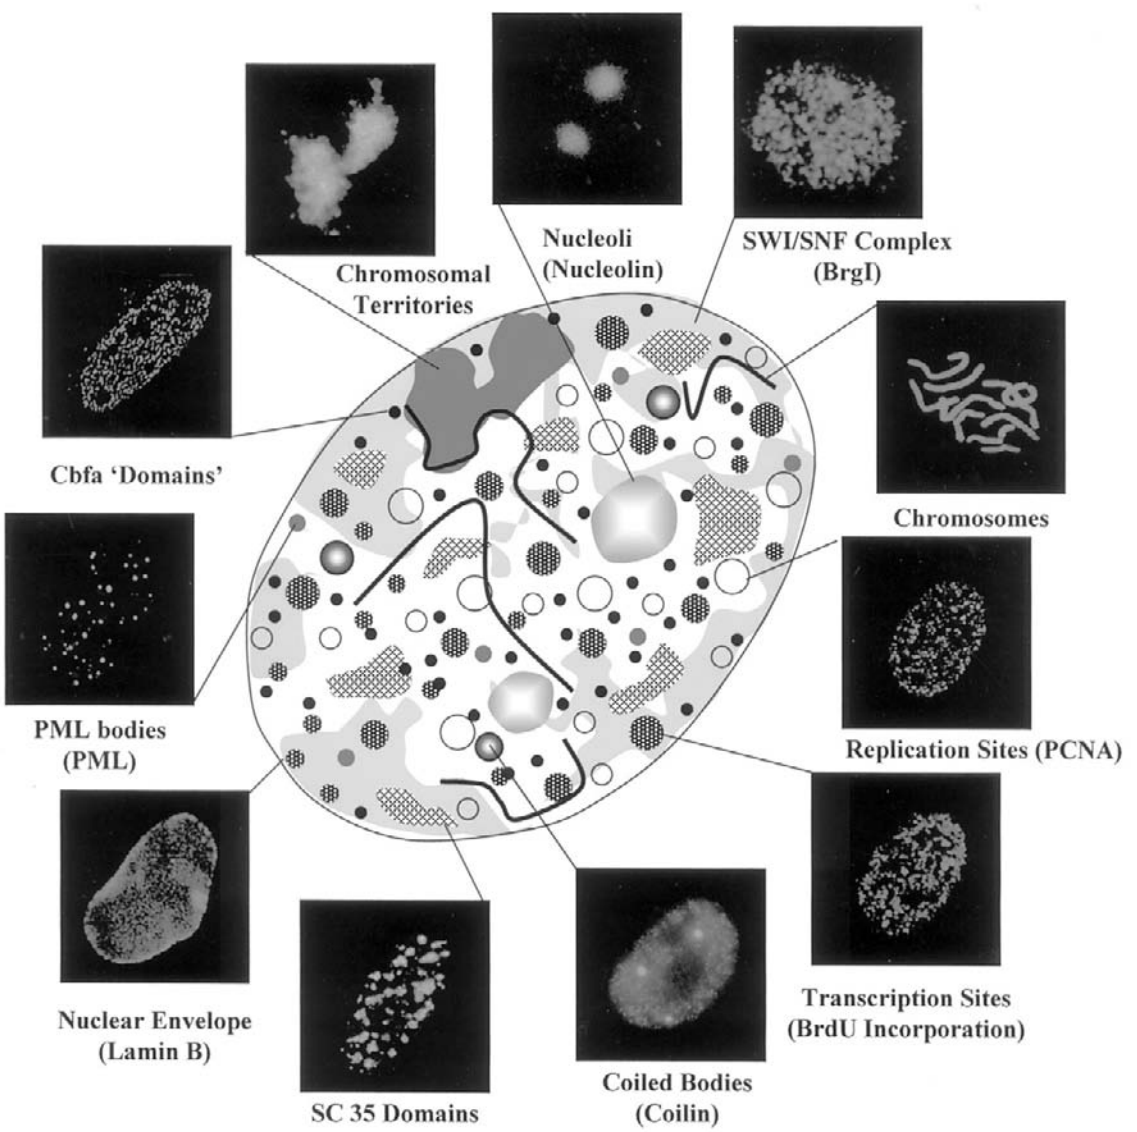

Figure 2 Subnuclear compartmentalization of nucleic acids and regulatory proteins into specialized domains. Nuclear functions are organized into distinct, nonoverlapping subnuclear domains (illustrated schematically in the center). Immunofluorescence microscopy of the nucleus *in situ* has revealed the distinct subnuclear distribution of vital nuclear processes, including (but not limited to) DNA replication sites (Ma *et al.,* 1998); chromatin remodeling, e.g., mediated by the SWI/SNF complex (Reyes *et al.,* 1997) and Cbfa factors (Javed *et al.,* 1999; Prince *et al.,* 2001; Zeng *et al.,* 1998); structural parameters of the nucleus, such as the nuclear envelope, chromosomes, and chromosomal territories (Ma *et al.,* 1999); Cbfa domains for transcriptional control of tissue-specific genes; and RNA synthesis and processing involving, for example, transcription sites (Wei *et al.,* 1999), SC35 domains (reviewed in Shopland and Lawrence, 2000), coiled bodies (Platani *et al.,* 2000), and nucleoli (Dundr *et al.,* 2000). Subnuclear PML bodies of unknown function (McNeil *et al.,* 2000) have been examined in numerous cell types. All of these domains are associated with the nuclear matrix. Each panel is reproduced with permission from the journal and authors of the indicated references. (See also color plate.)

Chromatin Organization: Packaging Genomic DNA in a Manner That Controls Access to Genetic Information

Chromatin structure and nucleosome organization provide architectural linkages between gene organization and components of transcriptional control (Fig. 1). During the past three decades, biochemical and structural analyses have defined the dimensions and conformational properties of the nucleosome, the primary unit of chromatin structure. Each nucleosome consists of approximately 200bp of DNA wrapped in two turns around an octameric protein core containing two copies each of histones H2A, H2B, H3, and H4. A fifth histone, the linker histone H1, binds to the nucleosome and promotes the organization of nucleosomes into a higher order structure, the 30-nm fiber. Nucleosomal organization reduces distances between promoter elements, thereby supporting interactions between the modular components of transcriptional control. The higher order chromatin structure further reduces nucleotide distances

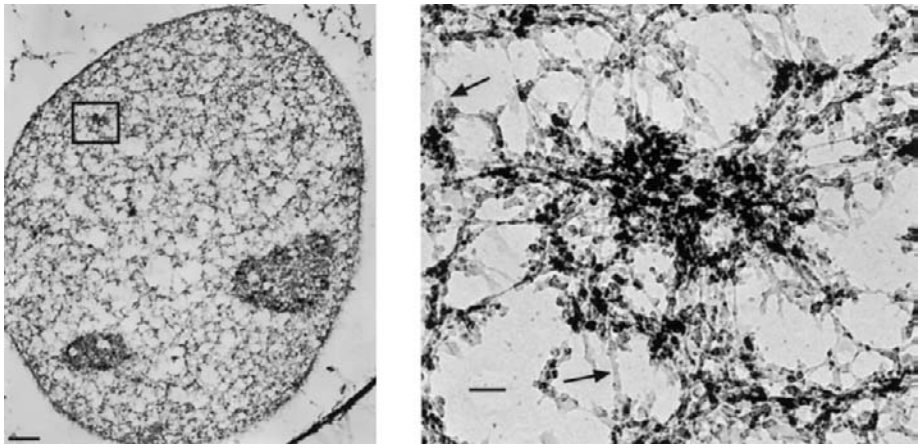

Figure 3 Electron micrograph of the nuclear matrix. A resinless preparation of the cell reveals the nuclear matrix subnuclear domain. (Left) Nuclear matrix intermediary filaments distributed throughout the nucleus. The two denser areas represent the nucleoli. Bar: 1 μm. (Right) The boxed area is enlarged. A higher magnification of the nuclear matrix reveals an interchromatin granule cluster where the processing of RNA transcripts occurs, as well as the anastomosing network of fibers and filaments that support structural and regulatory activities within the nucleus. Arrows point to 10-nm filaments, which may provide an underlying structure of the nuclear matrix. Bar: 100 nm. Reproduced in part from Nickerson (2001) with permission.

between regulatory sequences. Folding of nucleosome arrays into solenoid-type structures provides a potential for interactions that support synergism between promoter elements and responsiveness to multiple signaling pathways.

It has been well established that the presence of nucleosomes generally blocks the accessibility of transcription factors to their cognate-binding sequences (Workman and Kingston, 1998). Extensive analyses of chromatin structure have indicated that the most active genes exhibit increased nuclease sensitivity at promoter and enhancer elements. These domains generally reflect alterations in classical nucleosomal organization and binding of specific nuclear factors. Thus, nuclease digestion has been widely used to probe structures *in vivo* and *in vitro* based on the premise that the chromatin accessibility to nuclease digestion reflects chromatin access to nuclear regulatory molecules. Chromatin immunoprecipitation assays that utilize antibodies to acetylated histones or transcription factors provide the basis for defining the presence of modified histones in chromatin complexes at single nucleotide resolution within gene regulatory elements.

Changes in chromatin organization have been documented under many biological conditions where modifications of gene expression are necessary for the execution of physiological control. Transient changes in chromatin structure accompany and are linked functionally to developmental and homeostatic-related control of gene expression. Long-term changes occur when the commitment to phenotype-specific gene expression occurs with differentiation. However, superimposed on the remodeling of chromatin structure and nucleosome organization that renders genes transcriptionally active are additional alterations in the packaging of DNA as chromatin to support steriod hormone responsive enhancement or dampening of transcription.

During the past several years there have been major advances in the ability to experimentally address the molecular mechanisms that mediate chromatin remodeling. A family of proteins and protein complexes have been described in yeast and in mammalian cells (Cote *et al.,* 1994; Imbalzano, 1998; Kwon *et al.,* 1994; Peterson *et al.,* 1998; Vignali *et al.,* 2000) that promote transcription by altering chromatin structure (Vignali *et al.,* 2000). These alterations render DNA sequences containing regulatory elements accessible for binding cognate transcription factors and mediate protein–protein interactions that influence the structural and functional properties of chromatin. Although the mechanisms by which these complexes function remain to be formally defined, there is general agreement that the increase in DNA sequence accessibility does not require the removal of histones (Cote *et al.,* 1998; Lorch *et al.,* 1998; Schnitzler *et al.,* 1998). Rather, multiple lines of evidence suggest that remodeling of the nucleosomal structure involves alterations in histone–DNA and/or histone–histone interactions.

All chromatin remodeling complexes that have to date been reported include a subunit containing ATPase activity (Cairns *et al.,* 1994, 1996; Cote *et al.,* 1994; Dingwall *et al.,* 1995; Ito *et al.,* 1997; Kwon *et al.,* 1994; LeRoy *et al.,* 1998; Randazzo *et al.,* 1994; Tsukiyama *et al.,* 1994, 1999; Tsukiyama and Wu, 1995; Varga-Weisz *et al.,* 1997; Wade *et al.,* 1998; Wang *et al.,* 1996a, b; Xue *et al.,* 1998; Zhang *et al.,* 1998) (Table I) and have been shown to be critical for modifying nucleosomal organization. Because these subunits share significant homology, it has been suggested that they belong to a new family of proteins with a function that has been highly conserved throughout evolution (Vignali *et al.,* 2000).

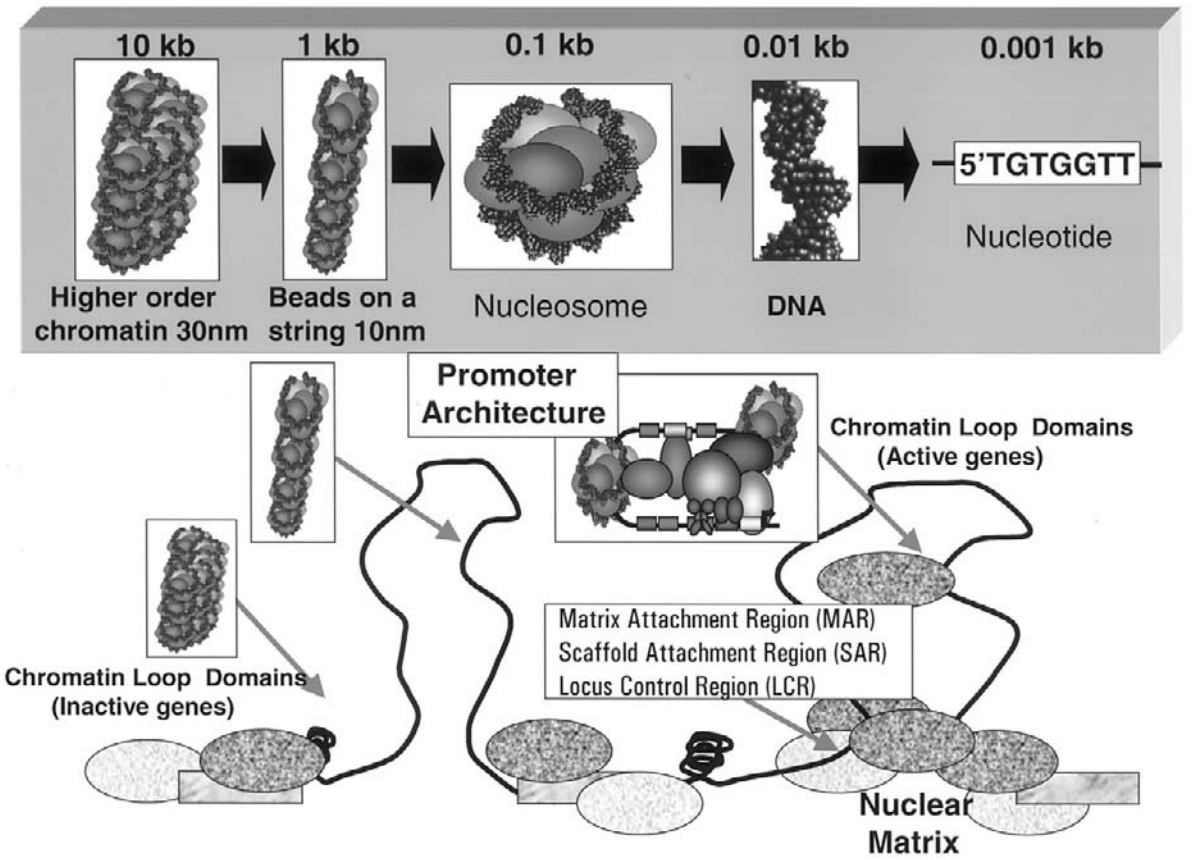

Figure 4 Chromatin organization within the nucleus. (Top) Different levels of DNA organization at different lengths of scale [10 kb to single basepair resolution (0.001 kb)]. The *in situ* organization of DNA within the nucleus involves formation of chromatin loop domains with various degrees of chromatin packaging, including highly condensed chromatin (inactive genes) and partially extended loops near transcriptionally active genes (lower). Anchorage of these loop domains to dynamic architectural complexes (referred to as the nuclear matrix) maintains chromatin in distinct topological states, which accommodate the independent regulation of genes in different chromosomal regions. Distinct conformations of chromatin and posttranslational modifications of histones located in gene promoters support a three-dimensional organization (promoter architecture) that permits specific regulatory protein/protein interactions between distal and proximal regions. (See also color plate.)

Posttranslational modifications of histones have also been implicated in the physiological control of chromatin structure for the past three decades. However, recent findings have functionally linked histone acetylation with changes in nucleosomal structure that alter the accessibility to specific regulatory elements (Workman and Kingston, 1998). For example, acetylation of the N termini of nucleosomal histones has been directly correlated with transcriptional activation. Moreover, it has been observed that core histone hyperacetylation enhances the binding of most transcription factors to nucleosomes (Ura *et al.,* 1997; Vettese-Dadey *et al.,* 1994, 1996). Nevertheless, there have been reports that chromatin hyperacetylation blocks steroid hormone transcriptional enhancement and steriod-dependent nucleosomal alterations (Bresnick *et al.,* 1990, 1991; Montecino *et al.,* 1999). Within this context, it has been shown that hyperacetylation of nuclear proteins alters the chromatin organization of the bone tissue

Table I Nucleosome Remodeling Complexes

Complex	Subunit with ATPase activity	Origin
SWI/SNF	SWI2/SNF2	Yeast
SWI/SNF	BRG 1 BRM	Human
BRAHMA	BRM	*Drosophila*
RSC	STHI	Yeast
NURF	ISWI	*Drosophila*
ACF	ISWI	*Drosophila*
CHRAC	ISWI	*Drosophila*
RSF	hSNF2h	Human
yISWI	yISWI1 yISWI2	Yeast
hNURD	hCHD3 hCHD4	Human
Mi-2	xCHD3/4	*Xenopus*

specific osteocalcin gene promoter in a manner that prevents vitamin D-mediated transcriptional upregulation. By combining nuclease accessibility, indirect end labeling, and ligation-mediated polymerase chain reaction (PCR) analysis, it was demonstrated that protein–DNA interactions that promote formation of a distal DNase I hypersensitive site do not occur under conditions of hyperacetylation (Montecino *et al.,* 1999).

A major breakthrough in addressing the physiological role of histone acetylation experimentally came with the purification and subsequent cloning of the catalytic subunits of yeast and mammalian nuclear histone acetyltransferases (HAT) (Table II). Gcn5 encodes a 55-kDa protein in yeast that acetylates both histones H3 and H4 (Brownell *et al.,* 1996). It has been suggested that Gcn5 is part of a larger protein complex designated SAGA (Grant *et al.,* 1997) that includes proteins that are also present in complexes involved in transcriptional regulation (Workman and Kingston, 1998). Other proteins that contain nuclear HAT activity are p300 and its related homologue CBP (Ogryzko *et al.,* 1996). These two proteins function as transcriptional adaptors that interact with several transcription factors, including CREB, Jun, Fos, Myb, and Myo D, as well as with nuclear steroid hormone receptors (Arany *et al.,* 1994; Arias *et al.,* 1994; Bannister *et al.,* 1995; Chakravarti *et al.,* 1996; Chrivia *et al.,* 1993; Dai *et al.,* 1996; Kamei *et al.,* 1996; Kwok *et al.,* 1994; Oelgeschlager *et al.,* 1996; Yuan *et al.,* 1996). In addition, human and yeast TAFII250 have HAT activity (Mizzen *et al.,* 1996). TAFII250 is part of the TFIID complex that recognizes the TATA sequence at the promoter region of most genes and initiates the formation of transcription preinitiation complexes. The presence of HAT activity in this complex suggests that histone acetylation may be a requirement for transcription factor interaction with nucleosomal DNA.

P/CAF, another protein that contains HAT activity, is highly homologous to both the yeast Gcn5 and the human homologue hGNC5. P/CAF interacts with p300 and CBP to form functional complexes (Yang *et al.,* 1996). These findings are consistent with the formation of complexes containing multiple HAT activities that can accommodate requirements for specificity of histone acetylation under different biological conditions.

Table II Histone Acetyltransferase (HAT)

HAT	Origin
Gcn5	*Tetrahymena* Yeast Mammalian
PCAF	Human
p300/CBP	Human
TAFII250	Human
	Drosophila Yeast
SRC-1	Human
ACTR	Human
Esa1	Yeast
Tip60	Human

Nuclear HAT activity appears to be critical during steroid hormone-dependent transcriptional activation. It has been reported that coactivation factors that include ACTR contain HAT activity (Chen *et al.,* 1997) and recruit p300 and P/CAF to ligand-bound nuclear hormone receptors. This is an example of a multiprotein complex containing three different HAT activities (p300/CBP, P/CAF, and ACTR) that contribute to modifications of nucleosomal histones that are linked functionally to competency for chromatin remodeling that occurs during ligand-dependent transcriptional regulation (Fondell *et al.,* 1996).

For histone acetylation to be a physiologically relevant component of transcriptional control there is a requirement for a cellular mechanism to reverse this posttranslational modification. Histone deacetylases (HDACs), which remove acetate moieties from histone proteins enzymatically, have been studied extensively during the past several years. Multiple forms of this enzyme have been identified and characterized in several organisms (Brosch *et al.,* 1992; Georgieva *et al.,* 1991; Grabher *et al.,* 1994; Lechner *et al.,* 1996; Lopez-Rodas *et al.,* 1992; reviewed in Khochbin *et al*., 2001). The mammalian form, designated HDAC1, was found to be homologous to the yeast form designated Rpd3 (Taunton *et al.,* 1996). It has been reported that the unliganded thyroid and retinoid receptors can mediate transcriptional repression via interaction with corepressor molecules that include SMRT and N-CoR (Chen and Evans, 1995; Horlein *et al.,* 1995). These corepressors can nucleate the formation of high molecular weight complexes containing HDAC activity. These findings indicate that, in general, histone acetylation correlates with activation and suppression of gene expression, confirming that remodeling of chromatin structure and nucleosome organization is obligatory for biological control of transcription.

Histone phosphorylation contributes to modifications in histone–DNA and histone–histone interactions that influence nucleosome placement and chromatin organization. Kinases that mediate histone phosphorylation respond to regulatory information transduced through signaling pathways in a biologically specific manner. The biologically responsive reconfiguration of chromatin is frequently accompanied by the phosphatase-dependent dephosphorylation of histones that occurs in the absence of protein degradation. Other posttranslational modifications of histones that influence chromatin organization include methylation, ubiquitination, and poly ADP ribosylation. The extensive utilization of methylation in biological control is reflected by the methylation of transcription factors and DNA. DNA methylation is frequently associated with transcriptional repression.

Higher Order Nuclear Organization: Interrelationships of Transcriptional Regulatory Machinery with Nuclear Architecture

The necessity for both nuclear architecture and biochemical control to regulate gene expression is becoming increasingly evident. An ordered organization of nucleic acids and regulatory proteins to assemble and sustain macromolecular complexes that provide the machinery for transcription requires stringent, multistep mechanisms. Each component of transcriptional control is governed by responsiveness to an integrated series of cellular signaling pathways. Each gene promoter selectively exercises options for regulating factor interactions that activate or repress transcription. All transcriptional control is operative *in vivo* under conditions where, despite low representation of promoter regulatory elements and cognate factors, a critical concentration is essential for a threshold that can initiate sequence-specific interactions and functional activity.

Historically, there was a dichotomy between pursuit of nuclear morphology and transcriptional control. However, the growing experimental evidence indicating that components of gene regulatory mechanisms are associated architecturally strengthens the nuclear structure–function paradigm. Are all regulatory events that control gene expression linked architecturally? Can genetic evidence formally establish consequential relationships between nuclear structure and transcription? What are the mechanisms that direct genes and regulatory factors to subnuclear sites that support transcription? How are boundaries established that compartmentalize components of gene expression to specific subnuclear domains? Can the regulated and regulatory parameters of nuclear structure–function interrelationships be distinguished? These are key questions that must be addressed experimentally to validate components of gene expression that have been implicated as dependent on nuclear morphology. From a biological perspective, it is important to determine if breaches in nuclear organization are related to compromised gene expression in diseases that include cancer where incurred mutations abrogate transcriptional control.

Nuclear Matrix: A Scaffold for the Architectural Organization of Regulatory Complexes

The identification (Berezney and Coffey, 1975) and *in situ* visualization (Fey *et al.,* 1984; Nickerson *et al.,* 1990) of the nuclear matrix (Fig. 3), together with the characterization of a chromosome scaffold (Lebkowski and Laemmli, 1982), were bases for pursuing the control of gene expression within the three-dimensional context of nuclear architecture.

The anastomosing network of fibers and filaments that constitute the nuclear matrix supports the structural properties of the nucleus as a cellular organelle and accommodates modifications in gene expression associated with proliferation, differentiation, and changes necessary to sustain phenotypic requirements in specialized cells (Bidwell *et al.,* 1994; Dworetzky *et al.,* 1990; Getzenberg and Coffey, 1990; Nickerson *et al.,* 1990). Regulatory functions of the nuclear matrix include but are by no means restricted to DNA replication (Berezney and Coffey, 1975), gene location (Zeng *et al.,* 1997), imposition of physical constraints on chromatin structure that support formation of loop domains, concentration and targeting of transcription factors (Dworetzky *et al.,* 1992; Nelkin *et al.,* 1980; Robinson *et al.,* 1982; Schaack *et al.,* 1990; Stief *et al.,* 1989; van Wijnen *et al.,* 1993), RNA processing and transport of gene transcripts (Blencowe *et al.,* 1994; Carter *et al.,* 1993; Lawrence *et al.,* 1989; Spector, 1990; Zeitlin *et al.,* 1987), and posttranslational modifications of chromosomal proteins, as well as imprinting and modifications of chromatin structure (Davie, 1997).

Initial correlations between the representation of nuclear matrix proteins and phenotypic properties of cells supported involvement of the nuclear matrix in regulatory activities (Bidwell *et al.,* 1994; Dworetzky *et al.,* 1990; Fey and Penman, 1988; Getzenberg and Coffey, 1990; Nickerson *et al.,* 1990). Additional evidence for participation of the nuclear matrix in gene expression came from reports of qualitative and quantitative changes in the representation of nuclear matrix proteins during the differentiation of normal diploid cells (Dworetzky *et al.,* 1990) and in tumor cells (Bidwell *et al.,* 1994; Getzenberg *et al.,* 1991, 1996; Keesee *et al.,* 1994; Khanuja *et al.,* 1993; Kumara-Siri *et al.,* 1986; Long and Ochs, 1983; Partin *et al.,* 1993; Stuurman *et al.,* 1989). More direct evidence for functional linkages between nuclear architecture and transcriptional control was provided by demonstrations that cell growth (Dworetzky *et al.,* 1992; Schaack *et al.,* 1990; van Wijnen *et al.,* 1993) and phenotypic (Dickinson *et al.,* 1992; Merriman *et al.,* 1995; Nardozza *et al.,* 1996) regulatory factors are nuclear matrix associated and by modifications in the partitioning of transcription factors between the nuclear matrix and the nonmatrix nuclear fraction when changes in gene expression occur (van Wijnen *et al.,* 1993).

Contributions of the nuclear matrix to control of gene expression is further supported by involvement in regulatory events that mediate histone modifications (Hendzel *et al.,* 1994), chromatin remodeling (Cote *et al.,* 1994; Imbalzano, 1998; Kwon *et al.,* 1994; Peterson *et al.,* 1998; Workman and Kingston, 1998), and processing of gene transcripts (Blencowe *et al.,* 1994; Carter *et al.,* 1993; Ciejek *et al.,* 1982; Iborra *et al.,* 1998; Jackson *et al.,* 1998; Nickerson *et al.,* 1995; Pombo and Cook, 1996; Wei *et al.,* 1999). Instead of addressing chromatin remodeling and transcriptional activation as complex but independent mechanisms, it is biologically meaningful to investigate the control of genome packaging and expression as interrelated processes that are operative in relation to nuclear architecture (Fig. 4). Taken together with findings that indicate important components of the machinery for both gene transcription and replication are confined to nuclear matrix-associated subnuclear domains (Iborra *et al.,* 1998; Jackson *et al.,* 1998; Lamond and Earnshaw, 1998; Wei *et al.,* 1998; Zeng *et al.,* 1998), the importance of nuclear architecture to intranuclear compartmentalization of regulatory activity is being pursued.

SUBNUCLEAR DOMAINS: NUCLEAR MICROENVIRONMENTS PROVIDE A STRUCTURAL AND FUNCTIONAL BASIS FOR SUBNUCLEAR COMPARTMENTALIZATION OF REGULATORY MACHINERY

An understanding of interrelationships between nuclear structure and gene expression necessitates knowledge of the composition, organization, and regulation of sites within the nucleus that are dedicated to DNA replication, DNA repair, transcription, and processing of gene transcripts. During the past several years there have been development

s in reagents and instrumentation to enhance the resolution of nucleic acid and protein detection by *in situ* hybridization and immunofluorescence analyses. We are beginning to make the transition from descriptive *in situ* mapping of genes, transcripts, and regulatory factors to visualization of gene expression from the three-dimensional perspective of nuclear architecture. Figure 2 displays components of gene regulation that are associated with the nuclear matrix. Initially, *in situ* approaches were utilized primarily for the intracellular localization of nucleic acids. Proteins that contribute to control of gene expression were first identi-fied by biochemical analyses. We are now applying high-resolution *in situ* analyses for the primary identification and characterization of gene regulatory mechanisms under *in vivo* conditions.

We are increasing our understanding of the significance of nuclear domains to the control of gene expression. These local nuclear environments that are generated by the multiple aspects of nuclear structure are tied to the developmental expression of cell growth and tissue-specific genes. Historically, the control of gene expression and characterization of structural features of the nucleus were pursued conceptionally and experimentally as minimally integrated questions. At the same time, however, independent pursuit of nuclear structure and function has occurred in parallel with the appreciation that several components of nuclear architecture are associated with parameters of gene expression or control of specific classes of genes.

For the most part, biochemical parameters of replication and transcription have been studied independently. However, paradoxically, from around the turn of the last century it was recognized that there are microenvironments within the nucleus where regulatory macromolecules are compartmentalized in subnuclear domains. Chromosomes and the nucleolus provided the initial paradigms for the organization of regulatory machinery within the nucleus. Also, during the last several decades, linkages have been established between subtleties of chromosomal anatomy and replication as well as gene expression. Regions of the nucleolus are understood in relation to ribosomal gene expression. The organization of chromosomes and chromatin is well accepted as reflections of functional properties that support competency for transcription and the extent to which genes are transcribed.

It has been only recently that there is an appreciation for the broad-based organization of regulatory macromolecules within discrete nuclear domains (reviewed in Cook, 1999; Kimura *et al.,* 1999; Lamond and Earnshaw, 1998; Leonhardt *et al.,* 1998; Ma *et al.,* 1998, 2000; Misteli, 2000; Misteli and Spector, 1999; Zhong *et al.,* 2000; Scully and Livingston, 2000; Smith *et al.,* 1999; Stein *et al.,* 2000a, b; Stommel *et al.,* 1999; Verschure *et al.,* 1999; Wei *et al.,* 1998; Wu *et al.,* 2000; Zeng *et al.,* 1998; Zhao *et al.,* 2000). Examples of intranuclear compartmentalization now include but by no means are restricted to SC35 RNA processing sites, PML bodies, the structural and regulatory components of nuclear pores that mediate nuclear–cytoplasmic exchange (Moir *et al.,* 2000), coiled (Cajal) bodies, and replication foci, as well as defined sites where steroid hormone receptors and transcription factors reside (Glass and Rosenfeld, 2000; Leonhardt *et al.,* 2000; McNally *et al.,* 2000). The integrity of these subnuclear microenvironments is indicated by structural and functional discrimination between each architecturally defined domain. Corroboration of structural and functional integrity of each domain is provided by the uniqueness of the intranuclear sites with respect to composition, organization, and intranuclear distribution in relation to activity (Hirose and Manley, 2000; Lemon and Tjian, 2000).

We are now going beyond mapping regions of the nucleus that are dedicated to replication and gene expression. We are gaining insight into interrelationships between the subnuclear organization of the regulatory and transcriptional machinery with the dynamic assembly and activity of macromolecular complexes that are required for biological control during development, differentiation, maintenance of cell and tissue specificity, homeostatic control, and tissue remodeling (Javed *et al.,* 2000; Stein *et al.,* 2000b). Equally important, it is becoming evident that the onset and progression of cancer (McNeil *et al.,* 2000; Stein *et al.,* 2000b; Tibbetts *et al.,* 2000) and neurological disorders (Skinner *et al.,* 1997) are associated with and potentially functionally coupled with perturbations in the subnuclear organization of genes and regulatory proteins that relate to aberrant gene replication, repair, and transcription.

Linkage of Nuclear Architecture to Biological Control of Skeletal Gene Expression

Chromatin Remodeling Renders Skeletal Genes Accessible to Regulatory Factors That Control Competency for Transcription

Alterations in the chromatin organization of the osteocalcin gene promoter during osteoblast differentiation provide a paradigm for remodeling of chromatin structure and nucleosome organization that is linked to long-term commitment to phenotype-specific gene expression (Montecino *et al.,* 1994b, 1996). The osteocalcin gene encodes a 10-kDa bone-specific protein that is induced in late-stage osteoblasts at the onset of extracellular matrix mineralization (Aronow *et al.,* 1990; Owen *et al.,* 1990).

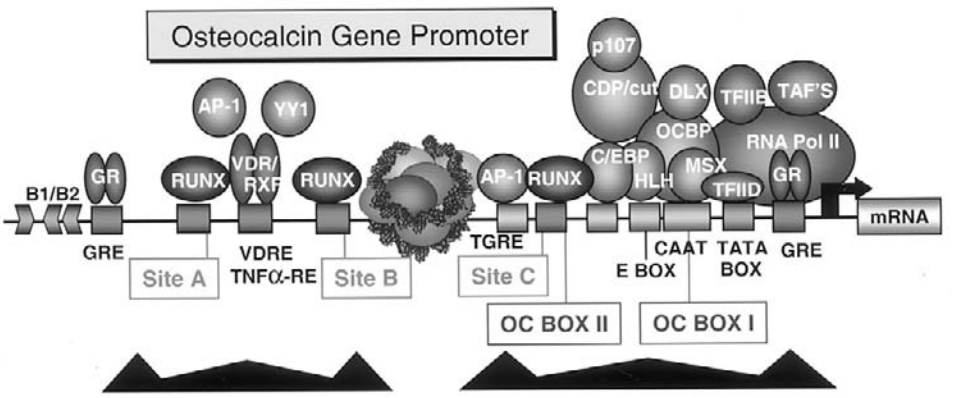

Figure 5 The osteocalcin promoter as a blueprint for responsiveness to osteogenic signals. This schematic representation of promoter elements and cognate factors in the rat osteocalcin promoter depicts three binding sites for Runx2/Cbfa1 (red symbols), steroid hormone responsive sequences and the cognate hormone receptor dimers (blue symbols); a vitamin D responsive element (VDRE); glucocorticoid responsive elements (GRE) and recognition motifs for osteoblast-related transcription factors, e.g., the leucine zipper proteins C/EBP and AP1, homeodomain proteins Dlx5, Msx2, and CDP/cut, helix-loop-helix proteins (yellow symbols), as well as components of the general transcription initation machinery [e.g., the TATA-binding complex (TFIID) and associated factors (TAFs)]. OC boxes I and II represent the principal rate-limiting elements that activate the OC gene in bone cells. The mRNA cap site (hooked arrow) is located at the 3′ end of the promoter, and the regulatory boundary of the promoter at the 5′ end is demarcated by repetitive sequences (e.g., B1 and B2 repeats; horizontal chevrons). A positioned nucleosome resides between distal and proximal promoter domains in the active promoter. Black bars indicate DNase I hypersensitivity observed when the osteocalcin gene is transcribed and which increase in intensity in response to vitamin D. (See also color plate.)

Transcription of the osteocalcin gene is controlled by a modularly organized promoter with proximal basal regulatory sequences and distal hormone responsive enhancer elements (Banerjee *et al.,* 1996; Bortell *et al.,* 1992; Demay *et al.,* 1990; Ducy and Karsenty, 1995; Guo *et al.,* 1995; Hoffmann *et al.,* 1994; Markose *et al.,* 1990; Merriman *et al.,* 1995; Tamura and Noda, 1994; Towler *et al.,* 1994) (Fig. 5 see also color plate). The osteocalcin gene is not expressed in non osseous cells nor is it transcribed in osteoprogenitor cells or early stage proliferating osteoblasts. Following the postproliferative onset of osteoblast differentiation, transcription of the osteocalcin gene is regulated by Runx2 (Fig. 6, see also color plate). Maximal levels of transcription are controlled by the combined activities of the vitamin D response element, C/EBP site, AP-1 regulatory elements, and the OC box. Linear organization of the OC gene promoter reveals proximal regulatory elements that control basal and tissue-specific activity. These include the OC box for homeodomain protein binding and an osteoblast-specific complex, the TATA domain, a Runx site, and a C/EBP site. The distal promoter contains a vitamin D responsive enhancer element (VDRE) that is flanked by Runx sites (Fig. 5). The control of transcription is dependent on protein–DNA interactions in the basal and upstream elements that are in part dependent on the accessibility of cognate regulatory sequences and additionally on the consequences of mutually exclusive protein–DNA interactions.

A relevant example of mutually exclusive occupancy at an OC gene promoter element is competition by YY1 and the vitamin D receptor (VDR) for the VDRE. Such regulatory factor occupancy at the VDRE provides a mechanism for enhancement by VDR/RXR heterodimers and suppression of competency for vitamin D-dependent enhancement by YY1 under appropriate biological conditions (Fig. 7, see also color plate). There is additionally a requirement to account mechanistically for protein–protein interactions between regulatory factors that are components of proximal basal and upstream enhancer complexes. Here mutually exclusive protein–protein interactions of YY1 or VDR (VDRE associated) with TFIIB (TATA associated) occur and must be explained in relation to conformational properties of the OC promoter that can support interactions of these distal and proximal regulatory complexes.

The dynamics of chromatin organization and remodeling permit developmental and steroid hormone responsive changes in the OC gene promoter to accommodate transcriptional requirements. Figures 6 and 7 schematically depict modifications in chromatin structure and nucleosome organization that parallel competency for transcription and the extent to which the osteocalcin gene is transcribed. Changes in chromatin are observed in response to physiological mediators of basal expression and steroid hormone responsiveness. This remodeling of chromatin provides a basis for the involvement of nuclear architecture in growth factor and steroid hormone responsive control of osteocalcin gene expression during osteoblast phenotype development and in differentiated bone cells.

Basal expression and enhancement of osteocalcin gene transcription are accompanied by two changes in the

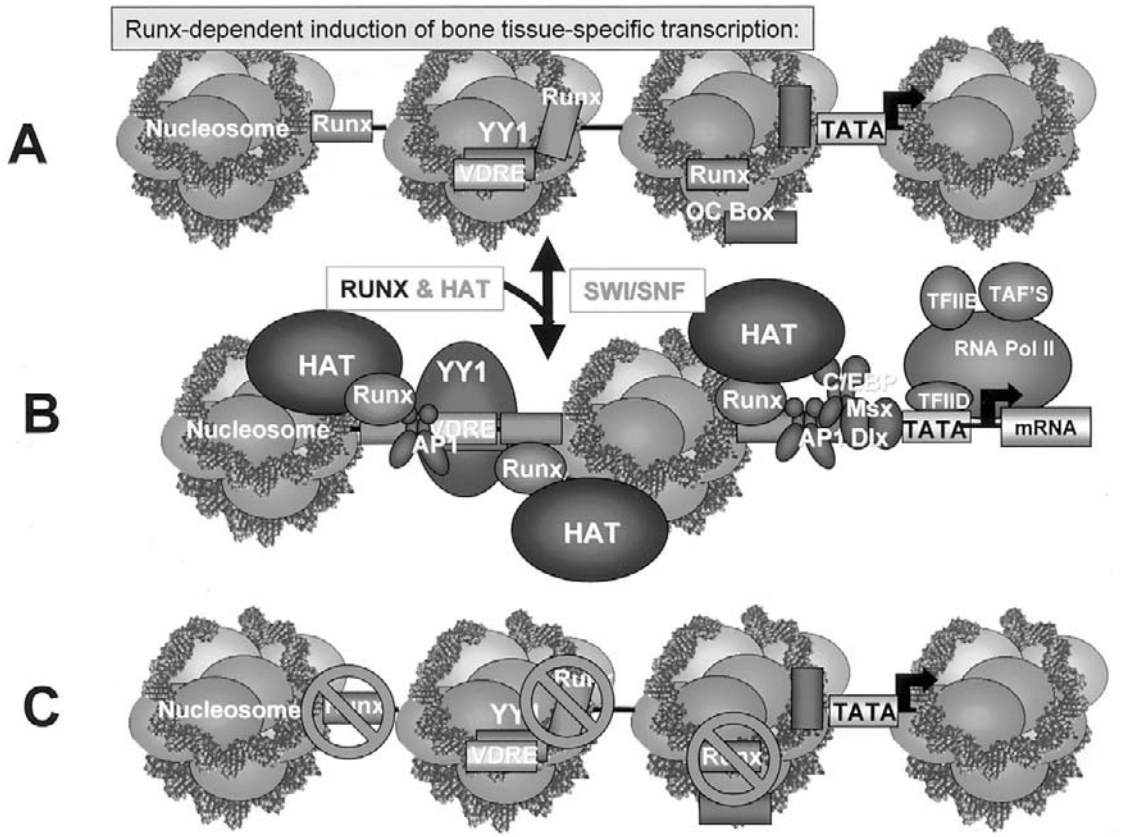

Figure 6 Runx2/Cbfa1-dependent remodeling of the osteocalcin gene promoter. (A) The inactive promoter in nonosseous cells is organized as condensed chromatin in an array of nucleosomes. (B) Induction of osteocalcin gene expression by Runx2/Cbfa1 proteins occurs concomitant with modifications in nucleosomal organization through the recruitment of histone acetyl transferases (HATs) and chromatin remodeling proteins (e.g., SWI/SNF). The interactions of Runx2 proteins with strategically spaced sites in the OC promoter may constrain the position of a nucleosome between proximal and distal promoter domains to facilitate accessibility of the distal vitamin D responsive sequences and proximal bone tissue-specific elements to principal regulatory factors. (C) Mutation of the Runx sites results in the loss of nuclease hypersensitive sites and chromatin remodeling, reflected by an 80% reduction of OC promoter activity in a genomic context. (See also color plate.)

structural properties of chromatin (Fig. 7). DNase I hypersensitivity of sequences flanking the basal, tissue-specific element and the vitamin D enhancer domain is observed (Breen *et al.,* 1994; Montecino *et al.,* 1994a, b). Together with changes in nucleosome placement, a basis for accessibility and *in vivo* occupancy of transactivation factors to basal and steroid hormone-dependent regulatory sequences can be explained. In early stage proliferating normal diploid osteoblasts, when the osteocalcin gene is repressed, nucleosomes are placed in the proximal basal domain and in the vitamin D responsive enhancer promoter sequences. Nuclease hypersensitive sites are not present in the vicinity of these regulatory elements. In contrast, when osteocalcin gene expression is transcriptionally upregulated postproliferatively and vitamin D-mediated enhancement of transcription occurs, the proximal basal and upstream steroid hormone responsive enhancer sequences become nucleosome free and these regulatory domains are flanked by DNase I hypersensitive sites.

Translational positioning of the nucleosomes reflects protein–DNA interactions within the OC promoter that accounts for both formation of the nuclease hypersensitive sites and OC gene transcriptional activity. The Runx2 transcriptional factor is required for developmentally regulated osteocalcin expression (Banerjee *et al.,* 1997; Ducy *et al.,* 1997). Mutations that eliminate Runx-binding sites in the OC promoter prevent chromatin remodeling (Javed *et al.,* 1999) and decrease transcription dramatically. In addition, mutations of the Runx sites that flank the VDRE result in a loss of vitamin D responsiveness, reflecting the requirement of Runx sites for correct promoter architecture (Fig. 6). Runx factors have been shown to form a scaffold for the assembly of multimeric complexes of proteins with histone acetylase and histone deacytelase activities (Westendorf and Hiebert, 1999) that support chromatin remodeling (Figs. 8 and 9, see also color plates). Such complexes are in part influenced by the position of Runx sites in a promoter and protein–protein interactions with factors at nearby

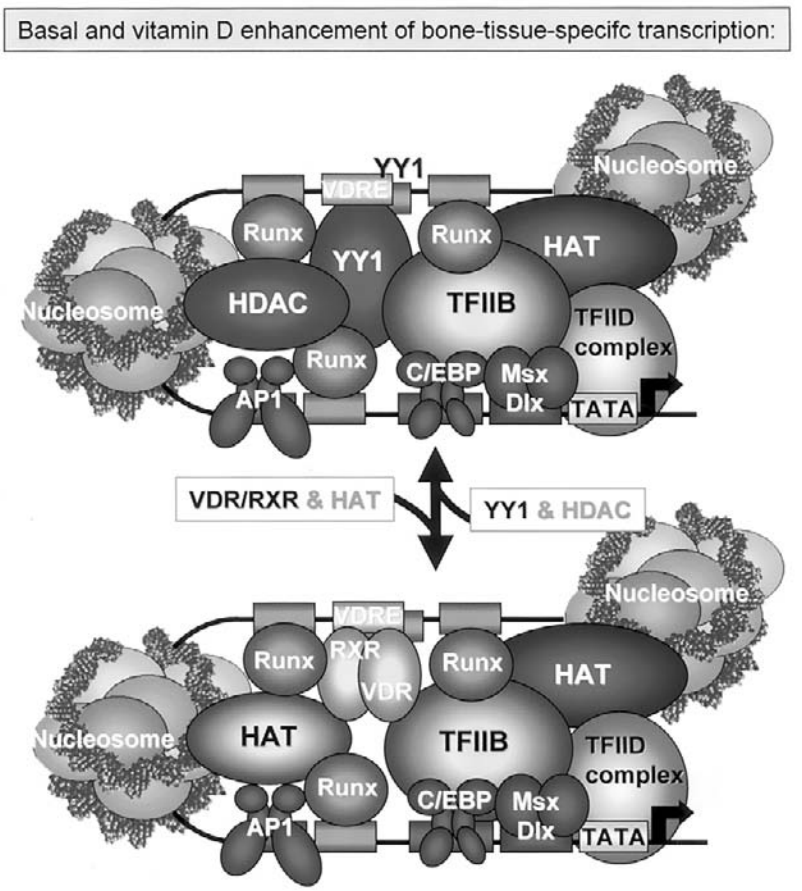

Figure 7 Spatial organization of the osteocalcin promoter during bone tissue-specific basal transcription and vitamin D enhancement. Upon activation of the osteocalcin gene, the promoter adopts a specialized nucleosomal organization involving two accessible regions spanning proximal elements (e.g., AP1, C/EBP, and Msx/Dlx, blue), distal elements (e.g., VDRE, yellow), and a nucleosome (gold) with restricted mobility that is flanked by Runx2 sites (red). In the basal state (top), transcription factors bound to the OC promoter are associated with specific histone acetyl transferases (HATs) that promote an "open" chromatin conformation and protein/protein bridges between distal and proximal elements. Vitamin D-dependent transcription is attenuated in the absence of ligand by the binding of YY1 to a site overlapping with the VDRE that precludes receptor binding and by sequestration of TFIIB, which normally functions as a stimulatory cofactor for the vitamin D response. Upon ligand binding to the vitamin D receptor (VDR) (bottom), VDR displaces YY1 at the distal VDRE, which supports productive interactions with TFIIB at the proximal promoter, as well as recruits additional HATs that further open up the OC gene locus. (See also color plate.)

regulatory elements. Thus, multimerized Runx sites lose the ability to provide an assay for the precise function of gene regulation in the context of a specific promoter. These interactions contribute strong enhancer activity of the osteocalcin gene and downregulation of the bone sialoprotein gene in osteoblasts (Javed *et al.,* 2001), as illustrated in Fig. 9. The developmental and steroid hormone transitions in chromatin are thereby mediated by Runx-dependent protein–DNA and protein–protein interactions. Occupancy of multiple factors at other regulatory elements in the context of the three-dimensional structure of the promoter provides a basis for additional protein–protein interactions that further contribute to the control of transcription.

Intranuclear Trafficking to Subnuclear Destinations: Directing Skeletal Regulatory Factors to the Right Place at the Right Time

The traditional experimental approaches to transcriptional control have been confined to the identification and characterization of gene promoter elements and cognate regulatory factors. However, the combined application of *in situ* immunofluorescence together with molecular, biochemical, and genetic analyses indicates that several classes of transcription factors exhibit a punctate subnuclear distribution. This punctate subnuclear distribution persists after the removal of soluble nuclear proteins and nuclease-digested

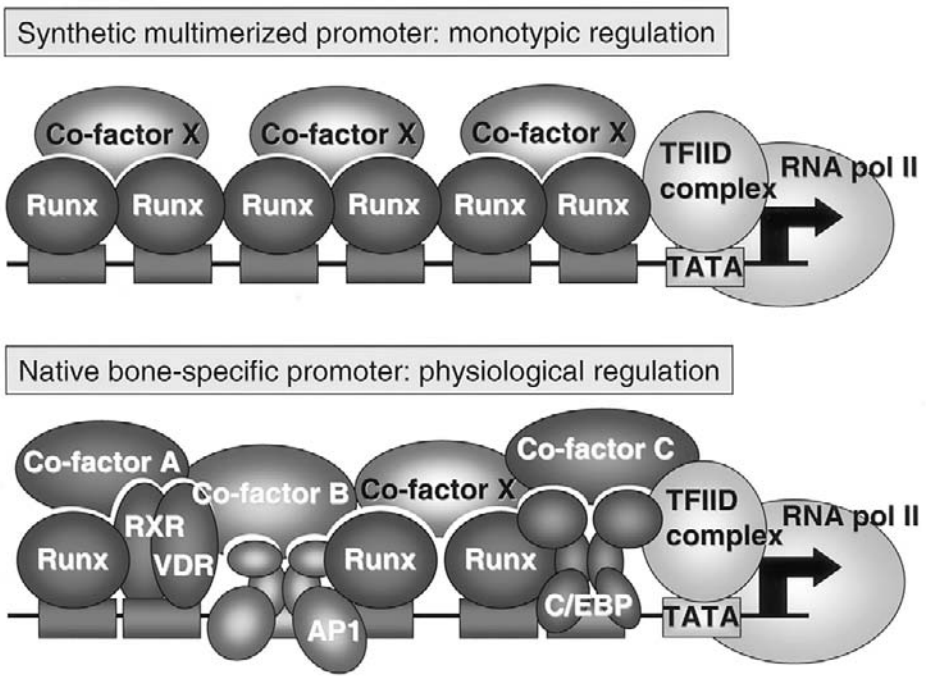

Figure 8 Physiological regulation of gene transcription based on the intricate organization of natural gene promoters. The potential for regulatory interactions of transcription factors and cofactors at synthetic promoters containing multimerized binding sites for Runx/Cbfa (top) and native Runx/Cbfa responsive promoters (bottom) is shown. The natural organization of bone-specific promoters represents a blueprint for physiological control of gene expression and responsiveness to osteogenic factors. Transcriptional control involves irregularly arranged elements (horizontal cylinders) that bind Runx2/Cbfa1 proteins, as well as different classes of transcription factors that synergize with Runx2/Cbfa1 (RXR/VDR, AP1, C/EBP)(oval structures). Synergism involves the association of distinct types of cofactors (e.g., A, B, C, and X) that recognize protein surfaces in Runx2/Cbfa1 and RXR/VDR, AP1, or C/EBP to form heteromeric promoter structures that recruit the TFIID transcriptional initiation complex and RNA polymerase II. The monotypic repetition of Runx elements in synthetic promoters (top) reduces the potential for cofactor interactions and artificially amplifies one component of the transcriptional response. (See also color plate.)

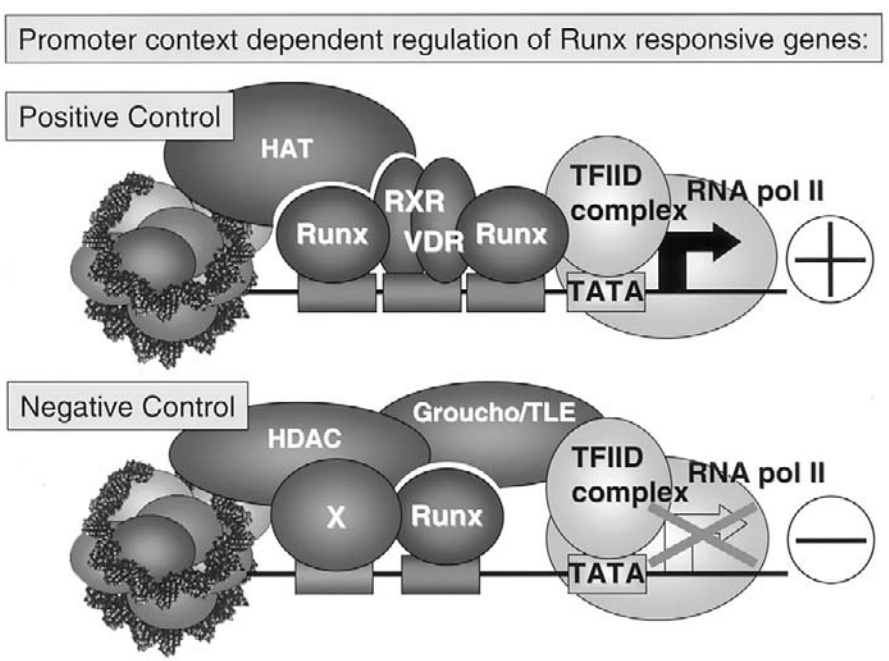

Figure 9 Positive and negative control of Runx2/Cbfa1 responsive genes. Runx2/Cbfa1 is a multifunctional protein that can synergize with different sequence-specific DNA-binding proteins (e.g., AP1, C/EBP) and associate with positive (e.g., Smads, p300) or negative (e.g., groucho/TLE, HDACs) gene regulatory cofactors depending on the promoter context of bone tissue-specific genes. Possible interactions accommodating the positive (top) and negative (bottom) regulation of transcription are shown. Depending on the cell type, coregulatory proteins may modulate transcriptional levels of the gene rather than completely repress the gene as illustrated. (See also color plate.)

chromatin. We propose that the intranuclear organization of regulatory proteins could be linked functionally to their competency to affect gene expression (e.g., Guo *et al.,* 1995; Htun *et al.,* 1996; Nguyen and Karaplis, 1998; Stenoien *et al.,* 1998; Verschure *et al.,* 1999; Zeng *et al.,* 1997). Therefore, one fundamental question is the mechanism by which this compartmentalization of regulatory factors is established within the nucleus. This compartmentalization could be maintained by the nuclear matrix, which provides an underlying macromolecular framework for the organization of regulatory complexes (Berezney and Jeon, 1995; Berezney and Wei, 1998; Penman, 1995). However, one cannot dismiss the possibility that nuclear compartmentalization is activity driven (Misteli, 2000; Pederson, 2000).

Insight into architecture-mediated transcriptional control can be gained by examining the extent to which the subnuclear distribution of gene regulatory proteins affects their activities. We and others observed that members of the Runx/Cbfa family of hematopoietic and bone tissue-specific transcription factors (Banerjee *et al.,* 1997; Chen *et al.,*

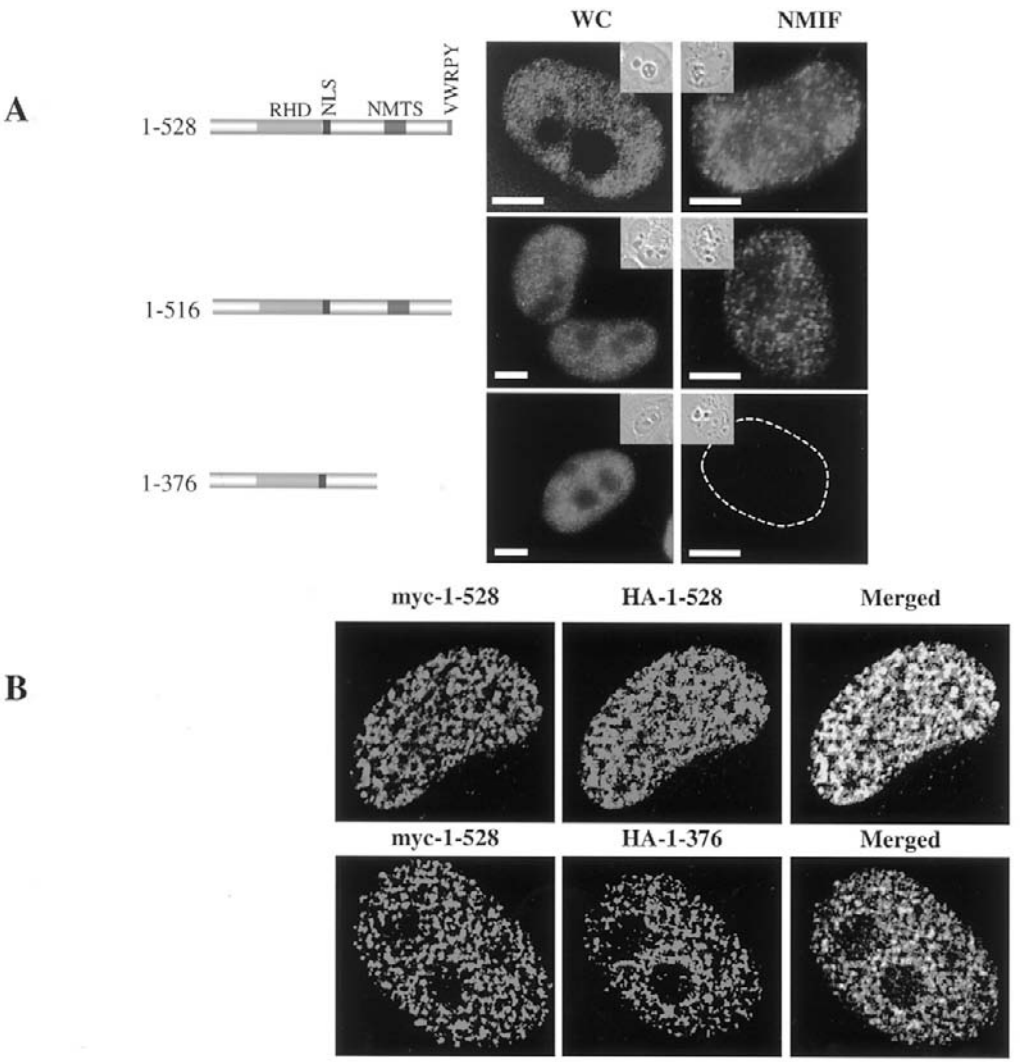

Figure 10 Identification and function of the intranuclear targeting signal (NMTS) that directs Runx factors to nuclear matrix-associated subnuclear domains. (A) Immunofluorescence and differential interference contrast (small inserts) images of whole cell (WC) and nuclear matrix intermediate filament (NMIF) preparations of cells transfected with constructs encoding Runx (Cbfa/AML) related proteins that possess or lack the intranuclear-trafficking signal. The location of the conserved domains, runt DNA-binding domain (RHD), nuclear import signal (NLS), the VWRPY interaction motif for Groucho/TLE proteins, and the intranuclear-trafficking signal (NMTS) that includes a context-dependent transactivation domain in the C-terminal region are indicated. The NMTS was initially defined by deletion mutants of Runx (Cbfa/AML) transcription factors that were assayed for nuclear import and trafficking to punctate nuclear matrix-associated subnuclear sites that support gene expression. Deletion of the NMTS (mutant 1-376) does not compromise nuclear import (WC, whole cells) but subnuclear distribution is abrogated (NMIF). (B) Merged images of Runx2 WT 1-528 (myc tag) and Runx2 mutant protein 1-376 (HA tag) in transfected whole cells show that the absence of NMTS misdirects the factor to domains in the nucleus different from wild type (WT), revealed by distinct red and green foci (bottom). WT proteins, each carrying different fluorescent tags (myc and HA), colocalize to the same sites reflected by a yellow merged image (top). This control demonstrates that fluorescent tags do not influence subnuclear targeting. (See also color plate.)

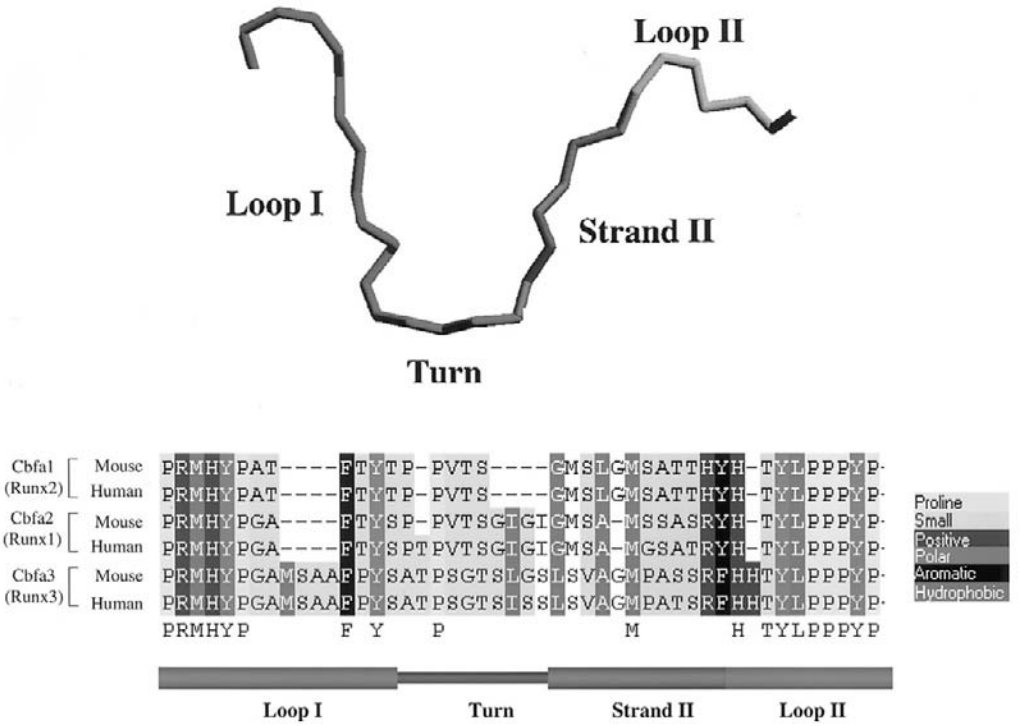

Figure 11 Structure and sequence conservation of the NMTS characterizing Runx1 factors. X-ray diffraction crystallography was carried out on the Runx1 NMTS domain fused to glutathione *S*-transferase at a resolution of –2.7 A. Two loop domains connected by a flexible glycine hinge (turn) are predicted (Tang *et al.,* 1999). Sequence alignment of the segments of the Runx2, Runx1, and Runx3 proteins containing the NMTS. Loop I and loop II are protein-interacting domains for Smad (Zhang *et al.,* 2000) and YAP (Yagi *et al.,* 1999). Comparison of mouse and human sequences shows conservation among the factors and species. The Runx nomenclature for Runt-related transcription factors, recently adopted by the Human Genome Organization, is indicated. (See also color plate.)

1998; Merriman *et al.,* 1995; Zeng *et al.,* 1997, 1998) exhibit a punctate subnuclear distribution and are associated with the nuclear matrix (Zeng *et al.,* 1997). Biochemical and *in situ* immunofluorescence analyses (Fig. 10, see also color plate) established that a 31 residue segment designated the nuclear matrix targeting signal (NMTS) near the C terminus of the Runx factor is necessary and sufficient to mediate association of these regulatory proteins to nuclear matrix-associated subnuclear sites at which transcription occurs (Zeng *et al.,* 1997, 1998). The NMTS functions autonomously and can target a heterologous protein to the nuclear matrix. Furthermore, the NMTS is independent of the DNA-binding domain as well as the nuclear localization signal, both of which are in the N-terminal region of the Runx protein. The unique peptide sequence of the Runx NMTS (Zeng *et al.,* 1997, 1998) and the defined structure obtained by X-ray crystallography (Tang *et al.,* 1998a, 1999) support the specificity of this targeting signal. These data are compatible with a model in which the NMTS functions as a molecular interface for specific interaction with proteins and/or nucleic acids that contribute to the structural (Fig. 11, see also color plate) and functional activities of nuclear domains (Fig. 12). However, at present we cannot formally distinguish whether this interaction between the NMTS and its putative nuclear acceptor strictly reflects targeting or retention.

The idea that specific mechanisms direct regulatory proteins to sites within the nucleus is reinforced by the identification of targeting signals in the glucocorticoid receptor (Htun *et al.,* 1996; Tang *et al.,* 1998b; van Steensel *et al.,* 1995), PTHRP (Nguyen and Karaplis, 1998), the androgen receptor (van Steensel *et al.,* 1995), PIT1 (Stenoien *et al.,* 1998), and YY1 (Guo *et al.,* 1995; McNeil *et al.,* 1998). These targeting signals do not share sequence homology with each other or with the Runx/Cbfa transcription factors. Furthermore, the proteins each exhibit distinct subnuclear distributions. Thus, a series of trafficking signals are responsible for directing regulatory factors to nonoverlapping sites within the cell nucleus. Collectively, the locations of these transcription factors provide coordinates for the activity of gene regulatory complexes.

The importance of architectural organization of regulatory machinery for bone-restricted gene expression is evident from the intranuclear localization of Runx2 coregulatory proteins that control OC gene expression. For example, TLE/Groucho, a suppressor of Runx-mediated transcriptional activation, colocalizes with Runx2 at punctate subnuclear sites (Javed *et al.,* 2000). The Yes-associated protein represents another example of a Runx coregulatory factor that is directed to Runx subnuclear sites when associated with Runx (Zaidi *et al.,* 2000).

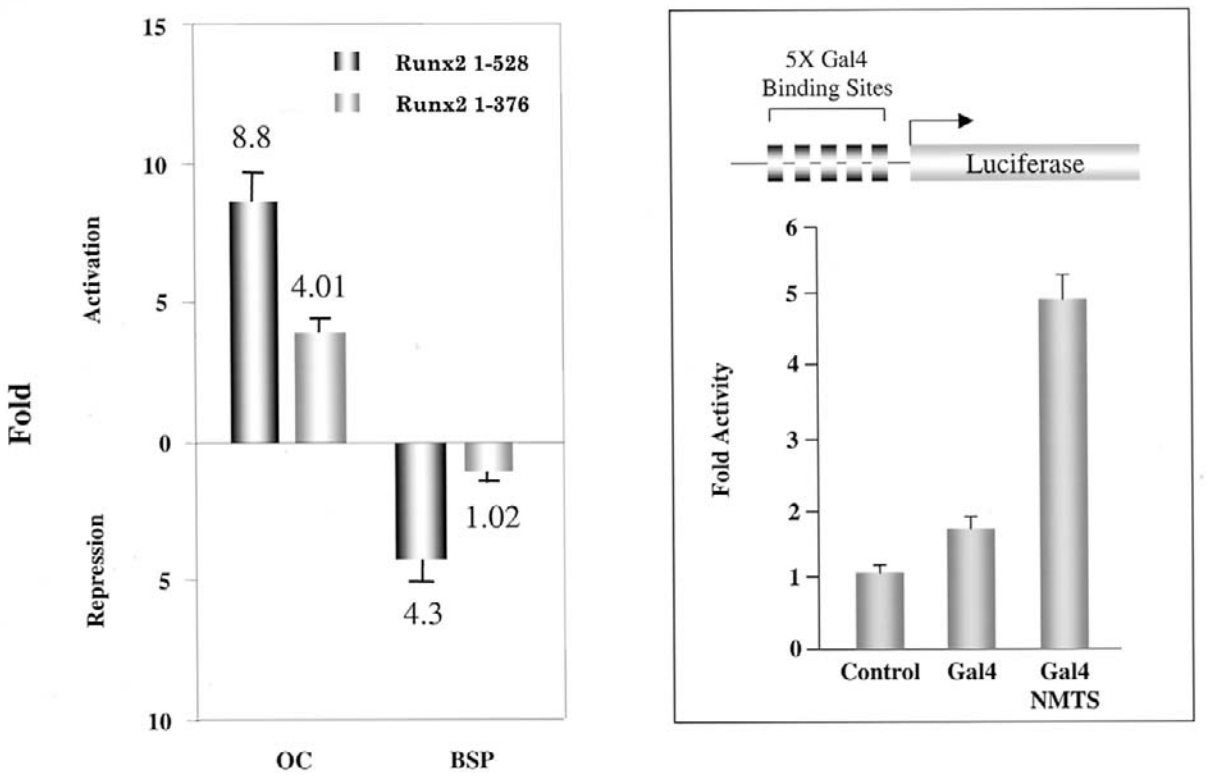

Figure 12 Functional activity of the NMTS. The NMTS supports transcription of promoters as demonstrated by two experimental approaches. (Left) Decreased activation of the osteocalcin promoter (−1.1 kbp OC) and decreased repression of the bone-sialoprotein (−1 kbp BSP) are observed with mutant Cbfa1 lacking the C terminus containing the NMTS (1–376) when compared to WT (1–528). Transient transfections in Hela cells (Javed *et al.*, 2000). (Right) Using the Gal-4 activation system, an NMTS (Runx2)-Gal4 fusion protein increased luciferase activity fourfold over Gal4, reflecting the intrinsic transactivation functions of the NMTS. The control represents empty vector (Zeng *et al.,* 1998).

Intranuclear targeting of regulatory factors is a multistep process, and we are only beginning to understand the complexity of each step. However, biochemical and *in situ* analyses have shown that at least two trafficking signals are required: the first supports nuclear import (the nuclear localization signal) and the second mediates interactions with specific sites associated with the nuclear matrix (the nuclear matrix-targeting signal). Given the multiplicity of determinants for directing proteins to specific destinations within the nucleus, alternative splicing of messenger RNAs might generate different forms of a transcription factor that are targeted to specific intranuclear sites in response to diverse biological conditions. Furthermore, the activities of transcription complexes involve multiple regulatory proteins that could facilitate the recruitment of factors to sites of architecture-associated gene activation and suppression.

Requirements for Understanding Functional Interrelationships between Nuclear Architecture and Skeletal Gene Expression

The regulated and regulatory components that interrelate nuclear structure and function must be established experimentally. A formidable challenge is to define further the control of transcription factor targeting to acceptor sites associated with the nuclear matrix. It will be important to determine whether acceptor proteins are associated with a preexisting core filament structural lattice or whether a compositely organized scaffold of regulatory factors is assembled dynamically.

An inclusive model for all steps in the targeting of proteins to subnuclear sites cannot yet be proposed. However, this model must account for the apparent diversity of intranuclear targeting signals. It is also important to assess the extent to which regulatory discrimination is mediated by subnuclear domain-specific trafficking signals. Furthermore, the checkpoints that monitor the subnuclear distribution of regulatory factors and the sorting steps that ensure both structural and functional fidelity of nuclear domains in which replication and expression of genes occur must be defined biochemically and mechanistically.

There is emerging recognition that the placement of regulatory components of gene expression must be coordinated temporally and spatially to facilitate biological control. The consequences of breaches in nuclear structure–function relationships are observed in an expanding series of diseases that include cancer (McNeil *et al.,* 1999; Rogaia *et al.,* 1997; Rowley, 1998; Tao and Levine, 1999; Weis *et al.,* 1994; Yano *et al.,* 1997; Zeng *et al.,* 1998) and neurological disorders (Skinner *et al.,* 1997). Findings indicate the requirement for the fidelity of Runx/Cbfa/AML subnuclear localization to

support regulatory activity for skeletogenesis *in vivo*. While many of the human mutations in Runx2 associated with cleidocranial dysplasia occur in the DNA-binding domain, several mutations have been identified in the C terminus, which disrupt nuclear matrix association (Zhang *et al.,* 2000). As the repertoire of architecture-associated regulatory factors and cofactors expands, workers in the field are becoming increasingly confident that nuclear organization contributes significantly to the control of transcription. To gain increased appreciation for the complexities of subnuclear organization and gene regulation, we must continue to characterize mechanisms that direct regulatory proteins to specific transcription sites within the nucleus so that these proteins are in the right place at the right time.

CHAPTER 12

Type I Collagen

Structure, Synthesis, and Regulation

Introduction

Type I collagen is the most abundant extracellular protein of bones and is essential for bone strength. This chapter first discusses the structure and biosynthesis of type I collagen and how its synthesis is regulated by cytokines, hormones, and growth factors. It then discusses recent results about the organization of regulatory elements in type I collagen genes, many of which are based on studies in transgenic mice.

Collagens can be defined as "structural proteins of the extracellular matrix which contain one or more domains harboring the conformation of a collagen triple helix" (Van der Rest and Garrone, 1991). The triple helix motif is composed of three polypeptide chains whose amino acid sequence consists of Gly-X-Y repeats. Due to this particular peptide sequence, each chain is coiled in a left-handed helix, and the three chains assemble in a right-handed triple helix, where Gly residues are in the center of the triple helix and where the lateral chains of X and Y residues are on the surface of the helix (Van der Rest and Garrone, 1991). In about one-third of the cases X is a proline and Y is an hydroxyproline; the presence of hydroxyproline is essential to stabilize the triple helix and is a unique characteristic of collagen molecules. At the time of this review, 19 different types of collagens have been described, which are grouped in subfamilies depending on their structure and/or their function (for review, see Vuorio and de Crombrugghe, 1990; Van der Rest and Garrone, 1991).

Type I, type II, type III, type V, and type XI collagens form the group of fibrillar collagens. The characteristic feature of fibrillar collagens is that they consist of a long continuous triple helix, which self-assembles into highly organized fibrils. These fibrils have a very high tensile strength and play a key role in providing a structural framework for body structures such as skeleton, skin, blood vessels, intestines, or fibrous capsules of organs. Type I collagen, which is the most abundant protein in vertebrates, is present in many organs and is a major constituent of bone, tendons, ligaments, and skin. Type III collagen is less abundant than type I collagen but its distribution essentially parallels that of type I collagen with the exception of bones and tendons, which contain virtually no type III collagen. Moreover, type III collagen is relatively more abundant in distensible tissues such as blood vessels than in nondistensible tissues. Type V collagen is present in tissues that also contain type I collagen. Type II collagen is a major constituent of cartilage and is also present in the vitreous body. As type II, type XI collagen is present in cartilage.

Type IX, type XII, and type XIV collagens constitute the family of fibril-associated collagens [or fibril-associated collagens with interrupted triple helices (FACIT)]. These collagens are associated with fibrillar collagens and could mediate interactions between fibrillar collagens and other components of the extracellular matrix, or between fibrillar collagens and cells. They are composed of three functional domains (Van der Rest and Garrone, 1991): one that interacts with collagen fibrils, one that projects out of the fibril,

and one that is not a triple helical domain, which interacts with extracellular matrix components or with cells. Type IX collagen, which is the best characterized molecule of this family, is present at the surface of type II collagen fibrils and is covalently cross-linked to these fibrils. Type XII and type XIV collagens are thought to be associated with type I collagen molecules. Type XVI and type XIX collagens, which have been described recently, could also belong to the FACIT family (Myers *et al.,* 1994; Pan *et al.,* 1992).

Collagen-forming sheets are composed of type IV collagen and type VIII collagen. Type IV collagen forms a complex three-dimensional network, which is the major component of basement membranes. Type VIII collagen assembles in hexagonal lattices to form Descemet's membrane and separates corneal endothelial cells from the stroma. Type X collagen, which is synthesized exclusively by hypertrophic chondrocytes, has a high degree of structural similarity with type VIII collagen and could belong to the same family, but its physiological role remains elusive (Rosati *et al.,* 1995).

Structure and Synthesis of Type I Collagen

Structure

Each molecule of type I collagen is typically composed of two α1 chains and one α2 chain [$\alpha1(I)_2-\alpha2(I)$] coiled around each other in a characteristic triple helix, but a very small number of type I collagen molecules can be formed by three α1 chains [$\alpha1(I)_3$]. Both the α1 chain and the α2 chain consist of a long helical domain preceded by a short N-terminal peptide and followed by a short C-terminal peptide (Fig. 1) (for reviews, see Prockop, 1979; Prockop and Kivirikko, 1984; Vuorio and de Crombrugghe, 1990; Van der Rest and Garrone, 1991).

Type I collagen is secreted as a propeptide, but the N telopeptide and the C telopeptide are cleaved rapidly by specific proteases (Fig. 1), and mature molecules assemble to form fibrils. In fibrils, molecules of collagen are parallel to each other; they overlap each other by multiples of 67 nm (distance D), with each molecule being 4.4 D (300 nm) long; there is a 40-nm (0.6 D) gap between the end of a molecule and the beginning of the other (Fig. 2). This quarter-staggered assembly explains the banded aspect displayed by type I collagen fibrils in electron microscopy. In tissues, type I collagen fibrils can be parallel to each other and form bundles (or fibers), as in tendons, or they can be oriented randomly and form a complex network of interlaced fibrils, like in skin. In bone, hydroxyapatite crystals seem to lie in the gaps between collagen molecules.

Synthesis

TRANSCRIPTION

In humans the gene coding for the α1 chain of type I collagen is located on the long arm of chromosome 17 (17q21.3–q22), and the gene coding for the α2 chain is located on the long arm of chromosome 7 (7q21.3–q22). Both genes have a very similar structure (Chu *et al.,* 1984; D′Alessio *et al.,* 1988; de Wet *et al.,* 1987), and this structure is also very similar to that of genes coding for other fibrillar collagens (Vuorio and de Crombrugghe, 1990). The difference in size between the two genes [18 kb for the α1(I) gene and 38 kb for the α2(I) gene] is explained by differences in the size of the introns.

The triple helical domain of the α1 chain is coded by 41 exons, which code for Gly-X-Y repeats, and by two so-called

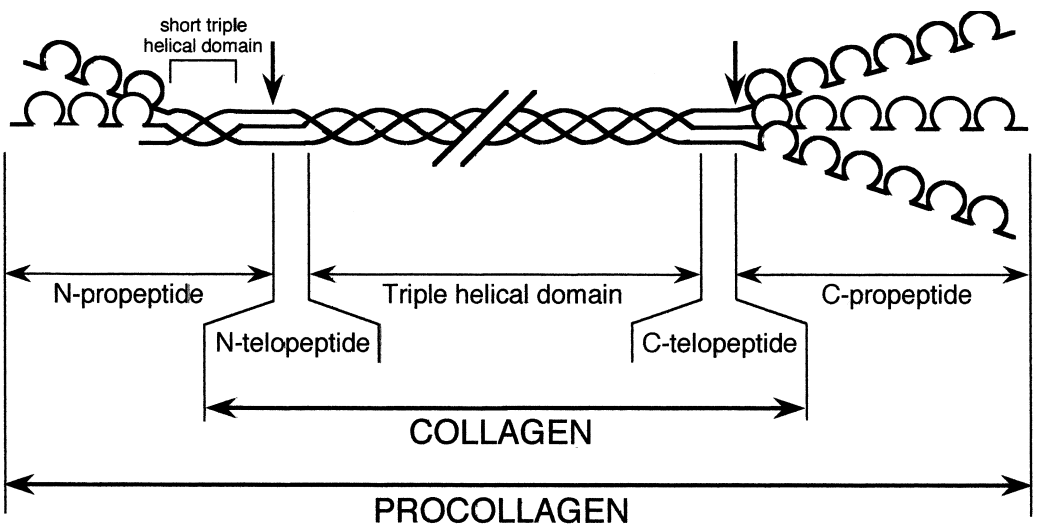

Figure 1 Schematic representation of a type I collagen molecule. Vertical arrows indicate cleavage sites between the mature collagen molecule, the N propeptide and the C propeptide.

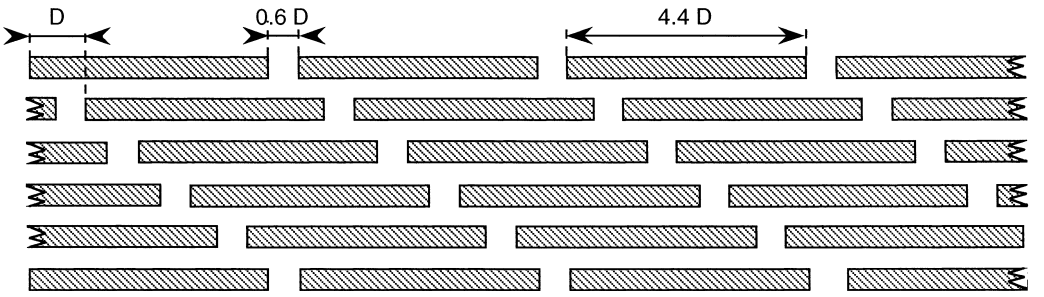

Figure 2 Schematic representation of the quarter-staggered assembly of type I collagen molecules into fibrils. Each collagen molecule is 4.4 D long. Molecules overlap each other by a distance D or multiples of D. There is a 0.6 D gap between the ends of two adjacent nonoverlapping molecules (D = 67 nm).

joining exons. These joining exons code in part for the telopeptides and in part for Gly-X-Y repeats, which are part of the triple helical domain (Fig. 3). The triple helical domain of the α2 chain is coded by 42 exons, plus two joining exons (Fig. 3). Each of the corresponding exons coding for the triple helical domain of the α1 chain and for the triple helical domain of the α2 chain has a similar length (Table I). The only exception is that exons 34 and 35 in the α2 gene, which are 54 bp long each, correspond to a single 108-bp 34/35 exon in the α1 gene. Except for the two joining exons, each exon starts exactly with a G codon and ends precisely with a Y codon, and all the exons are 54, 108 (54 $\times$ 2), 162 (54 $\times$ 3), 45, or 99 bp long (Table I). This organization suggests that exons coding for triple helical domains could have originated from the amplification of a DNA unit containing a 54-bp exon embedded in intron sequences. One hundred and eight- and 162-bp exons would result from a loss of intervening introns. Forty-five- and 99-bp exons would result from recombinations between two 54 exons (Vuorio and de Crombrugghe, 1990; Yamada *et al.,* 1980).

For both the α1 chain and the α2 chain, the C propeptide plus the C telopeptide are coded by 4 exons [exons 48–51 of the α1(I) gene, exons 49–52 of the α2(I) gene]. The first of these exons codes for the end of the triple helical domain, the C-terminal telopeptide, and the beginning of the C-terminal propeptide. The three other exons code for the rest

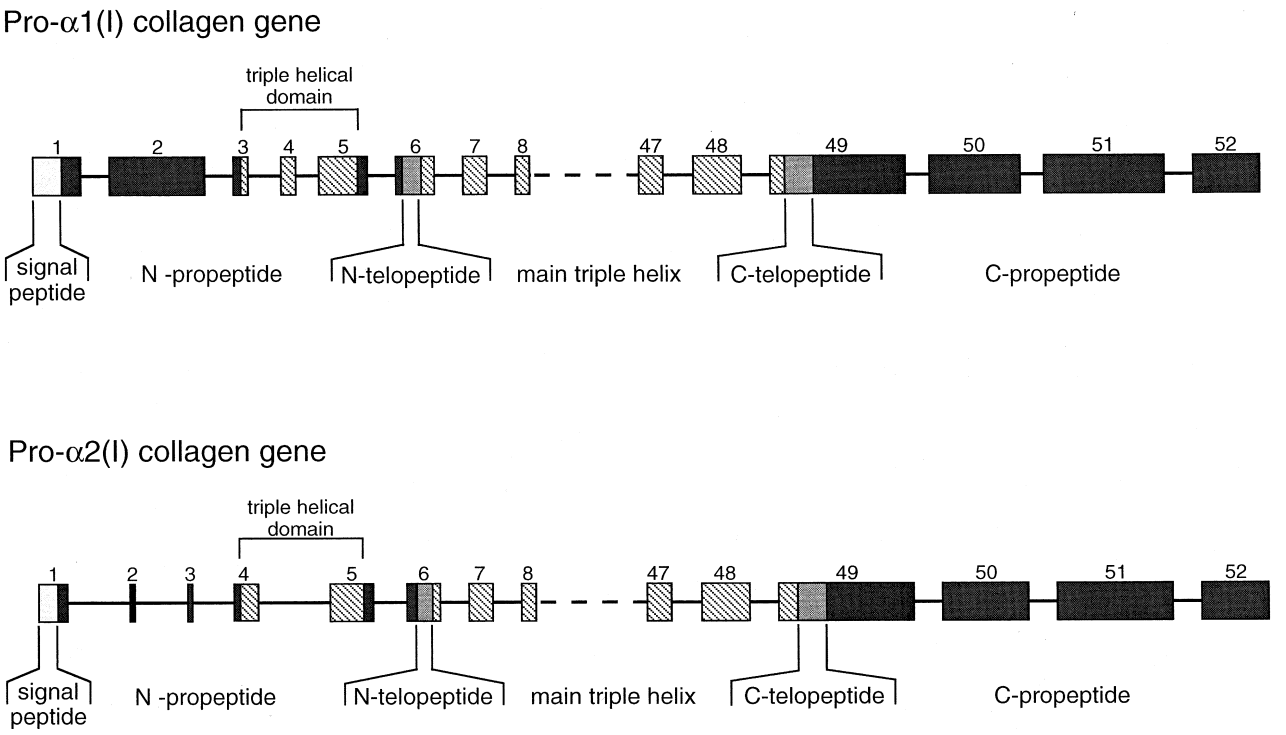

Figure 3 Exon structure of type I procollagen genes. For each chain, the signal peptide is encoded by part of exon 1; the N propeptide is encoded by part of exon 1, by exons 2–5, and by part of exon 6; the N telopeptide is encoded by part of exon 6; the triple helix is encoded by part of exon 6 (joining exon), by exons 7–48, and by part of exon 49 (joining exon); the C telopeptide is encoded by part of exon 49; and the C propeptide is encoded by part of exon 49 and by exons 50–52. Note that N propeptides contain a short helical domain.

Table I Size of Exons Coding for the Triple Helical Domain of Type I Collagen[a]

Exon	Size (bp)	Exon	Size (bp)	Exon	Size (bp)
7	45	21	108	35	54
8	54	22	54	36	54
9	54	23	99	37	108
10	54	24	54	38	54
11	54	25	99	39	54
12	54	26	54	40	162
13	45	27	54	41	108
14	54	28	54	42	108
15	45	29	54	43	54
16	54	30	45	44	108
17	99	31	99	45	54
18	45	32	108	46	108
19	99	33	54	47	54
20	54	34	54	48	108

[a]In the pro-α 1(I) collagen gene, exons 33 (54 bp) and 34 (54 bp) are replaced by a single 108-bp 33/34 exon. The two joining exons (exon 6 and exon 49) are not considered in this table (see text for details).

of the C-terminal propeptide (Fig. 3). The C-terminal propeptide has a globular structure, which is stabilized by two intrachain disulfide bonds (Fig. 1). It contains three (α2 chain) or four (α1 chain) additional cysteine residus that form interchain disulfide bonds. The formation of disulfide bonds precede the triple helix formation and plays an essential role in the intracellular assembly of the three α chains (see Translational and Posttranslational Modifications).

The signal peptide, the N propeptide, and the N telopeptide of the α1 chain, as well as of the α2 chain, are coded by the first six exons (Fig. 3). The N propeptide of the α1 chain contains a cysteine-rich (10 cysteine residue) globular domain, a short triple helical domain, and a short globular domain, which harbors the N-terminal peptidase cleavage site (Fig. 1). The N-terminal propeptide of the α2 chain does not contain a cysteine-rich domain but a short globular domain (Fig. 1). The function of N-terminal propeptides is poorly understood. It has been suggested that they have a role in regulating the diameter of fibrils and/or the rate of transcription of type I collagen chains; moreover, removal of propeptides is a prerequisite for proper fibrillogenesis.

The 3′-untranslated region of both the α1(I) gene and the α2(I) gene contains more than one polyadenylation site, which explains that mRNAs with different sizes will be generated. As in many other genes, the functional role of these different polyadenylation sites are still unknown.

Translation and Posttranslational Modifications

After being transcribed, the pre-mRNA undergoes exon splicing, capping, and addition of a poly(A)tail, which gives rise to a mature mRNA. These mature mRNAs are then translated in polysomes, and the resulting proteins undergo extensive posttranslational modifications before being assembled in a triple helix and released in the extracellular space (for reviews, see Prockop *et al.,* 1979, Prockop and Kivirikko, 1984).

Signal peptides are cleaved from the chains when their N-terminal end enters the cisternae of the rough endoplasmic reticulum.

Both the pro-α1 chain and the pro-α2 chain undergo hydroxylation and glycosylation, and these modifications are essential for the assembly of type I collagen chains in a triple helix. About 100 proline residues in the Y position of the Gly-X-Y repeats, a few proline residues in the X position, and about 10 lysine residues in the Y position undergo hydroxylation, respectively, by a prolyl 4-hydroxylase, a prolyl 3-hydroxylase, and a lysyl hydroxylase. Hydroxylation of proline to hydroxyproline is critical to obtain a stable triple helix, and at 37°C, stable folding in a riple helical conformation cannot be obtained before at least 90 prolyl residues have been hydroxylated. These hydroxylases have different requirements to be active, and in particular they can act only when prolyl or lysyl residues occupy the correct position in the amino acid sequence of the α chain and when peptides are not in a triple helical configuration. Moreover, these enzymes require ferrous ions, molecular oxygen, α-ketoglutarate, and ascorbic acid to be active. This requirement for ascorbic acid could explain some of the consequences of scurvy on wound healing. When lysyl residues become hydroxylated, they serve as a substrate for a glycosyltransferase and for a galactosyltransferase, which add glucose and galactose, respectively, to the ε-OH group. As for hydroxylases, glycosylating enzymes are active only

when the collagen chains are not in a triple helical conformation. Glycosylation interferes with the packaging of mature molecules into fibrils, and increased glycosylation tends to decrease the diameter of fibrils.

While hydroxylations and glycosylations described previously occur, and after a mannose-rich oligosaccharide is added to the C propeptide of each pro- α chain, C propeptides from two α1 chains and one α2 chain associate with the formation of intrachain and interchain disulfide bonds. After prolyl residues have been hydroxylated, and the three C propeptides have associated, a triple helix will form at the C-terminal end of the molecule and then extend toward the N-terminal end; this propagation of the triple helical configuration occurs in a "zipper-like fashion" (Prockop, 1990). If prolyl residues are not hydroxylated or if interchain disulfide bonds are not formed between the C propeptides, the α chain will not fold in a triple helix. Hsp47, which is a collagen-specific molecular chaperone, then stabilizes the triple-helical forms of type I collagen molecules in the endoplasmic reticulum (Tasab *et al.,* 2000; Nagai *et al.,* 2000). As soon as procollagen molecules are in a triple helical conformation, they are transported from the rough endoplasmic reticulum into Golgi vesicles and secreted in the extracellular space. In contrast, in the absence of triple helical folding, collagen molecules will not be secreted.

In the extracellular space, a specific procollagen aminopepeptidase and a specific procollagen carboxypeptidase cleave the propeptides, giving rise to mature collagen molecules (Fig. 1). Cleavage of the propeptide decreases the solubility of collagen molecules dramatically. The free propeptides are believed to be involved in feedback regulation of collagen synthesis.

Fibrillogenesis

In the extracellular space, the molecules of mature collagen assemble spontaneously into quarter-staggered fibrils (Fig. 2); this assembly is directed by the presence of clusters of hydrophobic and of charged amino acids on the surface of the molecules. Fibril formation has been compared to crystallization in that it follows the principle of "nucleated growth" (Prockop, 1990). Once a small number of molecules have formed a nucleus, it grows rapidly to form large fibrils. During fibrillogenesis, some lysyl and hydroxylysyl residus are deaminated by a lysine oxidase, which deaminates the ε-NH_2 group, giving rise to aldehyde derivatives. These aldehydes will associate spontaneously with ε-NH_2 groups from a lysyl or hydroxylysyl residue of adjacent molecules, forming interchain cross-links. These cross-links will increase the tensile strength of the fibrils considerably.

Consequences of Genetic Mutations on Type I Collagen Formation

Osteogenesis imperfecta (also known as "brittle bone disease") is a genetic disease characterized by an extreme fragility of bones. Genetic studies have shown that it is due to a mutation in the coding sequence of either the pro-α1(I) gene or the pro- α2(I) gene, and more than 150 mutations have been identified (for review, see Kuivaniemi *et al.,* 1997). Most severe cases of osteogenesis imperfecta result from mutations that lead to the synthesis of normal amounts of an abnormal chain, which can have three consequences. First, the structural abnormality can prevent the complete folding of the three chains in a triple helix, e.g., if a glycine is substituted by a bulkier amino acid that will not fit in the center of the triple helix. In this case, the incompletely folded triple helical molecules will be degraded intracellularly, resulting in a phenomenon known as "procollagen suicide." Second, some mutations appear not to prevent folding of the three chains in a triple helix, but presumably prevent proper fibril assembly. For example, D. Prockop's group has shown that a mutation of the pro-α1(I) gene that changed the cysteine at position 748 to a glycine produced a kink in the triple helix (Kadler *et al.,* 1991). Finally, some mutations will not prevent triple helical formation or fibrillogenesis but might modify the structural characteristic of the fibrils slightly and thus affect their mechanical properties. In all these cases, the consequence on the mechanical properties of bone is probably similar. Mild forms of osteogenesis imperfecta most often result from a functionally null allele, which decreases the production of normal type I collagen. Null mutations are usually the result of the existence of a premature stop codon or of an abnormality in mRNA splicing. In these cases, the abnormal mRNA appears to be retained in the nucleus (Redford-Badwal *et al.,* 1996; Johnson *et al.,* 2000). A mouse model of *osteogenesis imperfecta* has been obtained by using a knock-in strategy that introduced a $Gly^{349} \rightarrow Cys$ mutation in the pro-α1(I) collagen gene (Forlino *et al.,* 1999). This model faithfully reproduced the human disease.

Ehlers-Danlos syndrome type VIIA and VIIB are two rare dominant genetic diseases characterized mainly by an extreme joint laxity. They result from mutations in the pro-α1(I) collagen gene (Ehlers-Danlos syndrome type VIIA) or in the pro-α2(I) collagen gene (Ehlers-Danlos syndrome type VIIB) that interfere with the normal splicing of exon 6, and a little less than 20 mutations have been described. These mutations can affect the splice donor site of intron 7 or the splice acceptor site of intron 5; in the latter case, there is efficient recognition of a cryptic site in exon 6 (Byers *et al.,* 1997). Thus, these mutations induce a partial or complete excision of exon 6. They do not appear to affect the secretion of the abnormal pro-collagen molecules, but they are responsible for the disappearance of the cleavage site of the N-terminal propeptide and thus for the presence of patially processed collagen molecules in fibrils that fail to provide normal tensile strength to tissues (Byers *et al.,* 1997). Nevertheless, these mutations seem to affect the rate of cleavage of the N-terminal propeptide rather than to completely prevent it, which explains that the phenotype is less severe than for patients who do not have a functional N-proteinase (Ehlers-Danlos syndrome type VIIC).

Regulation of Type I Collagen Synthesis

Different cytokines, hormones, vitamins, and growth factors can modify type I collagen synthesis by osteoblasts and/or fibroblasts (Table II). The effects of these molecules have been studied mainly *in vitro* using either bone organ cultures or cell cultures. In only a few instances, the *in vivo* effects of these factors on type I collagen synthesis have been studied. A degree of complexity is due to the fact that some factors can act directly on type I collagen synthesis but can also act indirectly by modifying the secretion of other factors, which will themselves affect type I collagen synthesis. For example, TNF-α will directly inhibit type I collagen production, but it will also induce the secretion of prostaglandin E_2 (PGE_2) and of IL-1, which will directly affect type I collagen production. Furthermore, PGE_2 will induce the production of IGF-1, which also modifies the rate of type I collagen synthesis.

Growth Factors

Transforming Growth Factor β

In mammals, the transforming growth factor β (TGF-β) family consists of three members (TGF-β1, TGF-β2, and TGF-β3), which have similar biological effects but have different spatial and temporal patterns of expression. These three molecules are part of a large family, the TGF-β superfamily, which also contains proteins such as bone morphogenetic proteins (Kingsley, 1994). TGF-βs are secreted by many cell types, including monocytes/macrophages, lymphocytes, platelets, fibroblasts, osteoblasts, and osteoclasts (Thompson *et al.,* 1989; Thorp *et al.,* 1992). Synthesis by bone cells is quantitatively important because, *in vivo*, the highest levels of TGF-β are found in platelets and bone (Seyedin *et al.,* 1985). Nearly all cells, including osteoblasts and fibroblasts, have TGF-β receptors (Massagué, 1990).

Regulation of type I collagen synthesis by TGF-β has been studied mostly using TGF-β1. It is secreted as pro-TGF-β1, and its propeptide is cleaved in the extracellular space, giving rise to mature TGF-β1. Mature TGF-β1 then associates noncovalently with a dimer of its N-terminal propeptide (also called LAP, for latency-associated peptide), which is itself often disulfide linked to other proteins called LTBPs (for latent TGF-β1 binding proteins). These complexes are devoid of biological activity and can be considered as a storage form of TGF-β1. They increase the stability of TGF-β1 and target it to cell surfaces and extracellular matrix. One of the key steps in regulating the activity of TGF-β1 is the cleavage of latent TGF-β1 from LAP and LTBPs, but the factors responsible for the *in vivo* transformation of latent TGF-β1 into active TGF-β1 are still poorly known. Calpain, cathepsin, or oxygen-free radicals can activate TGF-β1 *in vitro,* but their *in vivo* roles are unknown. Plasmin can activate TGF-β1 *in vitro,* and different groups have postulated that it might play a role *in vivo* (Munger *et al.,* 1997), but plasminogen-null mice did not replicate the phenotype of TGF-β1-null mice, and the pathology of these mice could be alleviated by the removal of fibrinogen (Kulkarni *et al.,* 1993; Bugge *et al.,* 1996). Thrombospondin-1 is also able to transform latent TGF-β1 into active TGF-β1 *in vitro,* and analysis of mice harboring a targeted disruption of the corresponding gene suggests that it probably plays an important role *in vivo* (Crawford *et al.,* 1998). In particular, the phenotype of *thrombospondin-1*-null mice was relatively similar to the one of *TGF-*β1-null mice, and fibroblasts isolated from the former mice had a decreased ability to activate TGF-β1. Nevertheless, thrombospondin-1 is probably not the only molecule that activates TGF-β *in vivo* (Abdelouahed *et al.,*

Table II Schematic Representation of the Effects of Soluble Molecules on Type I Collagen Synthesis by Osteoblastic Cells

2000). Once active, TGF-β1 binds to specific receptors that belong to the family of serine-threonine kinase receptors (reviewed in Massagué, 1998). It first binds to type II receptors (TBR-II), and then type I receptors (TBR-I) bind to TGF-β1–TBR-II complexes. TGF-β1 molecules, which are present within the extracellular space as homodimers, probably bind two TBR-II and then two TBR-I. When TGF-β1 is bound to its receptors, TBR-II phosphorylates TBR-I, which becomes activated and phosphorylates intracellular proteins called Smad 2 and Smad 3. This phosphorylation modifies the conformation of the Smad proteins and enables them to heterooligomerize with Smad 4, which is another member of the Smad family of proteins. Smad 2–Smad 4 complexes and Smad 3–Smad 4 complexes are then translocated into the nucleus, where they bind to specific DNA sequences called Smad-binding elements, and act as transcription factors (Fig. 4, see also color plate). Several transcription factors and transcriptional coactivators have been shown to cooperate with Smad complexes, such as Sp1, Ap-1, PEBP2/CBF, TFE-3, ATF-2, or CBP/p300 (reviewed in Attisano and Wrana, 2000).

The role of TGF-β on type I collagen synthesis has been demonstrated both *in vivo* and *in vitro. In vivo,* subcutaneous injections of platelet-derived TGF-β in newborn mice increased type I collagen synthesis by dermal fibroblasts with formation of granulation tissue (Roberts *et al.,* 1986). Injections of platelet-derived TGF-β onto the periostea of parietal bone of newborn rats stimulated bone formation, and thus accumulation of extracellular matrix (Noda and Camilliere, 1989). Transgenic mice that overexpressed mature TGF-β1 developed hepatic fibrosis and renal fibrosis (Sanderson *et al.,* 1995). Increased expression of TGF-β2 in osteoblasts in transgenic mice resulted in an osteoporosis-like phenotype with progressive bone loss. The bone loss was associated with an increase in osteoblastic matrix deposition and osteoclastic bone resorption (Erlebacher and Derynck, 1996). Conversely, expression of a dominant-negative TGF-β receptor mutant in osteoblasts led to decreased bone remodeling and increased trabecular bone mass (Filvaroff *et al.,* 1999). In humans, mutations in the latency-associated peptide of TGF-β1 (LAP) causes Camurati–Engelmann disease, a rare sclerosing bone dysplasia inherited in a autosomal-dominant matter. It is unclear whether these mutations impair the ability of the LAP to inhibit TGF-β activity or whether the mutations cause accelerated degradation of TGF-β (Kinoshita *et al.,* 2000; Janssens *et al.,* 2000). Administration of anti-TGF-β antibodies or administration of decorin (which binds to TGF-β and neutralizes its biological activity) downmodulated extracellular matrix accumulation in a model of proliferative glomerulonephritis (Border *et al.,* 1990, 1992; Isaka *et al.,* 1996). *In vitro,* TGF-β stimulates the synthesis

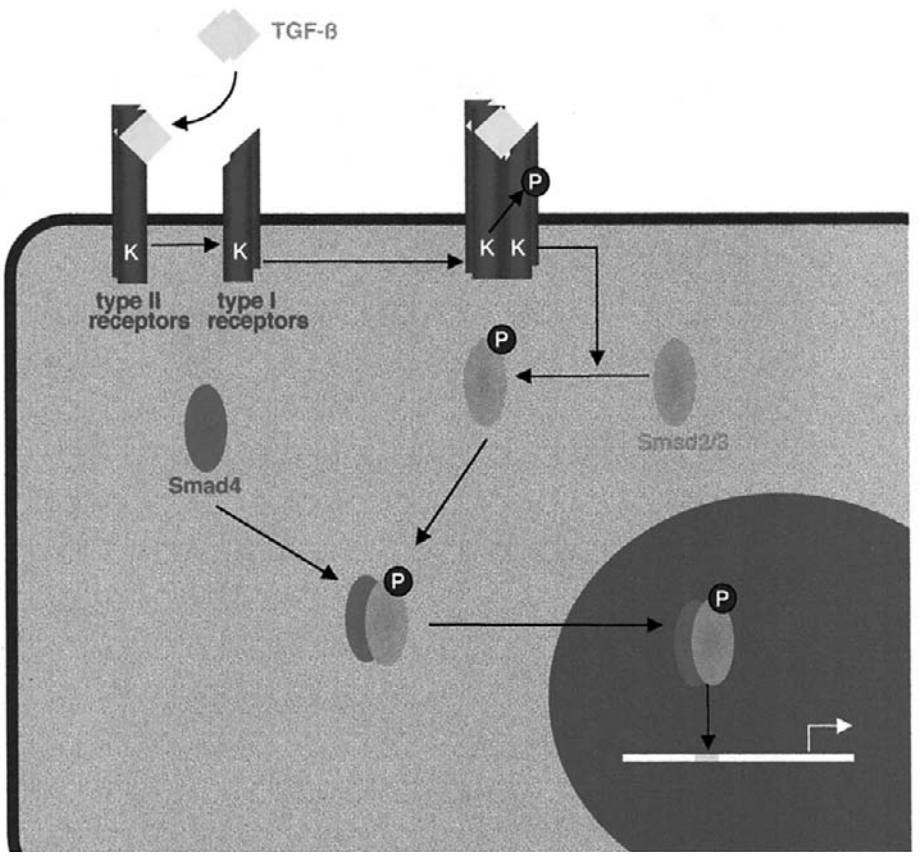

Figure 4 Schematic representation of the Smad signaling pathway mediating transcriptional effects of TGF-β (see text for details). (See also color plate.)

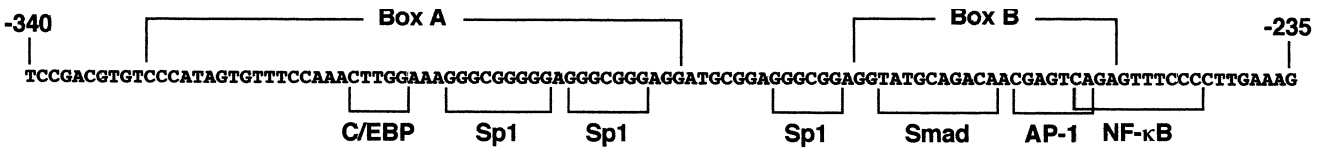

Figure 5 Schematic representation of the cytokine responsive element (CyRC) in the human pro-α2(I) promoter. Sp1, Smad, and AP-1 have been shown to bind to this element and have been implicated in the positive transcriptional effects of TGF-β, whereas C/EBP and NF-κB have been shown to participate in the inhibitory effects of TNF-α.

of most of the structural components of the extracellular matrix by fibroblasts and osteoblasts, including type I collagen (for a review, see Massague, 1990). It also decreases extracellular matrix degradation by repressing the synthesis of collagenases and stromelysins and by increasing the synthesis of tissue inhibitors of metalloproteinases (TIMPs). It increases lysyl-oxidase activity, which may favor interchain cross-linking in collagen fibrils (cf. supra) (Feres-Filho *et al.,* 1995). Finally, it stimulates the proliferation of both fibroblasts and osteoblasts, in contrast to its inhibitory effect on the proliferation of epithelial cells. Moreover, TGF-β may have a role in controlling the lineage-specific expression of type I collagen genes during embryonic development, as there is an excellent temporal and spatial correlation between activation of type I collagen genes and presence of immunoreactive TGF-β in the extracellular environment (Niederreither *et al.,* 1992). Data suggest that part of the profibrotic properties of TGF-β may be indirect, mediated by an increased production of a cysteine-rich protein called connective tissue growth factor (CTGF) (reviewed in Grotendorst, 1997). Expression of the *CTGF* gene in fibroblasts is strongly induced by TGF-β but not by other growth factors, and intradermal injections of TGF-β in neonatal mice induced an overexpression of *CTGF* in skin fibroblasts (Igarashi *et al.,* 1993; Frazier *et al.,* 1996). *In vitro,* CTGF is chemotactic and mitogenic for fibroblasts and it increases the production of type I collagen by these cells, whereas *in vivo* intradermal injections of CTGF induce the formation of a granulation tissue similar to the one induced by injections of TGF-β1 (Frazier *et al.,* 1996; Duncan *et al.,* 1999).

In vitro, TGF-β acts at a pretranslational level, increasing mRNA levels of the pro-α1(I) and pro-α2(I) transcripts. This increase in type I collagen mRNA levels can be due to an increase in the transcription rate of type I collagen genes and/or to an increase in procollagen mRNA stability, with the relative contribution of these two mechanisms depending on cell types and on cultures conditions. For example, mRNA stability was increased in confluent but not in subconfluent cultures of Swiss mouse 3T3 cells (Penttinen *et al.,* 1988).

The effect of TGF-β on transcription of the human pro-α2(I) collagen gene involves Smad complexes (Chen *et al.,* 1999, 2000a). It seems to be mediated through a sequence of the promoter located between 378 and 183 bp upstream of the start site of transcription and is called "TGF-β responsive element," as demonstrated by transfection experiments (Inagaki *et al.,* 1994). Footprinting experiments performed with this sequence revealed two distinct segments interacting with DNA-binding proteins, called box A and box B (Inagaki *et al.,* 1994) (Fig. 5). Box A, which is located between -330 and -286, corresponds to a promoter sequence of the mouse pro-α2(I) collagen gene, which plays an important role in mediating TGF-β effects on transcription (Rossi *et al.,* 1988). It contains two binding sites for Sp1 (Inagaki *et al.,* 1994; Greenwel *et al.,* 1997), as well as a binding site for C/EBP. Box B, which is located between -271 and -250, contains a CAGA box that binds Smad 3/Smad 4 complexes (Zhang *et al.,* 2000), as well as a binding site for AP-1 (Chung *et al.,* 1996) and a potential binding site for NF-kB (Kouba *et al.,* 1999). Data have shown that Smad 3/Smad 4 complexes can bind to box B and mediate TGF-β-induced stimulation of the pro-α2(I) collagen gene, in cooperation with Sp1 proteins that bind to box A (Zhang *et al.,* 2000). The role of AP-1 in mediating the effects of TGF-β has also been suggested, but it is still controversial (Chang and Goldberg, 1995; Chung *et al.,* 1996; Greenwel *et al.,* 1997; Zhang *et al.,* 2000). The transcriptional coactivator CBP/p300, which can bind to Smad complexes, also plays an important role in mediating the effects of TGF-β on the transcriptional activity of the pro-α2(I) collagen gene (Ghosh *et al.,* 2000). Thus, TGF-β probably activates the transcription of the pro-α2(I) collagen gene through the binding of a multimeric complex, which includes Smad 3/Smad 4, Sp1, CBP/p300, and possibly AP-1.

A TGF-β response element has been described about 1.6 kb upstream of the start site of transcription in the rat pro-α1(I) collagen gene (Ritzenthaler *et al.,* 1993) and between-174 and -84 bp in the human pro-α1 collagen gene (Jimenez *et al.,* 1994). The latter sequence contains an Sp1-like binding site and, as boxes A plus B in the human pro-α2(I) promoter, could bind a multimeric complex containing Sp1 or an Sp1-related protein (Jimenez *et al.,* 1994), but none of these two sequences seems to contain a potential Smad-binding site.

INSULIN-LIKE GROWTH FACTORS

Insulin-like growth factor I (IGF-I) is synthesized by many cells, including bone cells, and, unlike other growth factors, circulates in blood. It can stimulate osteoblast and

fibroblast proliferation and increase type I collagen production by these cells. Its effect on type I collagen production by osteoblasts has been demonstrated by using both fetal rat calvariae and osteoblastic cells, and it is related to an increase in corresponding mRNA transcripts (McCarthy *et al.,* 1989a; Thiebaud *et al.,* 1994; Woitge *et al.,* 2000). *In vivo,* administration of IGF-I to hypophysectomized rats increased mRNA transcripts for pro-α1(I) and pro-α2(I) collagen genes in parietal bones (Schmid *et al.,* 1989).

Insulin-like growth factor II (IGF-II), which is produced by bone cells and is one of the most abundant growth factors found in bone extracellular matrix, can also stimulate type I collagen synthesis by osteoblastic cells, with an increase in corresponding mRNA transcripts (McCarthy *et al.,* 1989a; Strong *et al.,* 1991; Thiebaud *et al.,* 1994).

Basic Fibroblast Growth Factor

Basic fibroblast growth factor (bFGF) inhibits type I collagen synthesis by bone organ cultures (Canalis *et al.,* 1988; Hurley *et al.,* 1992), by osteoblastic cells (Hurley *et al.,* 1993; McCarthy *et al.,* 1989b; Rodan *et al.,* 1989), by dermal fibroblasts (Ichiki *et al.,* 1997), and by vascular smooth muscle cells (Kyperos *et al.,* 1998). This inhibitory effect is associated with a decrease in the levels of type I collagen mRNAs (Hurley *et al.,* 1993; Rodan *et al.,* 1989), and the action of bFGF has been shown to be mediated at a transcriptional level (Hurley *et al.,* 1993; Kyperos *et al.,* 1998). Moreover, studies of MC3T3-E1 osteoblastic cells stably transfected with a construct containing either a 2.3-kb segment or a 3.6-kb segment of the rat pro-α1(I) proximal promoter cloned upstream of the CAT reporter gene have shown that the activity of the reporter gene was inhibited by bFGF only in cells harboring the 3.6-kb segment of the promoter, which suggests that a bFGF responsive element is located between 2.3 and 3.6 kb upstream of the start site of transcription (Hurley *et al.,* 1993).

Cytokines

Tumor Necrosis Factor α

Tumor necrosis factor α (TNF-α) is a cytokine secreted mainly by monocytes/macrophages, but osteoblasts seem to be able to produce TNF-α under certain conditions (Gowen *et al.,* 1990). After being cleaved from its propeptide, TNF-α undergoes trimerization and binds to type I receptors, which transduce most of the effects of TNF-α, or to type II receptors. TNF-α stimulates fibroblast and osteoblast proliferation (Gowen *et al.,* 1988), inhibits the production of extracellular matrix components, including type I collagen, and increases collagenase production and thus extracellular matrix degradation. It also counteracts the stimulation of type I collagen production induced by TGF-β. *In vivo,* inoculation of nude mice with TNF-α-producing cells decreased type I collagen production in skin and liver, impaired wound healing, and decreased TGF-β1 synthesis in skin (Buck *et al.,* 1996; Hoglum *et al.,* 1998). In contrast, in two models of pulmonary fibrosis, the administration of anti-TNF-α antibodies decreased collagen production (Piguet *et al.,* 1989, 1990), but this effect may be indirect due to an inhibition of the inflammatory reaction induced by TNF-α. In tissue culture, TNF-α ibited the production of type I collagen by rat fetal calvaria, osteoblastic cells (Bertolini *et al.,* 1986; Canalis, 1987; Centrella *et al.,* 1988; Nannes *et al.,* 1989), and by fibroblastic cells (Diaz *et al.,* 1993; Mauviel *et al.,* 1991; Solis-Herruzo *et al.,* 1988). TNF-α also increases PGE_2 and interleukin 1 (IL-1) production by osteoblasts and fibroblasts, which themselves modulate type I collagen synthesis (cf. infra).

Inhibition of collagen synthesis in fibroblasts by TNF-α is associated with a decrease in mRNA levels for the pro-α1(I) and pro-α2(I) transcripts and in the transcription of type I collagen genes (Solis-Herruzo *et al.,* 1988). In dermal fibroblasts, transfection experiments using the human pro-α2(I) collagen proximal promoter cloned upstream of a reporter gene have shown that the effects of TNF-α on transcription are mediated by the same sequence that mediates the effects of TGF-β (cf. supra), and this sequence has been renamed "cytokine responsive complex" or CyRC (Inagaki *et al.,* 1995; Kouba *et al.,* 1999; Greenwel *et al.,* 2000). TNF-α has been shown to induce the binding of NF-κB and of CCAAT/enhancer-binding proteins (C/EBP) to CyRC (Kouba *et al.,* 1999; Greenwel *et al.,* 2000). These factors may decrease the activity of the pro-α2(I) promoter by interacting with Sp1 proteins bound to CyRC, as TNF-α did not influence the activity of the pro-α2(I) proximal promoter when cells were stably transfected with a cDNA encoding a dominant-negative Sp1 (Zhang *et al.,* 2000). The antagonist activities of TGF-β and TNF-α may be the result of steric interactions between transcription factors binding to CyRC. Furthermore, TNF-α has been shown to activate AP-1, which can interact with Smad proteins and with CBP/p300 "off-DNA" (Verrecchia *et al.,* 2000).

Transfection studies performed using hepatic stellate cells and the rat pro-α1(I) proximal promoter have shown that a sequence located between -378 and -345 bp mediated the inhibitory effects of TNF-α (Iraburu *et al.,* 2000). They could be mediated through the binding of proteins of the C/EBP family, such as C/EBP delta and p20C/EBP beta, which is reminiscent of results obtained with the pro-α2(I) promoter (Iraburu *et al.,* 2000; Greenwel *et al.,* 2000). Other TNF-α response elements have been identified within the pro-α1(I) collagen gene, between -101 and -38 bp and between 68 and 86 bp, using dermal fibroblasts and hepatic stellate cells, respectively (Mori *et al.,* 1996; Hernandez *et al.,* 2000). The latter *cis*-acting element binds proteins of the Sp1 family, while the proteins binding to the former one have not been identified (Mori *et al.,* 1996; Hernandez *et al.,* 2000). Using two lines of transgenic mice harboring the growth hormone reporter gene under the control of either 2.3 kb of the human pro-α1(I) proximal promoter plus the first intron or 440 bp of this promoter plus the first intron, Chojkier's group has reported that different *cis*-acting elements mediate the

inhibitory effects of TNF-α, depending on the tissue (Buck *et al.,* 1996; Hoglum *et al.,* 1998). In skin, the inhibitory effect of TNF-α on the activity of the reporter gene was mediated through a *cis*-acting element located between -2.3 kb and -440 bp (Buck *et al.,* 1996). In contrast, in liver, it was mediated through an element located between -440 and $+$ 1607 bp (Hoglum *et al.,* 1998).

Interleukin 1

Interleukin 1 (IL-1) is a cytokine secreted mainly by monocytes/macrophages, but also by other cells, including fibroblasts, osteoblasts, synoviocytes, and chondrocytes. Two forms of IL-1 have been described, IL-1α and IL-1β, which have little primary structure homology but bind to the same receptor and have similar biological activities.

In vitro, IL-1 has an inhibitory effect on type I collagen production by osteoblasts, which is due to an inhibition of type I collagen gene transcription (Harrison *et al.,* 1990). Nevertheless, it can be masked when low doses of IL-1 are used, as this cytokine stimulates the production of PGE_2 (Smith *et al.,* 1987), which in turn can modulate type I collagen synthesis (cf. arachidonic acid derivatives). Slack *et al.* (1993) have suggested that the inhibitory effects of IL-1 on the transcription of the human pro-α1(I) collagen gene by osteoblasts could be mediated through the binding of AP-1 to the first intron of the gene, but this hypothesis has not been confirmed.

In vitro, the direct effect of recombinant IL-1 on fibroblastic cells is most often an increase in type I collagen production, but sometimes this enhancing effect is apparent only when the IL-1-induced synthesis of PGE_2 is blocked by indomethacin (Diaz *et al.,* 1993; Duncan *et al.,* 1989; Goldring and Krane, 1987). It is mediated through an increase in mRNA levels, but the respective roles of an increase in transcription rate or in mRNA stability are not known.

Interferon γ

Interferon γ (IFN-γ) is a cytokine produced both by monocytes/macrophages and by type I helper T cells. *In vivo,* IFN-γ decreases cutaneous fibrosis after wounding (Granstein *et al.,* 1989) or after insertion of an alloplastic implant (Granstein *et al.,* 1987). *In vitro,* IFN-γ decreases osteoblast and fibroblast proliferation and type I collagen synthesis by these cells (Czaja *et al.,* 1987; Diaz and Jimenez, 1997). This latter effect seems to be due to a decrease in type I collagen mRNA stability (Czaja *et al.,* 1987; Kahari *et al.,* 1990) and in the transcription rate of the pro-α1(I) collagen gene (Rosenbloom *et al.,* 1984; Diaz and Jimenez, 1997; Yuan *et al.,* 1999). Transfection studies using different segments of the human pro-α1(I) proximal promoter have shown the existence of an IFN-γ response element between -129 and -107 bp, which can bind transcription factors of the Sp1 family (Yuan *et al.,* 1999). In the human pro-α2(I) collagen gene, an IFN-γ response element has been identified between -161 and 125 bp using transfection experiments in dermal fibroblasts (Higashi *et al.,* 1998).

Other Cytokines

Interleukin 4 (IL-4) is secreted by type 2 helper T cells and by mastocytes. *In vitro,* IL-4 increases type I collagen production by human fibroblasts by increasing both transcriptional levels of type I collagen genes and stability of the corresponding mRNAs (Postlethwaite *et al.,* 1992; Serpier *et al.,* 1997).

Interleukin 10 (IL-10), which is secreted mainly by monocytes/macrophages, inhibits type I collagen genes transcription and type I collagen production by skin fibroblasts (Reitamo *et al.,* 1994).

Oncostatin M is produced mainly by activated T cells and monocytes/macrophages and belongs to the hematopoietic cytokine family. It is mitogenic for fibroblasts and stimulates type I collagen production by fibroblasts by increasing transcriptional levels of type I collagen genes (Duncan *et al.,* 1995; Ihn *et al.,* 1997). Transfection studies performed using different segments of the human pro-α2(I) collagen gene have shown that a 12-bp segment located between -131 and -120 bp, and that contains a TCCTCC motif, mediated the stimulatory effects of oncostatin M (Ihn *et al.,* 1997).

Arachidonic Acid Derivatives

PGE_2, a product of the cyclooxygenase pathway, is synthesized by various cell types, including endothelial cells, monocytes/macrophages, osteoblasts, and fibroblasts. Its production by these latter cells is increased by IL-1 and TNF-α. PGE_2 has a biphasic effect on type I collagen synthesis by bone organ cultures and by osteoblastic cells. At low concentration, it increases type I collagen synthesis, whereas at higher concentrations it decreases type I collagen synthesis (Raisz and Fall, 1990). PGE_2 induces the production of IGF-I by osteoblastic cells, and part of the stimulatory effect of low doses of PGE_2 on type I collagen production seems to be indirect, mediated by a stimulation of IGF-I production (Raisz *et al.,* 1993). Nevertheless, part of this stimulatory effect is independent of IGF-I production and persists after blocking the effects of IGF-I (Raisz *et al.,* 1993ba). It is of note that when PGE_2 is added to fibroblasts in culture, it inhibits type I collagen synthesis and decreases the levels of the corresponding mRNAs (Fine *et al.,* 1989).

Most of the effects of PGE_2 are mediated through an increase in cAMP levels (Yamamoto *et al.,* 1988), and the activation of collagen synthesis by low doses of PGE_2 could be due to such a mechanism, as cAMP analogs can also increase collagen synthesis in bone (Fall *et al.,* 1994). In contrast, the inhibitory effect of PGE_2, which has been shown to be due to an inhibition of transcription of type I collagen genes, is not mediated through a cAMP-dependent pathway but through a pathway involving the activation of protein kinase C (Fall *et al.,* 1994; Raisz *et al.,* 1993ab). A study using an osteoblastic cell line transfected stably with various segments of the rat pro-α1(I) promoter cloned upstream of a CAT reporter gene has shown that PGE_2 acts

through an element located more than 2.3 kb upstream of the start site of transcription (Raisz *et al.,* 1993a). A more recent study using fibroblasts transfected transiently with a construct containing 220 bp of the mouse pro-α1(I) proximal promoter has shown that PGE_2 can also act through a cis-acting element located within this promoter segment (Riquet *et al.,* 2000).

Hormones and Vitamins

CORTICOSTEROIDS

It has been known for many years that the administration of corticosteroids to patients results in osteoporosis and growth retardation. In mice, corticosteroids have also been shown to decrease collagen production in calvariae (Advani *et al.,* 1997). *In vitro,* incubation of fetal rat calvariae with high doses of corticosteroids, or with lower doses but for a prolonged period of time, decreased the synthesis of type I collagen (Canalis, 1983; Dietrich *et al.,* 1979); this inhibitory effect could also be observed with osteoblastic cell lines (Hodge and Kream, 1988). Nuclear runoff experiments performed using osteoblasts derived from fetal rat calvariae showed that glucocorticoids downregulate transcriptional levels of the pro-α1(I) collagen gene, as well as stability of the corresponding mRNA (Delany *et al.,* 1995). Because corticosteroids inhibit the secretion of IGF-I, part of their inhibitory effect on type I collagen synthesis could be indirect (cf. supra), but calvariae from IGF-I-null mice maintain their responsiveness to glucocorticoids (Woigte *et al.,* 2000). Glucocorticoids can also stimulate type I collagen synthesis by bone organ cultures under certain culture conditions, or by some osteoblastic cell lines, but a study performed with various osteoblastic clones derived from the same cell line has suggested that the stimulation of type I collagen synthesis was indirect, secondary to the induction of differentiation of osteoblastic cells toward a more mature phenotype (Hodge and Kream, 1988).

When added to fibroblasts in culture, corticosteroids usually decrease type I collagen synthesis by acting at a pretranslational level, which is in agreement with their *in vivo* effect on wound healing (Cockayne *et al.,* 1986; Raghow *et al.,* 1986). Stable transfection experiments using the mouse pro-α2(I) proximal promoter fused to a CAT reporter gene and transfected into fibroblasts have shown that sequences located between -2048 and -981 bp and between -506 and -351 bp were important for the corticosteroid-mediated inhibition of transcription, but the *cis*-acting element(s) responsible for this inhibition has not yet be identified (Perez *et al.,* 1992).

PARATHYROID HORMONE

In vitro, parathyroid hormone inhibits type I collagen synthesis by osteoblastic cell lines as well as by bone organotypic cultures (Dietrich *et al.,* 1976; Kream *et al.,* 1986). This inhibitory effect is associated with a decrease in the levels of procollagen mRNAs (Kream *et al.,* 1980, 1986). When calvariae of transgenic mice harboring a 1.7-, 2.3-, or 3.6-kb segment of the rat pro-α1(I) proximal promoter were cultured in the presence of parathyroid hormone, there was a parallel decrease in the incorporation of [^{3}H]proline and in the activity of the reporter gene, suggesting that the pro-α1(I) collagen promoter contains a *cis*-acting element located downstream of -1.7 kb, which mediates the inhibition of the pro-α1(I) collagen gene expression induced by parathyroid hormone (Kream *et al.,* 1993; Bogdanovic *et al.,* 2000). Furthermore, the effect of parathyroid hormone on the levels of expression of the reporter gene were mimicked by cAMP and potentiated by a phosphodiesterase inhibitor, suggesting that the inhibitory effects of parathyroid hormone are mediated mainly by a cAMP-signaling pathway (Bogdanovic *et al.,* 2000).

VITAMIN D

In vitro, the active metabolite of vitamin D_3, $1,25(OH)_2D_3$, has been shown to inhibit type I collagen synthesis by bone organ cultures and by osteoblastic cells, and this inhibitory effect is due to an inhibition of the transcription of type I collagen genes (Bedalov *et al.,* 1998; Harrison *et al.,* 1989; Kim and Chen, 1989; Rowe and Kream, 1982). Transfection studies performed with the rat pro-α1(I) proximal promoter led to the identification of a vitamin D responsive element between -2.3 and -1.6 kb (Pavlin *et al.,* 1994). Nevertheless, when transgenic mice harboring a 1.7-kb segment of the rat pro-α1(I) promoter cloned upstream of a CAT reporter gene were treated with $1,25(OH)_2D_3$, the levels of expression of the CAT reporter gene decreased, which suggests that a vitamin D response element is located downstream of -1.7 kb (Bedalov *et al.,* 1998). Similarly, when calvariae from these mice were cultured in the presence of $1,25(OH)_2D_3$, it inhibited reporter gene expression (Bedalov *et al.,* 1998). It is of note that part of the effects of vitamin D on type I collagen could be mediated through an inhibition of the production of IGF-I, as vitamin D has been shown to inhibit IGF-I production (Scharla *et al.,* 1991).

An increase in type I collagen synthesis after treatment of primary osteoblastic cells or of osteoblastic cell lines with vitamin D has also been reported, and this would also be due to a pretranslational effect of vitamin D (Franceschi *et al.,* 1988; Kurihara *et al.,* 1986). To explain the opposite effects of this hormone, it has been suggested that vitamin D could increase type I collagen synthesis in relatively immature cells, whereas it would inhibit this synthesis in more mature osteoblastic cells (Franceschi *et al.,* 1988). As for glucocorticoids, the stimulatory effect of vitamin D could be indirect, secondary to the induction of differentiation of osteoblastic cells toward a more mature phenotype.

THYROID HORMONES

Thyroid hormones have been shown to inhibit type I collagen production by cardiac fibroblasts, and this effect was associated with a decrease in the levels of pro-α1(I) mRNA (Chen *et al.,* 2000b). Transfection studies have shown that thyroid hormones modulate transcriptional levels of the

pro-α1(I) collagen gene through a *cis*-acting element located between −224 and 115 bp (Chen *et al.,* 2000b).

Transcriptional Regulation of Type I Collagen Genes

Expression of the pro-α1(I) collagen gene and the pro-α2(I) collagen gene is coordinately regulated in a variety of physiological and pathological situations. In many of these instances it is likely that the control of expression of these two genes is mainly exerted at the level of transcription, suggesting that similar transcription factors control the transcription of both genes.

This section considers successively the proximal promoter elements of these genes and then the nature of cell-specific enhancers located in other areas of these genes. Information about the various DNA elements has come from transient expression experiments in tissue culture cells, *in vitro* transcription experiments, and experiments in transgenic mice. *In vitro* transcription experiments and large measure transient expression experiments identify DNA elements that have the potential of activating or inhibiting promoter activity. These DNA elements can be used as probes to detect DNA-binding proteins. However, transient expression and *in vitro* transcription experiments do not take into account the role of the chromatin structure in the control of gene expression. Transgenic mice are clearly the most physiological system to identify tissue-specific elements; the DNAs that are tested are integrated into the mouse genome and their activities are presumably also influenced by their chromatin environment. In transgenic mice experiments, the *E scherichia coli* β-galactosidase reporter gene offers the advantage that its activity can be detected easily by the X-Gal histochemical stain so that the cell types in which the transgene is active can be identified by histology.

Transient transfection experiments using various sequences of either the pro-α1(I) proximal promoter or the pro-α2(I) proximal promoter cloned upstream of a reporter gene and introduced in fibroblasts have delineated positive and negative *cis*-acting regulatory segments in these two promoters. Footprint experiments and gel-shift assays performed using these regulatory elements as DNA templates have also delineated sequences that interact with DNA-binding proteins. However, only a few transcription factors that bind to these promoter regulatory sequences have been identified precisely.

Proximal Promoters of Type I Collagen Genes

CIS-ACTING ELEMENTS AND TRANSCRIPTION FACTORS BINDING TO THE MOUSE PRO-A2(I) PROXIMAL PROMOTER

Several functional *cis*-acting elements have been identified in the 350-bp proximal promoter of the mouse pro-α2(I) collagen gene. One of these is a binding site for the ubiquitous CCAAT-binding protein, CBF. This transcription factor is formed by three separate subunits, named A, B, and C, which have all been cloned and sequenced (Maity *et al.,* 1990; Sinha *et al.,* 1995; Vuorio *et al.,* 1990). All three subunits are needed for CBF to bind to the sequence containing the CCAAT box located between -84 and -80 and activate transcription (Maity *et al.,* 1992). *In vitro* data suggest that the A and C subunits first associate to form an A−C complex and that this complex then forms a heteromeric molecule with the B subunit (Sinha *et al.,* 1995). Mutations in the CCAAT box that prevent the binding of CBF decrease the transcriptional activity of the pro-α2(I) proximal promoter three to five times in transient transfection experiments of fibroblastic cell lines (Karsenty *et al.,* 1988). Purified CBF as well as CBF composed of its three recombinant subunits also activate the pro-α2(I) promoter in cell-free nuclear extracts previously depleted of CBF (Coustry *et al.,* 1995). Two of the three subunits of CBF contain transcriptional activation domains.

In addition to the binding site for CBF, footprinting experiments and gel-shift studies identified other binding sites in the first 350 bp of the mouse pro-α2(I) promoter. Three GC-rich sequences, located at about −160 bp (between −176 and −152 bp), −120 bp (between −131 and −114 bp), and −90 bp (between −98 and −75 bp), have been shown to interact with DNA-binding proteins by footprint experiments and gel-shift assays (Hasegawa *et al.* 1996). The corresponding regions were also protected in *in vivo* and *in vitro* footprinting experiments performed using the human pro-α2(I) promoter (Ihn *et al.,* 1996). A deletion in the mouse promoter encompassing these three footprinted sequences completely abolished the transcriptional activity of the pro-α2(I) proximal promoter in transient transfection experiments using fibroblastic cell lines. Proteins binding to these redundant sites are mainly ubiquitous proteins and include Sp1, proteins different from Sp1 that bind to an Sp1 consensus-binding site, and proteins that bind to a Krox consensus site. Proteins that bind to the two proximal segments also bind to the most upstream GC-rich segment, with the exception of CBF, suggesting a redundancy among functionally active DNA segments of the pro-α2(I) proximal promoter. Transfection experiments and gel-shift assays performed using the human pro-α2(I) promoter have suggested that the *cis*-acting element located at −160 bp also binds a repressor element (Ihn *et al.,* 1996).

The mouse pro-α2(I) proximal promoter has been shown to bind NF1/CTF about 300 bp upstream of the start site of transcription (between −310 and −285 bp), and the binding site for this transcription factor appears to be involved in mediating the effects of TGF-β on transcription of the pro-α2(I) gene (Rossi *et al.,* 1988); however, this site is not present in the human promoter. Other studies identified three short *cis*-acting GC-rich elements in the human pro-α2(I) collagen gene between −330 and −255, which are capable of binding Sp1 (Tamaki *et al.,* 1995), as well as an Ap-1-binding site (Chang and Goldberg, 1995; Chung *et al.,* 1996), a binding site for NF-κB (Kouba *et al.,* 1999), one for C/EBP (Greenwel *et al.,* 2000), and one for Smad

complexes (Zhang *et al.,* 2000) (Fig. 5). Additional studies presented evidence that a protein complex, which includes Sp1 and Smad proteins, binds to this segment of the human promoter and participates in the TGF-β activation of this promoter (Inagaki *et al.,* 1994; Greenwel *et al.,* 1997; Zhang *et al.,* 2000). This *cis*-acting element has also been shown to mediate the inhibitory effects of TNF-α (Inagaki *et al.,* 1995) through the binding of NF-κB (Kouba *et al.,* 1999) and/or C/EBP (Greenwel *et al.,* 2000) (Fig. 5). The antagonist activities of TGF-β and TNF-α may result from sterical interactions between different DNA-binding proteins. Due to the ability of this *cis*-acting element to mediate the effects of both TGF-β and TNF-α, Ramirez' group suggested naming it "cytokine responsive element" (or CyRC).

TRANSCRIPTION FACTORS BINDING TO THE MOUSE PRO-α1(I) PROXIMAL PROMOTER

In the mouse pro-α1(I) collagen gene, the sequence between -220 and the TATA box presents strong homologies with the sequence of the pro-α2(I) gene in the same region. This DNA segment contains binding sites for DNA-binding factors that also bind to the proximal pro-α2(I) promoter (Karsenty and de Crombrugghe, 1990). These DNA elements in the pro-α1(I) proximal promoter include a binding site for CBF between -90 and -115 (Karsenty and de Crombrugghe, 1990). A second CCAAT box located slightly more upstream is, however, unable to bind CBF, suggesting that sequences surrounding the CCAAT motif also have a role in CBF binding. DNA transfection experiments with the pro-α1(I) promoter showed that point mutations in the CBF-binding site decreased promoter activity (Karsenty and de Crombrugghe, 1990). The CBF-binding site is flanked by two identical 12-bp repeat sequences that are binding sites for Sp1 and probably other GC-rich binding proteins (Nehls *et al.,* 1991). In transient transfection experiments, a mutation in the binding site that prevents the binding of Sp1 surprisingly increased the activity of the promoter, and overexpression of Sp1 decreased the activity of the promoter (Nehls *et al.,* 1991). It is possible that several transcription factors with different activating potentials bind to overlapping binding sites and compete with each other for binding to these sites; the overall activity of the promoter could then depend on the relative occupancy of the different factors on the promoter DNA. Two apparently redundant sites between -190 and -170 and between -160 and -130 bind a DNA-binding protein previously designated inhibitory factor 1 (IF-1), as substitution mutations in these sites that abolished DNA binding resulted in an increase in transcription (Karsenty and de Crombrugghe, 1990). Formation of a DNA–protein complex with these two redundant elements in the pro-α1(I) promoter was also shown to be competed by the sequence of the pro-α2(I) promoter between -173 and -143, suggesting that both type I promoters contained binding sites for the same protein (Karsenty and de Crombrugghe, 1991). Experiments have shown that a new member of the Krox family, designated c-Krox, binds to these two sites in the pro-α1(I) promoter (Galéra *et al.,* 1994). In addition, c-Krox binds to a site located near the CCAAT box in the pro-α1(I) promoter and to three GC-rich sequences in the pro-α2(I) proximal promoter, located between -277 and -264 bp, between -175 and -143 bp, and near the CCAAT box, respectively (Galéra *et al.,* 1996). c-Krox appears to be expressed preferentially in skin (Galéra *et al.,* 1994), but data suggest that it is also expressed in chondrocytes and plays a role in regulating the expression of the pro-α1(II) collagen gene (Galéra *et al.,* 2000).

The 220-bp pro-α1(I) proximal promoter is extremely active both in transient transfection experiments and in *in vitro* transcription experiments (Maity *et al.,* 1988; Karsenty and de Crombrugghe, 1990). It is likely that the high transcriptional activity in these systems is due to a combination of active transcription factors that bind to this proximal promoter. Other protected regions have been identified by footprint experiments in the pro-α1(I) proximal promoter upstream of -220 bp, but the transcription factors binding to these protected sequences still remain to be identified (Ravazzolo *et al.,* 1991).

Overall, several DNA-binding proteins bind to the proximal promoters of the two type I collagen genes; these proteins, which include CBF, Sp1, and other GC-rich binding proteins, are mainly ubiquitous proteins. It is likely that their transcriptional function and eventually their DNA-binding properties offer opportunities for regulation by intracellular signaling pathways triggered by a variety of cytokines.

Organization of Upstream Segments of Type I Collagen Genes

ORGANIZATION OF UPSTREAM ELEMENTS IN THE PRO-α1(I) COLLAGEN GENE

In complete contrast with its high level activity in transient expression and *in vitro* transcription experiments, the 220-bp pro-α1(I) proximal promoter is almost completely inactive in stable transfection experiments (J. Rossert *et al.,* unpublished observations) and in transgenic mice (Rossert *et al.,* 1996). Data obtained with transgenic mice harboring various fragments of the mouse pro-α1(I) proximal promoter indicate that upstream elements are needed for the tissue-specific expression of this gene (Rossert *et al.,* 1995). These experiments also suggest a modular arrangement of separate *cis*-acting elements that activate the pro-α1(I) gene in different type I collagen-producing cells (Rossert *et al.,* 1995). Transgenic mice harboring 900 bp of the mouse pro-α1(I) proximal promoter expressed the *lacZ* and luciferase reporter genes almost exclusively in skin. When mice harbored 2.3 kb of the pro-α1(I) proximal promoter, both transgenes were expressed at low levels in skin and at high levels in osteoblasts and odontoblasts, but they were not expressed in other type I collagen-producing cells. Finally, when transgenic mice contained 3.2 kb of the pro-α1(I) proximal promoter cloned upstream of the *lacZ* gene, this reporter gene

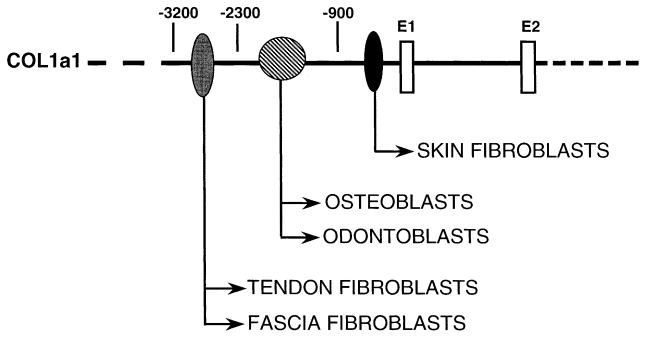

Figure 6 Schematic representation of the modular arrangement of different regulatory domains identified in the mouse pro-α1(I) collagen promoter. We postulate that still other regulatory domains remain to be identified. E1; exon 1; E2; exon 2.

was expressed at high levels in osteoblasts and in odontoblasts, but also in tendon and fascia fibroblasts. These results suggested the hypothesis that separate lineage-specific *cis*-acting elements would activate the pro-α1(I) collagen gene in osteoblasts, in odontoblasts, and in different subpopulations of fibroblasts (Fig. 6). Data obtained for human and rat pro-α1(I) collagen genes are also consistent with such a modular arrangement of different regulatory elements (Dodig *et al.,* 1996; Bogdanovic *et al.,* 1994; Liska *et al.,* 1994; Pavlin *et al.,* 1992). The direct consequence of such a modular arrangement is that it should be possible to selectively modulate the activation of type I collagen genes in well-defined subpopulations of type I collagen-producing cells. Analyses of transgenic mice harboring different segments of the mouse pro-α1(I) promoter located between -3.2 and -19.5 kb only identified a *cis*-acting element located between -7 and -8 kb that specifically enhanced reporter gene expression in uterus (Krempen *et al.,* 1999; Terraz *et al.,* 2001). Thus, *cis*-acting elements that activate the gene in most fibroblastic cells are probably located upstream of -19.5 kb or downstream of the transcription start site.

One *cis*-acting element responsible for the activation of the mouse pro-α1(I) collagen gene in osteoblasts has been identified precisely by generating transgenic mice harboring various segments of the mouse pro-α1(I) proximal promoter cloned upstream of a minimal promoter [first 220 bp of the pro-α1(I) proximal promoter] and of the *lacZ* gene (Rossert *et al.,* 1996). This 117-bp segment, located between -1656 and -1540 bp, is a minimal sequence able to induce high levels of expression of the reporter gene in osteoblasts. In these mice the transgene becomes active at the same time during embryonic development when osteoblasts first appear in the different ossification centers. This so-called "osteoblast-specific element" can be divided into three subsegments that have different functions. The 29-bp A segment, which is located most 5' (-1656 to -1628 bp), is required to activate the gene in osteoblasts. A deletion of the A element or a 4-bp mutation in the TAAT sequence of this segment completely abolished the expression of the reporter gene in osteoblasts of transgenic mice. The C segment, which is located at the 3' end of the 117-bp sequence (-1575 to -1540 bp), is required to obtain consistent high level expression of the reporter gene in transgenic mice. When this C segment was deleted, the *lacZ* gene was expressed at very low levels and only in a small proportion of transgenic mice. The function of the intermediary segment (B segment) is still poorly understood, but it could be to prevent a promiscuous expression of the gene and in particular expression of the gene in the nervous system. When this B element was deleted, the *lacZ* gene was expressed at high levels in osteoblasts, but also in some discrete areas of the nervous system. This 117-bp osteoblast-specific element is very well conserved among species (Fig. 7), and the essential role of the A element has been confirmed using transgenic mice harboring a 3.6-kb segment of the rat pro-α1(I) proximal promoter with a mutation in the TAAT sequence of the A element (Dodig *et al.,* 1996). Footprint experiments and gel-shift assays have identified a DNA-binding protein that is present only in nuclear extracts from osteoblastic cell lines, and which binds to the A element (Rossert *et al.,* 1996; Dodig *et al.,* 1996), but the DNA for this transacting factor remains to be cloned.

ORGANIZATION OF UPSTREAM ELEMENTS OF THE MOUSE PRO-α2(I) PROMOTER

The activity of the mouse 350-bp pro-α2(I) proximal promoter in transgenic mice is very low compared to that of

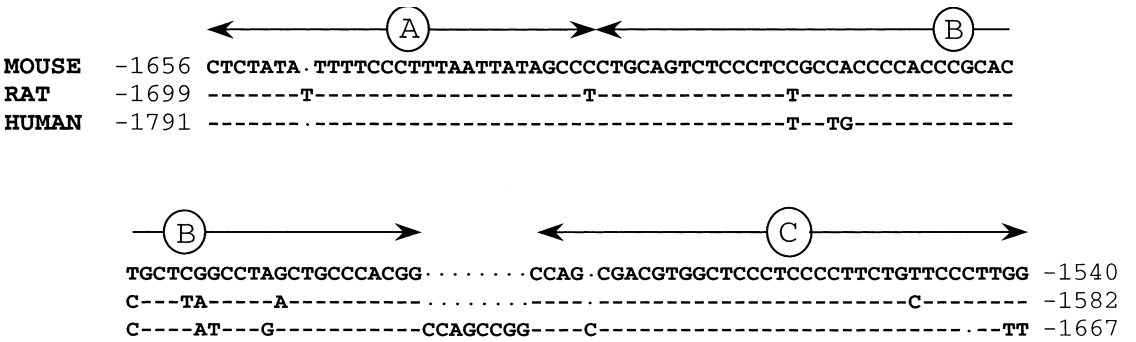

Figure 7 Sequence of the 117-bp "osteoblast-specific element." This element has been identified within the mouse pro-α1(I) collagen promoter, but highly similar sequences exist in the human and in the rat pro-α1(I) collagen promoter. From Rossert *et al.* (1996).

the corresponding endogenous gene. Although this low-level activity appears to be present selectively in fibroblasts and mesenchymal cells (Niederreither *et al.,* 1992), the precise sequences and the factors responsible for this tissue specificity have not yet been identified. Results have shown that upstream elements are also involved in the control of the tissue-specific expression of this gene and are needed for high-level expression (Bou-Gharios *et al.,* 1996). An element located 13 to 17.5 kb upstream of the start site of transcription, and named "far upstream enhancer," increased the levels of expression of the *lacZ* and luciferase reporter genes considerably when it was cloned upstream of the 350-bp mouse pro-α2(I) proximal promoter. Moreover, this element by itself contributed to the tissue-specific expression of a reporter gene. Indeed, when it was cloned upstream of a minimal promoter that has no tissue-specific expression by itself [first 220 bp of the pro-α1(I) proximal promoter], it conferred a tissue-specific expression to the *lacZ* reporter gene in transgenic mice.

Interestingly, in transgenic mice harboring the *lacZ* reporter gene cloned downstream of a pro-α2(I) promoter segment containing the far upstream enhancer, fibroblastic cells expressed the *lacZ* reporter gene at very high levels but only a subset of osteoblastic cells expressed this reporter gene, whereas odontoblasts and fully differentiated tendon fibroblasts did not (Bou-Gharios *et al.,* 1996). In 15.5-day embryos and newborn mice, the reporter gene was expressed selectively in the mandible, in the clavicles, and mainly in the growing parts of the calvaria, whereas other bones, including long bones of the limbs and ribs, essentially did not express the *lacZ* gene. Only occasionally could some expression be seen in regions of periosteal ossification, but areas of endochondral ossification were always negative. Moreover, in addition to this spatially restricted pattern of expression, there was also a temporal restriction in the pattern of expression of the *lacZ* reporter gene in osteoblasts, and the regions that expressed the reporter gene at highest levels correlated with regions of new bone growth. The molecular mechanisms underlying this heterogenous expression of the *lacZ* reporter gene in osteoblasts are still unknown, but two different explanations could account for it. First, the osteoblasts that form intramembranous bone and the ones that form endochondral bone could respond to different genetic programs of development. In addition to the program directing expression of both type I collagen genes in all osteoblasts, illustrated by transgenic mice harboring the osteoblast element present in the pro-α1(I) collagen promoter, a program would exist that would be mainly active in osteoblasts at the growing edges of membranous bones. Second, expression of the *lacZ* reporter gene in newly formed osteoblasts of membranous bones could be due to the fact that the *lacZ* reporter gene is expressed by mesenchymal precursors of fully differentiated osteoblasts and that the *E. coli* β-galactosidase protein can still be detected some time after the gene is no longer transcribed actively. Besides this heterogenous expression of the *lacZ* reporter gene in bone, the lack of expression of the *lacZ* gene in odontoblasts and in fully differentiated tendon fibroblasts suggests that other elements exist that control expression in these cells and strongly supports a modular organization of different regulatory domains in the mouse pro-α2(I) promoter, as described for the pro-α1(I) promoter.

MODE OF ACTION OF TISSUE-SPECIFIC ELEMENTS

The mode of action of the different lineage-specific transcription elements and their postulated cognate-binding proteins is still unknown, but a study of hypersensitive sites (Bou-Gharios *et al.,* 1996; Liau *et al.,* 1986) and *in vivo* footprinting experiments (Chen *et al.,* 1997) strongly suggest that the chromatin structure of discrete areas in the regulatory regions of type I collagen genes is different in cells when these genes are being transcribed actively compared to cells in which they are silent. These experiments suggest that in intact cells expressed ubiquitously, transcription factors such as CBF bind to the proximal promoters of type I collagen genes only in cells in which the genes are transcribed actively. While *in vivo* footprint experiments show a protection of the CCAAT box in different fibroblastic cell lines, such a protection does not exist in cell lines that do not produce type I collagen. Similarly, hypersensitive sites corresponding to the far upstream enhancer of the pro-α2(I) promoter can be detected only in cells that express type I collagen. The importance of chromatin structure is also highlighted by comparison of transient and stable transfection experiments (J. Rossert *et al.,* unpublished observations). When a chimeric construct harboring the pro-α1(I) osteoblast-specific element cloned upstream of a minimal promoter and of the *lacZ* reporter gene was transfected stably in different cell lines, it was expressed in the ROS17/2 osteoblastic cell line, but not in two fibroblastic cell lines or in a cell line that does not produce type I collagen. In contrast, in transient transfection experiments, the same chimeric construction was expressed at high levels by all cell lines. These results suggest a model where the binding of a lineage-specific transcription factor to specific enhancer segments of type I collagen genes would result in opening the chromatin around the promoter and allow ubiquitous transcription factors to bind to the proximal promoter and to activate transcription of the genes.

First Intron Elements

FIRST INTRON OF THE PRO-α1(I) COLLAGEN GENE

Different negative or positive regulatory segments have been identified within the first intron, but most of the transcription factors binding to these regulatory segments are still unknown. A sequence of the first intron of the human pro-a1(I) gene located about 600 bp downstream of the transcription start site binds AP-1, and a mutation that abolished this binding diminished the expression of a reporter gene in transient transfection experiments (Liska *et al.,* 1990). Another segment of the first intron of the human gene, which extends from 820 to 1093 bp, has been shown

to inhibit the activity of a reporter gene in transient transfection experiments (Liska *et al.,* 1992). This sequence contains two binding sites for an Sp1-like transcription factor, and mutations in these two Sp1-binding sites tended to increase the activity of the reporter gene (Liska *et al.,* 1992). An Sp1-binding site is also located at about 1240 bp, in the human gene, and a frequent G→T polymorphism in this Sp1-binding site (G1242T) has been linked with low bone mineral density and increased risk of osteoporotic vertebrate fracture (Grant *et al.,* 1996), which suggests that it may be important for normal levels of type I collagen synthesis by osteoblasts.

The phenotype of Mov 13 mice suggested that the first intron of the pro-α1(I) collagen gene could play a role in the expression of this gene. These mice, which harbor a retrovirus in the first intron of the pro-α1(I) collagen gene (Harbers *et al.,* 1984), express this gene in osteoblasts and odontoblasts, but not in fibroblastic cells (Kratochwil *et al.,* 1989; Löhler *et al.,* 1984; Schwarz *et al.,* 1990). Nevertheless, the presence of tissue-specific regulatory elements in the first intron of the pro-α1(I) collagen gene has long been controversial. Two groups have reported that in transgenic mice harboring the proximal promoter of either the human or the rat pro-α1(I) gene, the pattern of expression of the reporter gene was the same whether or not these mice harbored the first intron of the pro-α1(I) collagen gene (Bedalov *et al.,* 1994; Sokolov *et al.,* 1993). In contrast, data obtained by *in situ* hybridization in transgenic mice harboring 2.3 kb of the human pro-α1(I) proximal promoter suggested that the first intron of this gene was necessary to obtain high-level expressions of the transgene in the dermis of skin (Liska *et al.,* 1994). Only mice harboring the first intron, in addition to the 2.3-kb proximal promoter segment, expressed the human growth hormone reporter gene at high levels in skin. In order to clarify this issue, Bornstein's group generated knock-in mice with a targeted deletion of most of the first intron (Hormuzdi *et al.,* 1998). Mice homozygous for the mutated allele developed normally and showed no apparent abnormalities. Nevertheless, in heterozygous mice, the mutated allele was expressed at normal levels in skin, but at lower levels in lung and muscle, and its levels of expression decreased with age in these two tissues. Thus, the first intron does not play a role in the tissue-specific expression of the pro-α1(I) gene, but it seems to be important for maintaining normal transcriptional levels of this gene in certain tissue.

First Intron of the pro-α2(I) Collagen Gene

The first intron of the mouse pro-α2(I) gene has also been shown to contain a tissue-specific enhancer in transient transfection experiments (Rossi and de Crombrugghe, 1987). In transgenic mice, however, the presence of this tissue-specific enhancer apparently had no effect on the pattern of expression of a CAT reporter gene (Goldberg *et al.,* 1992). Furthermore, the *trans*-acting factors binding to this enhancer are still unknown.

Posttranscriptional Regulation of Type I Collagen

Even if the control of expression of type I collagen genes appears to be mainly exerted at the level of transcription, type I collagen production can also be regulated at a posttranscriptional level. For example, TGF-b and IFN-g modulate not only the levels of transcription of type I collagen genes, but also the stability of the corresponding mRNAs (cf. supra). Similarly, activation of hepatic stellate cells is associated with a dramatic increase in the stability of the pro-α1(I) collagen mRNA. Run-on experiments have shown that the half-life of this mRNA was increased about 15-fold in activated rat hepatic stellate cells when compared with quiescent ones (Stefanovic *et al.* 1997).

Analysis of the 3′-untranslated region of the mouse pro-α1(I) mRNA has led to the identification of a C-rich sequence, located 24 nucleotides downstream of the stop codon, that plays a critical role in the regulation of mRNA stability (Stefanovic *et al.,* 1997) through the binding of a complex containing a protein called αCP2. When a construct containing a mutation in this C-rich sequence was transfected in NIH/3T3 fibroblasts, the half-life of the corresponding mRNA was only 35% of the half-life of the wild-type mRNA (Stefanovic *et al.,* 1997). Furthermore, αCP2 could also enhance the translational rate of the pro-α1(I) gene through interactions with poly(A)-binding proteins. The binding of αCP2 to the pro-α1(I) mRNA could be regulated by posttranlational modifications of this protein, such as phosphorylations (Lindquist *et al.,* 2000). Another protein, α1-RBF67, also binds to the 3′-untranslated region of the pro-α1(I) mRNA and may regulate its stability (Määttä *et al.,* 1994).

The sequence of the mouse pro-α1(I) mRNA surrounding the start codon could also play a role in regulating mRNA stability. This sequence has been shown to form a stem–loop structure, and mutations that prevent its formation decreased the stability of the mRNA dramatically (Stefanovic *et al.,* 1999). In cells that produce high levels of type I collagen, such as fibroblasts and activated hepatic stellate cells, a protein complex can bind to this stem–loop, provided that the mRNA is capped, and this binding probably increases the stability of the mRNA (Stefanovic *et al.,* 1999).

Perspectives

To further understand the activity of type I collagen genes in osteoblasts, the proteins that bind to osteoblast-specific elements will need to be identified and their cDNAs cloned. One will also have to examine the interactions between these and other proteins binding to osteoblast-specific enhancers and the proteins that bind to the proximal promoter elements. Similar questions will also need to be answered for other cell-type-specific enhancers that control expression of the type I collagen genes in other cell types. The mechanisms by which the chromatin of the proximal promoters of the type I collagen genes is selectively disrupted in cells that synthesize the type I collagen

chains and the role played in this disruption by DNA-binding proteins will also need to be addressed. In addition, the transcription factors that mediate the effects of cytokines need to be identified further, and the modulation of their activities in response to intracellular signaling triggered by these cytokines will need to be characterized.

CHAPTER 13

Collagen Cross-Linking and Metabolism

Simon P. Robins and Jeffrey D. Brady
Skeletal Research Unit, Rowett Research Institute, Aberdeen AB21 9SB, Scotland

Introduction

In constituting about 90% of the matrix protein of bone, collagen clearly play an important role in determining the characteristic of the tissue. Much of the research on collagen has focused on the extensive postribosomal modifications that occur during biosynthesis of the molecule, as these intracellular changes have major influences on the assembly, cross-linking, mineralization, and degradation of collagen fibrils. The aim of this chapter is to bring together current knowledge on the mechanisms of collagen cross-linking and how these are influenced by specific postribosomal modifications. These changes are also viewed in the context of collagen metabolism, with particular reference to the utilization of certain collagen metabolites as markers of bone metabolism.

Although some 20 genetically distinct collagen types are known (von der Mark, 1999), bone contains predominantly the principal a fibrillar form, collagen type I, but with small amounts of collage V and III. Collagen V interacts with type I fibrils (Birk *et al.,* 1988) and may have some regulatory role on fibril diameter and orientation, as has been shown for cornea. Collagen III in bone is generally limited to anatomically distinct regions, such as tendon insertion sites (Keene *et al.,* 1991). Thus, for the purposes of this chapter, the properties of collagen type I will be considered, as these dominate the primarily structural function of collagen in bone.

Cross-Link Formation

As reviewed in Chapter 12, collagen type I fibrils form spontaneously within the extracellular space once the N- and C-terminal propeptides of procollagen have been removed by specific proteases. During fibrillogenesis, the final enzymatic modification of collagen occurs: conversion of lysine or hydroxylysine residues within both N- and C-terminal telopeptides to aldehydes by lysyl oxidase. Subsequently, all collagen cross-linking steps occur spontaneously by virtue of the specific alignment of molecules within the fibrils.

As indicated in an overview of the cross-linking process (Fig. 1), the hydroxylation state of telopeptide lysine residues is crucial in determining the pathway of collagen cross-linking; this step is determined by an intracellular modification during collagen biosynthesis.

Hydroxylation of telopeptide lysine residues is known to be accomplished by a separate enzyme system to that which hydroxylates lysines in the central chain portion destined to become the helix. Indirect evidence for the existence of an enzyme, now referred to as telopeptide lysyl hydroxylase (TLH), was obtained from the lack of effect of purified helical lysyl hydroxylase on isolated telopeptides (Royce and Barnes, 1985). More direct evidence has been obtained from a family with a rare form of osteogenesis imperfecta, Bruck syndrome, characterized by bone fragility in affected individuals: their bone collagen lacks any cross-links derived from the hydroxylysine pathway and contains only immature, telopeptide lysine-derived cross-links (Bank *et al.,* 1999). It has been suggested that of the known variants of helical lysyl hydroxylase (procollagen-lysine, 2-oxoglutarate, 5-dioxygenase 1, 2, and 3: PLOD1–3), it was tissue-specific expression of PLOD2 that largely accounted for telopeptide hydroxylation in osteoblastic cells (Uzawa *et al.,* 1999). PLOD2, which has been localized to chromosome 3, is, however, unlikely to be a candidate for the defect in Bruck syndrome, as the latter was shown to be located on chromosome 17 (Bank *et al.,* 1999). There also appear to be

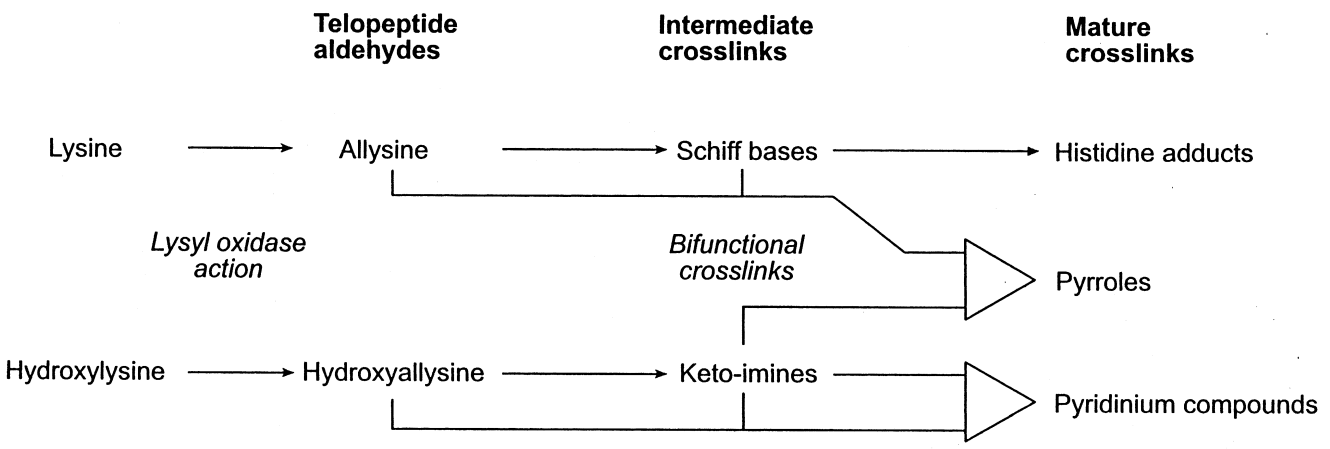

Figure 1 Formation of collagen cross-links from lysine- or hydroxylysine-derived telopeptide aldehydes giving rise to Schiff base or ketoimine difunctional bonds, respectively. On maturation, the Schiff bases are converted primarily to nonreducible, histidine adducts, whereas the ketoimines react with hydroxylysine aldehyde or a second ketoimine to give pyridinium cross-links. Pyrrole cross-link formation requires the presence of both lysine- and hydroxylysine-derived products.

tissue-specific forms of telopeptide lysyl hydroxylase, as indicated by the normal patterns of cross-linking observed in the adjacent ligament (mainly collagen type I) and cartilage (collagen type II) of Bruck syndrome patients (Bank *et al.,* 1999). Further studies of the TLH enzyme systems should provide a better understanding of the tissue-specific control of collagen cross-linking.

Cross-Link Structure

Intermediate Cross-Links

The preponderance of hydroxylysine aldehydes in bone collagen telopeptides ensures that most of the difunctional cross-links initially formed are relatively stable bonds. Thus, in contrast to tissues such as skin, where the telopeptide lysine aldehydes interact with adjacent molecules to give Schiff base (-N = CH-) cross-links, the presence of the hydroxyl group allows an Amadori rearrangement to a more stable, ketoimine form. Both the Schiff base and the ketoimine forms of cross-link are reducible by borohydride, a technique that enabled the Schiff base compounds to be stabilized for identification (Bailey *et al.,* 1974). Although the ketoimine bonds are sufficiently stable to allow isolation of peptides containing these bonds, the cross-links are quantified after reduction with borohydride to the well-characterized compounds dihydroxylysinonorleucine (DHLNL) and hydroxylysinonorleucine (HLNL).

The reducible, bifunctional cross-links are referred to as intermediates because of their conversion during maturation of the tissue to nonreducible compounds, which are generally trivalent. Such a process can therefore be considered to provide additional stability to the fibrillar network, although, because of some ambiguities in the mechanisms involved, this has not been demonstrated directly.

Pyridinium Cross-Links

One of the first maturation products of the intermediate cross-links to be identified was pyridinoline (PYD) or hydroxylysyl pyridinoline (HP), a trifunctional 3-hydroxypyridinium compound (Fujimoto *et al.,* 1978). An analogue, deoxypyridinoline (DPD) or lysyl pyridinoline (LP), has also been identified in bone (Ogawa *et al.,* 1982). Both of these compounds (Fig. 2) are derived from intermediate ketoimines by reaction either with another difunctional cross-link (Eyre and Oguchi, 1980) or with a free hydroxylysine aldehyde group (Robins and Duncan, 1983). The chemistry of these two proposed mechanisms are very similar, but there are implications in terms of structural function of the cross-links. The involvement of two difunctional compounds results in a cross-link between three collagen molecules, whereas the alternative mechanism is more likely to link only two molecules (see Fig. 2).

Pyrroles

The notion that collagen contained pyrrolic cross-links was developed by Scott and colleagues (1981) based on the observation that tissues solubilized by enzyme treatment gave a characteristic pink color with *p*-dimethylaminobenzaldehyde. These compounds were termed Ehrlich chromogens (EC) and, in later experiments, diazo-affinity columns were used to bind covalently the pyrrole-containing peptides from enzyme digests of bone (Scott *et al.,* 1983) and skin (Kemp and Scott, 1988); these were partially characterized by amino acid analysis. A similar affinity chromatography approach was used to demonstrate that Ehrlich chromogen cross-links were present at the same loci as the pyridinium cross-links in bovine tendon (Kuypers *et al.,* 1992). This work culminated in a proposed structure and mechanism of formation for pyrroles analogous to that for pyridinium cross-link formation: this mechanism involves

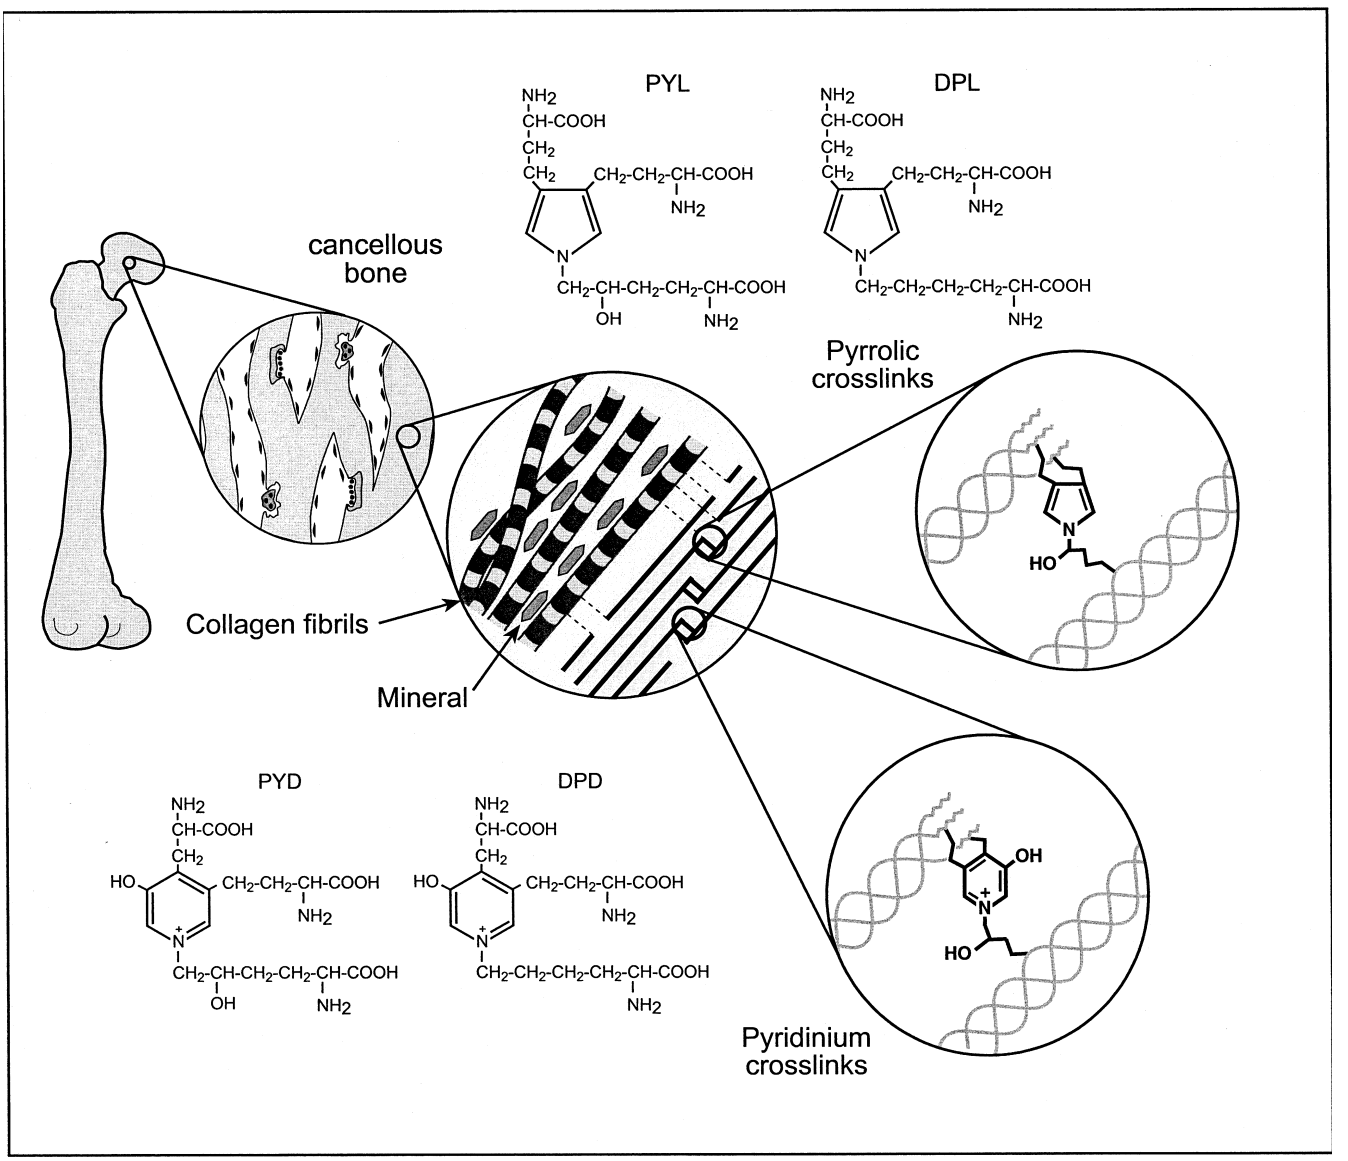

Figure 2 Stabilization of bone matrix by pyridinium and pyrrolic cross-links. Slightly higher concentrations of the mature cross-links are present in cortical compared with remodeling cancellous bone (inset) showing schematically mineralized collagen fibrils having a banded appearance arising from the precise alignment of collagen molecules in a quarter-staggered array. The overlap is stabilized by cross-links at both N- and C-terminal ends. (Insets) Pyridinium and pyrrole compounds linking N-terminal telopeptides to an adjoining helix: cross-linking may also involve telopeptides from two different molecules in register. Pyridinium cross-links are present at both N- and C-terminal sites, but pyrroles are located predominantly at the N terminus. Depending on the degree of hydroxylation of the helical lysine residue, two analogues of both the pyridinium and the pyrrolic cross-links are formed.

reaction of a difunctional, ketoimine cross-link with a lysyl aldehyde- rather than hydroxylysyl aldehyde-derived component (Kuypers *et al.,* 1992), where the latter may be a second difunctional cross-link (Hanson and Eyre, 1996).

Isolation and characterization of the pyrrolic cross-link(s) have been hampered by the instability of the pyrrole to acid or alkali hydrolysis. The use of repeated enzyme digestion of decalcified bone matrix to isolate pyrrole-containing peptides was not possible because, as these peptides were reduced in size and enriched, the pyrrole tended to oxidize or polymerize. By synthesizing new Ehrlich reagents, however, it has been possible to both stabilize the pyrrolic cross-links and facilitate their isolation and characterization by mass spectrometry (Brady and Robins, 2001). Both predicted analogues of the pyrrole (Fig. 2) were identified as the derivatized cross-link. Consistent with previous nomenclature, the trivial names pyrrololine (PYL) and deoxypyrrololine (DPL) have been proposed for the underivatized cross-links, which have been synthesized chemically (Adamczyk *et al.,* 1999).

Location of Cross-Links

Within the quarter-staggered, fibrillar array of collagen molecules, almost all cross-links have been shown to be

located at the 4D overlap position (see Fig. 2). Thus, N-telopeptide-derived cross-links are linked to the C-terminal part of the helix [residue 930 in the α1(I) chain], whereas C-telopeptide-derived cross-links are adjacent to the N-terminal end of the helix at residue 87. Because there is no oxidizable lysine in the C-telopeptide of the α2(I) chain, a more restricted number of cross-links is possible at this site compared to the N-terminal end. It has been established that the pyridinium and pyrrole cross-links are both located at these sites but that there are differences in their relative amounts. Thus, in bone collagen, the pyrrolic cross-links involve predominantly the N-terminal telopeptide (Hanson and Eyre, 1996), although there is some evidence for their location at the C-terminal end (Brady and Robins, 2001). Pyridinium cross-links are present at both ends of the molecule (Hanson and Eyre, 1996; Robins and Duncan, 1987) but, in human tissue, there is more DPD relative to PYD at the N terminus compared with the C-telopeptide-derived cross-linking region (Hanson and Eyre, 1996). The helical Hyl residue toward the N-terminal end (residue 87) is much more likely to be glycosylated than its C-terminal counterpart so that glycosylated pyridinium cross-links are relatively common, whereas glycosylated pyrrolic cross-links have not yet been detected.

Spectrum of Cross-Linking

The variations in telopeptide lysine hydroxylation give rise to a spectrum of different cross-linking patterns (Fig. 3). Bone collagen occupies a central position in this spectrum by virtue of the partial hydroxylation within the telopeptides, resulting in the formation of both pyridinium and pyrrolic cross-links. In cartilage, where telopeptide hydroxylation is essentially complete, only pyridinium cross-links are present with no pyrrolic forms. At the opposite end of the spectrum, skin also has no pyrrolic cross-links because of the absence of any telopeptide lysyl hydroxylase activity in this tissue. Helical lysyl hydroxylase activity has a much less profound effect on cross-link composition (Fig. 3) but does control the relative proportions of PYD:DPD and PYL:DPL.

Age-Related Changes in Lysine-Derived Cross-Links

The conversion of intermediate, borohydride-reducible cross-links to pyridinium compounds is well documented, but the stoichiometry is less clear. Studies of the aging *in vitro* of bone indicated a 2:1 molar ratio of the ketoimine precursor to the pyridinium cross-link (Eyre, 1981), an observation that is consistent with the proposed mechanism of formation of the trivalent cross-link (Eyre and Oguchi, 1980). Because of the difficulties in measuring specifically pyrrole cross-links, there is little information to date on their changes during maturation and with age. As relatively reactive species, pyrrolic cross-links have the potential to undergo further interactions within the fibril during the aging process. Preliminary analyses using specialized reagents (J. Brady, unpublished results) suggest

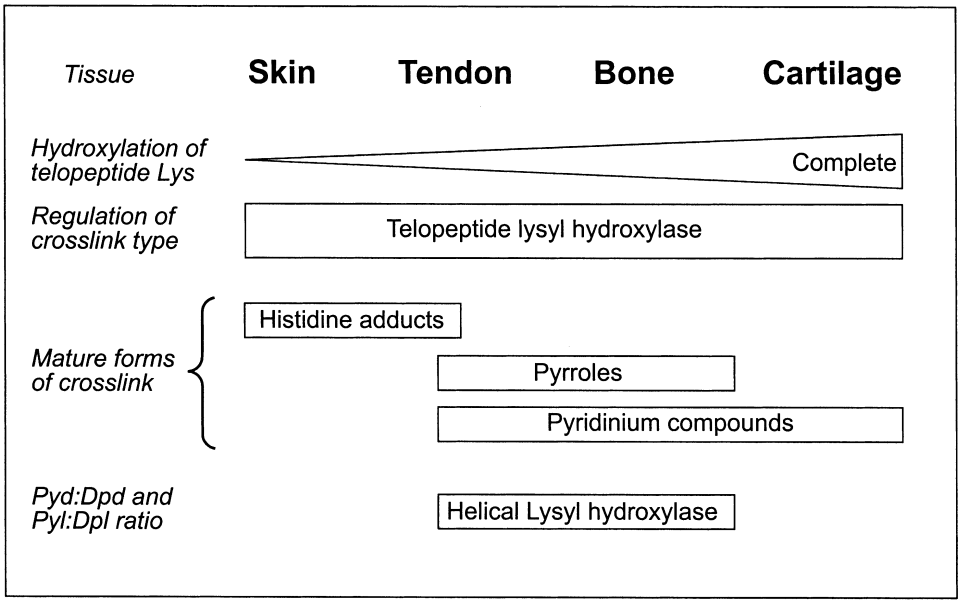

Figure 3 Spectrum of tissue-specific cross-linking resulting from the activity of telopeptide lysyl hydroxylase to give complete hydroxylation in cartilage but no significant hydroxylation of telopeptide lysine in skin collagen. The action of this intracellular enzyme regulator leads to the differences shown in mature cross-links. Pyrrolic cross-links are absent at the extremes of activity but are major components of bone and some tendons. The action of the intracellular enzyme, helical lysyl hydroxylase, regulates the relative proportions of mature pyridinium and pyrrolic cross-links in bone and tendon.

that, although the concentrations of pyrrole cross-links in adult bone collagen remain relatively constant during adult life, much higher concentrations are present in bone from adolescent and younger age groups. In this respect, therefore, pyrroles differ markedly from pyridinium cross-links, where the concentrations in bone increase in the first two decades of life and remain constant thereafter (Eyre *et al.,* 1988).

In most soft tissues, the content of intermediate, reducible bonds is very low after the cessation of growth (Robins *et al.,* 1973), but bone is unusual in retaining a relatively large proportion of reducible bonds. One possible reason for this is the continual turnover through the remodeling of bone, resulting in a higher proportion of recently formed fibrils compared with other tissues. In support of this view, low bone turnover in osteopetrotic rats was found to be associated with high concentrations of pyridinium cross-links in cancellous and compact bone, which were partially normalized by the restoration of osteoclast formation with colony-stimulating factor 1 treatment (Wojtowicz *et al.,* 1997). Another possible explanation for relatively low concentrations of mature cross-links in bone is that the mineralization process itself inhibits the maturation of reducible bonds to mature cross-links. Support for the latter has been obtained from *in vitro* experiments, which showed that the rate of conversion for demineralized bone was much higher than for bone without demineralization (Eyre, 1981). The ultimate concentrations of pyridinium cross-links attained in these experiment were, however, not markedly different and it is unclear whether the observed differences in kinetics play an important part *in vivo*. Other studies have indicated that the mineralization process causes alterations in the molecular packing of bone collagen fibrils, resulting in the cleavage of intermediate cross-links (Otsubo *et al.,* 1992). An alternative view is that the patterns of collagen cross-links produced, and by implication the structure attained, are instrumental in regulating mineralization. These conclusions derive from experiments using model systems where changes were observed in the total amounts of pyridinium cross-links and, more importantly, the Pyd/Dpd ratio in mineralizing turkey tendon (Knott *et al.,* 1997) and canine fracture callus (Wassen *et al.,* 2000).

Other Age-Related Changes

Changes in protein structure due to age-related modifications such as progressive deamidation, racemization, or nonenzymatic glycosylation of specific amino acid residues are well recognized. These changes have profound effects on the functional properties of the matrix and may alter interactions with cells and other matrix constituents, thus affecting the metabolism of the protein. Although a detailed discussion of the many protein modifications that occur during aging is beyond the scope of this chapter, specific changes due to isomerization and racemization of aspartyl residues in collagen telopeptides are discussed because of its implications for the measurement of collagen metabolites as bone resorption markers.

Isomerization and Racemization of Asp in Telopeptides

The racemization of amino acids in proteins has long been used as a means of assessing the "age" of proteins (Helfman and Bada, 1975). Different amino acids racemize at different rates, but aspartyl (or asparaginyl) residues racemize particularly rapidly because of the association with isomerization events. Conversion to a D-aspartyl or -asparaginyl residue occurs more readily when this residue is adjacent to a glycine, thus allowing the formation of a succinimide intermediate, which leads to L- and D- isomers of both α and β forms (Fig. 4). Early studies of collagen structure utilized the presence of susceptible aspartyl- or asparaginyl-glycyl bonds to affect specific cleavage at that site with hydroxylamine (Bornstein, 1970). The presence of isomeric forms of -Asp-Gly- bonds in collagen telopeptides was recognized by Fledelius and colleagues (1997a), who showed that the proportion of β-aspartyl residues within the C-terminal telopeptide of α1(I) increased with age in human and animal tissues. Measurements in urine reflected similar age changes, with higher α/β ratios detected in children compared with adults (Fledelius *et al.,* 1997a). Later studies of the Asp-Gly bond in the N-telopeptide of the α2(I) chain revealed that isomerization also occurs at this end of the molecule (Brady and Robins, 1999), although there were some differences between N- and C-terminal telopeptides in the relative α/β ratios in bone and urine.

The isomerization and racemization of aspartyl residues in telopeptides potentially have applications in monitoring the relative rates of metabolism of different pools of bone. A systematic study of the kinetics of isomerization and racemization of C-telopeptide aspartyl residues using synthetic peptides aged *in vitro* indicated that the ratio most discriminatory in terms of indicating biological age was αL/αD (Cloos and Fledelius, 2000). Analysis of these ratios in bone samples using immunoassays specific for each form of CTx indicated that children and Paget's patients had a turnover time of 2–3 months, whereas those from healthy adults and patients with osteoporosis were longer lived. In an extension to these studies, analyses of the relative rates of turnover of a wide range of human tissues using the specific CTx immunoassays (Gineyts *et al.,* 2000) suggested that collagen turnover in most of the soft tissues examined, including arteries, heart, lung, and skeletal muscle, was much higher than that in bone. These rather surprising results probably arise because of the limited solubilization of the tissue with trypsin, although the amounts solubilized were not reported (Gineyts *et al.,* 2000). Without heat denaturation before trypsinization, however, only younger, less cross-linked tissue will be extracted, leading to an overestimate of the turnover rate. Reexamination of this topic with appropriate methodology is certainly warranted, but caution still needs to be exercised in quantifying enzyme digests of tissues where the immunoassays used have specific structural requirements.

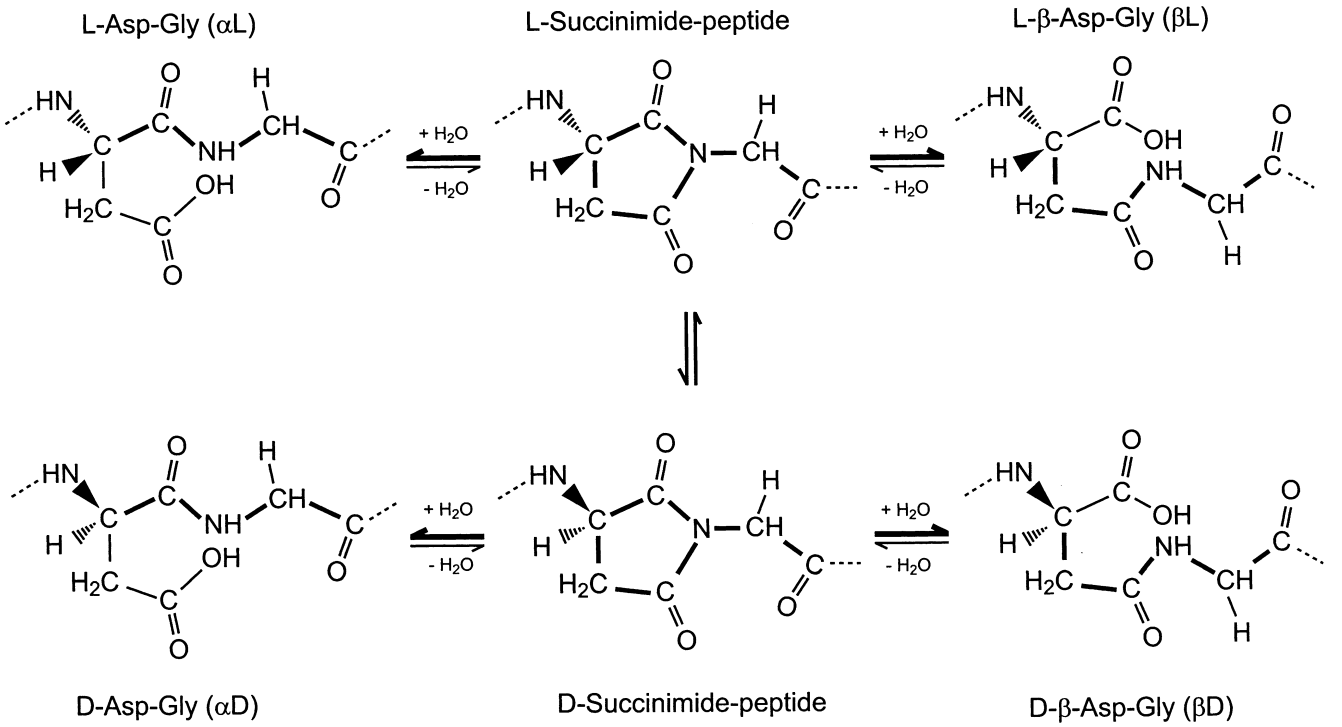

Figure 4 Isomerization and racemization of Asp-Gly peptides through succinimide intermediates giving rise to the αL, αD, βL, and βD forms detected within the C-terminal telopeptide of collagen type I in bone (Cloos and Fidelius, 2000). Interchange is predominantly through the succinimide, but some direct racemization of the peptides may also occur.

Degradative Pathways

Action of Osteoclastic Cells

The major role of osteoclasts in bone resorption has been discussed extensively in this volume and will not, therefore, be described here in detail. Of the many proteases expressed by osteoclasts, current evidence indicates that the cysteine proteinase cathepsin K plays a predominant part in degrading bone matrix. Initially cloned from rabbit osteoclasts (Tezuka *et al.,* 1997), cathepsin K was subsequently shown to be expressed predominantly in this cell type for other mammalian species. Unlike other cathepsins, this enzyme is capable of solubilizing demineralized, fibrillar bone collagen, and recombinant cathepsin K was shown to be more effective than the matrix metalloproteinases(MMPs) in this respect *in vitro* (Garnero *et al.,* 1998a). The importance of cathepsin K for bone metabolism *in vivo* was demonstrated by the discovery that pycnodysostosis, an autosomal recessive skeletal dysplasia, resulted from mutations in this enzyme (Gelb *et al.,* 1996). The lack of cathepsin K was later shown to give characteristic changes in the patterns of urinary bone markers (Nishi *et al.,* 1999), and confirmation that cathepsin K was important in determining the fragments produced from both N-terminal (Atley *et al.,* 2000) and C-terminal (Sassi *et al.,* 2000) sites of collagen type I was obtained from studies *in vitro*.

Although cathepsin K clearly has an important role in osteoclastic bone resorption, there are many other enzymes that may play a role. MMPs, which are abundant in bone (Knott *et al.,* 1997), include collagenases with the ability to cleave native collagen fibrils and gelatinases able to degrade further the denatured chain fragments produced.

Extraskeletal Processing of Collagen Fragments

Hepatic and Renal Influences

There is currently little evidence on whether the liver plays a significant role in the further processing of collagen fragments. Early studies showed that ^{125}I-labeled monomeric α1(I) chains injected into rats were taken up rapidly by liver endothelial and Kupffer cells (Smedsrod *et al.,* 1985). For the endothelial cells at least, this process was receptor mediated and was accompanied by lysosomal degradation of the denatured collagen chains. Whether the relatively small fragments of collagen that emanate from bone will be similarly sequestered and metabolized by the liver is unknown and further experimental evidence is needed.

In contrast, there is good evidence that the kidney has an important role in controlling the patterns of collagen degradation products from bone and other tissues. Initially, evidence was again obtained from animal experiments in which immunostaining of rat kidney sections with antibodies recognizing only denatured collagen showed large accumulations of collagen fragments in proximal renal tubules (Rucklidge *et al.,* 1986). Subsequent studies following the

fate of injected ^{3}H-labeled collagen fragments by autoradiography showed rapid uptake by proximal tubule epithelial cells and vacuolar transport to lysosomes (Rucklidge *et al.,* 1988) where antibody reactivity was lost, presumably through degradation of the peptides.

Analyses of serum and urinary concentrations of pyridinium cross-link components in children provided evidence that free pyridinium cross-links were in part produced in the kidney (Colwell and Eastell, 1996). This study showed that the proportion of free Dpd in serum was about half that in urine. Analysis of free Dpd in serum for older children revealed a negative correlation with the total cross-link output (Colwell and Eastell, 1996) and a similar correlation was noted in urine for a group of pre- and postmenopausal women (Garnero *et al.,* 1995). These data led to the hypothesis that the renal processing of collagen fragments was a saturable process whereby increased collagen turnover resulted in a progressive decrease in the proportion of free cross-links and a corresponding increase in their peptide forms (Colwell and Eastell, 1996; Garnero *et al.,* 1995; Randall *et al.,* 1996). This hypothesis is probably an oversimplification, however, as an analysis of the results for a wide range of healthy individuals and patients with metabolic bone diseases indicated only a weak correlation between the proportion of free Dpd and total cross-link output (Robins, 1998). Comparisons of serum and urinary immunoassays for telopeptide markers indicated a greater degree of renal processing of the N-terminal relative to C-terminal components (Fall *et al.,* 2000), although it is unclear whether this is related to the increased protease resistance of C-telopeptides imparted by the presence of isoaspartyl residues. Several studies have established that the patterns of collagen cross-link-containing components can be affected by various treatments for disease (Garnero *et al.,* 1995; Robins, 1995; Kamel *et al.,* 1995), and the effects of amino-bisphosphonates have received most attention in this respect.

Effects of Bisphosphonates

Much interest in this aspect was created by a report that measurements of free and peptide-bound cross-links in patients receiving acute, intravenous treatment with pamidronate for 3 days showed essentially no changes in free pyridinium cross-link concentrations, whereas there were large decreases in telopeptide-based assays and, to a lesser extent, in HPLC measurements of total cross-links (Garnero *et al.,* 1995). Although these finding appeared to over-estimate the bisphosphonate effects compared with another similar study (Delmas, 1993), subsequent investigations of the effects of longer term bisphosphonate treatment have confirmed that there are changes in the patterns of collagen degradation components. Treatment of postmenopausal women with the amino-bisphosphonate neridronate over a 4-week period resulted in a significant increase in the proportion of free Dpd (Fig. 5), with an apparently greater response to therapy in the peptide-bound fraction (Tobias *et al.,* 1996). This study also showed that there were no changes in the proportion of free Pyd, leading to an increased Pyd/Dpd ratio in the peptide fraction (Fig. 5). The changes in cross-link ratio were initially thought to represent altered tissue contributions to the cross-links, but, as Dpd is more prevalent at the N-terminal portion of collagen (Hanson and Eyre, 1996), these changes probably indicate differential effects on proteolytic degradation of the N- and C-telopeptide cross-linked regions.

Bisphosphonates appear to inhibit bone resorption through several mechanisms involving direct effects on osteoclasts and their precursors (Flanagan and Chambers, 1991; Murakami *et al.,*1995; Hughes *et al.,* 1995) or indirectly through effects on osteoblasts (Sahni *et al.,* 1993). Two classes of these compounds may be distinguished pharmacologically, with the more potent, nitrogen-containing bisphosphonates acting primarily through inhibition of protein prenylation (Benford *et al.,* 1999). Specifically, amino-bisphosphonates have been shown to activate caspase-3-like enzymes, the cysteine proteinases that act as the main executioner enzymes during apoptosis. It is conceivable, therefore, that these compounds may also affect the activity of enzymes involved in the degradation of collagen fragments. Whether this occurs in bone, which seems likely in view of the accumulation of bisphosphonates in this tissue, or in other organs involved in peptide processing is at present unknown. Thus, in addition to inhibiting bone resorption, bisphosphonates may also alter the patterns of collagen degradation products, a fact that is crucial in interpreting biochemical monitoring of these processes (see later).

Release of Cross-Linked Components from Bone *in Vitro*

The use of osteoclastic cells cultured on dentine slices or with bone particles has given information on the mechanisms and extent of collagen degradation in bone. Cross-linked N-telopeptide fragments (NTx) were shown to be released into medium from human bone, whereas no free pyridinium cross-links could be detected by HPLC (Apone *et al.,* 1997). Confocal microscopy of labeled bone surfaces has revealed the intracellular pathway of proteins, including degraded collagen type I, through osteoclasts (Nesbitt and Horton, 1997), and preliminary studies show that cathepsin K colocalized with the degrading collagen (Nesbitt *et al.,* 1999). These types of study, combining immunolocalization of collagen fragments with the response to enzyme inhibitors, provide a powerful technique to address the cellular mechanism of bone collagen resorption. Cathepsin K was shown to solubilize demineralized bone *in vitro* through cleavage at sites in both the telopeptides and within the collagen helix (Garnero *et al.,* 1998a). Size-exclusion chromatography of cathepsin K-digested bone has confirmed the extensive degradation of collagen, with immunodetection telopeptide fragments in the range of 2–12 kDa for NTx and 2–4 kDa for CTx (J. Brady and S. Robins, unpublished results).

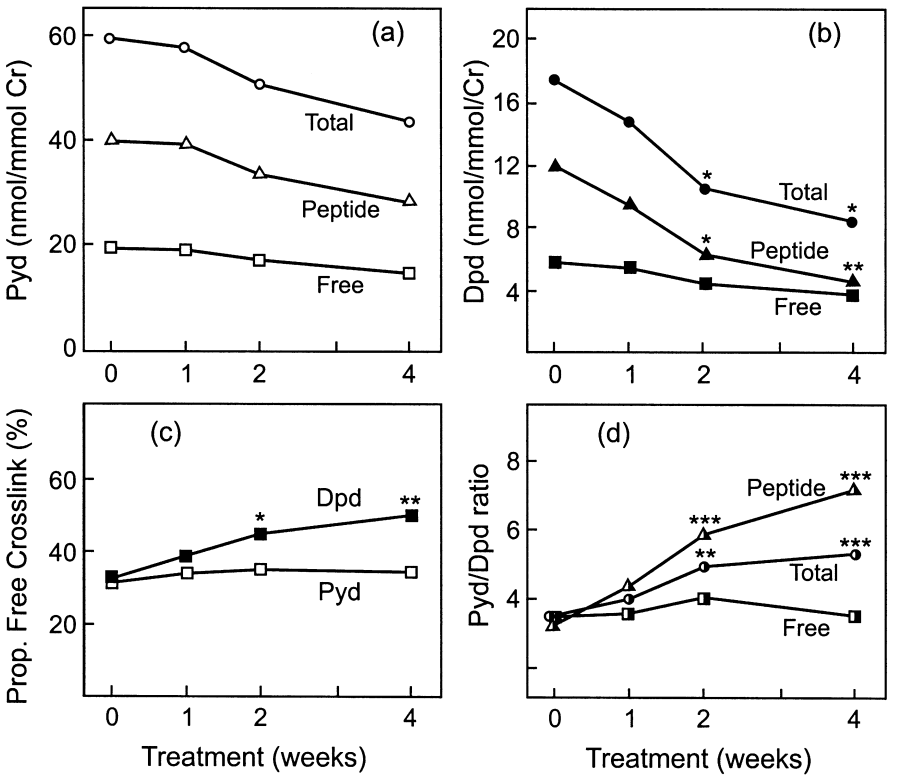

Figure 5 Effects on urinary pyridinium cross-link excretion of treating postmenopausal women with the amino-bisphosphonate neridronate for 4 weeks. In collections made at baseline, 1, 2, and 4 weeks, the concentrations of total (circles) and free (squares) Pyd (open symbols) and Dpd (closed symbols) were measured by HPLC allowing calculation of the peptide forms (triangles). Data are shown for Pyd (a) and Dpd (b), as well as the proportions of free cross-link (c) and the Pyd/Dpd ratio (d). Bisphosphonate treatment was accompanied by a significant rise in the proportion of free Dpd in urine (c) and consequent increases in Pyd/Dpd for the total and peptide forms (* $p \leq 0.01$; ** $p \leq 0.001$; *** $p < 0.001$, versus baseline). Results are the means for six individuals; error bars are omitted for clarity. Data are from Tobias *et al.* (1996).

Collagen Metabolites as Markers of Bone Metabolism

N- and C-Terminal Propeptides as Formation Markers

Procollagen type I, the initially synthesized product, is about 50% larger than the collagen molecule in fibrils, having large extension peptides at both N- and C-terminal ends. These propeptides are removed *en bloc* by separate proteases at or near the cell surface during secretion of the molecule. The intact C-terminal propeptide (PICP) containing intermolecular disulfide bonds can be detected in the blood as a 100- kDa component (Melkko *et al.,* 1990) and several commercial assays are now available. The assay has been used successfully to assess growth (Trivedi *et al.,* 1991), but its sensitivity to relatively small changes in bone formation, such as those accompanying menopause, has been rather limited.

Immunoassays for the N-terminal propeptide of procollagen I (PINP) have received renewed interest. A component isolated from amniotic fluid referred to as fetal antigen 2 was shown to be the N-propeptide (Teisner *et al.,* 1992). In serum, there are components related to the N-propeptide having apparent molecular masses of about 100 and 30 kDa, but different assays react differently with these components (Orum *et al.,* 1996; Melkko *et al.,* 1996). It has been suggested (Risteli *et al.,* 1995) that the smaller component is a degradation product related to the short helical domain, but there is currently some doubt about this interpretation (Jensen *et al.,* 1998). Although preliminary clinical data using PINP assays are encouraging, the fact the PINP and PICP assays can, in certain clinical applications, give different results emphasizes the importance of gaining further knowledge about the degradative pathways and clearance of these molecules.

Strategies for the Development of Bone Resorption Markers

Because of the importance of collagen type I in the properties of bone, it is perhaps not surprising that most bone resorption markers are based on components or fragments of this protein. Until the mid-1980s, urinary hydroxyproline was the main bone resorption assay available but, in the intervening years, advances in the knowledge of collagen structure and metabolism have not only led to the development of new markers, but also a greater appreciation of the

drawbacks inherent in hydroxyproline measurements. It is, however, important to keep in mind the difficulties with hydroxyproline measurements, as it is these criteria that form the basis for judging the improvements of the new markers.

URINARY HYDROXYPROLINE

The fact that hydroxyproline is present in all genetically distinct types of collagen (van der Mark, 1999) and in many other proteins with collagenous domains, such as the complement component C1q, lung surfactant protein, and acetylcholinesterase, creates a major drawback in terms of tissue specificity. In certain diseases, C1q turnover may be particularly elevated (Krane *et al.,* 1977), making significant contributions to hydroxyproline excretion. Nevertheless, because of continual remodeling, bone always represents a major contributor to any resorption marker. It has been estimated that in normal adults, bone degradation constitutes about 50% urinary hydroxyproline excretion, but this figure is much higher when bone turnover is elevated, as in Paget's disease (Deacon *et al.,* 1987). Collagen synthesis may also give rise to hydroxyproline excretion in two ways. The first arises because the N-propeptide of procollagen type I contains a short helical segment with hydroxyproline residues, which comprise just under 10% of the total. Release and subsequent degradation of the N-propeptide during fibril formation therefore contribute to the hydroxyproline pool. The second, perhaps more important, contributor of hydroxyproline from collagen synthesis is from the degradation of newly synthesized procollagen before secretion of the molecule. Experiments *in vitro* have shown that intracellular degradation appears to comprise a basal, lysosome-mediated level of about 15% of the total procollagen synthesized, but this can be augmented by other mechanisms to give up to 40% degradation of newly synthesized, hydroxyproline-containing protein (Bienkowski, 1984). Even taking into account the various contributors to the hydroxyproline pool, an added difficulty in using this marker is the fact that about 90% of released hydroxyproline is metabolized in the liver, a proportion that is assumed to be constant but there is little confirmatory experimental evidence. Two other problems with urinary hydroxyproline affect the applicability of the marker. The first is the well-documented contribution from dietary sources of hydroxyproline, thus necessitating the imposition of gelatin-free diets for at least 1 day before collection of the sample. The second is the practical difficulty in performing the assay, which requires hydrolysis of the sample and often an extraction with organic solvents.

Thus, criteria to be considered in judging improved bone resorption markers include specificity for bone, degradation only of mature tissue, lack of metabolism of marker, lack of necessity for dietary precautions, and ease of measurement.

URINARY HYDROXYLYSINE GLYCOSIDES

This assay was originally introduced primarily as a means to overcome the need for dietary restrictions before sampling, as the urinary glycosides were shown to be almost independent of dietary intake (Segrest and Cunningham, 1970). Collagen contains both mono- and di-saccharide derivatives O-linked to hydroxylysine, but the former, galactosyl-hydroxylysine (Gal-Hyl), predominates in bone and the urinary concentrations provide reasonable measures of resorption rate (Krane *et al.,* 1977; Bettica *et al.,* 1992). This marker may, however, be derived from all collagen precursors, and the values obtained will potentially be affected considerably by the intracellular degradation of procollagen. Renewed interest in the urinary assay was generated by the development of HPLC assay methods for urine (Moro *et al.,* 1984; Yoshihara *et al.,* 1993) and serum (Al-Dehaimi *et al.,* 1999), but measurement of Gal-Hyl remains labor-intensive and the few immunoassays that have been described (Leigh *et al.,* 1998) appear not to have been widely used.

PYRIDINIUM CROSS-LINKS

As discussed earlier, pyridinium cross-links are maturation products of lysyl oxidase-mediated cross-linking and their concentrations in urine therefore reflect only the degradation of insoluble collagen fibers and not of any precursors. The ratio Pyd:Dpd in urine is similar to the ratio of these two cross-links in bone, suggesting that both of the cross-links are likely to be derived predominantly from bone. Because of its more restricted tissue distribution, generally to mineralized tissues (Eyre *et al.,* 1984; Seibel *et al.,* 1992), Dpd is often described as a more bone-specific marker: this notion was reenforced by the close correlation between Dpd excretion and an independent, stable isotope method for determining bone turnover rate (Eastell *et al.,* 1997). Initially, the assays for pyridinium cross-links were HPLC methods with a hydrolysis and prefractionation step (Black *et al.,* 1988); despite later automation of the procedure (Pratt *et al.,* 1992), these procedures are time-consuming. The observation that the ratio of free to peptide-bound cross-links was similar in urine from healthy individuals and from patients with a range of metabolic bone disorders (Robins *et al.,* 1990; Abbiati *et al.,* 1993) opened the way for direct analysis of urine samples without the need for the hydrolysis step. This in turn led to the development of specific immunoassays for Dpd (Robins *et al.,* 1994) or for both pyridinium cross-links (Gomez *et al.,* 1996), and some of these immunoassays are now more widely available on multiple clinical analysers. The excretion of pyridinium cross-links has been shown to be independent of dietary ingestion of these compounds (Colwell *et al.,* 1993). Overall, therefore, these markers satisfy most of the criteria for bone markers outlined previously. Changes in the metabolism of the pyridinium components can, however, give rise to problems, particularly where this leads to alterations in the proportions of free to bound cross-links. Treatment with amino-bisphosphonates appears to give particular problems in this respect, as discussed later.

PEPTIDE ASSAYS

Instead of using cross-links themselves as markers, several groups have developed assays based on specific

antibodies raised against isolated collagen peptides containing the cross-links. The NTx and ICTP assays exemplify this type of development.

NTx Assay The antigen for the cross-linked N-telopeptide assay was isolated from the urine of a patient with Paget's disease of bone, and an immunoassay based on a monoclonal antibody was developed (Hanson *et al.,* 1992). This assay showed detectable reaction with urine from normal individuals, as well as large increases associated with elevated turnover. Although the antibody recognizes components in urine containing pyridinium cross-links (Hanson *et al.,* 1992), this type of cross-link is not essential and peptides containing pyrrolic cross-links may also be detected (Hanson and Eyre, 1996). Some form of cross-link must, however, be present for antibody recognition, thus ensuring that only degradation products of mature tissue are detected.

ICTP Assay This assay detects fragments from the C-telopeptide region of collagen type I. The antigen was a partially purified, cross-linked peptide from a bacterial collagenase digest of human bone collagen (Risteli *et al.,* 1993). Again, the isolated peptide contained pyridinium cross-links, but this type of bond was not essential for reactivity with the rabbit antiserum used in the assay. The ICTP assay was designed as a serum assay, which distinguishes it from most other bone resorption markers that were originally intended for urinary measurements. Although the ICTP assay fulfills many of the marker criteria discussed previously, metabolism of the analyte has proved to be an important factor limiting its application. The observation that cathepsin K cleaves within the epitope for the ICTP antibody (Sassi *et al.,* 2000) appears to explain why this assay is relatively insensitive to changes in bone remodeling mediated by normal osteoclastic activity. In contrast, pathological increases in bone degradation, such as those occurring in myeloma (Elomaa *et al.,* 1992) or metastatic bone disease (Aruga *et al.,* 1997), are well detected by the assay, as other enzyme systems, probably including MMPs, seem to be involved.

CTx Assay Development of the CTx assay involved an alternative strategy. Instead of using isolated cross-linking components, the antigen used initially was a synthetic octapeptide corresponding to the C-terminal telopeptide sequence containing the lysine residue involved in cross-linking (Bonde *et al.,* 1994). The aim of this procedure was to detect all types of cross-linking moieties and not be restricted by isolating specific components. Such a strategy was valid in detecting all collagen fragments derived from the C terminus but was less secure in avoiding the measurement of all collagen precursors. In fact, the synthetic peptide used contained a proportion of the more antigenic isoaspartyl residues, giving rise to the assay now referred to as β-CTx. The presence of the time-dependent modification in the analyte was beneficial in terms of the applicability of the assay, as this ensured that all components detected would be from mature collagen and not from any precursors. Later development of an assay specific for α-CTx (Fledelius *et al.,* 1997b) raised the possibility of utilizing the α/β ratio as an additional index of bone metabolism by indicating the "age" of the bone being resorbed. This approach proved to be valid for high turnover states such as Paget's disease (Garnero *et al.,* 1998b) but of limited value in other situations. The main reason for this is that the rate of isomerization of aspartyl residues is relatively rapid compared with the average time collagen remains in bone between deposition and resorption. The latter is probably of the order of 5 years (Eriksen, 1986), whereas the half-time of C-terminal β-Asp formation in bone is about 6 months (Cloos and Fledelius, 2000). Thus, full equilibrium of the different aspartyl isomers is generally achieved before the bone is resorbed. In a preliminary report, however, measurement of α/β ratios, including racemic variants of CTx in a large prospective study, was shown to be related to the risk of fracture in a 5-year follow-up (Garnero *et al.,* 2000). The group who fractured appeared to have less mature bone as indicated by a relative increase in α components; whether these changes resulted from an increased turnover of collagen at preexisting microfracture sites is as yet unclear.

With two α1(I) chain telopeptides in each collagen molecule, isomerization of aspartyl residues can give rise to cross-linked components containing α-α, α-β, or β-β forms (Fledelius *et al.,* 1997a), which can lead to uncertainties for data interpretation. An assay format involving two antibodies each recognizing a β-form C-telopeptide ensures that only fully mature molecules are detected (Rosenguist *et al.,* 1998; Christgau *et al.,* 1998). This form of assay, which is applicable to both urine and serum, represents a significant advance and is also available on multiple clinical analyzers.

Disturbances of Degradative Metabolism

As discussed previously, treatment with amino-bisphosphonates represents a major area of uncertainty in the application of bone resorption markers. Because the proportion of free pyridinium cross-links is increased by the treatment, the apparent decrease in bone resorption indicated by these markers is less than the true value. This change is measurable and has been well documented. The pools of peptides undergoing further degradation to give free cross-links are, however, those being measured by the NTx and CTx assays. Consequently, the changes in degradative metabolism caused by bisphosphonates will result in decreased concentrations of these peptides larger than those warranted by the decrease in true bone resorption: the extent of these overestimates of bone resorption rate cannot be ascertained easily. In practical terms, these considerations have a limited impact on the applications of these markers to monitor treatment. Where more precise indications of the true changes in bone resorption rate are required, however, the use of total (hydrolyzed) pyridinium cross-links gives results less susceptible to changes in degradative metabolism.

Concluding Remarks

In the past decade, major advances have been made in understanding the structure and metabolism of bone collagen. In terms of cross-linking, most of the structural components have been identified, but more information is needed on the functional significance of the different cross-links. This is particularly true for the pyrroles, which correlative studies have suggested exert a relatively more important effect on biomechanical properties (Knott and Bailey, 1998). The way that collagen cross-linking affects the mineralization of bone is an intriguing question, but further studies are required to establish whether the patterns of cross-links formed play a causal or merely a permissive role.

The new biochemical markers of bone metabolism are providing an additional tool for the clinical management of patients. The bone resorption markers in particular represent a significant improvement over previously available methods. Whether based on specific cross-link components or on cross-linked, collagen type I telopeptides, the methods have good specificity for bone, provided that no abnormal fibrotic pathologies, such as liver cirrhosis, are present. Most of the markers are, however, susceptible to changes in degradative metabolism, and the development of simple, direct assays that overcome these problems provides ample challenges for future research.

CHAPTER 14

Bone Matrix Proteoglycans and Glycoproteins

Pamela Gehron Robey

Craniofacial and Skeletal Diseases Branch, National Institute of Dental and Craniofacial Research, National Institutes of Health, Bethesda, Maryland 20892

Introduction

While the organic matrix of bone is composed primarily of collagen(s) (as reviewed in a previous chapter), the existence of other noncollagenous components was first postulated by Herring and co-workers in the 1960s. Using degradative techniques, a variety of carbohydrate-containing moieties were extracted and partially characterized (Herring *et al.,* 1974). The major breakthrough in the chemical isolation and characterization of noncollagenous bone matrix proteins came with the development of techniques whereby proteins could be extracted in an intact form (Termine *et al.,* 1980; Termine *et al.,* 1981). While these procedures were suitable for the isolation of the more abundant bone matrix proteins, the advent of osteoblastic cultures that faithfully retain phenotypic traits of cells in this lineage allowed for the discovery of other proteins that end up in the matrix. While they are not as abundant as the so-called structural elements, their importance in bone physiology cannot be underestimated. This has been underscored by the identification of mutations in a number of these proteins that result in abnormal bone. Many of these low-abundance proteins are discussed in subsequent chapters.

Collagen(s) is by far and away the major organic constituent of bone matrix (Table I). However, collagen may not be the direct nucleator of hydroxyapatite deposition. Physicochemical studies based on predictions of the surface topography of the hydroxyapatite unit cell predict that such a nucleator would have a β-pleated sheet structure, a feature that is not found in the predicted structure of the collagen molecule (Addadi *et al.,* 1985). In addition, collagen is not present in the extracellular environment in an unbound form. In other words, there are a large number of matrix proteins that have been found to bind to collagen, thereby forming fibrils, and it is probable that collagen serves as a scaffolding upon which nucleators are oriented. Consequently, the nucleators of hydroxyapatite deposition are most likely members of the noncollagenous components of the organic bone matrix. This chapter discusses the major structural proteins (proteoglycans and glycoproteins) found in bone matrix. These proteins have been reviewed extensively (Gokhale *et al.,* 2001). This is an area that is expanding rapidly due to the generation of better tools, such as antibodies, cDNA probes, and genomic constructs. These reagents have been quite useful in determining the pattern and regulation of expression. Furthermore, the development of transgenic animals that either overexpress or are deficient in these proteins has also provided insight into their potential function.

Proteoglycans

This class of molecules is characterized by the covalent attachment of long chain polysaccharides (glycosaminoglycans, GAGs) to core protein molecules. GAGs are composed of repeating carbohydrate units that are sulfated to varying degrees and include chondroitin sulfate (CS), dermatan sulfate (DS), keratan sulfate (KS), and heparan sulfate (HS). Different subclasses of proteoglycan are generally characterized by the structure of the core protein and by the nature of the GAG (Table II). Although other

Table I Characteristics of Collagen-Related Genes and Proteins Found in Bone Matrix

Collagens	Gene	Protein	Function
Type I	COL1A1 17q21.3-22 18 kb, 51 exons 7.2 and 5.9 kb mRNA COL1A2 7q21.3-22 35 kb, 52 exons 6.5 and 5.5 kb mRNA	$[\alpha1(I)_2\alpha2(I)]$ $[\alpha1(I)_3]$	Most abundant protein in bone matrix (90% of organic matrix), serves as scaffolding, binds and orients other proteins that nucleate hydroxyapatite deposition
Type X	COL10A1	$[\alpha1(x)_3]$	Present in hypertrophic cartilage but does not appear to regulate matrix mineralization
Others: Type III Type V	COL3A1 2q24.3-q31 COL5A1 COL5A2 2q24.3-q31 COL5A3	$[\alpha1(III)]_3$ $[\alpha1(V)_2\alpha2(V)]$ $[\alpha1(V)\alpha2(V)\alpha3(V)]$	Present in bone in trace amounts, may regulate collagen fibril diameter, their paucity in bone may explain the large diameter size of bone collagen fibrils
FACITS ?			

types of molecules can be sulfated, proteoglycans bear greater than 95% of the sulfate groups within any organic matrix (Schwartz, 2000).

Aggrecan and Versican (PG-100)

There are two large chondroitin sulfate proteoglycans associated with skeletal tissue that are characterized by core proteins with globular domains at the amino and carboxy termini and by binding to hyaluronan to form large aggregates. Aggrecan is virtually cartilage specific, but mRNA levels have been detected in developing bone (Wong *et al.,* 1992). In the nanomelic chick, there is a mutation in the aggrecan core protein such that it is not expressed in cartilage (Primorac *et al.,* 1999). However, there is a slight effect on bones that form via the intramembranous pathway, an unexpected finding as these bones would not be expected to be affected by abnormal cartilage development.

Closely related, but not identical, is a soft connective tissue-enriched proteoglycan termed versican, which is most localized to loose, interstitial mesenchyme in developing bone. It has been hypothesized that it captures space that will ultimately become bone (Fisher *et al.,* 1985). It is this proteoglycan that is being destroyed as osteogenesis progresses. It is noteworthy that the core protein of versican contains EGF-like sequences (Zimmermann *et al.,* 1989), and release of these sequences may influence the metabolism of cells in the osteoblastic lineage. As osteogenesis progresses, versican is replaced by two members of another class of proteoglycans that contain core proteins of a different chemical nature (Fisher *et al.,* 1985).

Decorin (PG-II) and Biglycan (PG-I)

The two small proteoglycans that are heavily enriched in bone matrix are decorin and biglycan, both which contain chondroitin sulfate chains in bone, but bear dermatan sulfate in soft connective tissues. They are characterized by core proteins that contain a leucine-rich repeat sequence, a property shared with proteins that are associated with morphogenesis such as *Drosophila* toll protein and chaoptin, the leucine-rich protein of serum and adenylate cyclase (Fisher *et al.,* 1989). The three-dimensional structure of another protein containing this repeat sequence, ribonuclease inhibitor protein, has been determined by physicochemical methods, and the structure predicts a highly interactive surface for protein binding (Kobe *et al.,* 1995).

While decorin and biglycan share many properties due to the large degree of homology of their core proteins, they are also quite distinct, as best demonstrated by their pattern of expression (Bianco *et al.,* 1990). In cartilage, decorin is found in the interterritorial matrix away from the chondrocytes, whereas biglycan is in the intraterritorial matrix. In keeping with this pattern, during endochondral bone formation, decorin is widely distributed in a pattern that is virtually indistinguishable from that of type I collagen. It first appears in preosteoblasts, is maintained in fully mature osteoblasts, and is subsequently downregulated as cells become buried in the extracellular matrix to become osteocytes. However, biglycan exhibits a much more distinctive pattern of distribution. It is found in a pericellular location in distinct areas undergoing morphological delineation. It is upregulated in osteoblasts and, interestingly, it is maintained in osteocytic lacunae. It is speculated that osteocytes act as mechanoreceptors within the bone matrix (Burger *et al.,* 1999) and that proteoglycans, possibly biglycan or cell

Table II Gene and Protein Characteristics of Proteoglycans, Leucine-Rich Repeat Proteins, and Glycosaminoglycans in Bone Matrix

	Gene	Protein	Function
Versican (PG-100)	5q12-14 90 kb, 15 exons one splice variant 10, 9, 8 kb mRNAs	1×10^6 intact protein, ~360 kDa core, ~12 CS chains of 45 kDa, G1 and G3 globular domains with hyaluronan-binding sites, EGF and CRP-like sequences	May "capture" space that is destined to become bone
Decorin	12q21-23 >45 kb, 9 exons alternative promoters, 1.6 and 1.9 kb mRNA	~130 kDa intact protein, ~38-45 kDa core with 10 leucine-rich repeat sequences, 1 CS chain of 40 kDa	Binds to collagen and may regulate fibril diameter, binds to TGF-β and may modulate activity, inhibits cell attachment to fibronectin
Biglycan	Xq27 7 kb, 8 exons 2.1 and 2.6 kb mRNA	~270 kDa intact protein, ~38-45 kDa core protein with 12 leucine-rich repeat sequences, exons, 2 CS chains of 40 kDa	May bind to collagen, may bind to TGF-β, pericellular environment, a genetic determinant of peak bone mass
Fibromodulin	1q32 8.5 kb, 3 exons	59 kDa intact protein, 42 kDa core protein with leucine-rich repeat sequences, one N-linked KS chain	Binds to collagen, may regulate fibril formation, binds to TGF-β
Osteoglycin (Mimecan)	9q21,3-22 33kb, 8 exons 3.7 kb mRNA	299 aa precursor, 105 aa mature protein leucine-rich repeat sequences	Binds to TGF-β, no GAG in bone, keratan sulfate in other tissues
Osteoadherin	9q21.3-22 4.5 kb mRNA	85 kDa intact protein, 47 kDa core protein, 11 leucine-rich repeat sequences, RGD sequence	May mediate cell attachment
Hyaluronan	Multigene complex	Multiple proteins associated outside of the cell, structure unknown	May work with versican-like molecule to capture space destined to become bone

surface-associated molecules (such as heparan sulfate proteoglycans), may act as transducers of sheer forces within canaliculi. Transgenic mice that are deficient in decorin have primarily thin skin (Danielson *et al.,* 1997), whereas mice deficient in biglycan fail to achieve peak bone mass and develop osteopenia (Xu *et al.,* 1998).

Although decorin and biglycan are found in soft connective tissues that do not mineralize, their presence in osteoid makes them potential candidates as nucleators of hydroxyapatite precipitation. Decorin does not appear to be a direct nucleator, as it has no effect on hydroxyapatite precipitation or crystal growth in solution assays, and it has a low affinity for calcium. In similar assays, biglycan has varying effects depending on concentration. While biglycan has a low affinity for calcium, at low concentrations it facilitates hydroxyapatite precipitation but inhibits precipitation at high concentration. It is thought that sulfate-containing molecules must be removed prior to matrix mineralization and that they may mask sites that will ultimately act as nucleators. Consequently, it is unlikely that decorin or biglycan are initiators of matrix mineralization (reviewed in Gokhale *et al.,* 2001).

Both decorin and biglycan have been found to bind to transforming growth factor (TGF)-β and to regulate its availability and activity (Schonherr *et al.,* 2000). Decorin binds to collagen (decorating collagen fibrils), as does biglycan. Another activity has been demonstrated by *in vitro* cell attachment assays where decorin and biglycan were both found to inhibit bone cell attachment, presumably by binding to fibronectin and inhibiting its cell–matrix-binding capabilities (Grzesik *et al.,* 1994). It is not clear how this *in vitro* phenomenon relates to normal bone cell physiology, but it points to a role for these proteoglycans in modulating cell–matrix interactions.

Other Leucine-Rich Repeat Sequence Proteins and Proteoglycans

Interestingly, there are at least 60 proteins that have been found to contain the leucine-rich repeat sequence (LRR), and many of them are also proteoglycans (small leucine-rich proteoglycans, SLRPs) (Matsushima *et al.,* 2000). One LRR found in bone is osteoglycin, previously termed osteoinductive factor and later found to be a protein bound to TGF-β (Ujita *et al.,* 1995). This molecule is similar but not identical to the proteoglycan PG-Lb, which has now been found to be epiphycan, localized primarily in epiphyseal cartilage. More recently, another LRR has been localized to developing bone. Unlike other LRRs, it has an aspartic acid-rich amino sequence and, for this reason, has been named asporin (Henry *et al.,* 2001; Lorenzo *et al.,* 2001). Other members of the SLRP family found in bone include fibromodulin, which contains keratan sulfate and binds to collagen fibrils in regions distinctly different from those of decorin (Hedbom *et al.,* 1993), and osteoadherin, which also contains the cell attachment sequence RGD (Sommarin *et al.,* 1998). While these proteins appear to be "born to bind," definitive functions are not known. Other proteoglycans have been isolated from a variety of animal species by using varying techniques such as HAPGIII (so named for its ability to bind to hydroxyapatite) and PG-100, which has been shown subsequently to be homologous to versican as reviewed previously (Gokhale *et al.,* 2001).

Although not generally found in the extracellular matrix, heparan sulfate proteoglycans found associated with, or intercalated into, cell membranes may be very influential in regulating bone cell metabolism. The receptors for several growth factors (TGF-β and FGFs, to name two) have been found to associate with heparan sulfate (either bound covalently to core proteins or as free glycosaminoglycans). These associations are now known to modulate growth factor and receptor activity (Schonherr *et al.,* 2000). One class of heparan sulfate proteoglycans is linked to cell membranes by phosphoinositol linkages that are cleavable by phospholipase C (glypicans). Consequently, their activity may be in the pericellular environment or in the extracellular matrix. Intercalated heparan sulfate proteoglycans (the syndecan family) have been postulated to regulate cell growth, perhaps through association with various factors (Vlodavsky *et al.,* 1995). The complete cast of heparan sulfate proteoglycans present in the cellular and pericellular environment is not yet complete.

Hyaluronan

This unsulfated glycosaminoglycan is not attached to a protein core and is synthesized by a completely different pathway (Table II). While other glycosaminoglycans are formed by the transfer of growing glycosaminoglycan chains from a lipid carrier (dolichol phosphate) to a protein carrier, hyaluronan is synthesized in the extracellular environment by a group of enzymes that are localized on the outer cell membrane. Large amounts of hyaluronan are synthesized during early stages of bone formation and may associate with versican to form high molecular weight aggregates, although this association has not been demonstrated to occur in developing bone. Very little is known about the potential function of hyaluronan in bone formation, but in other tissues it is speculated to participate in cell migration and differentiation (Fedarko *et al.,* 1992).

Glycoproteins

Virtually all of the bone matrix proteins are modified posttranslationally to contain either N- or O-linked oligosaccharides, many of which can be modified further by the addition of phosphate and/or sulfate (Table III). In general, compared to their soft connective tissue counterparts, bone matrix proteins are modified more extensively and in a different pattern. In some cases, differences in posttranslational modifications result from differential splicing of heterogeneous nuclear RNA, but in general, it results from differences in the activities of enzymes located along the intracellular pathway of secretion. The pattern of posttranslational modifications may be cell type specific and consequently may be of use in distinguishing protein metabolism from one tissue type versus another. The development of probes and antibodies against these types of tissue-specific determinants may be of great diagnostic value.

The number of glycoproteins that have been identified in bone matrix grows by leaps and bounds every year. This is due in part to the explosion of sequence information from cDNA libraries, where one has the ability to pick up even the scarcest of clones. What follows next is a brief description of the more abundant bone matrix glycoproteins that most likely play major structural as well as metabolic roles. Other glycoprotein species have been identified primarily as growth factors, produced both endogenously and exogenously, and will be covered in more detail elsewhere in this volume.

Osteonectin (SPARC, Culture Shock Protein, and BM40)

With the development of procedures to demineralize and extract bone matrix proteins without the use of degradative enzymes, osteonectin was one of the first proteins isolated in intact form. This molecule was so named due to its ability to bind to Ca^{2+}, hydroxyapatite, and collagen and to nucleate hydroxyapatite deposition (Termine *et al.,* 1981). The osteonectin molecule contains several different structural features, the most notable of which is the presence of two EF hand high-affinity calcium-binding sites. These structures are usually found in intracellular proteins, such as calmodulin, that function in calcium metabolism (reviewed in Yan *et al.,* 1999).

Table III Gene and Protein Characteristics of Glycoproteins in Bone Matrix

	Gene	Protein	Function
Alkaline phosphatase	1 50 kb, 12 exons alternative promoters, one RFLP 2.5, 4.1 4.7 kb mRNA	Two identical subunits of ~80 kDa, disulfide bonded, tissue specific post-translational modifications	Potential Ca^{2+} carrier, hydrolyzes inhibitors of mineral deposition such as pyrophosphates
Osteonectin	5q31-33 20 kb, 10 exons, one RFLP, 2.2, 3.0 kb mRNA	~35–45 kDa, intra molecular disulfide bonds, α helical amino terminus with multiple low affinity Ca^{2+} binding sites, two EF hand high affinity Ca^{2+} sites, ovomucoid homology, glycosylated, phosphorylated, tissue-specific modifications	May mediate deposition of hydroxyapatite, binds to growth factors, may influence cell cycle, positive regulator of bone formation
Tetranectin	Two genes 12 kb, 3 exons 1 kb mRNA	21 kDa protein composed of four identical subunits of 5.8 kDa, sequence homologies with asialoprotein receptor and G3 domain of aggrecan	Binds to plasminogen, may regulate matrix mineralization

Although osteonectin is highly enriched in bone, it is also expressed in a variety of other connective tissues as specific points during development, maturation or repair processes *in vivo.* SPARC (secreted protein, acidic, rich in cysteine) was identified after induction by cAMP in teratocarcinoma cells and was found to be produced at very early stages of embryogenesis. Interestingly, if osteonectin is inactivated by the use of blocking antibodies during tadpole development, there is a disruption of somite formation and subsequent malformations in the head and trunk (Purcell *et al.,* 1993). Mice that are deficient of osteonectin present with severe cataracts (Bassuk *et al.,* 1999) and develop osteoporosis (Delany *et al.,* 2000).

Constitutive expression in the adult tissue is limited to cells associated intimately with mineralized tissues, such as hypertrophic chondrocytes, osteoblasts, and odontoblasts, and ion-transporting cells, such as mammary epithelium, distal tubule epithelium in the kidney, and salivary epithelium (cells associated with basement membrane, hence the name BM-40). Transient expression has been noted in other cell types, such as decidual cells in the uterus and in testis when cells are undergoing a maturation event. *In vitro,* expression appears to be deregulated rapidly, resulting in expression by cells that would not be expressing high levels *in situ,* hence its designation as a culture shock protein.

There have been numerous studies using both intact molecule and peptides derived from different regions. Many of these structure–function studies have been performed in endothelial cell cultures, from which culture shock protein was originally isolated. From these studies, osteonectin has been implicated in regulating the progression of the cell through the cell cycle, cell shape, cell–matrix interactions, binding to metal ions, binding to growth factors, and modulating enzymatic activities (Yan *et al.,* 1999). However, many of these activities have not been found or have not been tested in osteoblastic cultures. It should also be recognized that the activity of a peptide might not occur *in vivo* when it is taken out of context of the intact protein or naturally occurring degradative products.

Tetranectin

This tetrameric protein has been identified in woven bone and in tumors undergoing mineralization (Wewer *et al.,* 1994). This protein shares sequence homologies with globular domains of aggrecan and asialoprotein receptor, but it is not known what function it plays in bone metabolism to date.

RGD-Containing Glycoproteins

Some of the major glycoproteins in bone matrix also contain the amino acid sequence Arg-Gly-Asp (RGD), which conveys the ability of the extracellular matrix protein to bind to the integrin class of cell surface receptors (Ruoslahti, 1996) (Table IV). This binding is the basis of many cell attachment activities that have been identified by *in vitro* analysis; however, it should be noted that it is not yet clear how this *in vitro* activity translates into *in vivo* physiology. The bone matrix contains at least eight RGD-containing glycoproteins [collagen(s), thrombospondin, fibronectin, vitronectin, fibrillin, osteoadherin, osteopontin, and bone sialoprotein]. While this

Table IV Gene and Protein Characteristics of Glycoproteins in Bone Matrix - Continued RGD-Containing Glycoproteins

RGD-containing glycoproteins	Gene	Protein	Function
Thrombospondins	TSP-1 - 15q15 TSP-2 - 6q27 TSP-3 - 1q21-24 TSP-4 - 5q13 COMP - 19p13.1 4.5–16 kb, 22 exons 4.5–6.1 kb mRNA	~450 kDa molecule, three identical disulfide-linked subunits of ~150–180 kDa, homologies to fibrinogen, properdin, EGF, collagen, von Willebrand, *P. falciparum* and calmodulin, RGD at the C terminal globular domain	Cell attachment (but usually not spreading), binds to heparin, platelets, type I and V collagens, throm fibrinogen, laminin, bin, plasminogen and plasminogen activator inhibitor, histidine-rich glycoprotein, TSP-2 is a negative regulator of bone formation
Fibronectin	2p14-16, 1q34-36 50 kb in chicken, 50 exons, multiple splice forms, 6 RFLPs, 7.5 kb mRNA	~400 kDa with two non-identical subunits of ~200 kDa, composed of type I, II, and III repeats, RGD in the 11th type III repeat 2/3 from N terminus	Binds to cells, fibrin heparin, gelatin, collagen
Vitronectin	17q ~70 kDa, RGD close to N 4.5 kb, 8 exons, 1.7 kb mRNA	Cell attachment protein, terminus, homology to somatomedin B, rich in cysteines, sulfated, phosphorylated	binds to collagen, plasminogen and plasminogen activator inhibitor, and to heparin
Fibrillin	15q15-23, 5 (two different genes), 110 kb, 65 exons, 10 kb mRNA	350 kDa, EGF-like domains, RGD, cysteine motifs	May regulate elastic fiber formation
Osteopontin	4q13-21 8.2 kb, 7 exons, multiple alleles, one RFLP, one splice variant, several alleles 1.6 kb mRNA	~44-75 kDa, polyaspartyl stretches, no disulfide bonds, glycosylated, phosphorylated, RGD located 2/3 from the N-terminal	Binds to cells, may regulate mineralization, may regulate proliferation, inhibits nitric oxide synthase, may regulate resistance to viral infection, a regulator of bone resorption
Bone sialoprotein	4q13-21 15 kb, 7 exons, 2.0 mRNA	~46-75 kDa, polyglutamyl stretches, no disulfide bonds, 50% carbohydrate, tyrosine-sulfated, RGD near the C terminus	Binds to cells, may initiate mineralization
BAG-75	Gene not yet isolated, mRNA not yet cloned	~75 kDa, sequence homologies to phosphophoryn, osteopontin and bone sialoprotein, 7% sialic acid, 8% phosphate	Binds to Ca^{2+}, may act as a cell attachment protein (RGD sequence not yet confirmed), may regulate bone resorption

would appear to be a case of extreme redundancy, both *in vivo* and *in vitro* analysis indicates that the proteins are not equivalent in their abundance or pattern of expression during bone formation and in other tissues or in their *in vitro* activities (Grzesik *et al.,* 1994).

Thrombospondins

Thrombospondins are a family of multifunctional proteins. Thrombospondin-1 was first identified as the most abundant protein in platelet α granules, but is found in many tissues during development, including bone (Robey *et al.,* 1989). Subsequently, four other members have been described, including the identification of COMP (cartilage oligomeric matrix protein) as thrombospondin-5 (Adolph *et al.,* 1999; Newton *et al.,* 1999). In bone, all forms are present, synthesized by different cell types at different stages of maturation and development (Carron *et al.,* 1999). Thrombospondins have many proposed activities, including binding to a large number of matrix proteins and cell surface proteins. *In vitro,* it mediates bone cell adhesion in an RGD-independent fashion, indicating the presence of other sequences in the molecule that

are required. Furthermore, cell spreading requires the synthesis of other proteins. The thrombospondin-2-deficient mouse has been found to have increased cortical thickness compared to normal littermates (Hankenson *et al.,* 2000), perhaps due to the fact that it appears to be a stimulator of bone resorption (Carron *et al.,* 1995)

Fibronectin

Fibronectin is synthesized by many connective tissue cells and is a major component of serum. There are a large number of different mRNA splice variants such that the number of potential forms is quite high. Consequently, bone matrix could contain fibronectin that originates from exogenous as well as endogenous sources (reviewed in Romberger, 1997). The precise form that is present in cells in the osteoblastic lineage is unknown. Fibronectin is produced during early stages of bone formation and has been found to be highly upregulated in the osteoblastic cell layer. Interestingly, bone cell attachment to fibronectin *in vitro* is in an RGD-independent fashion (Grzesik *et al.,* 1994). However, this correlates well with the expression of the fibronectin receptor, $\alpha_4\beta_1$, which binds to a sequence other than RGD in the fibronectin molecule and is also expressed by some osteoblastic cells. Cell–matrix interactions mediated by fibronectin–$\alpha_4\beta_1$ binding may play a role in the maturation sequence of cells in the osteoblastic lineage.

Vitronectin

This serum protein, first identified as S-protein due to its cell-spreading activity, is found at low levels in mineralized matrix (Grzesik *et al.,* 1994). Its cell surface receptor, $\alpha_v\beta_3$, is distributed broadly throughout bone tissue. There may also be endogenous synthesis of a related form (Seiffert, 1996). In addition to cell attachment activity, it also binds to and affects the activity of the plasminogen activator inhibitor (Schvartz *et al.,* 1999).

Fibrillins

In addition to the RGD sequence, fibrillin-1 and fibrillin-2 are glycoproteins that also contain multiple EGF-like repeats. They are major components of microfibrils, and mutations in these genes lead to Marfan's syndrome, which exhibits abnormalities in bone growth (Ramirez *et al.,* 1999). It is not yet known if it is produced at a specific stage of bone formation, remodeling, or turnover; however, it is known that they associate with LTBP (latent TGF-β-binding protein) in microfibrils. (Dallas *et al.,* 2000).

Small Integrin-Binding Ligands with N-linked Glycosylation (SIBLINGs)

Several bone matrix proteins are characterized by the presence of relatively large amounts of sialic acid. Interestingly, they are clustered at 4q21-23 and appear to have arisen by gene duplication. The two best characterized, osteopontin and bone sialoprotein, also contain the RGD sequence, as does another one of the family members, dentin matrix protein-1 (DMP-1). For this reason, the family has been termed SIBLINGs (Fisher *et al.,* 2001). Other SIBLINGs include dentin sialoprotein, DSP, and dentin phosphoprotein, DPP, which are coded for by the same gene, now termed dentin sialophosphoprotein, DSPP (Butler *et al.,* 1995). The latest member of the family, matrix extracellular glycoprotein, MEPE, was isolated from ongogenic osteomalacic tumors and may contribute to the renal phosphate exhibited by these patients (Rowe *et al.,* 2000). There may also be another member of the family, BAG-75 (Gorski *et al.,* 1997); however, primary sequence information and chromosomal localization are unavailable at this time.

Osteopontin (Spp, BSP-I)

This sialoprotein was first identified in bone matrix extracts, however, it was also identified as the primary protein induced by cellular transformation. In bone, it is produced at late stages of osteoblastic maturation corresponding to stages of matrix formation just prior to mineralization. *In vitro,* it mediates the attachment of many cell types, including osteoclasts. In osteoclasts, it has also been reported to induce intracellular signaling pathways as well. In addition to the RGD sequence, it also contains stretches of polyaspartic acid and it has a fairly high affinity for Ca^{2+}; however, it does not appear to nucleate hydroxyapatite formation in a number of different assays. Osteopontin has been reviewed by Sodek *et al.* (2000) and is covered in greater detail in another chapter in this volume.

Bone Sialoprotein (BSP-II)

The other major sialoprotein is bone sialoprotein, composed of 50% carbohydrate (12% is sialic acid) and stretches of polyglutamic acid (as opposed to polyaspartic acid in osteopontin). The RGD sequence is located at the carboxy terminus of the molecule, whereas it is located centrally in osteopontin. The sequence is also characterized by multiple tyrosine sulfation consensus sequences found throughout the molecule, in particular in regions flanking the RGD (Fisher *et al.,* 1990). Sulfated BSP has been isolated in a number of animal species, however, the levels appear to be variable.

Bone sialoprotein exhibits a more limited pattern of expression than osteopontin. In general, its expression is tightly associated to mineralization phenomena (although there are exceptions). In the skeleton, it is found at low levels in chondrocytes, in hypertrophic cartilage, in a subset of osteoblasts at the onset of matrix mineralization, and in osteoclasts (Bianco *et al.,* 1991). Consequently, BSP expression marks a late stage of osteoblastic differentiation and an early stage of matrix mineralization. Outside of the skeleton, BSP is found in trophoblasts in placental membranes, which

in late stages of gestation fuse and form mineralized foci. A BSP-deficient mouse has been generated, but reportedly does not exhibit a skeletal phenotype, possibly due to compensation of BSP function by other SIBLINGs.

BSP may be multifunctional in osteoblastic metabolism. It is very clear that it plays a role in matrix mineralization as supported by the timing of its appearance in relationship to the appearance of mineral and its Ca^{2+} binding properties. BSP has a very high affinity for calcium. The polyglutamyl stretches were thought to be solely responsible for this high affinity, however, studies using recombinant peptides suggest that while the polyglutamyl stretches are required, they are not the sole determinants (Stubbs *et al.,* 1997). Unlike osteopontin, BSP does nucleate hydroxyapatite deposition in a variety of assays.

It is also clear from *in vitro* assays that BSP is capable of mediating cell attachment, most likely through interaction with the somewhat ubiquitous $\alpha_v\beta_3$ (vitronectin) receptor. Bone cells attach to the intact molecule in an RGD-dependent fashion. However, when BSP is fragmented, either endogenously by cells or using commercially available enzymes, the fragment most active in cell attachment does not contain the RGD sequence (Mintz *et al.,* 1993). Studies indicate that the sequence upstream from the RGD mediates attachment (in an RGD independent fashion) and suggest that the integrin-binding site is more extended than had been envisioned previously (Stubbs, 1996). Sequences flanking the RGD site are often tyrosine sulfated. However, it is not known how sulfation influences BSP activity, as *in vitro,* unsulfated BSP appears to be equivalent in its activity. Once again, it is not clear if currently available *in vitro* assays are sufficiently sophisticated to determine what influence posttranslational modifications, such as sulfation, have on the biological activity. In addition to sulfation, conformation of the RGD site may also influence the activity of the protein. While the RGD region in fibronectin is found in a looped-out region that is stabilized by disulfide bonding, there are no disulfide bonds in BSP. However, the flanking sequences most likely influence the conformation of the region. It also appears the cyclic conformations have a higher affinity for cell surface receptors than linear sequences (van der Pluijm *et al.,* 1996).

Dentin Matrix Protein-1 (DMP-1)

Although DMP-1 was originally thought to be specific to dentin, it was subsequently found to be synthesized by osteoblasts as well (D'Souza *et al.,* 1997). However, its function in bone metabolism is not presently known.

Serum Proteins

The presence of hydroxyapatite in the bone matrix accounts for the adsorption of a large number of proteins that are synthesized elsewhere and brought into the vicinity via the circulation (Delmas *et al.,* 1984). Most of these proteins are synthesized in the liver and hematopoietic tissue and represent classes of immunoglobulins, carrier proteins, cytokines, chemokines, and growth factors. Interestingly, some of these proteins are also synthesized endogenously by cells in the osteoblastic lineage. It is not known if the origin of a particular factor (and hence proteins with potentially different posttranslational modifications) affects biological activity or not.

Although serum proteins are not synthesized locally, they may have a significant impact on bone metabolism (Table V). Albumin, which is synthesized by the liver, is concentrated in bone severalfold above levels found in the circulation. It is not known whether it plays a structural role in bone matrix formation; however, it does have an influence on hydroxyapatite formation. In *in vitro* assays, albumin inhibits hydroxyapatite growth by binding to several faces of the seed crystal (Garnett *et al.,* 1990).

Table V Gene and Protein Characteristics of Serum Proteins Found in Bone Matrix

Serum proteins	Gene	Protein	Function
Albumin	4q11-22 17kb, 15 exons	69 kDa, nonglycosylated, one sulfhydryl, 17 disulfide bonds, high-affinity hydrophobic-binding pocket	Inhibits hydroxyapatite crystal growth
α_2HS glycoprotein	3 two RFLP 1.5 kb mRNA	Precursor protein of fetuin, cleaved to form A and B chains that are disulfide linked, Ala-Ala and Pro-Pro repeat sequences, N-linked oligosaccharides, cystatin-like domains	Promotes endocytosis, has opsonic properties, chemoattractant for monocytic cells, bovine analog (fetuin) is a growth factor

In addition to this inhibitory activity, it also inhibits crystal aggregation.

Another serum protein, α_2-HS-glycoprotein, is even more highly concentrated in bone than albumin (up to 100× more concentrated). It is known that α_2-HS-glycoprotein is the human analog of bovine fetuin (Ohnishi *et al.,* 1993). This protein is synthesized as a precursor that contains a disulfide bond linking the amino and carboxy-terminal regions. Subsequently, the midregion is cleaved and removed from the molecule, yielding the A and B peptides (much in the same way that insulin is processed). In rat, the midregion is not removed and the molecule consists of a single polypeptide. This protein also contains cystatin-like domains (disulfide-linked loop regions), and another member of this family has been identified in bone matrix extracts.

α_2-HS-glycoprotein has many proposed functions that may also be operative in bone cell metabolism. In other cell culture systems, it has been proposed to promote endocytosis and to have opsonic properties. It is also a chemoattractant for monocytic cells, and consequently, it may influence the influx of osteoclastic precursor cells into a particular area (Nakamura *et al.,* 1999). Furthermore, it is a transforming growth factor-β type II receptor mimic and cytokine antagonist (Demetriou *et al.,* 1996). Fetuin, the bovine homologue has been found to be a major growth-promoting factor in serum. Consequently, this protein may play a very important role in bone cell metabolism irrespective of whether it is synthesized locally or not.

Other Proteins

γ-carboxy glutamic acid-containing proteins are also major constituents of bone matrix (Table VI) and are reviewed in another chapter. In addition to the proteins described earlier there are representatives of many other classes of proteins in the bone matrix, including proteolipids, enzymes and their inhibitors (including metalloproteinases and TIMPs, plasminogen activator and plasminogen activator inhibitor, matrix phosphoprotein kinases, lysosomal enzymes), morphogenetic proteins, and growth factors (reviewed in Gokhale *et al.,* 2001). While their influence on bone cell metabolism is highly significant and they may cause significant alterations of the major structural elements of bone matrix, they are not necessarily part of the structural scaffold of bone matrix (with the possible exception of proteolipids). Important aspects of many of these classes of proteins are reviewed elsewhere.

Control of Gene Expression

In vivo and *in vitro* analysis clearly indicates that the timing and location of bone matrix protein expression are controlled by cells in the osteoblastic lineage as they progress toward maturation. The sequence of molecular events that regulate this progression is mediated by *cis*- and *trans*-acting factors present in the nucleus. *cis*-acting factors (also known as response elements) are present in the promoter region of the gene (the sequence upstream from the gene transcription start site). *cis*-acting factors can be roughly separated into two types: those that serve as binding sites for DNA polymerases (TATA, CAAT) and those that serve as binding sites for *trans*-acting (nuclear binding) factors. The interaction of *cis*-acting sequences within the promoter and *trans*-acting factors thereby modulates the activity of DNA polymerases, resulting in either activation or suppression of gene activity.

Utilizing both *in vitro* and *in vivo* analysis, virtually all of the promoters of the bone matrix protein genes have been characterized. Numerous *cis*-acting elements have been identified in all of the genes by direct sequence analysis, and their activity in serving as binding sites for *trans*-acting nuclear factors has been tested in DNA footprint and mobility assays.

Table VI Gene and Protein Characteristics of γ Carboxy Glutamic Acid-Containing Proteins in Bone Matrix

Gla-containing proteins	Gene	Protein	Function
Matrix Gla protein	12p 3.9 kb, 4 exons	~15 kDa, five Gla residues, one disulfide bridge, phosphoserine residues	May function in cartilage metabolism, a negative regulator of mineralization
Osteocalcin	1 1.2 kb, 4 exons	~5 kDa, one disulfide bridge, Gla residues located in α helical region	May regulate activity of osteoclasts and their precursors, may mark the turning point between bone formation and resorption
Protein S			May be made primarily in the liver, protein S deficiency may result in osteopenia

The most reliable information appears to be derived from studies utilizing transgenic animals that have been engineered to contain parts of the promoter, either wild type or mutated, linked to a reporter molecule, such as chloramphenicol transferase, β-galactosidase, or luciferase. This stance stems from studies of type I collagen, and alkaline phosphatase gene expression whereby sequences identified as active by *in vitro* analysis were not active when placed in the animal. Transgenic animals of this sort have been generated for many of the bone matrix protein promoters and have provided a great deal of information on what factors are controlling both the timing and the location of bone matrix protein expression during bone formation. Salient features of the bone matrix protein promoters are listed in TableVII.

Although not complete, the mechanism by which the pattern of gene expression is controlled during osteogenesis is becoming clearer. This is due in large part to the identification of CBFA1, a transcription factor that is required for bone formation during development and for modeling and remodeling after birth (Ducy, 2000). Deletion of this gene resulted in the generation of mice that were completely devoid of bone (Komori *et al.,* 1997). The promoters of bone matrix proteins expressed at late stages of osteoblastic maturation, osteopontin, bone sialoprotein, and osteocalcin, all have CBFA1-binding sites (Ducy *et al.,* 1997), although it appears that CBFA1 represses bone sialoprotein expression (Javed *et al.,* 2001). After osteogenic commitment by CBFA1 expression, other factors clearly play a role in fine tuning the timing and location of bone matrix protein expression, such as steroid nuclear hormone receptors (Kraichely *et al.,* 1998), members of the Ets1 family (Trojanowska, 2000), and nuclear matrix proteins (Thunyakitpisal *et al.,* 2001), to name just a few. Much has been learned, but there is still much to be discovered.

Table VII Promoter Characteristics of Bone-Related Genes

Protein	Polymerase-binding sites	*cis*-acting factors	*trans*-acting factors
Collagens			
alpha1(I)	TATA, CCAAT, CT rich, AG rich	SP1, VDRE, NF1	CAAT-binding protein, two silencers, VDR
alpha2(I)	CCAAT, CT rich	NF1	CAAT-binding protein, CTF/NF1
Proteoglycans			
Versican	TAATA, CCAAT	+/− elements, XRE, SP1, CRE	CAAT-binding factor
Decorin	Two promoters 1a- GC rich 1b - two TATA, one CAAT	AP1, AP5, NF-κb, Pu/Py mirror repeat	
Biglycan	GC rich	SP1, AP1, AP2, NF1, NF-κb	
Fibromodulin	Analysis unavailable		
Glycoproteins			
Alkaline phosphatase	Two promoters, GC rich, TATA	3 SP1s	VDR, RAR
Osteonectin	GA repeats, S1 sensitve	SP1, AP1, CRE, GHE, HSE, MRE, 1st intron, four CCTG repeats	GGA-binding protein
Tetranectin	Analysis unavailable		
Thrombospondin	Three genes, TATA, GC rich, inverted CAAT	AP1, AP2, SP1, NFY, SRE, Egr1 Egr1	c-Jun
Fibronectin	TATA, CAAT, GC rich	CRE, SP1	ATF2
Vitronectin	Analysis not available		
Fibrillin	TATA, CCAAT, GC rich		
Osteopontin	Inverted CCAAT, TATA, GC box	+/− elements, SP1, AP, AP4, AP5, RAE, TPA, PEA3, THR, GHV, VDRE	VDR, CBFA1-binding site
Bone sialoprotein	Inverted TATA, inverted CCAAT	AP1, CRE, Homeobox, RARE, p53, GRE, VDRE, 1st intron, poly Py, poly AC, YY-1, supressor?	VDR, CBRA1-binding sites
BAG-75	Not yet cloned		
Gla-proteins			
Matrix Gla protein	TATA, CAAT	RARE, VDRE	VDR, RA
Osteocalcin	TATA, CCAAT, overlaps with other elements	OC Box, AP1, AP2, VCE, VDRE, CRE, GRE, NF1, MSX, VA	VDR, c-Fos, CBFA1-binding site
Protein S	Analysis not available		
Serum proteins			
Albumin	TATA, CCAAT	PGRBS, GRE	C/EBP, NHF1, FTF, NF1
α_2HS glycoprotein	Analysis unavailable		

Bone Matrix Glycoproteins and Ectopic Calcifications

The development of sensitive radiographic techniques, in addition to histological observations, has lead to the description of ectopic calcifications in many different pathological disorders. While dystrophic mineralization has long been noted, it was not thought that bone matrix proteins played a role in generating this type of mineralization. Dystrophic mineralization is brought about by cell death (perhaps in the form of apoptosis) and not by the physiological pathways mediated by collagen or matrix vesicles. It may be a real phenomenon in some cases (in particular, in muscle trauma), but bone matrix proteins are now being identified in mineralized foci in several different pathological states. Osteonectin, osteopontin, and bone sialoprotein have been found in mineralized foci in primary breast cancer (Bellahcene *et al.,* 1997). Bone sialoprotein has also been found in other cancers, such as prostate, thyroid, and lung (Bellahcene and Castronovo, 1997; Bellahcene *et al.,* 1997, 1998; Waltregny *et al.,* 1998).

There are several ways in which these proteins can be localized to these foci. It is possible that in some cases, the area mineralizes dystrophically and the bone matrix proteins are adsorbed from the circulation due to their affinity to hydroxyapatite. In some cases, however, mRNAs for bone matrix proteins have been identified and it appears that the proteins are actually synthesized by resident cells that have been triggered (by factors that have yet to be identified). Mammacarcinoma cells are an example of this type of change in phenotypic expression (Bellahcene *et al.,* 1997).

Given the fact that bone matrix proteins are present in these mineralized foci, the next question is why? One clue may be provided by the fact that several of the tumors that contain these mineralized foci, such as breast and prostate cancer, show a propensity to metastasize to bone. However, it is not known how bone matrix protein expression influences the metastatic process. It is possible that the transformation event that caused the expression of the bone matrix proteins to begin with also caused a change in cell surface receptor expression such that if the cells are able to traverse the circulatory system (i.e., get into and out of blood vessels), they are able to attach to and associate with marrow stromal, as would circulating hematopoietic cells. However, it is possible that the expression of bone matrix proteins such as bone sialoprotein and osteopontin allows the cells to lodge in bone matrix due to their high affinity for hydroxyapatite that may be transiently available due to a resorption event.

Another example of ectopic calcification is seen in atherosclerosis, again, associated with the production of bone matrix proteins (Bini *et al.,* 1999). However, in this case, it may be that a population of stem cells exists that are normally quiescent, but then are induced to become osteogenic again by factors that are not known. The aorta has its own vasculature, which may harbor these stem cells. Supporting this hypothesis, pericytes from the retinal vasculature have been shown to undergo bone formation in vitro and *in vivo* (Doherty *et al.,* 1998).

Summary

Bone matrix proteoglycans and glycoproteins are proportionally the most abundant constituents of the noncollagenous proteins in bone matrix. Proteoglycans with protein cores composed of the leucine-rich repeat sequences (decorin, biglycan, fibromodulin, osteoadherin) are the predominant form found in mineralized matrix, although hyaluronan-binding forms (in particular, versican) are present during early stages of osteogenesis. They participate in matrix organization and in regulating growth factor activity. Glycoproteins such as alkaline phosphatase, osteonectin, RGD-containing proteins (osteoadherin, thrombospondin, fibronectin, vitronectin, osteopontin, bone sialoprotein), fibrillin, and tetranectin are produced at different stages of osteoblastic maturation. They exhibit a broad array of functions ranging from control of cell proliferation, cell–matrix interactions, and mediation of hydroxyapatite deposition. The ectopic expression of bone matrix proteins may also play a significant role in pathological states such as bone metastasis in certain forms of cancer and atherosclerosis.

CHAPTER 15

Osteopontin

Masaki Noda

David T. Denhardt
Department of Cell Biology and Neuroscience, Rutgers University, Piscataway, New Jersey

Osteopontin (OPN) is one of the noncollagenous proteins present in bone matrix (Mark *et al.,* 1987). Independently, it was found to be present in the plasma of patients bearing highly metastatic tumors (Brown *et al.,* 1994). Another line of study revealed that the same molecule was expressed at high levels by activated T cells (Singh *et al.,* 1990). OPN was also characterized as a molecule that regulates the calcification of urinary stones because an antibody raised against it was able to block the formation of calcium oxalate-based stones (Shiraga *et al.,* 1992). The presence of OPN in various types of organs, including those with and without matrix, and also in plasma, suggests that this molecule could act both as a structural molecule and as a humoral factor, or cytokine (Nanci, 1999; Rittling and Denhardt, 1999; Denhardt *et al.,* 2001). The recent accumulation of a body of new data has opened a new era of studies on OPN function. This chapter focuses on these novel features of OPN.

Structure of Osteopontin

The amino acid sequence of OPN has been determined for a number of species (Sodek *et al.,* 2000a). The conservation of much of the sequence among these species suggests that this molecule has had a fundamental role in biological systems during evolution. OPN consists of about 300 amino acids. Importantly, an RGDS (arginine, glycine, aspartate, serine) motif is located in the midportion of the molecule. A thrombin cleavage site is located just carboxyl-terminal to the RGDS motif (Senger *et al.,* 1994; Bautista *et al.,* 1994); the products of thrombin cleavage can be observed when serum preparations are analyzed by gel electrophoresis. However, intact OPN is more abundant than the cleavage product in blood (Kon *et al.,* 2000). Therefore, to assay the intact OPN concentration in human blood, plasma rather than serum should be prepared to avoid the effect of thrombin, which is activated in the process of serum preparation. Consideration has been given to measuring circulating OPN levels by ELISA to identify people with high risk for diseases such as osteoporosis or to evaluate the response of patients to particular clinical treatments. However, the fact that OPN is sequestered by factor H may be a complication (Fedarko *et al.,* 2000).

Clinical measurements of OPN in the circulatory system are not restricted only to patients with involutional bone diseases; such measurements may also be relevant to the evaluation of patients with metastatic tumors, with certain kinds of immunodeficiencies, with neuronal diseases, and with urinary stones. At this point, however, it is not certain what would be the contribution of intact OPN to such a diagnosis; also the significance of the levels of its cleavage products, or the function of the cleavage products, in each situation is unclear.

OPN is modified posttranslationally by phosphorylation, the addition of sugars, such as sialic acid, and sulfation (Nagata *et al.,* 1989; Beninati *et al.,* 1994; Sørensen *et al.,* 1995; Neame and Butler, 1998; Zhu *et al.,* 1997; Safran *et al.,* 1998). The levels of glycosylation, sulfation, and phosphorylation vary depending on the organs and the time after synthesis when OPN modification is assessed. Phosphorylation modulates osteoblastic and osteoclastic functions and has been suggested to affect the efficiency of binding to various cell types (Saavedra, 1994; Lasa *et al.,* 1997; Katayama *et al.,* 1998; Ashkar *et al.,* 2000). Sulfation can affect the formation of mineralized bone nodules

in culture (Nagata, 1989). So far, these data are mostly *in vitro,* and therefore, the significance of such posttranslational modifications in the physiological environment, i.e., *in vivo,* has not been elucidated. Transgenic ("knock-in") mice having mutations in sites of posttranslational modifications may help elucidate the specific function of each of the modifications.

OPN is encoded in seven exons (Craig and Denhardt, 1991; Hijiya *et al.,* 1994; Crosby *et al.,* 1995); however, additional, or alternative, exons are sometimes expressed because more than one mRNA species has been observed in Northern analyses. In the case of human OPN, alternative splicing may produce isoforms (Young *et al.,* 1990; Crivello and Delvin, 1992; Parrish and Ramos, 1997). Functional difference among the isoforms as well as the difference in the expression patterns in various tissues, has not yet been clearly documented. As mentioned earler, OPN has been identified in many tissues, and in these tissues this molecule could mediate communication between cells. Thus, OPN could be regarded as a cytokine. Modification and/or splicing would allow more opportunities for this molecule to function differently under particular conditions, thus contributing to the specificity of the signaling between cells.

OPN interacts with the molecules constituting bone matrix. Proteins in the bone matrix are 90% type I collagen and 10% a variety of noncollagenous proteins. OPN is known to bind covalently to fibronectin via transglutamination, and transglutamination of OPN increases its binding to collagen (Beninati *et al.,* 1994; Kaartinen *et al.,* 1999). Other molecules, such as bone sialoprotein (BSP), also bind covalently to type I collagen. Osteocalcin suppresses transglutaminase-catalyzed cross-linking of OPN (Kaartinen *et al.,* 1997). Such a network and mutual regulation among matrix proteins in bone may facilitate conformational changes of the molecules and hence could add additional functions or activation/inactivation switches to the molecules depending on the sites and composi-tion of the interaction between the molecules. So far, however, whether such covalent bonding between matrix proteins and OPN or other noncollagenous molecules plays any role in the physiological maintenance of the bone during the remodeling cycle or in pathological situations such as osteoporosis or osteopenia requires further elucidation of the functional aspects of this interaction.

Another structural uniqueness of OPN is a run of 10–12 aspartic acid residues. This motif gives rise to a localized high negative charge that may be important for the binding of OPN to bone mineral. OPN has a strong affinity to calcified matrix, such as bone, and also to pathological calcifications, such as those seen in sclerotic glomeruli and atherosclerosis. The high affinity of OPN to calcium has been suggested to modulate the nucleation of calcium phosphate during mineralization (Boskey, 1995; Contri *et al.,* 1996; Srivatsa *et al.,* 1997; Sodek *et al.,* 2000b); however, initial studies on the OPN-deficient mouse failed to indicate the presence of any major defect in mineralization (Rittling *et al.,* 1998). Possibly, the role of OPN in bone mineralization is compensated for by other regulatory systems for mineralization.

The molecular conformation of OPN may be altered by the binding of calcium in a manner dependent on the concentration of the Ca^{2+} ion. It has been proposed that depending on such calcium ion-dependent conformational changes, OPN may reveal binding motifs such as the RGD sequence to its cognate receptors or to any other interactive extracellular matrix protein (Singh *et al.,* 1993; Bennett *et al.,* 1997). The dependence of the structure of OPN on the calcium concentration is an attractive feature of this molecule with regard to modulation of its function, e.g., during bone resorption by osteoclasts. For instance, when osteoclasts resorb bone, there are significant changes in the calcium concentration in the secondary lysosome-like closed space underneath the resorbing osteoclast. This calcium concentration may render signals through the calcium sensing receptor (CsR), a seven membrane-spanning type receptor (Kameda *et al.,* 1998; Kanatani *et al.,* 1999). In addition to such calcium signaling, OPN may change its conformation depending on the calcium levels, thereby affecting cell function through its binding to the receptors expressed on the surface of the osteoclasts, such as $\alpha_v\beta_3$. However, it remains to be seen whether there is any functional significance of putative calcium-dependent structural changes in the OPN molecule.

OPN was first found as a secreted protein, and consequently one of the many names that have been given to it is secreted phosphoprotein (SPP) (Denhardt and Guo, 1994). In fact, when osteoblast-like cells such as ROS17/2.8 cells were stained for OPN protein, no major signal can be observed inside the cells. However, OPN mRNA expression in these cells and protein expression in the medium were easily detectable. Therefore, a major part of the OPN protein moves out of the cell immediately after its synthesis. However, the presence of an intracellular form of OPN has been shown (Zohar *et al.,* 1998, 2000).

Whether the intracellular form of OPN is different from other forms of OPN with regard to alternative splicing or posttranslational modifications is not known. The intracellular form of OPN was colocalized with CD44 in extensions of the osteoclasts known as podosomes, but not in the perinuclear regions where BSP has been observed (Suzuki *et al.,* 2000). Therefore, CD44 and OPN as well as the colocalized $\alpha_v\beta_3$ receptors probably form a complex that facilitates osteoclast movement. As osteoblasts produce OPN and $\alpha_v\beta_3$, migration of osteoblasts may also be dependent on the intracellular form of OPN, CD44, and/or $\alpha_v\beta_3$ integrins (Suzuki, 2000). Like CD44, OPN may promote the multinucleation of osteoclast precursors, as it was observed that in OPN-null mice mononuclear cells are more abundant than multinucleated cells, similar to the situation in the CD44-deficient mouse. Migration experiments conducted *in vitro* using the Boyden chamber system indicated that the presence of OPN is required for efficient migration through the membrane pores. Further, this migration was dependent on the presence of ezrin and hyaluronan. OPN also acts after its binding to

$\alpha_v\beta_3$ integrins through Rho to stimulate gelsolin-associated phosphatidylinositol 3-kinase activity, podosome assembly, stress fiber formation, osteoclast motility, and bone resorption (Chellaiah *et al.,* 2000c).

Receptors for OPN

OPN binds to $\alpha_v\beta_1$, $\alpha_v\beta_3$, $\alpha_v\beta_5$, $\alpha_4\beta_1$, $\alpha_5\beta_1$, and $\alpha_9\beta_1$ integrins (Denhardt and Noda, 1998; Duong *et al.,* 2000; Zheng *et al.,* 2000; Barry *et al.,* 2000). With regard to CD44 binding to OPN, the domain in OPN that interacts with CD44 is not the glycine, arginine, aspartic acid, serine (GRGDS) motif (Katagiri *et al.,* 1999). It has been found that some melanoma cells bind in a non-RGD dependent manner to the v6/v7 isoform of CD44. During the interaction, CD44 may bind to another cell surface molecule, integrins β, and that association may in turn provide the optimal interaction for CD44 to OPN (Katagiri *et al.,* 1999). Details of the interaction of CD44 with OPN remain to be worked out. The presence of additional cell receptors, the various isoforms of CD44, and variable posttranslational modifications (phosphorylation and glycosylation) of OPN and CD44 are all complicating factors.

As OPN binds to the $\alpha_v\beta_3$ integrin, this integrin is considered to be responsible for major signals in response to the binding of OPN (Miyauchi *et al.,* 1991; Zimolo *et al.,* 1994). Postreceptor signaling via the $\alpha_v\beta_3$ integrin is dependent on the cellular background (Zheng *et al.,* 2000). In addition to regulating osteoclastic activity, OPN binding to the $\alpha_v\beta_3$ integrin activates osteoprotegerin expression and protects endothelial cells from apoptosis (Malyankar *et al.,* 2000).

Studies on β_3-deficient mice are relevant to understanding at least part of the function of OPN. Cells prepared from the bone marrow of β_3 knockout mice were able to differentiate into osteoclasts with efficiencies similar to the wildtype (McHugh *et al.,* 2000). This observation indicates that $\alpha_v\beta_3$ is not required for osteoclast formation. The β_3 knockout mice were relatively normal while they were young but they revealed osteosclerosis radiographically by 4 months, suggesting that aging is one of the factors that reveals a phenotype in these mice, again, somewhat similar to OPN-deficient mice. Also, similar to OPN-deficient mice, there was a 3.5-fold increase in osteoclast number, which would appear to compensate for the mild hypocalcemia in the mice. Osteoclasts developed from the bone marrow cells of these mice were less efficient than wild-type cells in excavating pits on dentin slices, showing some inability to resorb bone, again similar to osteoclasts derived from OPN-deficient mice. The difference appears to reside in the cytoskeleton, which is abnormal in the β_3 knockout mice, suggesting a defect in intracellular signaling compared to osteoclasts derived from OPN-deficient mice where formation of the cytoskeleton and actin rings appeared to be normal when the osteoclasts were developed by culturing in the presence of RANKL and M-CSF (Ihara *et al.,* 2001; McHugh *et al.,* 2000). Overall, these findings on β_3 knockout mice further support the notion that the OPN signaling integrin through β_3 integrin pathway is important in regulation of osteoclastic activities.

Osteopontin and Cell Attachment

OPN promotes the attachment of fibroblasts to plastic or glass substrates (Somerman *et al.,* 1988; Reinholt *et al.,* 1990; Helfrich *et al.,* 1992). In bone, OPN is expressed in osteoblasts and its expression is enhanced by vitamin D (Prince *et al.,* 1987). Osteoclasts also express OPN when they are vigorously resorbing bone in human osteoarthritis specimens (Merry *et al.,* 1993; Dodds *et al.,* 1995; Connor *et al.,* 1995). Osteoclasts express $\alpha_v\beta_3$ integrin at high levels (Horton *et al.,* 1995; Duong *et al.,* 2000). Although the $\alpha_v\beta_3$ integrin is not a specific marker of osteoclasts, monoclonal antibodies raised against osteoclasts appear to specifically visualize osteoclasts in bones due to its high abundance. Therefore, $\alpha_v\beta_3$ integrin can be used as one of the markers of osteoclasts.

Immunoelectron microscopic examination using colloidal gold particles indicated that OPN was observed underneath the clear zone of osteoclasts (Reinholt *et al.,* 1990). As clear zones are involved in the attachment of osteoclasts to the bone matrix, the location of OPN appeared to fit its hypothesized function. However, later experiments indicated that OPN may bind to $\alpha_v\beta_3$ integrin expressed on the basolateral surface of the osteoclasts and this binding also generates signals to modulate osteoclastic functions (Zimolo *et al.,* 1994; Zheng *et al.,* 2000). Therefore, including the intracellular form of OPN, osteoclasts could be regulated through more than one pathway of OPN signaling. However, it is not clear whether the intracellular form of OPN is the same in terms of its posttranslational modification as the form released into the extracellular environment that binds to the cells in an autocrine or paracrine manner. With regard to osteoblasts, some reports indicated the presence of the $\alpha_v\beta_3$ integrin on the surface of osteoblasts (Gronthos *et al.,* 1997) and, therefore, there could be a certain commonality in OPN function in osteoblasts and osteoclasts.

OPN is deposited along the cement line and lamina limitans after the cessation of bone resorption by osteoclasts (McKee and Nanci, 1996). This OPN may provide a signal to the osteoblasts that are attracted to the bone resorption sites to deposit bone matrix to fill the cavity. Although OPN-deficient mice do not contain OPN in the cement lines, the bone architecture by itself was not largely different from that of wild-type mice (Rittling *et al.,* 1998; Rittling and Denhardt, 1999). Therefore, significance of the signaling by OPN deposited at the cement line or lamina limitans may be minor *in vivo.* However, when the osteoclasts were cultured individually in an *in vitro* system, the absence of OPN resulted in reduced osteoclast function, indicating a role for this molecule, at least in these cells (Chellaiah *et al.,* 2000b; Ihara *et al.,* 2001).

Osteopontin-Dependent Intracellular Signaling

RGD-containing molecules, such as OPN, bind to integrins on the surface of osteoclasts and induce integrin clustering (Hruska *et al.,* 1995; Rodan and Rodan, 1997; Chellaiah *et al.,* 2000a,c; Duong *et al.,* 2000). This binding initiates intracellular signaling by the phosphorylation of tyrosine residues, including tyrosine 402 on PYK2. The phosphorylation of tyrosine residues leads to binding of Src via its SH2 domain, which then further increases phosphorylation of PYK2 at other sites (Duong *et al.,* 1998, 2000; Duong and Rodan, 1999). Such phosphorylation amplifies the signal, attracting other adaptor molecules to bind PYK2, thereby eliciting signals that activate cellular functions, including adhesion and cytoskeletal structure formation needed for osteoclastic actions, such as sealing zone formation and intracellular trafficking (Nakamura *et al.,* 1999). PYK2 also binds to CAS, however, this interaction is independent of tyrosine phosphorylation (on both of the two molecules).

In addition to interactions between kinases and adaptor molecules at focal adhesion sites, p21GTPase activity is also important in OPN-dependent signaling. One of the targets of rho, mDia1, which appears to be involved in the formation of the actin ring, associates with gelsolin located in the podosomes of osteoclasts (Chellaiah *et al.,* 2000b). In osteoclasts isolated from OPN-deficient mice, podosome structures were similar to those in wild-type mice; however, the mDia1 and gelsolin association was not observed and there was a reduction in osteoclast motility in response to vitronectin (Chellaiah *et al.,* 2000b). Relative to wild-type osteoclasts, OPN-deficient osteoclasts exhibited a decrease in CD44 expression on the cell surface. This defect in the surface expression of CD44 and dissociation between mDia1 and gelsolin was reversed by the addition of exogenous OPN. Thus, it was suggested that OPN-deficiency induces an impairment in the motility of osteoclasts by the suppression of CD44 expression on the cell surface as well as a disruption of the association between mDia1 and gelsolin, thereby suppressing podosome assembly. However, exogenously added OPN only stimulated the motility of osteoclasts, without correcting the depth of the pits formed on the dentin slices. Thus, the two phenomena of reduced CD44 expression and suppression of the formation of podosomes could be causing the osteoclastic cells to be hypomotile (Chellaiah *et al.,* 2000b). This may be the explanation for the inefficiency of osteoclasts in OPN-deficient mice.

Phenotype of Osteopontin-Deficient Mice

Because OPN-deficient mice produced independently in two laboratories do not show any structural alterations in bones at birth and during their subsequent growth period, there does not appear to be a requirement for OPN for normal development (Rittling *et al.,* 1998; Liaw *et al.,* 1998). In these OPN-deficient mouse strains, skeletal defects were not observed, whereas altered wound healing was noted by Liaw *et al.* (1998). Several possibilities have been proposed to explain the apparent lack of major bone phenotype. The first one was that in the absence of OPN, other related molecules, such as those containing RGDS, can compensate for the missing OPN. However, in OPN/vitronectin double knockout mice, no bone abnormalities were noted (Liaw *et al.,* 1998). Another possibility could be that the T-cell-based type I immune response deficiency that results from the absence of OPN (Ashkar *et al.,* 2000) could modify the response of bone due to the alteration in the cytokine network that is involved in the maintenance of both cellular immune responses and the mineralized skeleton.

Osteopontin Plays a Role in Estrogen Depletion-Induced Bone Loss

Although compensation may account for the normal development and normal maintenance of bone in OPN-deficient mice, the difference between the absence and the presence of OPN could be overt in circumstances of accelerated bone turnover, such as osteoporosis. A mouse osteoporosis model made by the ovariectomy-induced depletion of estrogen provided clues to answer the question on the role of OPN in the regulation of bone metabolism (Yoshitake *et al.,* 1999). After ovariectomy, both wild-type mice and OPN-deficient mice exhibited a similar reduction in uterine weight within 4 weeks, suggesting that the hormonal system in OPN-deficient mice was similar to that in wild-type mice, at least in terms of the uterine response to estrogens. That the estrogen system in OPN-deficient mice is normal is suggested by the normal rate of sexual maturation and growth, as well as the normal fertility and littermate size in OPN-deficient mice.

Micro-CT analysis indicated that trabecular bone was lost and that the porosity in the epiphyseal portion of the long bones was decreased by about 60% in ovariectomized wild-type mice (Yoshitake *et al.,* 1999). Micro-CT analysis of the epiphyseal region of the long bones in sham-operated OPN-deficient mice revealed a slight increase in the trabecular bone volume compared to sham-operated wild-type mice. Figure 1 shows that in contrast to the clear reduction in trabecular bone volume seen in wild-type mice after ovariectomy, no major reduction is observed in OPN-deficient mice. The preservation in the levels of bone volume even after ovariectomy could be due to the increase in bone formation, decrease in bone resorption, or both. Dynamic parameters for bone formation in these mice, such as bone formation rate/bone volume (BFR/BV), were increased in ovariectomized wild-type mice as shown previously. In the case of OPN-deficient sham-operated mice, the value was similar to sham-operated wild-type mice. However, no significant increase in BFR was observed in OPN-deficient mice, indicating the absence of high turnover status in bone metabolism even after ovariectomy. Similar basal levels of BFR suggest that bone formation activity in OPN-deficient mice is basically normal.

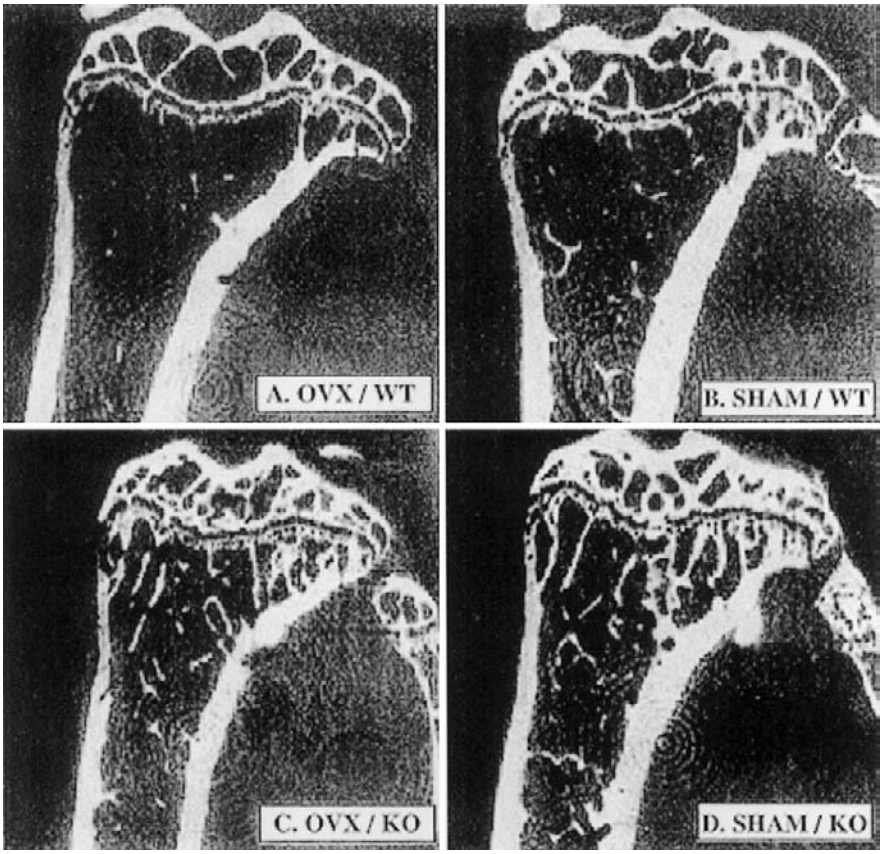

Figure 1 OPN deficiency suppresses ovariectomy-induced bone loss. Micro-CT images of the dissected tibia from ovariectomized and sham-operated mice, both wild type and OPN deficient, are shown. See Yoshitake *et al.* (1998) for further details.

Morphological examination also supported the suppression of ovariectomy-induced bone resorption in OPN-deficient mice. The number of osteoclasts was increased about threefold 4 weeks after ovariectomy in wild-type mice. In contrast, basal levels of osteoclast number were relatively high in OPN-deficient mice and were not increased even after depletion of estrogen. The large number of osteoclasts, together with the increased bone volume in OPN-deficient mice, is superficially paradoxical. However, it could be due to a feedback system in the body that maintains serum calcium levels tightly by increasing osteoclast number to compensate for the reduced efficiency of the osteoclasts to resorb calcium from bone. Even with such compensation, a defect in the ability of osteoclasts to resorb bone is suggested by the relatively large trabecular bone volume in sham-operated OPN-deficient mice (Fig. 1; Yoshitake *et al.,* 1999).

Osteopontin Facilitates Resorption and Angiogenesis of Ectopically Implanted Bone Discs

Angiogenesis is important for bone resorption because osteoclast progenitors are derived from hematopoietic precursor cells. However, it is not known whether OPN promotes bone resorption by stimulating angiogenesisis or by stimulating bone resorption via signaling through the bone matrix. Studies of ectopic bone (disc-shaped pieces punched out of the calvaria) implantation revealed a relationship between OPN and bone resorption associated with vascularization (Asou *et al.,* 2001). Wild-type bone implanted intramuscularly in the back of the wild-type mice was resorbed by about 25%. In contrast, bone from OPN-deficient mice implanted into OPN-deficient mice exhibited significantly less resorption (5%). Thus, about five-fold more bone was resorbed in the presence of OPN; this is illustrated in Fig. 2. The promotion of the resorption of ectopically implanted bone by OPN was associated with a larger number of osteoclasts attached to the surface of the wild-type bone than that in OPN-deficient bone. Furthermore, the number of CD34-positive vessels in the vicinity of bones implanted in OPN-deficient mice was reduced compared to the number of vessels in wild-type bones, suggesting that OPN deficiency may lead to a reduction in neovascularization of the ectopically implanted bones, and consequently a reduction in the number of osteoclasts and subsequent bone resorption efficiency. It is also possible that OPN may promote the survival of endothelial cells on the bone matrix.

Implantation of bone into muscle is suitable for the evaluation of bone resorption because of the higher vascularity of the tissues. However, detailed examination of the vascularization is difficult in intramuscular implantation experiments. Therefore, subcutaneous implantation was used

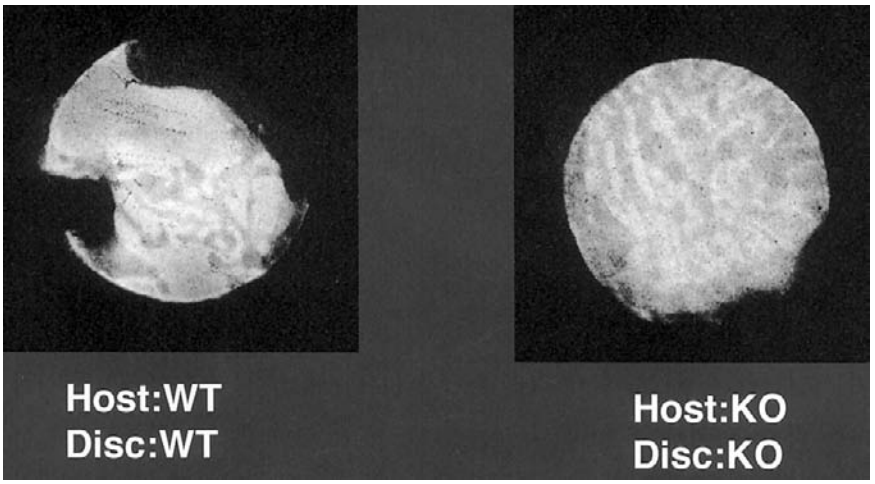

Figure 2 OPN is required for ectopic bone resorption. Bone discs derived from the calvaria were implanted intramuscularly as described by Asou *et al.* (2001). Four weeks after implantation, the discs were removed and examined using soft X-rays.

to examine vascularization without making histological sections (Asou *et al.,* 2001). Significant vascularization was observed in both wild-type and OPN-deficient mice. Interestingly, the length of the blood vessels and the number of branch points in the vasculature on the surface of the implanted bone were both decreased in the OPN-deficient bone relative to wild-type bone. This observation further supports the notion that OPN facilitates vascularization of bone tissue. In these subcutaneous implantation experiments the absence of OPN reduced the TRAP-positive area on the bone disc. These observations indicate that OPN *in vivo* facilitates vascularization in association with osteoclast recruitment, thereby stimulating bone resorption.

Cross mixing of the genotypes of implanted bone disc and host mouse indicated that when either the implanted bone disc or the host mouse was deficient in OPN, then bone resorption, as well as vascularization efficiency, was reduced to a value intermediate between wild-type and OPN-deficient mice. Overall, data indicated the importance of OPN for vascularization during bone resorption. Because the growth plate in OPN-deficient mice is mostly normal it is intriguing to know how the mechanisms involved in vascularization and/or chondroclast accumulation in growth plate metabolism are different from those involved in bone resorption and the related vascularization.

Parathyroid Hormone-Induced Bone Resorption in Organ Culture Requires the Presence of Osteopontin

As ovariectomy experiments suggest that OPN-deficient mice are resistant to bone loss, and ectopic bone implantation experiments indicate that these mice exhibit a reduced efficiency in bone resorption, it was suspected that OPN deficiency may cause a direct suppression of osteoclastic activity to resorb bone matrix. However, direct action of OPN in the process of bone resorption cannot be verified conclusively by ovariectomy experiments or ectopic bone resorption experiments per se. In this regard, bones in organ culture stimulated by parathyroid hormone have shown that OPN is directly responsible for bone resorption in the microenvironment of bone without influences from other humoral factors or vascularization (Ihara *et al.,* 2001). In these experiments, the release of $^{45}Ca^{2+}$ into the medium from $^{45}Ca^{2+}$-labeled forelimb bones excised from newborn OPN-deficient mice and cultured in the presence or absence of parathyroid hormone was measured.

The basal level of calcium release from organ cultures of forelimb bones of OPN-deficient mice was similar to that of wild-type bones. As reported previously, the presence of parathyroid hormone increased Ca^{2+} release from the cultured wild-type bones. However, as shown in Fig. 3, in the organ cultures of OPN-deficient forelimb bones, the increase in calcium release was not observed even in the presence of parathyroid hormone. Because parathyroid hormone increases osteoclast activities via stimulation of the expression of receptor activator of NFκB ligand (RANKL), soluble RANKL in combination with M-CSF was used to stimulate bone resorption. However, OPN-deficient bones failed to respond to RANKL and M-CSF, indicating that the deficiency is downstream of RANKL. Analysis of TRAP-positive cells in the cultured bones indicated that PTH treatment increased the number of these cells in wild-type bones. However, such an increase was not observed in the case of OPN-deficient bones, suggesting that the deficit resided in the inability to increase osteoclast number in the local environment of the bone rudiments. Because bone marrow cells or spleen cells taken from OPN-deficient mice were able to generate similar numbers of osteoclast-like TRAP-positive multinucleated cells with normal morphology compared to wild-type cells in culture in the presence of RANKL and M-CSF, the intrinsic ability of the progenitors to develop into osteoclasts per se is apparently not impaired in OPN-deficient mice. Actin ring formation and the distribution of Src appeared similar in osteoclasts developed in the presence of soluble RANKL and M-CSF in cultures of

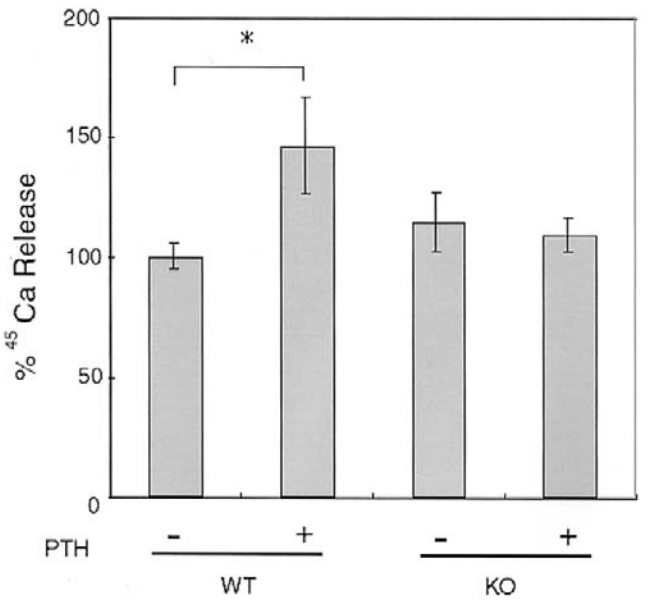

Figure 3 PTH fails to stimulate bone resorption in organ culture in the absence of OPN. Fetal forearm bones labeled with $^{45}Ca^{2+}$ were incubated in the presence of 10^{-7} *M* parathyroid hormone. After 6 days the amount of $^{45}Ca^{2+}$ in the medium was quantified. The percentage calcium released is determined relative to control cultures incubated in the absence of hormone (Ihara *et al.,* 2001).

spleen cells regardless of the presence or absence of OPN. These observations suggest that in the absence of OPN in the microenvironment, PTH is unable to stimulate the formation of TRAP-positive cells; enabling PTH action could therefore be one mechanism by which OPN promotes bone resorption.

Osteopontin and Metastatic Disease

Many types of tumor cells express OPN. OPN levels in the serum of patients bearing highly metastatic tumors have been known to be high (Koeneman *et al.,* 1999; Liaw and Crawford, 1999; Carey *et al.,* 1999; Goodison *et al.,* 1999). It has been suggested that tumor cells produce OPN that could protect tumor cells themselves against the attack by macrophages by suppressing their production of nitric oxide (NO), which can kill tumor cells (Hwang *et al.,* 1994; Denhardt and Chambers, 1994; Feng *et al.,* 1995; Rollo *et al.,* 1996). Another possibility is that OPN may be a positive factor for the attachment of tumor cells and/or may promote proliferation of the tumor cells. Melanoma cells are known to be highly metastatic, and the prognosis of patients bearing those tumors is poor. Bone is one of the sites of melanoma tumor metastases. Once tumor cells metastasize to bones, the mass due to the growth of the tumor causes severe pain and eventually destroys bone tissue, resulting in debilitating fractures. Thus, elucidation of the role of OPN in the process of tumor metastasis is important.

B16 murine melanoma cells attached more effectively to culture dish coated with recombinant OPN than with glutathione *S*-transferase (GST) control, while their proliferation was not affected by the presence of OPN (Nemoto *et al.,* 2001). The β_4 integrin and CD44 were detected in B16 melanoma cells, consistent with a previous report that these molecules may be involved in B16 cell attachment. An experimental metastasis assay based on the injection of B16 melanoma cells via an intracardiac route revealed a reduction in the number of melanoma tumors in the bones (5.4 $\pm$ 1.7) of OPN-deficient mice compared to the number in wild-type mice (11.5 $\pm$ 2.5). Figure 4 (see also color plate) shows an example. Injection of B16 cells into the left ventricle, which also gives rise to metastasis in nonskeletal tissues, yielded 6.5 $\pm$ 2.8 tumors in the adrenal glands of OPN-deficient mice and 17.8 $\pm$ 5.5 in wild-type animals. In the liver the number of melanoma metastasis was 102.6 $\pm$ 53.0 for wild-type mice and 62.2 $\pm$ 32.2 for OPN-deficient mice though the difference was not statistically significant (Nemoto *et al.,* 2001).

As reported previously, a different injection route for experimental metastasis ends up with the different efficiency of metastasis to the different tissues in OPN-deficient mice. When B16 melanoma cells were injected via the femoral vein, most of the metastases were found in the lung. The number of lung metastases in OPN-deficient mice was 37.8 $\pm$ 11.4, whereas the number in wild-type mice reached up

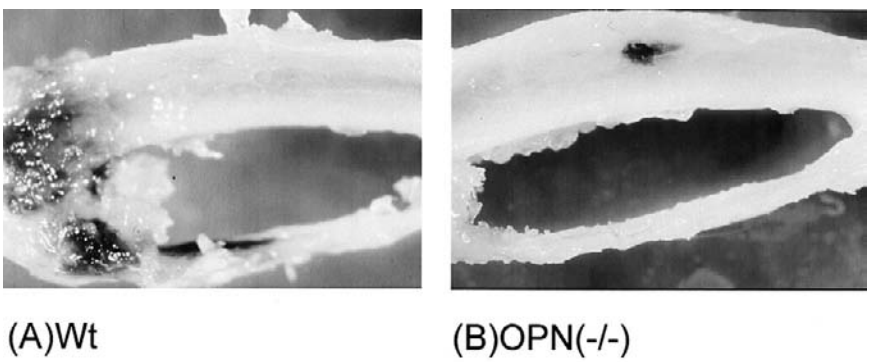

Figure 4 Experimental tumor metastasis to bone is facilitated in the presence of OPN. The B16 tumor cell metastases on the bones of wild-type and OPN-deficient mice observed 2 weeks after intracardiac injection of melanoma cells (Nemoto *et al.,* 2001). (See also color plate.)

to 126.7 ± 42, again indicating suppression by the absence of OPN ($p < 0.05$). Overall, these experimental metastasis data clearly indicated that the presence of OPN promotes the metastasis of B16 melanoma cells to bone as well as to soft tissues such as lung regardless of the route of injection. In B16 cells, expression of OPN *per se* was very low and hardly detectable by Northern blot analyses compared to MC3T3-E1, an osteoblastic cell line that expresses high levels of OPN. Although the possibility that B16 melanoma cells still produce sufficient OPN to contribute to the metastatic process cannot be excluded, the clear difference in the number of experimental metastases seen in wild-type host animals compared to OPN-deficient host animals indicates that at least the presence of OPN in the host makes a difference in the metastatic process (Nemoto *et al.,* 2001).

Metastasis of a tumor in an animal is a complex event initiated by the detachment of the cells from the primary tumor, followed by invasion into the vasculature (or lymphatics) and movement to other locations in the body where the tumor cells extravasate and establish themselves at a new site. Proliferation of the cells at that site and vascularization of the resulting tumor by the host animal produce an expanding tumor mass. Experimental metastasis by injection into the vascular system does not test the first steps in this process, steps that may also involve OPN. Even in the later part of the process, how OPN functions to promote metastasis remains to be elucidated. Among vascular tissues, endothelial cells express $\alpha_v\beta_3$ integrin. Thus, vascularization may be one of the steps affected by the absence of OPN. Unfortunately, our injection model did not allow us to examine the vascularization process because the animals started to die before the tumor foci were large enough to see an effect of vascularization. Within the limit of this model, it appears that OPN can promote the metastasis of tumor cells to various skeletal and nonskeletal sites. It is known that the efficiency of metastasis can vary depending on the tumor cells and tissues. The reduction of melanoma metastases in OPN-deficient mice observed in bone and lung suggests the involvement of a common mechanism operating in both tissues, for instance, possibly based on host macrophages. When tumor cells invade, host stromal cells have been suggested to produce OPN to attract macrophages, which in turn may suppress tumor formation (Crawford *et al.,* 1998). Our data suggest that OPN may be required in the initial attachment phase when the tumor cell is colonizing a new site.

Role of Osteopontin in Mediating Mechanical Stress

OPN is expressed in cells of the osteoblastic lineage, and possibly those including osteocytes (Noble and Reeve, 2000), which are exposed to mechanical stress (Terai *et al.,* 1999). Because chondrocytes express receptors for cell attachment molecules, i.e. $\alpha_v\beta_3$ integrins, they are also candidates for the perception of mechanical stress *in vivo* (Loeser, 2000). In addition, proximal kidney tubules express OPN in response to renin–angiotensin following mechanical stimulation, such as cell stretch. When an antisense oligonucleotide was introduced to block angiotensinogen or angiotensin 2 type I receptor expression, there was a significant decreased in OPN mRNA expression compared to unstretched cells (Ricardo *et al.,* 2000).

Smooth muscle cells also express osteopontin and respond to mechanical stress. Pulsatile pressure increases the proliferation of differentiated smooth muscle cells; in contrast, cells expressing low levels of smooth muscle cell differentiation markers exhibit decreased cell growth and decreased MAPK signaling in response to the mechanical stress (Cappadona *et al.,* 1999).

Integrin-binding forces in intact cells have been measured by using atomic-force microscopy. In cells attached to hexapeptides, 32–97 pN were measured. In contrast, for larger molecules such as OPN and BSP, the experiments showed different binding affinities. Therefore, the context of the RGD sequence has considerable influence on the final binding strength of the receptor interaction (Lehenkari and Horton, 1999).

In tooth movement, only 3.3% of the osteocytes in the inter radicular septum of rats expressed OPN in the absence of the pressure. However, upon the application of pressure, the number was increased to 87.5% within 48 hrs after initiation of the tooth movement. This movement was followed by a 17-fold increase in the number of osteoclasts on the pressure side. These responses were inhibited upon injection of an RGD peptide (Terai *et al.,* 1999). In another model of bone stress, distraction osteogenesis, chondrocyte-like cells in the osteotomized area expressed OPN, osteocalcin, and alkaline phosphatase; this region also includes many osteoblastic cells and preosteoblastic cells that are also expressing OPN at the boundary between fibrous tissue and new bone. The levels of OPN, osteonectin, bone matrix Gla protein, and osteocalcin mRNA expression were enhanced remarkably by the distraction force (0.25 mm/12 hrs) (Sato *et al.,* 1998).

In chondrogenic cells, induction of OPN expression by mechanical stress was found to be dependent on integrin receptors because OPN expression and the response to mechanical stimuli were blocked by the absence of fibronectin, and by the presence of an RGD competitor. (Carvalho *et al.,* 1998). These data indicate that ostopontin expression is enhanced in response to mechanical stimuli and that it is mediated by certain integrins recognizing fibronectin.

As mentioned, OPN expression is regulated by mechanical stress, whereas OPN itself is also involved in bone resorption, and possibly in bone formation. These observations suggest that OPN plays one or more roles during metabolic changes in response to mechanical loading. The question of whether OPN is involved in the mechanical stress-mediated regulation of bone metabolism was tested in a tail suspension model, which is one of the representative models to study unloading effects on bone metabolism (Vico, 1998; Vico *et al.,* 1998, 2000; Bikle and Halloran, 1999; Marie *et al.,* 2000). Unloading causes suppression of

bone formation in growing rodents; however, it has not been clear whether the bone resorption side is affected by tail suspension-based unloading in rodents.

To examine the role of OPN in regulation of bone loss induced by unloading, OPN-deficient mice were subjected to tail-suspension. Micro-CT analysis of the metaphyseal region of the long bones indicated an increase in sparsity in wild-type mice after unloading as expected. However, no such increase in sparsity was observed in OPN-deficient mice. Quantification of the fractional trabecular bone volume indicated about 50% reduction in the wild-type animals. In contrast, no such reduction in bone volume was observed in OPN-deficient mice (Ishijima *et al.,* 2001). Biochemically, a reduction in bone volume was reflected by the increase in the bone resorption marker deoxypyridinolin, which is secreted in the urine of the mice. In wild-type mice, deoxypyridinolin secretion was increased. However, no such increase was detected in the tail-suspended OPN-deficient mice, indicating that systemic bone resorption due to tail suspension was suppressed in OPN-deficient mice.

The cellular basis for the alteration in unloading-induced bone loss in OPN-deficient mice was revealed by histomorphometric analysis. As expected, the number of osteoclasts was increased by about 150% in wild-type mice; this increase was not observed in OPN-deficient mice. In parallel to the number of osteoclasts, the osteoclast surface was also increased in wild-type but not in OPN-deficient mice. This inability of osteoclasts to respond to unloading may be due to a defect in the signaling system to support osteoclastogenesis. However, *in vitro* osteoclastogenesis experiments using RANKL, and M-CSF indicated that TRAP-positive multinucleated cell formation was similar regardless of unloading or loading and/or difference in genotypes. Thus, suppression of the response to unloading in the case of osteoclastogenesis in OPN-deficient mice would be due to the signaling prior to osteoclastogenesis, as the intrinsic ability for osteoclastogenesis in the precursor cells per se does not seem to be impaired (Ihara *et al.,* 2001). Therefore, certain extracellular signaling could be lost in OPN-deficient mice. This possibility was also suggested by the analysis of the osteoblastic cells.

Osteoblasts are regarded as central players in regulating bone metabolism because they express receptors for parathyroid hormone, prostaglandins, and vitamin D—all major humoral factors that regulate bone metabolism. In addition, they are thought to be the cells that respond to mechanical stress. Analysis of osteoblastic activity in tail-suspended mice indicated suppression of bone formation rate as well as mineral apposition rate in wild-type mice, as has been reported previously. However, as illustrated in Fig. 5 (see also color plate), a reduction in the values of these two parameters of osteoblastic bone formation did not occur when OPN-deficient mice were subjected to unloading by tail suspension (Ishijima *et al.,* 2001). Because reduction of bone formation was not affected in experiments where bisphosphonate was administered to tail-suspended animals to

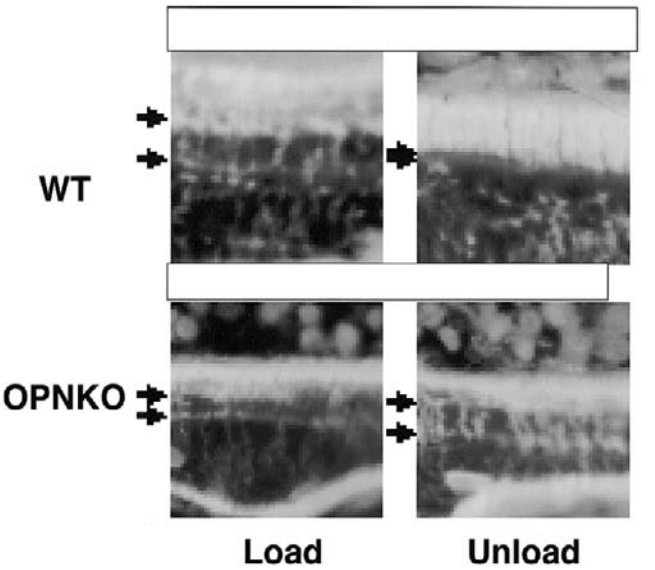

Figure 5 The reduction in bone formation induced in wild-type mice by mechanical stress does not occur in OPN-deficient mice. The hindlimbs of the mice were unloaded for 4 weeks prior to performing a calcein double-label analysis of the bone at the end of the tibia. Arrows indicate the lines of calcein labeling (light green). See Ishijima *et al.* (2001) for further details. (See also color plate.)

block bone resorption due to unloading, the two phenomena appear to be either regulated independently; alternatively, the bone resorption aspect could be downstream of the bone formation aspect. However, this may not be the case as increase in bone could be observed earlier than resorption after tail suspension relative to alterations in bone formation.

The inability of osteoblasts to respond to unloading in OPN-deficient mice suggests that OPN is involved in mediating the signaling induced by tail suspension to suppress the function of osteoblastic cells. This suppression, in turn, could give another signal to increase osteoclastic activities during the loss of bone mass in tail-suspended mice. Bone resorption due to unloading occurs immediately after the exposure of animals and human to agravity or to unloading conditions. However, it is not known whether such an early response of the osteoclasts to unloading is a direct or indirect phenomenon. Because osteoblastic activity, i.e., bone formation, can be detectable morphologically only after a relatively long stimulation period (a week or two) compared to bone resorption, and because the bone formation rate, though slow to change, is the most reliable marker for bone formation *in vivo,* it is possible that initial signals elicited by osteoblasts in the early period of time after exposure to loading and/or unloading have not yet been recognized by the current techniques.

To obtain further insight into the mechanism of the effects of mechanical stress, events occurring immediately after loading or unlaoding must be investigated by using methodology suitable to detect small changes in the metabolism or to detect signals elicited by the cells in the local environment. By such analyses it is still to be elucidated whether the absence of OPN by itself could impair sens-

ing of the mechanical stress in the case of OPN-deficient mice directly in the osteoblasts or indirectly by prohibiting osteoblastic cells via producing other possible loading-induced signals or by delivering the molecular messenger molecules to activate osteoclasts in response to unloading. Analyses of the events that are taking place at the interface between cells and extracellular components, as well as in the intracellular signaling process resulting in modified gene expression or protein function in the early period of unloading in the case of OPN-deficient mice, may yield clues to long-standing questions regarding how bone mass is lost in response to unloading. Studies have suggested that adherent bone cells unable to synthesize OPN tended to have a defect in their ability to respond to a fluid flow stimulus (Ishijima *et al.,* 2000; Denhardt, Krishna, Semeins, and Klein-Nulend, unpublished results).

Summary

As reviewed in the chapter, OPN plays a critical role in the maintenance of bone, especially as a molecule involved in the response of bones to external stress. It is also involved in other homeostatic defense mechanism in the mammalian organism. Further investigations are required to elucidate the molecular mechanisms of OPN action in mediating responses to inflammation, mechanical stress, angiogenesis, and accelerated bone resorption. Understanding the pathways of OPN signaling will contribute to the development of novel measures to cure patients suffering from many bone diseases, and other afflictions, in our aging modern society.

Introduction

This chapter surveys our knowledge of the proteinases expressed in bone. Although previously the osteoclast had been considered to be the main producer of proteinases in bone, it has become increasingly clear that osteoblasts play a significant role in the production of many of these proteinases. For example, it is true that the osteoclast secretes abundant lysosomal proteinases, especially cathepsin K (Vaes, 1988; Xia *et al.,* 1999; Yamaza *et al.,* 1998) and produces some of the neutral proteinases, e.g., matrix metalloproteinase-9 (MMP-9; Wucherpfennig *et al.,* 1994). However, osteoblasts, like their related cells fibroblasts, are able to secrete a host of proteinases, including neutral proteinases such as serine proteinases, plasminogen activators, and metalloproteinases such as collagenase-3, as well as lysosomal proteinases, e.g., cathepsins. Thus, osteoblasts, like fibroblasts, have the capacity to not only synthesize a range of matrix proteins, including type I collagen, but also have the ability to remodel their own extracellular matrix by the secretion of a range of proteinases. Proteinases can be classified into four groups: metalloproteinases e.g., collagenase-3; serine proteinases, e.g., plasminogen activator; cysteine proteinases, e.g., cathepsin K; and aspartic proteinases, e.g., cathepsin D.

This subdivision is based on the structure and the catalytic mechanism of the active site involving particular amino acid residues and/or zinc. In the following review of the proteinases synthesized in bone, we deal with each group according to this subdivision in the order just given. For some, much more is known than for others and they have warranted their own section.

Metalloproteinases

Matrix metalloproteinases (MMPs) are an important group of neutral proteinases thought to be involved in bone growth and bone remodeling. According to structural and functional characteristics, human MMPs can be classified into at least six different subfamilies of closely related members: collagenases, type IV collagenases (gelatinases), stromelysins, matrilysins, membrane-type MMPs (MT-MMPs), and other MMPs (Matrisian, 1992; Woessner, 1991; Vu and Werb, 2000). All matrix metalloproteinases are active at neutral pH, require Ca^{2+} for activity and contain Zn^{2+} in their active site. The catalytic domain of MMPs contains the conserved sequence HEXGH, which is believed to be the zinc-binding site. Metalloproteinases are secreted or inserted into the cell membrane in a latent form caused by the presence of a conserved cysteine residue in the prosegment, which completes the tetrad of zinc bound to three other residues in the active site. Cleavage of this pro-piece by other proteolytic enzymes (e.g., trypsin, plasmin, cathepsins, or other unknown activators) causes a loss of ~10 kDa of the pro-piece; this disrupts the cysteine association with the zinc and results in a conformational change in the enzyme yielding activation. Metalloproteinases all have homology to human fibroblast collagenase (collagenase-1, MMP-1) and all are inactivated by tissue inhibitors of metalloproteinases (TIMPs).

Activation of MMPs can occur via the plasminogen activator/plasmin pathway. Plasminogen activators convert plasminogen to plasmin, which subsequently can activate prostromelysin to stromelysin and procollagenase to col-

lagenase. The activated MMPs can then degrade collagens and other extracellular matrix proteins.

Apart from the regulation of secretion, activation, and/or inhibition, MMPs are substantially regulated at the transcriptional level (Matrisian, 1992; Crawford and Matrisian, 1996). Several MMPs contain specific regulatory elements in their promoter sequences. Human and rat stromelysin-1 and -2 contain activator protein-1 (AP-1) and polyoma enhancer activator-3 (PEA-3)-binding sites that may be important for basal levels and inducibility. AP-1 and PEA-3 consensus sequences have also been found in human, rabbit, and rat collagenase genes (Brinckerhoff, 1992; Selvamurugan *et al.,* 1998). The transcription factors Fos and Jun form heterodimers and act through the AP-1 sequence (Lee *et al.,* 1987; Chiu *et al.,* 1988; Angel and Karin, 1991), whereas c-*ets* family members bind at the PEA-3 sequence (Wasylyk *et al.,* 1993). The urokinase plasminogen activator gene also contains AP-1 and PEA-3-binding sites and, as a result, agents acting through these sites could lead to coordinate expression of many of these genes (Matrisian, 1992). Glucocorticoids and retinoids can suppress metalloproteinase synthesis at the transcriptional level (Brinckerhoff, 1992) by forming a complex with AP-1 transcription factors and inhibiting their action (Jonat *et al.,* 1990; Yang-Yen *et al.,* 1990). More recently, a new transcription factor-binding site has been identified in the collagenase-3 promoter as well as other bone-specific genes such as osteocalcin and osteopontin. This site is referred to as the runt domain (RD)-binding site or polyomavirus enhancer-binding protein-2A/osteoblast-specific element-2/nuclear matrix protein-2 binding site (Geoffroy *et al.,* 1995; Merriman *et al.,* 1995). Members of the core-binding factor (CBF) protein family (recently renamed RUNX by the Human Genome Organization), such as the osteoblastic transcription factor, CBFA1/RUNX2, bind to these RD sites (Kagoshima *et al.,* 1993). CBF/RUNX proteins are capable of binding to DNA as monomers, but can also heterodimerize with CBFB, a ubiquitously expressed nuclear factor (Kanno *et al.,* 1998; Ogawa *et al.,* 1993). CBFA1/RUNX2 is essential for the maturation of osteoblasts, and targeted disruption of the CBFA1/RUNX2 gene in mice produces skeletal defects that are essentially identical to those found in human cleidocranial dysplasia (Banerjee *et al.,* 1997; Ducy *et al.,* 1997; Mundlos *et al.,* 1997; Otto *et al.,* 1997).

Stromelysin

Stromelysin or MMP-3 degrades fibronectin, gelatin, proteoglycans, denatured type I collagen, laminin, and other extracellular matrix components (Chin *et al.,* 1985; Galloway *et al.,* 1983). Mesenchymal cells, such as chondrocytes and fibroblasts, are commonly found to secrete stromelysin (Matrisian, 1992). Transin, the rat homologue of human stromelysin, was originally discovered in fibroblasts transformed with the polyoma virus (Matrisian *et al.,* 1985). One importance of stromelysin comes from its implication in the activation of procollagenase (Murphy *et al.,* 1987), and the enzyme is thought to play a role, together with collagenase, in the destruction of connective tissues during disease states (Brinckerhoff, 1992).

Stromelysin is regulated by growth factors, oncogenes, cytokines, and tumor promoters. Epidermal growth factor (EGF) has been shown to increase stromelysin transcription through the induction of Fos and Jun, which interact at the AP-1 site in the promoter (McDonnell *et al.,* 1990). Platelet-derived growth factor is also important in the induction of stromelysin (Kerr *et al.,* 1988a). The protein kinase C activator, phorbol myristate acetate (PMA), is a notable stimulator of stromelysin transcription (Fini *et al.,* 1987; Brinckerhoff, 1992). Transforming growth factor-β (TGF-β), however, causes an inhibition of transin (rat stromelysin) expression (Matrisian *et al.,* 1986; Kerr *et al.,* 1988b) through a TGF-β inhibitory element (Kerr *et al.,* 1990).

In bone, stromelysin has been shown to be produced by normal human osteoblasts (Meikle *et al.,* 1992) after stimulation with PTH or monocyte-conditioned media (cytokine-rich). Similarly, Rifas *et al.* (1994) have shown that two human osteosarcoma cell lines (MG-63 and U2OS) secrete stromelysin and this may be increased by treatment with PMA, interleukin-1β (IL-1β), and tumor necrosis factor-α (TNF-α), but these authors were not able to find the enzyme in medium conditioned by cultured normal human osteoblasts. Mouse osteoblasts and osteoblastic cell lines also produce stromelysin-1 and demonstrate enhanced expression with $1,25(OH)_2D_3$, interleukin-1, or interleukin-6 treatment (Thomson *et al.,* 1989; Breckon *et al.,* 1999; Kusano *et al.,* 1998). There have also been reports that this stromelysin is expressed by osteoclasts (Witty *et al.,* 1992).

Type IV Collagenases (Gelatinases)

Type IV collagenases or gelatinases are neutral metalloproteinases requiring Ca^{2+} for activity and are involved in the proteolysis and disruption of basement membranes by degradation of type IV, V, and denatured collagens. There are two types of gelatinases, 72-kDa gelatinase (gelatinase A) or MMP-2 (Collier *et al.,* 1988) and 92-kDa gelatinase (gelatinase B) or MMP-9 (Wilhelm *et al.,* 1989). There are very distinct differences between the two gelatinases. The 72-kDa gelatinase has been found complexed to TIMP-2 (Stetler-Stevenson *et al.,* 1989), whereas the 92-kDa gelatinase has been found complexed to TIMP-1 (Wilhelm *et al.,* 1989). Regulation of the two gelatinases is also very distinct. Analysis of the genomic structure and promoter of the 72-kDa gelatinase has revealed that this gene does not have an AP-1 site or TATA box in the 5′ promoter region as all the other MMPs have been shown to have (Huhtala *et al.,* 1990). This enzyme is also not regulated by PMA and, in many cases, seems to be expressed constitutively rather than in a regulated fashion. In contrast, the 92-kDa gelatinase has a promoter very similar to the other MMPs and is regulated similarly (Huhtala *et al.,* 1991). Nevertheless, expression and activity of both types

of gelatinase are markedly stimulated by interleukin-1 (Kusano *et al.,* 1998).

In bone, as is to be expected, 72-kDa gelatinase is expressed constitutively by many osteoblastic preparations (Murphy *et al.,* 1989; Overall *et al.,* 1989; Rifas *et al.,* 1989, 1994; Meikle *et al.,* 1992) and is unchanged by treatment with any of the agents tested. The zymogen form of 72-kDa gelatinase is also resistant to activation by serine proteases, but MT1-MMP can initiate the activation of the 72 kDa progelatinase by cleavage of the Asn66-Leu peptide bond (Sato *et al.,* 1994).

The 92-kDa gelatinase is secreted by three osteosarcoma cell lines (TE-85, U2OS, and MG-63) (Rifas *et al.,* 1994) and, in some of the cell lines, can be stimulated by PMA, IL-1β, and TNF-α, analogous to these authors' observations regarding stromelysin. Similarly, they were unable to identify secreted 92-kDa gelatinase in the media of normal human osteoblasts or the human osteosarcoma cell line SaOS-2, which has been shown to have retained many characteristics of highly differentiated osteoblasts. Likewise, Meikle *et al.* (1992) found very little immunohistochemical staining for 92-kDa gelatinase in normal human osteoblasts. In fact, this enzyme has been found to be highly expressed by rabbit and human osteoclasts (Tezuka *et al.,* 1994a; Wucherpfennig *et al.,* 1994; Vu *et al.,* 1998). Indeed, a lack of expression of the 92 kDa gelatinase in mature osteoclasts of c-*fos*-null mice may be one of the reasons the animals exhibit an osteopetrotic phenotype (Grigoriadis *et al.,* 1994). Furthermore, studies of mice with a targeted inactivation of the gene indicate that the 92-kDa gelatinase plays a role in regulating endochondral bone formation, particularly of the primary spongiosa, possibly by mediating capillary invasion. Mice containing a null mutation in the 92-kDa gelatinase gene exhibit delays in vascularization, ossification, and apoptosis of the hypertrophic chondrocytes at the skeletal growth plates (Vu *et al.,* 1998). These defects result in an accumulation of hypertrophic cartilage in the growth plate and lengthening of the growth plate. These defects are reversible, and by several months of age the affected mice have an axial skeleton of normal appearance. It was postulated that the 92-kDa gelatinase is somehow involved in releasing angiogenic factors such as vascular endothelial growth factor (VEGF) that is normally sequestered in the extracellular matrix (Gerber *et al.,* 1999)

Membrane-Type Matrix Metalloproteinases

While most matrix metalloproteinases are secreted, a newly identified subtype called membrane-type matrix metalloproteinases (MT-MMPs) are inserted into the cell membrane (Sato *et al.,* 1997; Pei, 1999). These proteases contain a single transmembrane domain and an extracellular catalytic domain. Characteristically, MT-MMPs have the potential to be activated intracellularly by furin or furin-like proteases through recognition of a unique amino acid sequence: Arg-Arg-Lys-Arg111 (Sato *et al.,* 1996). To date, six MT-MMPs have been described, and MT1-MMP, MT2-MMP, and MT3-MMP have been shown to have a wide range of activities against extracellular matrix proteins (Pei and Weiss, 1996; Will *et al.,* 1996; Velasco *et al.,* 2000). A mouse cDNA homologue to MT4-MMP (mMT4-MMP) has been cloned (English *et al.,* 2000). MT4-MMP has the least degree of sequence identity to the other family members and has TNF-α convertase activity but does not activate pro-MMP2 (Puente *et al.,* 1996). Conversely, MT5-MMP and MT6-MMP may facilitate tumor progression through their ability to activate pro-MMP2 at the membrane of cells from tumor tissue (Llano *et al.,* 1999; Velasco *et al.,* 2000). As mentioned earlier, MT1-MMP (MMP-14) serves as a membrane receptor or activator of MMP-2 and possibly other secreted MMPs (Sato *et al.,* 1994). Further, studies indicate that MT1-MMP may also function as a fibrinolytic enzyme in the absence of plasmin and facilitate the angiogenesis of endothelial cells (Hiraoka *et al.,* 1998). MT1-MMP is highly expressed in embryonic skeletal and periskeletal tissues and has been identified in osteoblasts by *in situ* hybridization and immunohistochemistry (Apte *et al.,* 1997; Kinoh *et al.,* 1996). Targeted inactivation of the MT1-MMP gene in mice produces several skeletal defects that result in osteopenia, craniofacial dysmorphisms, arthritis, and dwarfism (Holmbeck *et al.,* 1999; Zhao *et al.,* 2000). Several of the notable defects in bone formation include delayed ossification of the membranous calvarial bones, persistence of the parietal cartilage vestige, incomplete closure of the sutures, and marked delay in the postnatal development of the epiphyseal ossification centers characterized by impaired vascular invasion. Histological observation suggested that the progressive osteopenia noted in these animals may be attributed to excessive osteoclastic resorption and diminished bone formation. This finding was supported by evidence that osteoprogenitor cells isolated from the bone marrow of these mutant mice demonstrate defective osteogenic activity.

Collagenases

Collagenases generally cleave fibrillar native collagens I–III at a single helical site and do so at neutral pH (Matrisian, 1992). The resultant cleavage products denature spontaneously at 37° C and become substrates for many enzymes, particularly gelatinases. The collagenase subfamily of human MMPs consists of three distinct members: fibroblast collagenase-1 (MMP-1), neutrophil collagenase-2 (MMP-8), and collagenase-3 (MMP-13) (Goldberg *et al.,* 1986; Freije *et al.,* 1994). An additional collagenase, called collagenase-4, has been identified in *Xenopus laevis* (Stolow *et al.,* 1996). At the present time, only one rat/mouse interstitial collagenase has been studied thoroughly and shown to be expressed by a range of cells, including osteoblasts. This collagenase has a high degree of homology (86%) to human collagenase-3 and is aptly named collagenase-3 (Quinn *et al.,* 1990). Rat collagenase-3 is secreted by osteoblasts, smooth muscle cells, and fibroblasts, in proenzyme form at

58 kDa, and is subsequently cleaved to its active form of 48 kDa (Roswit *et al.,* 1983). Efforts to isolate murine homologues of human collagenase-1 had been unsuccessful until recently, when two MMP-1-like genes, called Mcol-A and Mcol-B, which had 58 and 74% nucleotide sequence identity with human MMP-1, were identified within the MMP gene cluster on mouse chromosome 9 (Balbin *et al.,* 2001). When the cDNAs were expressed, however, only Mcol-A, and not Mcol-B, could degrade native type I and II collagens into the typical fragments and also degrade casein and gelatins (Balbin *et al.,* 2001). A murine ortholog of collagenase-2 has been identified by two groups (Lawson *et al.,* 1998; Balbin *et al.,* 1998). A role for Mcol-A, Mcol-B, or murine collagenase-2 in bone cell function has not been demonstrated, although human collagenase-2 is expressed in chondrocytes and other skeletal cells. In the report of Balbin *et al.* (2001), the expression of Mcol-A was limited to early embryos. It has also been shown that other MMPs [MMP-2 or gelatinase A (GelA or 72-kDa gelatinase) and MMP-14 or MT1-MMP, respectively] can function as collagenases *in vitro*. The collagenolytic activity of MMP-2 was demonstrated by using recombinant protein or after purifying the enzyme free of the TIMPs (Aimes and Quigley, 1995). An expressed soluble form of MMP-14 also has collagenase activity (Ohuchi *et al.,* 1997). These MMPs (-1, -2, -8, -13, and -14) all cleave each of the triple helical interstitial collagens at the same locus and therefore must also be considered to be collagenases.

In developing rat calvariae, we have found ample amounts of collagenase-3 by immunohistochemistry 14 days after birth (Davis *et al.,* 1998). These are always in select areas, mostly associated with sites of active modeling. At the cellular level, staining is associated with osteocytes and bone-lining cells that have the appearance of osteoblasts. Supporting these observations, Delaissé *et al.* (1988) have extracted abundant amounts of collagenase from developing mouse tibiae and calvariae. Originally, there was controversy regarding the cellular origin of bone collagenase. The osteoclast was reported to show immunohistochemical staining for collagenase (Delaissé *et al.,* 1993), but it was not determined whether this was a gene product of the osteoclast or was, perhaps, produced by osteoblasts/osteocytes and bound by the osteoclast through a receptor (see later). *In situ* hybridization of 17- to 19-gestational-day rat fetal long bones showed collagenase-3 expression only by chondrocytes, bone surface mononuclear cells, and osteocytes adjacent to osteoclasts; there was no evidence of expression in osteoclasts (Fuller and Chambers, 1995). Similarly, Mattot *et al.* (1995) showed expression of mouse collagenase-3 in hypertrophic chondrocytes and in cells of forming bone from humeri of mice at the 18th gestational day. Interestingly, the latter group found very little expression in any tissue other than mature cartilage and bone in mouse embryos. Related to this issue of whether osteoblasts or osteoclasts are a source of collagenase-3, it has been known for some time that bone explants from osteopetrotic mice (lack active osteoclasts) continue to produce abundant collagenolytic activity, either unstimulated or stimulated by bone-resorbing hormones (Jilka and Cohn, 1983; Heath *et al.,* 1990). Our interpretation from the evidence presented earlier is that the osteoblast/osteocyte and hypertrophic chondrocytes are the source of collagenases in skeletal tissue, whereas the osteoclast does not appear to express these genes. It should also be noted that the expression of MMP-13 assayed by *in situ* hybridization was strikingly reduced (Lanske *et al.,* 1996), although not absent, in the distal growth plate and midshafts of bones from PTH/PTHrP receptor−/−mouse embryos (Lanske *et al.,* 1998).

The remodeling of the fracture callus mimics the developmental process of endochondral bone formation. Excess tissue accumulates as callus prior to endochondral ossification followed by osteoclast repopulation. In collaboration with Dr. Mark Bolander, we demonstrated profuse concentrations of metalloproteinases in the fracture callus of adult rat long bones (Partridge *et al.,* 1993). The predominant cells observed to stain for collagenase-3 are hypertrophic chondrocytes during the phase of endochondral ossification; marrow stromal cells (putative osteoblasts) when the primary spongiosa is remodeled; and osteoblasts/osteocytes at a time when newly formed woven bone is being remodeled to lamellar bone. The consistent observation here is a role for this enzyme when a collagenous matrix must undergo substantial, rapid remodeling. This would indicate that the adult long bone has the ability to produce profuse levels of collagenase-3, but only when challenged, e.g., by a wound-healing situation.

Liu *et al.* (1995) have demonstrated that a targeted mutation encoding amino acids around the collagenase cleavage site in both alleles of the endogenous mouse type I collagen gene Col1a1 that results in resistance to collagenase cleavage leads to dermal fibrosis and uterine collagenous nodules. Nevertheless, these animals are able to develop normally to adulthood. Some of the major abnormalities only become apparent with increasing age. Studies of these mice revealed that homozygous mutant (r/r) mice have diminished PTH-induced bone resorption, diminished PTH-induced calcemic responses, and thicker bones (Zhao *et al.,* 1999). These observations imply that collagenase activity is necessary not only in older animals for rapid collagen turnover, but also for PTH-stimulated bone resorption. There were further observations regarding the abnormal skeletal phenotype and the effects of PTH in r/r mice (Zhao *et al.,* 2000). As early as 2 weeks of age, empty osteocyte lacunae were evident in the calvariae and long bones from r/r mice, and the number of empty lacunae increased with increasing age. Many persisting osteocytes, as well as periosteal cells in r/r calvariae, were *TUNEL* positive, whereas few *TUNEL*-positive cells were seen in +/+ calvariae. Evidence also indicates that collagenase cleavage takes place in periosteocytic ECM in wild type but not in r/r calvariae. Thus, normal osteocytes (and osteoblasts) and osteoclasts might bind to cryptic epitopes that are revealed by the collagenase cleavage of type I collagen by liganding the $\alpha_v\beta_3$ integrin to maintain their viability and, if such

signals are not induced (as postulated for the osteoclastic defect in r/r mice), they would undergo apoptosis and their lacunae would empty. Young r/r mice are also noted to develop thickening of the calvariae through the deposition of new bone predominantly at the inner periosteal surface; an increased deposition of endosteal trabecular bone was found in long bones in older r/r mice. Judging from the pattern of calcein labeling, the increased bone deposition in untreated r/r mice was accounted for by a marked activation of bone-forming surfaces. This pattern in untreated r/r mice resembled that in wild-type mice treated with PTH and might therefore be ascribable to secondary hyperparathyroidism, although significant differences in circulating levels of PTH in r/r compared to wild-type mice were not observed. Thus, the failure of collagenase to cleave type I collagen in r/r mice was associated with increased osteoblast and osteocyte apoptosis, yet, perhaps paradoxically, increased bone deposition.

Related to work in the whole animal, we have shown, together with Drs. Jane Lian and Gary Stein, that collagenase-3 is expressed late in differentiation in an *in vitro* mineralizing rat osteoblast culture system (Shalhoub *et al.,* 1992; Winchester *et al.,* 1999, 2000). When osteoblasts derived from fetal rat calvariae are grown in this culture system, they undergo development from an immature preosteoblast to a mature, differentiated osteoblast, which exists within a mineralized extracellular matrix [reviewed in Stein and Lian (1993) and Stein *et al.* (1990)]. The appearance of the enzyme in late differentiated osteoblasts may correlate with a period of remodeling of the collagenous extracellular matrix.

These observations regarding the differentiation of rat osteoblasts may explain the very low levels of human collagenase- 1 observed in cultures of normal human osteoblasts (Rifas *et al.,* 1989) where mRNAs and proteins were isolated from cells at confluence, but apparently not from mineralized cultures. Alternatively, the cultures may predominantly express the human homologue of rat collagenase-3, human collagenase-3 (rather than collagenase-1), which has been shown to be expressed by human osteoblasts, chondrocytes, and in synovial tissue, particularly in pathological conditions such as osteoarthritis (Johansson *et al.,* 1997; Mitchel *et al.,* 1996; Reboul *et al.,* 1996, Wernicke *et al.,* 1996). At the time that Rifas and colleagues conducted the work on human osteoblasts, human collagenase-3 had not been identified.

Canalis' group has conducted considerable research on the hormonal regulation of collagenase-3 in rat calvarial osteoblasts, including demonstrating stimulation by retinoic acid (Varghese *et al.,* 1994). More recently, they have demonstrated that triiodothyronine (T_3), platelet-derived growth factor (PDGF), and basic fibroblast growth factor (bFGF) all stimulate collagenase-3 transcription (Pereira, *et al.,* 1999, Rydziel, *et al.,* 2000; Varghese, *et al.,* 2000). Interestingly, they have also shown that insulin-like growth factors (IGFs) inhibit both basal and retinoic-stimulated collagenase expression (Canalis *et al.,* 1995) by these cells.

We have conducted many studies with the clonal rat osteosarcoma line UMR 106-01, which has been described as osteoblastic in phenotype (Partridge *et al.,* 1980, 1983). This cell line responds to all of the bone-resorbing hormones by synthesizing collagenase-3 (Partridge *et al.,* 1987; Civitelli *et al.,* 1989). In contrast to the physiological regulation of collagenase in fibroblasts (Woessner, 1991), synoviocytes (Brinckerhoff and Harris, 1981), and uterine smooth muscle cells (Wilcox *et al.,* 1994), the control of expression of this enzyme in bone and osteoblastic cells appears to have some distinct differences. First, it is stimulated by all the bone-resorbing hormones (Partridge *et al.,* 1987; Delaissé *et al.,* 1988), which act through different pathways, including protein kinase A (PKA; PTH and PGs), protein kinase C (PKC; PTH and PGs), tyrosine phosphorylation (EGF), and direct nuclear action [$1,25(OH)_2D_3$; retinoic acid]. Second, glucocorticoids do not inhibit stimulation by PTH (Delaissé *et al.,* 1988; T. J. Connolly, N. C. Partridge, and C. O. Quinn, unpublished observations) whereas retinoic acid stimulates collagenase-3 expression rather than inhibiting it (Delaissé *et al.,* 1988; Connolly *et al.,* 1994; Varghese *et al.,* 1994). Last, in rat osteosarcoma cells, PMA is unable to elicit a pronounced stimulatory effect on collagenase-3 gene expression.

Among the bone-resorbing agents tested, PTH is the most effective in stimulating collagenase-3 production by UMR cells. A single 10^{-7} *M* PTH dose significantly stimulates transient collagenase-3 secretion with maximal enzyme concentrations achieved between 12–24 hr (Partridge *et al.,* 1987; Civitelli *et al.,* 1989). This level is maintained at 48 hr, decreases to 20% of the maximum by 72 hr, and is ultimately undetectable by 96 hr. Because the enzyme is stable in conditioned medium and because experiments showed that this disappearance was not due to extracellular enzymatic degradation, we hypothesized that collagenase-3 was removed from the media through a cell-mediated binding process. Binding studies were conducted with ^{125}I-collagenase-3 at 4° C, which revealed a specific receptor for rat collagenase-3. This novel receptor is saturable, has high affinity ($K_d = 5$ nM), and has 12,000 receptors per UMR cell (Omura *et al.,* 1994). Further, we showed that binding of collagenase-3 in this fashion is responsible for the rapid internalization and degradation of collagenase-3. The processing of collagenase-3 in this system requires receptor-mediated endocytosis and involves sequential processing by endosomes and lysosomes (Walling *et al.,* 1998). In addition to UMR cells, we identified a very similar collagenase-3 receptor on normal, differentiated rat osteoblasts, rat and mouse embryonic fibroblasts, and human chondrocytes (Walling *et al.,* 1998; Barmina *et al.,* 1999). These results indicate that the function of the collagenase-3 receptor is to limit the extracellular abundance of collagenase-3 and, consequently, breakdown of the extracellular matrix.

Further investigation of the collagenase-3 receptor system has led us to conclude that collagenase-3 binding and internalization require a two-step mechanism both involving a specific collagenase-3 receptor and a member of the

low-density lipoprotein (LDL) receptor-related superfamily. For example, our ligand blot analyses demonstrate that ^{125}I-labeled collagenase-3 binds specifically to two proteins (approximately 170 and 600 kDa) present in UMR 106-01 cells (Barmina *et al.,* 1999). Of these two binding proteins, 170 kDa appears to be a high-affinity primary-binding site and the 600-kDa protein appears to be the low-density lipoprotein receptor-related protein responsible for mediating internalization. The LDL receptor superfamily represents a diverse group of receptors, including the LDL receptor, the low-density lipoprotein-related receptor protein (LRP), the VLDL receptor, and the gp330 receptor (Krieger and Herz, 1994). These plasma membrane receptors have a number of common features. All have a single membrane-spanning domain and several stereotyped repeats, both complement-like (for ligand binding) and EGF-like (for ligand dissociation). Each receptor in this family participates in receptor-mediated endocytosis, whereby the receptor–ligand complex is directed (via an NPXY signal in the receptor) to clathrin-coated pits and then internalized. Ligands bound by these receptors include LDL, VLDL, uPA-or tPA-PAI-1 complexes, tPA, lactoferrin, activated α_2-macroglobulin/proteinase complexes, apolipoprotein E-enriched β-VLDL, lipoprotein lipase, *Pseudomonas* exotoxin A, and vitellogenin (Krieger and Herz, 1994).

The striking stimulation of collagenase-3 secretion by bone-resorbing agents in UMR cells was shown to be paralleled by an even more striking induction of collagenase-3 mRNA. To undertake these studies, we isolated a cDNA clone to rat collagenase-3 (Quinn *et al.,* 1990). Examination of poly(A^+)RNA from PTH-treated UMR cells using this clone as a probe showed a ~l80-fold induction of collagenase-3 mRNA 4 hr after PTH treatment (Scott *et al.,* 1992) with a lag period of between 0.5 and 2 hr before collagenase-3 steady state mRNA levels rose above basal.

Nuclear run-on studies showed a comparable increase in transcription of the gene 2 hr after treatment with PTH. The PTH-induced increase in collagenase-3 transcription was completely inhibited by cycloheximide, whereas the transcriptional rate of β-actin was unaffected by inclusion of the protein synthesis inhibitor (Scott *et al.,* 1992). These results demonstrate that the PTH-mediated stimulation of collagenase-3 transcription requires *de novo* synthesis of a protein factor(s).

We used second messenger analogs to test which signal transduction pathway is of primary importance in the PTH-mediated transcriptional induction of the collagenase-3 gene. The cAMP analogue, 8BrcAMP, was capable of inducing collagenase-3 transcription to levels close to that of PTH. In contrast, neither the PKC activator, PMA, nor the calcium ionophore, ionomycin, when used alone, resulted in any increase in collagenase-3 gene transcription similar to that elicited by PTH after 2 hr of treatment (Scott *et al.,* 1992).

Thus, we demonstrated that PTH increases the transcription of collagenase-3 in rat osteoblastic osteosarcoma cells primarily by stimulation of the cAMP signal transduction pathway. Furthermore, the effect requires protein synthesis and a 1- to 1.5-hr lag period, suggesting that the transcriptional activation of the collagenase-3 gene may be the result of interactions with immediate early gene products. We next discovered that PTH transiently increases the mRNA expression of the AP-1 protein subunits c-fos and c-jun (Clohisy *et al.,* 1992). Both mRNA species were maximally induced within 30 min, well before the maximal transcription rate of 90 min for collagenase-3. Later we determined that PTH is responsible for phosphorylation of the cAMP response element-binding (CREB) protein at serine 133 (Tyson *et al.,* 1999). Once phosphorylated, the CREB protein binds a cAMP response element (CRE) in the c-fos promoter and activates transcription (Pearman *et al.,* 1996).

To further identify and delineate the signal transduction pathways involved in the PTH regulation of the collagenase-3 gene in osteoblastic cells, genomic clones of the rat collagenase-3 gene were isolated. The collagenase-3 gene has 10 exons (Rajakumar *et al.,* 1993), encoding a mRNA of ~2.9 kb, which in turn encodes the proenzyme with a predicted molecular weight of the core protein of 52 kDa (Quinn *et al.,* 1990). A large stretch of promoter region was isolated in one of these clones, and from this a series of deletion and point mutants were generated to identify the PTH-responsive region and subsequently the primary response genes, which convey the hormonal signal and bind to this region(s) of the collagenase-3 gene. The minimum PTH regulatory region was found to be within 148 bp upstream of the transcriptional start site (Selvamurugan *et al.,* 1998). This region contains several consensus transcription factor recognition sequences including SBE (Smad binding element), C/EBP (CCAAT enhancer-binding protein site), RD (runt domain-binding sequence), p53, PEA-3 (polyoma enhancer activator-3), and AP (activator protein)-1 and -2. The AP-1 site is a major target for the Fos and Jun families of oncogenic transcription factors (Chiu *et al.,* 1988; Lee *et al.,* 1987; Angel and Karin, 1991). The RD site is a target for core-binding factor proteins, specifically CBFA1/RUNX2. Mice containing a targeted disruption of the CBFA1/RUNX2 gene die at birth and lack both skeletal ossification and mature osteoblasts (Ducy *et al.,* 1997; Komori *et al.,* 1997; Otto *et al.,* 1997). These mutant mice also do not express collagenase-3 during fetal development, indicating that collagenase-3 is one of the target genes regulated by CBFA1/RUNX2 (Jimenez *et al.,* 1999). Additional experiments on the collagenase-3 promoter determined that both native AP-1 and RD sites and their corresponding binding proteins, AP-1 and CBFA1/RUNX2-related proteins, were involved in PTH regulation of the collagenase-3 promoter. Using gel-shift analysis, we further showed enhanced binding of c-Fos and c-Jun proteins at the AP-1 site upon treatment with PTH (Selvamurugan *et al.,* 1998), although there was no significant change in the level of CBFA1/RUNX2 binding to the RD site. We determined that PTH induces PKA-mediated posttranslational modification of CBFA1/RUNX2 and leads to enhanced collagenase-3 promoter activity in UMR cells (Selvamurugan *et al.,* 2000b). The binding of members of the AP-1 and CBF/RUNX families to their corresponding binding sites in the collagenase-3

promoter also appears to regulate collagenase-3 gene expression during osteoblast differentiation (Winchester *et al.,* 2000). As discussed earlier, collagenase-3 expression is regulated by a variety of growth factors, hormones, and cytokines, but the effects of these compounds appear to be cell type specific. Data obtained in breast cancer and other cell lines suggest that the differential expression of and regulation of collagenase-3 in osteoblastic compared to nonosteoblastic cells may depend on the expression of AP-1 factors and post-translational modifications of CBFA1/RUNX2 (Selvamurugan and Partridge, 2000; Selvamurugan *et al.,* 2000a). The close proximity of the AP-1 and RD sites and their cooperative involvement in the activation of the collagenase-3 promoter suggests that the proteins binding to these sites may also physically interact. Recent work indicates this to be the case, as CBFA1 directly binds c-Fos and c-Jun in both *in vitro* and *in vivo* experiments (D'Alonzo *et al.,* 2000).

Plasminogen Activators

The plasminogen activator (PA)/plasmin pathway is involved in several processes, including tissue inflammation, fibrinolysis, ovulation, tumor invasion, malignant transformation, tissue remodeling, and cell migration. The PA/plasmin pathway is also thought to be involved in bone remodeling by osteoblasts and osteoclasts. The pathway results in the formation of plasmin, another neutral serine proteinase, which degrades fibrin and the extracellular matrix proteins fibronectin, laminin, and proteoglycans. In addition, plasmin can convert matrix metalloproteinases, procollagenase, and prostromelysin to their active forms (Eeckhout and Vaes, 1977). Plasminogen has been localized to the cell surface of the human osteosarcoma line MG63, where its activity was enhanced by endogenous cell bound uPA (Campbell *et al.,* 1994).

The PA/plasmin pathway is regulated by members of the serpin family in addition to various hormones and cytokines. The primary function of this family of inhibitors is to neutralize serine proteinases by specific binding to the target enzyme. Serpins are involved in the regulation of several processes, including fibrinolysis, cell migration, tumor suppression, blood coagulation, and extracellular matrix remodeling (Potempa *et al.,* 1994). Members of this pathway involved in the regulation of the PA/plasmin pathway are plasminogen activator inhibitor-1 (PAI-1) and plasminogen activator inhibitor-2 (PAI-2), which regulate uPA and tPA; protease nexin-1, which regulates thrombin, plasmin, and uPA; and α_2-antiplasmin, which regulates plasmin. Active PAI-1 combines with uPA and tPA, forming an equimolar complex (Levin, 1986), exerting its inhibition through interactions with the active site serine. PAI-1 has been detected in media of cultured human fibrosarcoma cells (Andreasen *et al.,* 1986) and primary cultures of rat hepatocytes and hepatoma cells. PAI-1 was also detected from conditioned medium of rat osteoblast-like cells and rat osteosarcoma cells (Allan *et al.,* 1990).

Urokinase-Type Plasminogen Activator

The urokinase-type plasminogen activator is secreted as a precursor form of ~55 kDa (Nielsen *et al.,* 1988; Wun *et al.,* 1982). It is activated by cleavage into a 30-kDa heavy chain and a 24-kDa light chain, joined by a disulfide bond, with the active site residing in the 30-kDa fragment. Urokinase has a Kringle domain, serine proteinase-like active site, and a growth factor domain (GFD). The noncatalytic NH_2-terminal fragment contains the GFD and Kringle domain and is referred to as the amino-terminal fragment (ATF). Rabbani *et al.* (1990) demonstrated that ATF stimulated proliferation and was involved in mitogenic activity in primary rat osteoblasts and the human osteosarcoma cell line, SaOS-2. The GFD of the ATF is necessary for the binding of uPA to its specific receptor.

Tissue-Type Plasminogen Activator

The tissue-type plasminogen activator is secreted as a single-chain glycosylated 72-kDa polypeptide. This enzyme has been found in human plasma and various tissue extracts, as well as in normal and malignant cells. The cleavage of tPA forms a 39-kDa heavy chain and a 33-kDa light chain linked by a disulfide bond. The heavy chain has no proteinase activity, but contains two Kringle domains that assist in binding fibrin to plasminogen (Banyai *et al.,* 1983; Pennica *et al.,* 1983). Furthermore, the heavy chain contains a finger domain involved in fibrin binding (van Zonneveld *et al.,* 1986) and a GFD with homology to human and murine epidermal growth factor.

Plasminogen Activators in Bone

Plasminogen activator activity is increased in normal and malignant osteoblasts as well as calvariae by many agents, including PTH, $1,25(OH)_2D_3$, PGE_2, IL-1α, fibroblast growth factor, and EGF (Hamilton *et al.,* 1984, 1985; Thomson *et al.,* 1989; Pfeilschifter *et al.,* 1990; Cheng *et al.,* 1991; Leloup *et al.,* 1991; De Bart *et al.,* 1995). It should be noted that work suggests that PAs are not necessary for PTH- and $1,25(OH)_2D_3$-induced bone resorption (Leloup *et al.,* 1994). Expression of tissue-type plasminogen activator, urokinase-type plasminogen activator, plasminogen activator inhibitor-1, plasminogen activator inhibitor-2, protease nexin, and urokinase receptor isoform 1 (uPAR1) were detected in mouse osteoclasts using the reverse transcriptase–polymerase chain reaction (RT-PCR) (Yang *et al.,* 1997). Deletion of tPA, uPA, PAI-1, and plasminogen genes in mice can lead to fibrin deposition, some growth retardation, and inhibition of osteoclast ability to remove noncollagenous proteins *in vitro*, but no other significant effects on bone were reported (Carmeliet *et al.,* 1993, 1994; Bugge *et al.,* 1995; Daci *et al.,* 1999). There are conflicting data as to whether the increase in osteoblastic PA activity is due to an increase in the total amount of one or both of the PAs or is due to a decline in the amount

of PAI-1. All possible results have been observed, depending on which osteoblastic cell culture system is used or the method of identification of the enzymes. The latter have been difficult to assay categorically because there have not been abundant amounts of specific antibodies available for each of the rat PAs. Similarly, different groups have found the predominant osteoblastic PA to be uPA whereas others have obtained results indicating it to be tPA.

A range of agents have also been found to inhibit the amount of osteoblastic PA activity. These include glucocorticoids, TGF-β, leukemia inhibitory factor, and IGF-I (Allan *et al.,* 1990, 1991; Cheng *et al.,* 1991; Hamilton *et al.,* 1985; Lalou *et al.,* 1994; Pfeilschifter *et al.,* 1990). Where it has been examined, in many of these cases the decline is due to a substantial increase in PAI-1 mRNA and protein. Nevertheless, some of these agents also markedly enhance mRNA abundance for the PAs (Allan *et al.,* 1991), although the net effect is a decline in PA activity.

Cysteine Proteinases

The major organic constituent of the ECM of bone is fibrillar type I collagen, which is deposited in intimate association with an inorganic calcium/phosphate mineral phase. The presence of the mineral phase not only protects the collagen from thermal denaturation but also from attack by proteolytic enzymes (Glimcher, 1998). The mature osteoclast, the bone-resorbing cell, has the capacity to degrade bone collagen through the production of a unique acid environment adjacent to the ruffled border through the concerted action of a vacuolar proton pump ([V]-type H^+-ATPase) (Chakraborty *et al.,* 1994; Bartkowicz *et al.,* 1995; Teitelbaum, 2000) and a chloride channel of the Cl-7 type (Kornak *et al.,* 2001). Loss-of-function mutations in the genes that encode either this proton pump (Li *et al.,* 1999; Frattini *et al.,* 2000; Kornak *et al.,* 2000) or the chloride channel (Kornak *et al.,* 2001) lead to osteopetrosis. At the low pH in this extracellular space adjacent to the ruffled border, it is possible to leach the mineral phase from the collagen and permit proteinases that act at acid pH to cleave the collagen (Blair *et al.,* 1993). Candidate acid-acting proteinases are cysteine proteinases such as cathepsin K. Cathepsin K is highly expressed in osteoclasts (Drake *et al.,* 1996; Bossard *et al.,* 1996). Cysteine proteinases contain an essential cysteine residue at their active site that is involved in forming a covalent intermediate complex with its substrates (Bond and Butler, 1987). The enzymes are either cytosolic or lysosomal. The latter have an acidic pH optimum and make up the majority of the cathepsins. These enzymes are regulated by a variety of protein inhibitors, including the cystatin superfamily (Turk and Bode, 1991) and α_2-macroglobulin (Barrett, 1986). Their extracellular abundance must consequently be regulated by cell surface receptors for α_2-macroglobulin as well as the lysosomal enzyme targeting mannose-6-phosphate/IGF-II receptors.

Involvement of lysosomal cysteine proteinases in bone resorption has been indicated by many studies showing that inhibition of these enzymes prevents bone resorption *in vitro* as well as lowering serum calcium *in vivo* (Delaissé *et al.,* 1984; Montenez *et al.,* 1994). A more recently identified cathepsin, cathepsin K (Tezuka *et al.,* 1994b), was found to have substantial effects on bone. Mice containing a targeted disruption of cathepsin K were developed and found to exhibit an osteopetrotic phenotype characterized by excessive trabeculation of the bone marrow space (Saftig *et al.,* 1998, 2000). Additionally, cathepsin K mutations have been linked to pycnodysostosis, a hereditary bone disorder characterized by osteosclerosis, short stature, and defective osteoclast function (Gelb *et al.,* 1996). Immunohistochemistry revealed that the majority of the cysteine proteinases (cathepsins B, K, and L) and the aminopeptidases (cathepsins C and H) are products of osteoclasts (Ohsawa *et al.,* 1993; Yamaza *et al.,* 1998; Littlewood-Evans *et al.,* 1997), although immunoreactive staining for cathepsins B, C, and H was also seen in osteoblasts and osteocytes. It is notable that the most potent collagenolytic cathepsin at acid pH, cathepsin L, was strongly expressed in osteoclasts and very weakly in osteoblasts. Mathieu *et al.* (1994), however, have detected both cathepsins B and L as proteins secreted by their immortalized osteogenic stromal cell line, MN7. Oursler *et al.* (1993) have also demonstrated that normal human osteoblast-like cells produce cathepsin B and that dexamethasone can increase expression and secretion of this lysosomal enzyme by these cells. Interestingly, they also showed that dexamethasone treatment causes activation of TGF-β and, by the use of lysosomal proteinase inhibitors, ascribed a role for cathepsins B and D to activation of this growth factor.

Aspartic Proteinases

These lysosomal proteinases contain an aspartic acid residue at their active site and act at acid pH. Very little investigation has been conducted on these enzymes in bone cells except for the observations that cathepsin D, a member of this family, can be found by immunohistochemical staining in osteoblasts and osteocytes (Ohsawa *et al.,* 1993), and expression of this enzyme is increased markedly by dexamethasone treatment of human osteoblasts in culture (Oursler *et al.,* 1993).

Conclusions

The osteoblast has the ability to produce proteinases of all four classes, but far more is known about their production of collagenase and plasminogen activators, at least *in vitro*. We still do not know the absolute role of any of these osteoblastic enzymes *in vivo*. Further work with knockouts of the respective enzymes are likely the only way we will deter-

mine their required functions. These roles may not be restricted to assisting in the resorption process but may include functions to regulate bone development. Additionally, the osteoclast produces MMP-9 and cathepsin K, which appear to have similar roles in the two diverse processes.

CHAPTER 17

Integrins and Other Cell Surface Attachment Molecules of Bone Cells

Michael A. Horton,[*] Stephen A. Nesbitt,[*] Jon H. Bennett,[†] and Gudrun Stenbeck[*]

[*]Department of Medicine, Bone and Mineral Centre, The Rayne Institute, University College London, London WC1E 6JJ, United Kingdom; and [†]Department of Oral Pathology, Eastman Dental Institute, London WC1X 8LD, United Kingdom

Introductory Remarks: Adhesion and Bone Cell Function

Osteoclasts are the main cells responsible for the breakdown of the extracellular matrix of bone during normal and pathological bone turnover (see Chapters 7 and 8; Chambers, 2000). Osteoclastic bone resorption involves a series of developmental and regulatory steps that include the proliferation and homing to bone of hemopoietic progenitor cells; their differentiation into postmitotic osteoclast precursors, which express features of mature osteoclasts; fusion to form multinucleated cells; and migration of osteoclasts to the area of bone to be remodeled. Osteoclasts attach to the bone surface and polarize to create three discrete areas of plasma membrane: (1) the basolateral membrane, which faces the marrow space and is not in contact with the bone; (2) the "tight sealing", or clear, zone that is closely apposed to the bone matrix; and (3) the ruffled border, a highly convoluted area of plasma membrane, which faces the bone matrix and is surrounded by the sealing zone. The sealing zone (see later) forms a diffusion barrier and permits the localized accumulation of high concentrations of protons and proteases secreted via the ruffled border into an extracellular resorption compartment underneath the cell. Many of these steps involve adhesion between mature osteoclasts and osteoclast precursors and other cell types in the bone/bone marrow compartment and with components of the extracellular matrix of bone (some of these possible functional events are summarized in Table I).

Bone (re)modeling (see Chapters 3, 4, and 19) involves the coordinated response of osteoblasts, osteocytes, and osteoclasts. Osteoblasts (see Chapters 4 and 5) and bone-lining cells form a near-continuous layer covering the periosteal, endosteal, and trabecular bone; interactions between these cells and the organic matrix of bone are important determinants of osteoblast proliferation and differentiation. Osteocytes (see Chapter 6) are found in lacunae, set within the bone matrix, and are joined both to their neighbors and cells lining the bone surfaces by cytoplasmic processes, which pass through fine channels or canaliculi. Together, this interconnecting network of osteoblasts, bone-lining cells, and osteocytes provides a possible mechanism for the detection of physical or mechanical changes and the coordination of osteosynthetic and resorptive activity leading to remodeling. Cell–cell and cell–matrix communication is central to this process, and by inference, cell adhesion molecules will be key players in these events, both in normal skeletal homeostasis, growth, and development and in pathological situations where the balance between resorption and remodeling becomes disturbed (see Table I).

Connective tissue cells in general, and bone and cartilage cells in particular, are surrounded by an abundance of extracellular matrix. Chondroblasts, osteoblasts, and, to a lesser extent, osteocytes are responsible for the synthesis of the majority of the organic components of this matrix, whereas osteoclasts mainly degrade the matrix. The function of bone and cartilage cells reflects the matrix components that surround them; conversely, the composition of the matrix, i.e., the structure of cartilage and bone, is highly dependent

Table I Summary of Possible Functions of Cell Adhesion Receptors in Bone

Osteoclast development and function
Migration of committed osteoclast precursors from the bone marrow to sites of future resorption, exiting via specialized endothelial barriers
Homing to "bone" (using chemo-, haptotactic signals) and ingress across vascular endothelium
Recognition of, adhesion to, and migration upon "bone" matrix proteins
Fusion of postmitotic osteoclast precursors
Regulatory intercellular interactions with osteoblasts, leucocytes, and other cell types in marrow space; presentation of growth factors from extracellular matrix stores
Signal transduction (and control of osteoclast function) by interaction with matrix (via RGD and other sequences)
Cellular polarization, cytoskeletal (re)organization, tight sealing zone formation, and bone resorption
Cessation of resorption by detachment from matrix, cell migration, and regulation of osteoclast survival versus apoptosis
Osteoblasts (and osteocytes)
Transduction of mechanical signals within skeleton to regulate cell function
Adhesion to, and migration on, bone matrix, including unmineralized osteoid
Regulation of osteoblast maturation from mesenchymal stem cells
Regulation of mature cell function (gene expression, matrix synthesis, protease secretion, etc.)
Interaction with other bone cells (e.g., osteoclasts) and cells in the bone marrow compartment (e.g., marrow stroma, leukocytes)
Chondrocytes
Response to mechanical forces (e.g., in articular cartilage)
Maintenance of tissue integrity by matrix synthesis and assembly
Regulation of chondrocyte proliferation, maturation, gene expression, and cell survival
Mediation of response in cartilage to injury and disease

on the cellular function of chondroblasts, osteoblasts, and osteoclasts.

Cell–matrix interactions associated with osteoclastic bone resorption have been researched extensively (reviewed in Väänänen and Horton, 1995; Horton and Rodan, 1996; Helfrich and Horton, 1999; Duong *et al.,* 2000). Much less is known about cell–cell and cell–matrix interactions in osteoblasts and related populations, although there has been considerable progress since the first published analysis (Horton and Davies, 1989; Helfrich and Horton, 1999; Bennett *et al.,* 2001b). The best defined of these adhesive interactions are mediated by a particular class of cell adhesion molecule, the integrin receptors. Integrins are now known to be major functional proteins of osteoclasts and have become targets for potential therapeutic intervention in bone diseases such as osteoporosis. The balance of this chapter reflects this bias, but some discussion of the nature and function of other adhesion proteins, and cell adhesion receptors in other bone cell types, is included for completeness.

Overview of Cell Adhesion Molecule Structure

Adhesion Receptors and Their Ligands

Molecular and immunological approaches have led to considerable advances in our understanding of the range of cell membrane molecules that are capable of mediating cell adhesion. Detailed sequence and structural analysis (reviewed in Barclay *et al.,* 1997; Isacke and Horton, 2000) has enabled many of them to be grouped into "families," with related structure based on their content of highly homologous domains. Thus, for example, the immunoglobulin (Ig) superfamily, which formed the first class of homologous adhesion proteins to be identified, is characterized by an Ig domain of about 70–100 amino acids arranged between two sheets of antiparallel β strands, which is found in more than 100 molecules (Barclay *et al.,* 1997). The major groupings of adhesion receptor families are summarized in Table II; this identifies some specific examples, their regions of homology by which they are defined, their ligands, and the nature and specificity of their interactions with receptors. Individual members of the families have a diverse range of structures, tissue distribution, and functions, and it is outside the scope of this chapter to provide information other than in outline. The reader is referred to Barclay *et al.* (1997) and Isacke and Horton (2000) for further details; as integrin receptors form a major focus of this chapter, some basic structural information is provided in greater depth later.

Similar methods have been applied to elucidate the structure of the molecules recognized by cell adhesion proteins, i.e., their ligands; these include components of the extracellular matrix and plasma proteins and cell-associated matrix proteins (Table II; Ayad *et al.,* 1998) and cell membrane- associated "counterreceptors" (e.g., the "ICAMs," Table II). As with adhesion receptors, a range of structural domains are recognizable within their ligands, some of which have clearly defined functions; e.g., the well-characterized Arg-Gly-Asp (RGD) peptide motif, originally described in the protein fibronectin and now known to be present widely in many matrix proteins (Pierschbacher and Ruoslahti, 1984; Ruoslahti, 1996). The function of others, despite their frequency, remains unclear; thus, the function of EGF repeats in, for example, laminin is unknown. Interestingly, some of the domains that have been found in extracellular matrix proteins can also be identified in adhesion receptors (Table II), suggesting a shared function; e.g., hyaluronidate-binding sites have been found in both the matrix proteoglycan, versican, and the "homing" receptor, CD44.

The diversity of the types and combinations of cellular receptors and the complexity of the molecular structure of the extracellular matrix are reflected in the large number of functions that have been ascribed to "cell adhesion molecules." These include both true adhesive interactions, which are clearly seen in, for instance, cell-to-cell interactions regulating the immune response and the integrity of epithelial barriers, or via the increasingly identified signaling pathways

Table II Classes of Cell Adhesion Receptors and Their Ligands

Family	Homology region in receptor	Examples	CD No.	Ligands	Recognition motif in ligand/ counterreceptor	Extracellular matrix components with shared homology domain
Integrin	PEGG (all β chains) I domain (CD11, $\alpha 1 \alpha 2$)	gpIIbIIIa LFA-1 $\alpha_v\beta_3$ $\alpha_2\beta_1$ $\alpha_4\beta_1$	CD41/61 CD11/18 CD51/61 CD49b/29 CD49d/29	Blood proteins ICAM counterreceptor Matrix, blood proteins Collagen Fibronectin	RGD, KQAGDV ICAMs, etc. RGD DGEA, GER EILDV	Collagen VI, von Willebrand factor, cartilage matrix protein (integrin I domain)
Ig superfamily	Ig fold	ICAMs, VCAM N-CAM CD2	CD54, etc.	Heterophylic interaction Homophylic LFA-3 counterreceptor	Multiple KYSFNYDGSE	Perlecan (Ig fold) Fibronectin, tenascin, thrombospondin (N-CAM type III repeat)
Selectins	C-type lectin, EGF repeat Complement regulatory protein domain	L-, P-selectin	CD62	Glycam-1, PSGL-1, CD34, etc.	Sialyl Le^x (CD15), etc.	Aggrecan, versican (lectin) Laminin, tenascin, thrombospondin, aggrecan, veriscan (EGF repeat) Aggrecan, versican (complement regulatory domain)
Cadherins	LDRE repeat (110 amino acid module)	E-, N-cadherin		Homophylic	HAV	
Leucine-rich glycoproteins (LRG)	Leucine repeat (24 amino acid repeat)	Platelet gpIb	CD42b	Blood proteins	von Willebrand factor, thrombin	Biglycan, decorin
Mucins	Mucin side chain	Leukosialin	CD43 CD34	Selectins		Muc-1
CD36 family		Platelet gpIV	CD36	Thrombospondin, collagen	SVTCG (for thrombospondin)	Aggrecan, versican, link protein
CD44	Hyaluronidate-binding site		CD44	Hyaluronic acid, etc.		Aggrecan, versican, link protein

mediated by adhesion receptors, including integrins and cadherins. This includes events mediated through linkages to the F-actin cytoskeleton, leading to changes in cell shape and motility, and activation of Src family and other tyrosine kinases or mobilization of intracellular calcium, resulting in other functional changes downstream, such as activation of early response genes or protease secretion (termed "outside-in" signaling). Similarly, intracellular events can lead to the modification of receptor affinity and activity ("inside-out" signaling; e.g., the platelet integrin gpIIbIIIa will only bind fibrinogen after alterations in integrin conformation following activation on ligand binding to other nonintegrin receptors such as via the thrombin receptor).

Integrin Structure

Integrins (Hynes, 1987; Ruoslahti and Pierschbacher, 1987; Hynes, 1992; see also Isacke and Horton, 2000) are heterodimeric proteins whose constituent polypeptide chains, α and β, are linked noncovalently. Although originally identified by antibodies or direct purification, the primary structure of most integrin subunits has been deduced by cDNA cloning. To date, 17 different mammalian α subunits and 9 β subunits have been identified, forming 23 distinct heterodimers.

Both integrin subunits are transmembrane, N-glycosylated glycoproteins with a large extracellular domain, a single hydrophobic transmembrane region, and a short cytoplasmic domain (apart from β_4, which has a large intracellular domain not found in other integrins). Electron microscopy of several purified integrin dimers shows an extended structure with dimensions of approximately 10 by 20 nm, formed by an N-terminal globular "head" composed by the association of the two subunits, connected to the membrane by two "stalks."

α subunits vary in size from 120 to 180 kDa, and analysis of their cDNA sequences reveals several features in common. All contain seven homologous, tandem repeat sequences of approximately 60 amino acids length, with the last three or four containing putative divalent cation-binding sites showing similarity to the EF-hand loop structure seen in calmodulin. These sites are of critical importance to both ligand binding and subunit association. Some integrins contain an inserted, or "I," domain of approximately 200 amino acids between the second and third repeats (see Table II) that is involved in ligand binding. Other integrin α subunits are cleaved posttranslationally near the transmembrane domain.

β subunits are 90 to 110 kDa in size, apart from the 210-kDa β_4 chain. Their cDNA sequences show a high cysteine content (e.g., 56 Cys residues in β_3), largely concentrated in four 40 amino acid long segments that are internally disulfide bonded. Several conserved motifs in β chains are involved in ligand binding and interaction with cytoskeletal elements.

Integrins recognize highly specific peptide recognition sequences, such as the Arg-Gly-Asp (RGD) sequence present in fibronectin (Pierschbacher and Ruoslahti, 1984), in adhesion to extracellular matrix proteins, or Ig family members such as VCAM and ICAM in intercellular interactions. Cross-linking studies using radioactively labeled RGD peptide probes for the integrins $\alpha_v\beta_3$ and gpIIbIIIa, respectively (see Isacke and Horton, 2000), and mutational analysis have shown the ligand-binding site to be composed of distinct, relatively short elements in the N termini of both α and β subunits. When taken with the requirement for an "I" domain for ligand binding in some integrins, these data suggest that the interaction site depends on the composite structure formed by interplay of the two chains of the receptor, with ligand specificity reflecting subunit usage.

Integrins are linked to the F-actin cytoskeleton via interaction of the β subunit with actin-binding proteins, including α-actinin, vinculin, and talin. The cytoplasmic domain of the β subunit also associates with a signaling complex comprising kinases and phosphatases and various adaptor proteins. Ligand binding leads to the activation of one or more intracellular signal transduction pathways, which, in turn, contribute to the regulation of differentiation, cytoskeletal organization, and other aspects of cell behavior. Most information regarding signaling via integrins (Clark and Brugge, 1995; Dedhar *et al.,* 1999; Giancotti and Ruoslahti, 1999; Coppolino and Dedhar, 2000; Schlaepfer and Hunter, 1998) has come from studies in cells that produce focal contacts *in vitro;* here, the focal adhesion kinase FAK is targeted to focal adhesions, where it associates with the cytoskeleton and is activated by autophosphorylation. Downstream signaling pathways include association of Src family kinases with phosphorylated FAK and engagement of the Ras-MAP kinase pathway.

Cadherins

Cadherins (see Isacke and Horton, 2000; Chapter 18) are a large family of calcium-dependent transmembrane proteins that are associated with the catenin-linked actin cytoskeleton; they play prominent roles in morphogenesis and intercellular adhesion and signaling. Cadherins share several regions of high homology, with the greatest found in the short cytoplasmic domain; they have molecular masses of around 100–130 kDa. The extracellular domain contains repeats ("cadherin repeats") of around 110 amino acids, which contain negatively charged, calcium-binding motifs in the first three repeats and conserved cysteine residues in the fifth repeat. The ligand-binding site of cadherins is the conserved HAV motif located at the N-terminal region of the molecule in the first conserved extracellular repeat. Cadherins are divided into two main subsets of receptors: classical cadherins and protocadherins. The latter differ from classical cadherins in that they do not have a propeptide sequence and contain a variable number of cadherin repeats; this group includes a number of *Drosophila* gene products with cadherin-like sequences and a growing group of cadherin homologues with atypical functions and complexity increased by alternate splicing.

Cadherins are mediators of cell–cell adhesion and bind ligand mainly in a homophilic manner, although heterophilic binding between different cadherin molecules and with integrins occurs. On the cell surface, cadherins tend to be concentrated at cell–cell junctions, where they can associate with members of the Src kinase family, leading to the activation of signaling pathways.

CD44

CD44, also known as the hyaluronan or "homing" receptor, forms a family of transmembrane glycoproteins (see Isacke and Horton, 2000) with molecular masses of 80–200 kDa. They share an N-terminal region that is related to the cartilage proteoglycan core and link proteins. Alternative splicing of 20 exons and extensive posttranslational modification such as glycosylation and addition of chondroitin sulfate produces the wide variety of CD44 proteins. Chondroitin sulfate-containing variants can bind fibronectin, laminin, and collagen in addition to the extracellular matrix glycosaminoglycan hyaluronan, and CD44 binding to osteopontin has also been reported. CD44 functions, therefore, in a variety of ways, including cell–cell interaction, such as homing and endothelial transmigration of lymphocytes, and also cell–matrix adhesion. Malignant transformation of cells leads to the upregulation of CD44 expression, and metastatic tumors often express an altered repertoire of CD44 variants.

Immunoglobulin Superfamily

The immunoglobulin (Ig) family of receptors (see Isacke and Horton, 2000) all share a basic motif consisting of an Ig fold of between 70 and 110 amino acids organized into two antiparallel β sheets, which seem to serve as a scaffold upon which unique determinants can be displayed. There is considerable variation in the primary structure of the members of this family, and hence in their molecular weights, but their tertiary structure is well conserved. There are well over 100 members of this family currently known, all with different numbers of the basic Ig repeats. Their functions are wide ranging, with some members functioning as true signal-transducing receptors, whereas others have predominantly adhesive functions. Ligands for Ig family members include other Ig family members (identical, as well as nonidentical members), but also members of the integrin family and components of the extracellular matrix.

Selectins

Selectins (see Isacke and Horton, 2000) are a family of three closely related glycoproteins (P- and E- selectin expressed in endothelial cells and L-selectin expressed in leukocytes). Their common structure consists of an N-terminal Ca^{2+}-dependent lectin type domain, an EGF domain, and variable numbers of short repeats homologous to complement-binding sequences, a single transmembrane region, and a short cytoplasmic domain. Their molecular masses range from 75 to 140 kDa, with variably glycosylated forms expressed in different cell types. In general, the function of selectins is in leukocyte trafficking where they are involved in the earliest stages of leukocyte extravasation. Here, binding of the selectin ligand on the leukocyte to selectins expressed on the endothelial surface results in "rolling" of leukocytes over the endothelial surface, functions that have now been confirmed in knockout mice. Selectin ligands are specific oligosaccharide sequences in sialated and, often, sulfated glycans, such as sialyl-Lewis^x, although there is still considerable uncertainty about the natural ligands for selectins. The signal transduction pathways linked to selectins are only partially elucidated and include activation of the MAPK pathway.

Syndecans

Syndecans are a family of four cell surface proteoglycans (see Isacke and Horton, 2000), modified by heparan sulfate glycosaminoglycan chains on their extracellular domain. Their single transmembrane domain and cytoplasmic domains are highly conserved and are involved in signal transduction events and link to cytoskeletal elements. Syndecans function predominantly as coreceptors for other receptors, including integrins; this is thought to occur via the cytoplasmic domains of associated receptors rather than the syndecan molecule itself. They also bind members of the fibroblast growth factor family, which need heparan sulfate for signaling, and hence syndecans are involved in the regulation of cell growth and proliferation. Syndecans can also function as cell–matrix receptors, binding various matrix proteins (e.g., syndecan-1 binds to type I collagen, fibronectin, tenascin-C). In different cell types, syndecans have different patterns of glycosaminoglycans attached to their core protein and these influence ligand-binding capabilities. Thus, in one cell type, syndecan-I may contain heparan sulfate as well as chondroitin sulfate side chains and bind collagen, whereas in others a different binding pattern is observed where it only has heparan sulfate side chains.

Distribution and Function of Adhesion Receptors in Bone

There is a recent and fairly extensive literature on the expression of cell adhesion molecules by the stromal and matrix-forming components of the skeleton—osteoblasts, osteocytes, and chondrocytes (see later). For each cell type, a number of receptors, including integrins, have been detected. Although there is as yet no clear concensus as to their molecular phenotype, increasing data support a functional role for adhesion molecules in bone formation and cartilage homeostasis. There is a clearer picture for osteoclasts. Here, only three integrins have been described, and there is little evidence for expression of other adhesion proteins by mature osteoclasts other than CD44 (Athanasou

and Quinn, 1990; Hughes *et al.,* 1994; Nakamura *et al.,* 1995) and possibly some cadherin family members (Mbalaviele *et al.,* 1995, 1998; Ilvesaro *et al.,* 1998; see Chapter 18). Moreover, there is a strong functional correlate by which the antagonism of osteoclast integrins leads to a downregulation of osteoclastic bone resorption, an effect with clinical implications (see later).

Osteoclasts

Role of Integrins in Osteoclastic Bone Resorption

The first suggestion that adhesion receptors played a functional role in osteoclastic bone resorption was obtained when the monoclonal antibody 13C2 (Horton *et al.,* 1985) was found to inhibit bone resorption *in vitro* by human osteoclasts from the giant cell tumor of bone (osteoclastoma) (Chambers *et al.,* 1986). It was later established that the inhibitory effect was mediated via the $\alpha_v\beta_3$ vitronectin receptor, a member of the integrin family of cell adhesion molecules (Davies *et al.,* 1989).

Subsequent detailed phenotypic (reviewed in Horton and Davies, 1989; Horton and Rodan, 1996; Helfrich and Horton, 1999) and biochemical analyses (Nesbitt *et al.,* 1993) demonstrated that mammalian osteoclasts express three integrin dimers: $\alpha_v\beta_3$, the "classical" vitronectin receptor; $\alpha_2\beta_1$, a collagen/laminin receptor; and $\alpha_v\beta_1$, a further "vitronectin receptor" (data summarized in Horton and Rodan, 1996; Helfrich and Horton, 1999; but first demonstrated for β_3 by Beckstead *et al.,* 1986 and Horton, 1986) (see Fig. 1, see also color plate, and Table III). Mostly, the findings have been consistent among studies, and, where analysis has been possible, across species. Low to undetectable levels of $\alpha_v\beta_5$ are found in mature mammalian osteoclasts (Shinar *et al.,* 1993; Nesbitt *et al.,* 1993). There have, however, been reports that osteoclasts may express α_3 (Grano *et al.,* 1994) and α_5 (Steffensen *et al.,* 1992; Hughes *et al.,* 1993; Grano *et al.,* 1994), although this has not been a general finding. Some differences have been noted with avian osteoclasts, which additionally express β_2 integrins (Athanasou *et al.,* 1992), $\alpha_5\beta_1$, and, unlike in mammals, $\alpha_v\beta_5$ (Ross *et al.,* 1993); these latter integrins act as fibronectin receptors.

Adhesion of osteoclasts to the bone surface involves the interaction of osteoclast integrins with extracellular matrix proteins within the bone matrix. This has been studied in *in vitro* phenotypic analysis, cell adhesion assays, and organ cultures from several species (Horton and Davies, 1989; Flores *et al.,* 1992, 1996; Ross *et al.,* 1993; Ek-Rylander *et al.,* 1994; Sato *et al.,* 1990, 1994; Horton *et al.,* 1991, 1993, 1995; Helfrich *et al.,* 1992; Van der Pluijm *et al.,* 1994; Gronowicz and Derome, 1994; Hultenby *et al.,* 1993). The $\alpha_v\beta_3$ vitronectin receptor mediates RGD peptide-dependent adhesion to a wide variety of proteins containing the RGD sequence, including bone sialoproteins and several extracel-

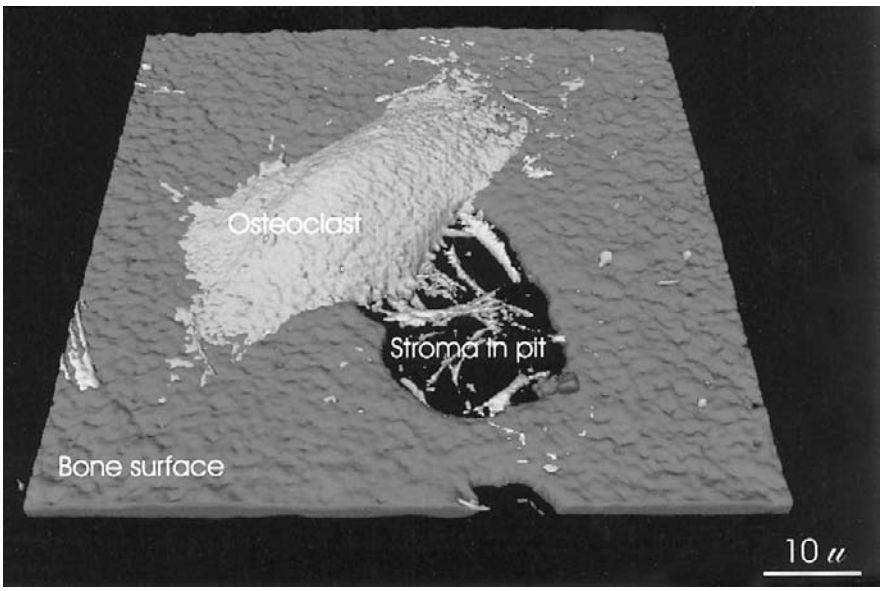

Figure 1 A three-dimensional image of a site of osteoclastic bone resorption. The isosurface image of an *in vitro* site of osteoclastic resorption was constructed from a series of optical sections gathered by immunofluorescence confocal microscopy (Leica TCS NT) (Nesbitt *et al.,* 2000) using Bitplane software. Immunostaining shows the $\alpha_v\beta_3$ integrin in green, the matrix proteins at the bone surface in blue, and the cortical F-actin in the surrounding stromal cells in red. The osteoclast (predominantly stained green) is resorbing through bone (in blue), and a trail of resorption (in black) appears behind the osteoclast in which the stromal cells (which do not express $\alpha_v\beta_3$ and thus show as red) are seen to follow. Original magnification: ×630; scale bar 10 μm. [A further example of a 3D image of osteoclasts can be viewed in an interactive format in the on-line publication by Lehenkari *et al.* (2000) at http://www-ermm.cbcu.cam.ac.uk/00001575h.htm.] (See also color plate.)

Table III Integrin and Other Receptors Expressed by Mature Human Osteoclasts[a]

	Receptor/integrin chain
Present[b]	
	$\alpha_v\beta_3$ ("vitronectin receptor")
	$\alpha_2\beta_1$
	$\alpha_v\beta_1$
	CD44
"Not detected"	
	α_1, α_{3-9} (VLAs), α_E
	β_2 and CD11, a, b, c (LFAs), α_d
	β_{4-8}
	gpIIb (αIIb)

[a]Data summarized from immunological analysis of human and rodent species (reviewed in Horton and Rodan, 1996) and biochemistry of human giant cell tumor osteoclasts (Nesbitt *et al.,* 1993). Some reports have suggested the presence of $\alpha_5\beta_1$ (Grano *et al.,* 1994; Hughes *et al.,* 1993; Steffensen *et al.,* 1992) and $\alpha_3\beta_1$ (Grano *et al.,* 1994) in osteoclasts. Some differences have been noted in avian osteoclasts (Athanasou *et al.,* 1992). α_{10} has not been examined for expression by osteoclasts. Aside from a publication describing expression of a truncated form of β_3 (Kumar *et al.,* 1997) in osteoclasts, no detailed analysis of "splice variants" has been reported.

[b]There are limited data on expression of "cadherins" in osteoclasts (Mbalaviele *et al.,* 1995, 1998; Ilvesaro *et al.,* 1998).

lular matrix and plasma proteins. In addition, mammalian (Helfrich *et al.,* 1992), but not avian (Ross *et al.,* 1993), osteoclasts adhere to type I collagen. Osteoclasts also express $\alpha_2\beta_1$ and $\alpha_v\beta_1$ integrins, and we have shown that β_1, but not β_3, mediates osteoclast adhesion to native collagens, mainly via $\alpha_2\beta_1$ (Helfrich *et al.,* 1996). Interestingly, osteoclast integrin-mediated adhesion to collagen is sensitive to RGD peptides, unlike collagen binding by integrins of other cells (Helfrich *et al.,* 1996).

The demonstration that antibodies recognizing the vitronectin receptor block osteoclast adhesion, combined with the limited integrin repertoire of these cells, suggested that it may be possible to influence bone resorption *in vitro,* either by RGD-containing peptides or by function-blocking antibodies to osteoclast integrins (reviewed in Horton and Rodan, 1996; Helfrich and Horton, 1999). The observation that the RGD sequence containing snake venom protein, echistatin, blocked bone resorption confirmed this hypothesis (Sato *et al.,* 1990). Subsequently, these findings were confirmed using linear and cyclic RGD peptides, peptidomimetic agents (Engelman *et al.,* 1997), snake venom proteins, and antibodies to α_v and β_3 components of the vitronectin receptor and, more recently, by the use of antisense oligodeoxynucleotides (Villanova *et al.,* 1999) in a variety of *in vitro* systems: resorption of bone slices, bone rudiment coculture, and calvarial or fetal long bone organ culture from chick, mouse, rat, rabbit, and human species (reviewed in Horton and Rodan, 1996; Helfrich and Horton, 1999). Blockade of the $\alpha_2\beta_1$ integrin with antibodies also inhibits bone resorption *in vitro* in isolated osteoclast assays (Helfrich *et al.,* 1996).

The snake venom peptides, echistatin and kistrin, have both been shown to induce hypocalcaemia in rats *in vivo* (Fisher *et al.,* 1993; King *et al.,* 1994): the former in the PTH-infused thyroparathyroidectomy model and the latter in parathyroid hormone-related protein (PTHrP)-induced hypercalcemia. Small cyclic RGD-containing peptides and peptidomimetics (Engelman *et al.,* 1997) also induce hypocalcemia in the former model. The inhibition seen *in vivo,* taken with the RGD sequence specificity observed with mutant (non-RGD sequence containing) echistatin (Fisher *et al.,* 1993; Sato *et al.,* 1994), suggests that integrins are mediating their hypocalcemic effect by inhibiting osteoclastic bone resorption. Direct action on an osteoclast integrin was first demonstrated in two *in vivo* experiments. First, a function-blocking antibody, F11, to the rat β_3 chain of the osteoclast $\alpha_v\beta_3$ integrin is hypocalcemic in the rat thyroparathyroidectomy model (Crippes *et al.,* 1996). Second, infusion of echistatin or peptidomimetics totally blocks the acute loss of trabecular bone seen in secondary hyperparathyroidism (Masarachia *et al.,* 1998) and following ovariectomy in the mouse (Yamamoto *et al.,* 1998; Engelman *et al.,* 1997). This latter observation strongly suggests that the inhibitory effect of RGD occurs via a direct action on bone, most likely via the $\alpha_v\beta_3$ integrin on osteoclasts, although other mechanisms cannot be totally excluded.

Evidence concerning the role of α_v and β_3 integrins in bone biology has been obtained from examining the phenotype of knockout mice (Bader *et al.,* 1998; McHugh *et al.,* 2000). From the foregoing, it would have been predicted that deletion of either component of the vitronectin receptor would produce a severe bone phenotype. Somewhat surprisingly, skeletal development was essentially normal in both sets of mice at birth. Perinatal mortality due to vascular abnormalities made further analysis of the role of α_v integrin(s) impossible in the α_v knockout mouse (Bader *et al.,* 1998). The β_3 knockout mouse (McHugh *et al.,* 2000) had the expected platelet defect of human Glanzmann thrombasthenia. However, only relatively mild skeletal changes—osteosclerosis and growth plate abnormalities—were seen on aging; the predicted osteopetrosis was not observed. Some data have been presented showing abnormal osteoclast function, but further analysis of this interesting phenotype, and of bone metabolism in patients with Glanzmann thrombasthenia, is awaited.

Nonintegrin Receptors in Osteoclasts

Studies have been carried out to assess the expression of nonintegrin adhesion receptors in osteoclasts. Earlier data (Horton and Davies, 1989) suggested the absence of a range of adhesion receptor families aside from integrins. More recently, data have been published indicating that osteoclasts express cadherin family members, including E-cadherin (Mbalaviele *et al.,* 1995, 1998; Ilversaro *et al.,* 1998) and the 67-kDa laminin receptor Mac-2 (Takahashi *et al.,* 1994). Additionally, CD44 is highly expressed in osteoclasts, although at the basolateral membrane and not at points of contact with the bone matrix (Athanasou and Quinn, 1990;

Hughes *et al.,* 1994; Nakamura *et al.,* 1995; Nakamura and Ozawa, 1996). There is no published information on the expression of selectins or syndecans by osteoclasts. A selectin-mediated mechanism for extravasation through endothelia of hemopoietic cells is well established; thus, selectins may be of interest to bone biologists, as they would be prime candidates for a role in osteoclast precursor migration to sites in bone to undergo their final differentiation.

While some of these proteins are not major components of mature osteoclasts, or only present on a subpopulation of "immature" osteoclasts, it is possible that they could be involved in osteoclast development, fusion, or functional maturation from hemopoietic stem cells. Whether novel, "osteoclast-restricted" nonintegrin adhesion receptors exist remains to be established.

Adhesion Molecules and Osteoclast Development

The question of which adhesion receptors are expressed, if any, during the development of osteoclasts from stem cells to committed, mononuclear, postmitotic precursors (functional mononuclear osteoclasts) has been difficult to address. This, in part, reflects the difficulty in isolating these cells prior to fusion and association with bone, although they are identifiable within the periosteum of developing bone anlagen as TRAP-positive, calcitonin-binding mononuclear cells that express the vitronectin receptor. Otherwise, evidence has been indirect and gained by using antibody or peptide inhibition in short-term murine and human peripheral blood or bone marrow cultures. Interpretation of such studies can prove problematic, as inhibitory effects can easily be indirect via other cell types critical for osteoclast differentiation, such as osteoblasts or marrow stromal cells. Thus, rodent osteoclast development *in vitro* is inhibited by the RGD-containing snake venom protein echistatin (Nakamura *et al.,* 1998b), implying a role for the vitronectin receptor or other RGD-sensitive integrin receptors. In contrast, osteoclast size or numbers are not altered greatly in rodents treated chronically with $\alpha_v\beta_3$ antagonists, suggesting no major influence on osteoclast differentiation or fusion *in vivo*. Studies with antibodies to $\alpha_2\beta_1$ (Helfrich *et al.,* 1996), presently limited to resorption and adhesion assays, suggest that a role in osteoclast fusion for this class of integrin is a distinct possibility. E- (but not P- or N-) cadherin has been reported to be expressed by human and rodent osteoclasts (Mbalaviele *et al.,* 1995, 1998). Function-blocking antibodies to E-cadherin and adhesion blocking "HAV peptide" inhibit osteoclast formation and fusion *in vitro,* as well as resorption by mature osteoclasts, supporting the view that this class of receptor may be active *in vivo* (Mbalaviele *et al.,* 1995; Ilvesaro *et al.,* 1998); however, because there is strong evidence for many cadherin types in osteoblasts (see later; Chapter 18), indirect effects may be more likely. There is also evidence for the involvement of β_2 integrins (Mac-1, Duong *et al.,* 1995; and LFA-1, Kurachi *et al.,* 1993) and α_4 (Duong *et al.,* 1994) and their respective counterreceptors ICAM-1 (Kurachi *et al.,* 1993; Duong *et al.,* 1995) and VCAM-1 (Duong *et al.,* 1994). Antibodies to CD44 have been shown to inhibit osteoclast formation in mouse marrow cultures, but bone resorption by differentiated osteoclasts was unaffected (Kania *et al.,* 1997). Because of the widespread distribution of CD44 in the bone/bone marrow compartment, it is difficult to assess whether this was a direct effect or mediated via other accessory cells in this *in vitro* system.

Knowledge of the range of receptors involved in osteoclast maturation prior to terminal function is important, as imbalances could lead to bone diseases such as osteoporosis. Moreover, the identification of novel (and possibly "osteoclast-specific") adhesion proteins on osteoclast precursors could well lead to the development of new therapeutic strategies.

Adhesion Molecules and Function of the Osteoclast Clear Zone

Osteoclasts resorb bone after a series of cellular polarization events. These compartmentalize the cell and are essential for bone resorption to proceed. After osteoclast attachment to the bone surface, the cell initiates a cytoskeletal rearrangement and creates a zone that separates dorsal (basolateral) and ventral plasma membranes. This clear, or "tight sealing," zone is "organelle free" (hence the term clear zone), rich in actin filaments, and is closely apposed to the bone surface (Holtrop and King, 1977). This membrane domain of the resorbing osteoclast maintains close apposition to the bone surface and encloses a further specialized secretory membrane, the ruffled border, and "isolates" the acidic microenvironment of the resorption lacuna (see Chapter 8). Protons and proteases cross the ruffled border and solubilize the adjacent bone matrix through demineralization and proteolytic activity. Subsequently, the bone matrix, including calcium and type I collagen fragments, is liberated and a resorption compartment forms beneath the cell.

The finding that osteoclast attachment to matrix-coated glass or bone is interrupted by integrin inhibitors led to the suggestion that the osteoclast tight seal may be mediated by integrins. Some data have supported the view that the vitronectin receptor is enriched in clear zones of resorbing osteoclasts (Reinholt *et al.,* 1990; Hultenby *et al.,* 1993; Nakamura *et al.,* 1996), as well as podosomes of osteoclasts cultured on glass (Zambonin-Zallone *et al.,* 1989; reviewed in Aubin, 1992). Others, however, have been unable to confirm this finding, reporting that the vitronectin receptor is undetectable in the sealing zone (Lakkakorpi *et al.,* 1991, 1993; Nakamura *et al.,* 1999; Duong *et al.,* 2000). Väänänen and Horton (1995) have argued previously that the dimensions of the integrin molecule, when compared to a membrane to bone gap of 2–10 nm, preclude a direct involvement of integrins in the maintenance of a "tight seal" during resorption, as opposed to a role in initial osteoclast attachment and cell movement, which is not in dispute. The molecular mech-

anism of the *attachment* process in the established clear zone of a resorbing, nonmigratory osteoclast thus remains to be established (Väänänen and Horton, 1995) and is likely to involve both cell autonomous characteristics of the osteoclast in combination with chemical and physical features of the bone matrix (Nakamura *et al.,* 1996), as described later.

Early work by Lucht suggested, using an *in vivo* model, that there is no tight sealing zone, as the endocytic marker, horseradish peroxidase, could be detected in the ruffled border area as early as 5 min after injection into the animal (Lucht, 1972). However, generation of a low pH zone underneath the actively resorbing osteoclast, against a substantially different surrounding media, requires the presence of a diffusion barrier. An alternate hypothesis is that the apposition of the osteoclast to the bone surface is not as tight as predicted, less than with high resistance, ion-impermeable epithelial tight junctions, and that the restriction of ionic movement from under the resorbing osteoclast is a combined feature of substrate (i.e., bone matrix) and osteoclast activity. Proton pumping by the osteoclast alters the properties of the bone surface (Delaissé *et al.,* 1987; Everts *et al.,* 1988), which one could envisage would result in swelling and physicochemical modification of the extracellular matrix. In fact, incubation of type I collagen under mild acidic conditions *in vitro* leads to the formation of a gel (Chandrakasan *et al.,* 1976), a process that one could also envisage taking place *in vivo* within the resorption pit. Generation of a collagenous gel at the resorption site would have a triple effect: (i) acting as a diffusion barrier by increasing the viscosity of the medium in immediate apposition to the resorption site, which in turn would decrease the diffusion coefficient of all substances in this area; (ii) acting as an ion-exchange matrix, as, due to the basic pI of collagen, the resorption pit would acquire an overall positive charge, which could serve as a trap for negatively charged molecules; and (iii) providing a matrix for hydrophobic interactions through the high content of nonpolar amino acid residues (~74%) in type I collagen. Released protons are likely to be tethered readily to the inorganic components of the bone matrix, which would reduce their free concentration and their mobility. As a consequence, a localized low pH zone would be established only at the site of proton release that could be sufficient to activate secreted lysosomal enzymes. The presence of such a pH gradient has also been suggested to accommodate the different pH requirements of collagenase and lysosomal enzymes in the resorption area (Delaissé *et al.,* 1993). During the resorption process, the low pH zone, followed by the collagenous gel zone, would advance further into the bone matrix, thus providing a localized microenvironment for bone resorption without the need for a static lateral tight seal (Fig. 2, see also color plate). An efficient osteoclast endocytotic mechanism would be responsible for the removal of the reaction products before they leave the resorption area by diffusion. In this model, the two processes of cell movement and resorption could occur simultaneously, events that would be difficult to integrate if stable, epithelium-like tight junctions were the basis of the osteoclast tight adhesion. This dynamic model also accounts for the apparently contrary role of integrins in osteoclast resorption. Without the need for a sterically close membrane–matrix contact zone, integrins could well be involved in the establishment and functioning of the sealing zone, in addition to their role in initial cell attachment and migration (Väänänen and Horton, 1995).

To test this hypothesis, Stenbeck and Horton (2000) examined the permeability of the osteoclastic sealing zone

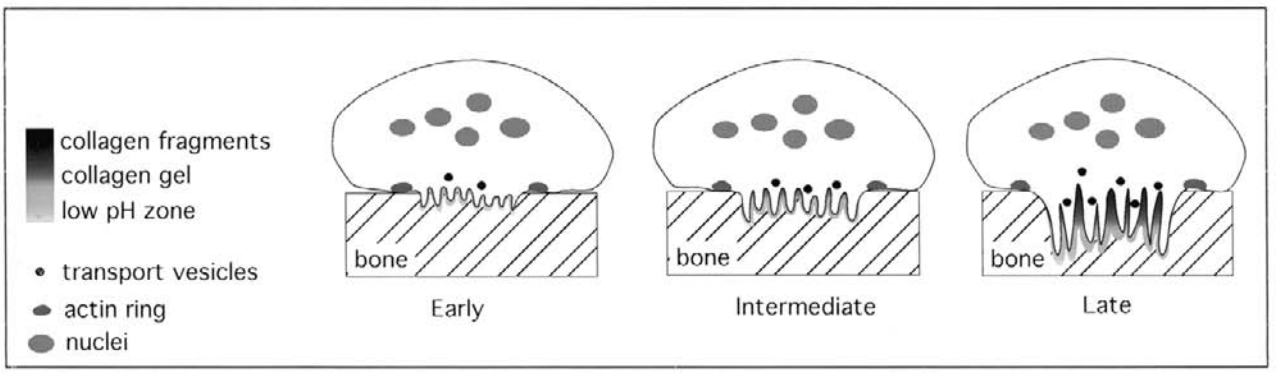

Figure 2 Model of the osteoclast sealing zone. During the early stages of resorption, the proton pump (VATPase) is inserted into the osteoclast plasma membrane that is enclosed by the actin ring (green). Proton extrusion by the VATPase leads to the formation of a localized low pH zone that dissolves the mineral content of the bone (yellow area). Proton movement is restricted by binding to hydroxyapatite. Lysosomal enzymes, secreted during the intermediate stages of resorption, digest the organic content of the bone in the low pH zone (red area). In the later stages of resorption, the ruffled border expands deep into the bone matrix by fusion of transport vesicles with the plasma membrane. The low pH zone moves with expansion of the ruffled border further into the bone matrix. The area behind the low pH zone consists of a collagenous "gel" that is endocytosed by the osteoclast (dark brown). This further restricts solute diffusion from below the osteoclast. However, because the net concentration of secreted and resorbed components is a balance between generation rate and limited diffusion rather than the presence of an impermeable barrier, externally added small molecules have access to the resorption area. Modified from Stenbeck and Horton (2000), with permission. (See also color plate.)

during bone resorption and migration in rabbit and human osteoclasts plated on dentine and bone. Using a series of fluorescent dyes of known molecular weight and different surface charge, it was established that negatively charged molecules with M_r up to 10,000 accumulate rapidly underneath actively resorbing osteoclasts. Live cell imaging shows that access underneath the osteoclasts occurred as early as 30 sec after the addition of the low molecular weight markers, as predicted by the dynamic sealing model proposed earlier (summarized in Fig. 2).

$\alpha_v\beta_3$-Mediated Signal Transduction

It has become increasingly clear, in a wide variety of cellular systems, that integrins can act as receptors capable of transducing signals. This results in biochemical changes within cells and induction of cell-specific early response genes and activation of nuclear transcription ("out-side-in" signaling), and in the modification of integrin activity ("inside-out" signaling) in response to signals generated via other receptor systems. Osteoclasts from a variety of species also respond to integrin ligands, either RGD-containing peptides or proteins or via antibody-mediated receptor cross-linking, in a number of ways indicative of direct signal transduction or changes mediated via cytoskeletal rearrangement (reviewed by Duong *et al.,* 2000; see Chapter 9). These include release of intracellular calcium stores, induction of protein tyrosine phosphorylation, and reorganiztion of the structural and signaling components of the cytoskeleton. Mammalian osteoclasts respond to integrin ligation with a prompt increase in intracellular calcium (Paniccia *et al.,* 1993; Shankar *et al.,* 1993; Zimolo *et al.,* 1994), whereas this is accompanied by a slower decrement in avian cells (Miyauchi *et al.,* 1991); the reason for this species difference is unclear. Reorganization and activation of cytoskeleton-associated tyrosine kinases are key downstream steps following osteoclast adhesion. c-Src has been found to be essential for osteoclast polarization and resorption in knockout mice (Soriano *et al.,* 1991), and c-Cbl has been suggested to act as a key mediator of c-Src action (Tanaka *et al.,* 1996). However, studies by Duong *et al.* (1998) have identified the focal adhesion kinase family member PYK2 as the major adhesion-dependent tyrosine kinase in osteoclasts. In contrast, FAK (focal adhesion kinase) is a minor kinase in osteoclasts (Tanaka *et al.,* 1995a; Duong *et al.,* 1998; Lakkakorpi *et al.,* 1999) when compared to its dominant role in adherent mesenchymal cells. Ligand binding or receptor clustering induces PYK2 phosphorylation by Src kinase in osteoclasts, and c-Src, PYK2, and actin form a stable complex on osteoclast adhesion. PYK2 colocalizes with F-actin in the ring-like structures characteristic of resorbing osteoclasts. Here, it associates directly with phosphorylated $p130^{cas}$ (Nakamura *et al.,* 1998a; Lakkakorpi *et al.,* 1999), which acts as an adaptor protein in the integrin–PYK2 signaling pathway. There is also evidence for recruitment of phosphatidyl inositol 3-kinase (PI3-K) to the cytoskeleton (Hruska *et al.,* 1995; Lakkakorpi *et al.,* 1997) where it associates with gelsolin (Chellaiah and Hruska, 1996).

The downstream effects of integrin-mediated signaling in osteoclasts have not been analyzed adequately (but see Chapter 9). Possibilities include roles in the onset of cellular polarization, transcytosis, and bone resorption; regulation of cell motility; and cessation of resorption and induction of adhesion-related apoptosis (Ruoslahti and Reed, 1994).

Integrins, Collagen-Binding Proteins and Transcytosis in Osteoclasts

Osteoclasts use transcytosis to remove degraded matrix from the active sites of bone resorption (Nesbitt and Horton, 1997; Salo *et al.,* 1997), enabling the osteoclast to maintain the integrity of the enclosed resorption site and facilitate cell migration and penetration into bone. Degraded bone matrix is endocytosed along the ruffled border and transported through the osteoclast in a vesicular pathway toward the basolateral surface of the cell; finally, it enters the extracellular space via a specialized exocytotic site located at the cell apex (Salo *et al.,* 1996). Thus, the transcytotic process utilized by osteoclasts is similar to that in epithelium and endothelium (Mostov *et al.,* 2000).

Reports have suggested that integrins may participate in transcytosis in an epithelial cell model (Ivanenkov and Menon, 2000) where the transport of adenovirus across cells was increased by RGD peptides. If osteoclasts use a similar RGD-dependent mechanism in transcytosis, then candidate receptors involved in the uptake of the bone matrix at the ruffled border would include $\alpha_2\beta_1$ and $\alpha_v\beta_3$ integrins, which, respectively, bind native and denatured collagens (Nesbitt *et al.,* 1993; Helfrich *et al.,* 1996). The proteolysis of collagenous matrix exposes cryptic RGD sites (Holliday *et al.,* 1997) during bone resorption, and engagement with the $\alpha_v\beta_3$ integrin could initiate endocytosis and subsequent transcytosis of the denatured collagenous matrix. Conversely, higher concentrations of RGD peptides, produced after extensive matrix proteolysis, could inactivate matrix transcytosis and, thus, lead to the cessation of resorption.

Another group of collagen-binding proteins in osteoclasts (Nesbitt *et al.,* 1994) are the annexins, a family of calcium-dependent phospholipid-binding proteins that exhibit a wide tissue distribution (reviewed by Raynal and Pollard, 1994). Annexins have been shown to participate in endocytosis, transcytosis, and exocytosis in several polarized cells (Burgoyne, 1994; Creutz, 1992; Wilton *et al.,* 1994), in addition to their role in a number of other cellular processes (Moss, 1997; Siever and Erickson, 1997). Evidence shows that annexin II participates in matrix transcytosis during bone resorption (Nesbitt and Horton, 1999). It is found at the cell surface of resorbing osteoclasts and colocalizes with degraded bone matrix in the resorption pit; it is also highly expressed within the basolateral cell body and at apical exocytotic sites. Furthermore, the addition of exogenous

annexin II to resorption cultures increases transcytosis of bone matrix and bone resorption by osteoclasts (Nesbitt and Horton, 1999). The ability of annexins to associate with membrane phospholipids, together with the collagen-binding capacity of osteoclast annexin II, may enable annexins to complex solubilized, degraded collagen with membrane structures associated with the transcytotic pathway, such as the ruffled border, intracellular transport vesicles, or the apical exocytotic site.

$\alpha_v\beta_3$ Integrin as a Therapeutic Target for Bone Disease

Early Studies and Rationale

Osteoporosis places a large and growing medical and financial burden on health services in developed countries; however, it remains a clinical area where, despite recent advances in therapy and diagnosis, there are still unmet needs. While potent drugs have been developed, e.g., bisphosphonates (see Chapter 78), the pharmaceutical industry is still developing novel antiresorptive agents. The $\alpha_v\beta_3$ vitronectin receptor presents a key step in the process on bone resorption *(vide supra),* which is being exploited by the pharmaceutical industry.

The development (for reviews, see Horton and Rodan, 1996; Hartman and Duggan, 2000; Miller *et al.,* 2000) of a number of orally active, nonpeptidic integrin antagonists, particularly based on modification of the RGD peptide motif identified in fibronectin by Pierschbacher and Ruoslahti in 1984, suggests that treatment of a range of bone diseases may be susceptible to strategies that involve the blockade of integrin function or modulation of their expression. The development of $\alpha_v\beta_3$ antagonist drugs has been aided considerably by the prior existence of an analogous set of agents that have been developed for use in thrombosis (see references in Hartman and Duggan, 2000; Miller *et al.,* 2000); the platelet integrin fibrinogen receptor, gpIIbIIIa/$\alpha_{IIb}\beta_3$, which is structurally related to the $\alpha_v\beta_3$ integrin on osteoclasts and shares the same β chain, is targeted. These are the first of the integrin antagonist "drugs" that have been approved for clinical use (Coller, 1997; Phillips and Scarborough, 1997; Theroux, 1998) and they form the paradigm for potential application to bone disease.

The functional role of $\alpha_v\beta_3$ in osteoclast biology, first examined by Horton and colleagues in antibody studies over a decade ago, has been confirmed in a large battery of *in vitro* systems and *in vivo* proof of concept studies *(vide supra).* Target specificity is aided by the *in vivo* distribution of $\alpha_v\beta_3$, which is expressed at high levels in osteoclasts (Horton, 1997). Much lower levels are found in platelets and megakaryocytes, kidney, vascular smooth muscle, some endothelia, and placenta (Horton, 1997). Thus, the therapeutic drug levels that would influence osteoclastic bone resorption are less likely to modify $\alpha_v\beta_3$ function at other sites. In certain pathological situations, though, tissue levels of $\alpha_v\beta_3$ are increased; for example, tumor microvessels show increased levels of $\alpha_v\beta_3$, as do melanoma cells when they metastasize (Horton, 1997), and these features are being exploited.

Strategies for Therapeutic Modification of Integrin Function

From basic principles, there are two main strategies for inhibiting cell adhesion molecule function therapeutically (Table IV). First, a direct approach: competitive antagonists of the receptor–ligand interaction can be developed, and this has been the usual pharmaceutical approach with the aim of producing orally active, synthetic nonpeptide mimetic agents. They have been identified by a variety of standard industry techniques, as summarized in Table IV (e.g., see Ferguson and Zaqqa, 1999; Wang *et al.,* 2000). Other approaches, such as using receptor-specific antibodies, peptides, and naturally occurring protein antagonists, together with molecular engineering, have generally been used in proof of principle experiments rather than as clinical drug candidates, although there are some notable examples of protein therapeutics in the field (for examples, see Table IV). Directly acting antagonists have entered clinical trial to modify activation-dependent platelet aggregation in thrombotic conditions via the integrin platelet fibrinogen receptor, gpIIbIIIa/$\alpha_{IIb}\beta_3$. Thus, ground-breaking trials [EPIC, EPILOG etc. (Tcheng, 1996)] have demonstrated efficacy of the humanized anti-gpIIIa monoclonal antibody 7E3 (ReoPro) in various ischemic heart conditions (Coller 1997). Results from trials with RGD mimetics [e.g., lamifiban, tirofiban (Ferguson and Zaqqa, 1999; Wang *et al.,* 2000)] and the cyclic KGD peptide integrilin have, though, been less impressive (Theroux, 1998). As with gpIIbIIIa-specific agents, the possibility of developing osteoclast $\alpha_v\beta_3$ (vitronectin receptor) antagonists as resorption inhibitors in bone disease was initially demonstrated *in vitro* using a variety of techniques to disrupt receptor function, and small molecule inhibitors of $\alpha_v\beta_3$ are now at the late stage of preclinical development or entering the early stages of clinical trial evaluation (Hartman and Duggan, 2000; Miller *et al.,* 2000). Thus, general principles for the use of adhesion receptor antagonists in disease have been established, and useful drugs are thus likely to be available for a wide variety of indications in the future.

The second approach is indirect, with the aim of modifying expression or intracellular function (such as signal transduction) of cell adhesion molecules, especially integrins. Some examples of such strategies are given in Table IV. The furthest advanced are the use of antisense oligonucleotide inhibitors of receptor protein synthesis. Because inhibitors of ICAM-1 expression are finding promise in the treatment of various inflammatory diseases, such as of the bowel or eye, then modulation of α_v expression by an antisense approach (Villanova *et al.,* 1999) could be a promising strategy. Likewise, a number of agents to block the function of c-Src, a cellular kinase that acts downstream in the signaling pathway of integrin receptors in bone cells, are being developed for the treatment of osteoporosis, based on the earlier

Table IV Strategies for Therapeutic Modification of Integrin Adhesion Receptor Function *in Vivo*

Direct approaches
Naturally occurring protein inhibitors and their engineered derivatives (e.g., RGD-containing snake venoms and proteins from ticks, leeches, etc.)[a]
Blocking antibodies, and their engineered derivatives, to adhesion molecules[b]
Arg-Gly-Asp (RGD) peptides and their chemical derivatives (e.g., designed to improve specificity and stability)[c]
Nonpeptidic mimetics,[d] produced via different compound selection strategies[e]
Indirect approaches
Altered receptor synthesis via use of antisense oligonucleotides[f]
Inhibition of adhesion receptor expression via regulatory cytokines and their receptors
Modification of integrin receptor function via regulatory integrin-associated proteins
Modulation of integrin receptor affinity (i.e., activation) for ligands
Modification of downstream receptor-associated signaling (e.g., c-Src and other kinases, adhesion-associated apoptosis genes)

[a] Echistatin has been used as a proof of concept inhibitor of $\alpha_v\beta_3$ in bone disease studies (Fisher *et al.,* 1993; Yamamoto *et al.,* 1998). Barbourin snake venom protein contains KGD instead of RGD and is the basis of selective inhibitors of platelet gpIIbIIIa (Phillips and Scarborough, 1997).

[b] Antibodies to gpIIbIIIa (i.e., 7E3, ReoPro, Centocor Inc) formed the first cell adhesion receptor inhibitor licensed for clinical use (in the various vascular/thrombotic condition, see Tcheng, 1996; Coller, 1997). A humanized $\alpha_v\beta_3$ antibody (clone LM609) is currently in clinical trial for cancer acting via induction of apoptosis in tumor vessels.

[c] Integrilin (Cor Therapeutics Inc), a cyclic KGD-containing peptide gpIIbIIIa inhibitor, is in clinical trial (Phillips and Scarborough, 1997; Coller, 1997), as are RGD-derived cyclic peptides with selectivity for $\alpha_v\beta_3$ [cyclic RGDfVA, E. Merck (Haubner *et al.,* 1996)].

[d] A number of companies have intravenous and orally active nonpeptidic gpIIbIIIa antagonists in clinical trial for platelet-related disorders (Phillips and Scarborough, 1997; Coller, 1997; Theroux, 1998). Analogous mimetics are in late preclinical development for inhibition of $\alpha_v\beta_3$ (Horton and Rodan, 1996; Hartman and Duggan 2000; Miller *et al.,* 2000) in bone disease and cancer.

[e] Structure–function, combinatorial chemistry, phage display, compound/natural product library screening, etc. (Lazarus *et al.,* 1993; Pasqualini *et al.,* 1995; Corbett *et al.,* 1997; Hoekstra and Poulter, 1998).

[f] Antisense therapeutics directed against adhesion receptors are in clinical trials; antisense oligonucleotides to α_v block bone resorption *in vitro* (Villanova *et al.,* 1999).

finding in knockout mice that c-Src plays a central role in osteoclastic bone resorption (Soriano *et al.,* 1991).

Current Drug Development Status of $\alpha_v\beta_3$ Antagonists for Use in Bone and Other Diseases

The action in bone models of several candidate mimetic $\alpha_v\beta_3$ antagonists has been reported by a number of companies, and their evolution has been reviewed by Hartman and Duggan (2000) and Miller *et al.* (2000); as yet, these are not drugs but still agents used for proof of concept and pharmaceutical experiments. Compounds based on a variety of proprietary scaffolds, which have all shown varying efficacy and specificity for $\alpha_v\beta_3$ in the number of *in vitro* screening assays, have inhibitory effects on the calcemic response in thyroparathyroidectomized rodents and bone-sparing responses in ovariectomy and other rodent models of increased bone turnover. Drug candidates with optimized pharmacokinetics/dynamics are about to enter clinical trials for bone disease and for other indications where $\alpha_v\beta_3$ is involved in disease pathogenesis.

Positive findings in proof of concept studies using small molecule mimetics in models of bone metabolism underline $\alpha_v\beta_3$ antagonists as promising candidates for a new class of bone disease therapeutics, although they still require optimization. Further, the expression, albeit at lower levels, of $\alpha_v\beta_3$ in other tissues suggests that their inhibition could produce unwanted side effects: for example, will they, on chronic administration, interfere with wound healing, the function of the related α_v integrins in respiratory tract or intestinal epithelium, or platelet ($\alpha_{IIb}\beta_3$-mediated) aggregation?

Finally, although $\alpha_v\beta_3$ antagonists have been developed for use in bone diseases, other clinical targets also show promise (such as rheumatoid arthritis, angiogenesis in eye diseases and cancer, vascular restenosis following coronary angioplasty, and direct targeting of tumours expressing $\alpha_v\beta_3$). These are all being investigated for possible new applications of $\alpha_v\beta_3$ antagonist drugs.

Osteoblasts

Osteoblasts are uniquely involved with the synthesis and maintenance of the bone matrix and lie in direct contact with the specialized extracellular matrix of bone; they also respond to the mechanical forces exerted on the skeleton and to the growth factors that regulate their function and that are entrapped in the surrounding extracellular matrix. Thus, it is likely that cell adhesion receptors play several important roles in bone cell function and that the maintenance of osteoblast adhesion would be a major function for the integrin family of matrix receptors. Some of the possible roles of adhesion receptors in osteoblasts are listed in Table I.

It is well established that osteoblast differentiation, maturation, and their function are regulated by their interaction with matrix components such as type I collagen (e.g., Lynch *et al.,* 1995; Masi *et al.,* 1992). The role of integrins and other adhesion molecules in the regulation of osteoblast precursor differentiation and functional maturation has yet, though, to be adequately investigated; however, preliminary data suggest that RGD-sensitive, β_1 integrins are involved (*vide infra;* Globus *et al.,* 1998; Gronowicz and Derome, 1994). Osteoblasts also partake in a wide variety of cell–cell interactions in the bone/bone marrow compartment (see Table I). Intercellular adhesion is likely to be conducted by adhesion proteins such as cadherins (see Chapter 18), but knowledge of their role in osteoblast function is limited (Babich and Foti, 1994). A role for integrins

in such interactions cannot be excluded, and the integrin counterreceptors, ICAM-1 and VCAM-I, as well as the CD2 counterreceptor, LFA-3, are all expressed by osteoblasts. Evidence shows that these receptors are involved in interactions of osteoblasts with T lymphocytes and subsequent secretion of cytokines (Tanaka *et al.,* 1995b); such events may be important in the regulation of skeletal turnover in inflammation.

Mechanical strain sensing within the skeleton is probably performed by the "bone-lining cells" that are not synthesizing matrix and lie on the bone surface and/or by the osteocyte network lying within the bone (reviewed elsewhere in this volume; see Chapters 2 and 6). Cell membrane integrins interacting with matrix could act as force transducers to modify cellular behavior (both locally in osteocytes and distantly via osteocyte processes interacting with osteoblasts on bone surfaces); this phenomenon has been demonstrated in other cell systems and is elegantly discussed by Ingber and colleagues (Wang and Ingber, 1994; Ruoslahti, 1997). There is some data on the nature of the structure of the matrix in the osteocyte lacunae, including adhesion proteins synthesized by osteocytes themselves (see references in Aarden *et al.,* 1996), and evidence has demonstrated a role for β_1 (but not β_3) integrins in osteocyte adhesion to a number of bone matrix proteins (Aarden *et al.,* 1996). A limited phenotypic analysis has been performed on human tissue and shows expression of β_1 integrins (Hughes *et al.,* 1993). CD44 has been found at a high level in osteocytes but in lower amounts in osteoblasts (Hughes *et al.,* 1994; Nakamura *et al.,* 1995), although its function has not been investigated. We thus can conclude that mechanical sensing by osteocytes could be mediated via integrin–matrix or other cell adhesion receptor coupling, but currently there is no experimental evidence to support this conclusion.

β_1 Integrins and Osteoblasts

A diverse range of integrins, particularly of the β_1 class, have been shown to be expressed by osteoblasts, including α_1 through α_5 (Brighton and Albelda, 1992; Clover and Gowen, 1992; Clover *et al.,* 1992; Grzesik and Gehron Robey, 1994; Horton and Davies, 1989a,b; Hughes *et al.,* 1993; Majeska *et al.,* 1993; Pistone *et al.,* 1996; Ganta *et al.,* 1997; Gronthos *et al.,* 1997; reviewed by Bennett *et al.,* 2001a), although there is some contradiction between different studies as to the specific heterodimers expressed. This may reflect the heterogeneity of osteoblast-like populations (see Chapter 4) and includes the possibility that cells at successive stages of osteoblast differentiation, from fetal or adult bone or from different anatomical sites, show different patterns of integrin expression. Nevertheless, trends are emerging. While they may express α_v integrins, osteoblastic cells differ from osteoclasts in that β_1 integrins appear to have the major functional role, which has been underscored by *in vivo* data (Zimmerman *et al.,* 2000). Several of these β_1 integrins have a high affinity for extracellular matrix components found in bone and adjacent matrix, such as collagen types I and III and fibronectin.

Collagen Receptors

The $\alpha_1\beta_1$, $\alpha_2\beta_1$, and $\alpha_3\beta_1$ integrins bind collagen, and immunological studies confirm that they are expressed by osteoblastic cells *in vivo* and *in vitro*. Collagen type 1 is the dominant bone matrix protein, and interactions involving these receptors are strong candidates for a role in regulating osteoblast behavior. Furthermore, functional studies have demonstrated that $\alpha_2\beta_1$–ligand binding leads to expression or upregulation of markers of osteoblastic differentiation (Xiao *et al.,* 1998). Cultures of osteoblast-like cells in the presence of inhibitors of α_2 function, such as blocking antibodies, modulate $\alpha_2\beta_1$-dependent expression of osteoblast markers (Takeuchi *et al.,* 1997). Others have shown that ligand binding by the α_2 integrin modulates cell motility and contraction of collagen gels *in vitro* (Riikonen *et al.,* 1995).

$\alpha_3\beta_1$ heterodimers bind collagen, fibronectin, and several other extracellular matrix proteins and are expressed by early osteoblastic cells from human bone (Bennett *et al.,* 2001a). Function-perturbing antibodies against the α_3 integrin inhibit the formation of mineralized nodules in rat calvarial osteoblast cultures (Moursi *et al.,* 1997).

Integrins and Fibronectin

Of the integrins that are fibronectin receptors, $\alpha_3\beta_1$, $\alpha_4\beta_1$, $\alpha_5\beta_1$, and α_v heterodimers are expressed in bone. Most are capable of binding a broad range of extracellular matrix proteins in bone, using both RGD-dependent (Puleo and Bizios, 1991) and independent mechanisms.

In vitro studies using an osteoblast culture model have shown that the selective fibronectin receptor, $\alpha_5\beta_1$, is expressed by cells of the osteoblast lineage, and evidence shows that it is important in both the development and maintenance of bone. Interruption of binding with blocking antibodies leads to inhibition of bone nodule formation by osteoprogenitor cells in rat calvarial cultures (Moursi *et al.,* 1996, 1997). In mature cells, $\alpha_5\beta_1$–ligand binding appears to be necessary for cell survival and receptor blockade leads to osteoblast apoptosis (Globus *et al.,* 1998).

Fibronectin is a normal constituent of human bone, but data on its distribution within the bone matrix are sparse, and it has been reported absent from mature lamellar bone (Carter *et al.,* 1991). Supporting evidence from rodent tissues suggests that fibronectin synthesis and expression are restricted to developing or immature bone (Weiss and Reddi, 1980; Cowles *et al.,* 1998). It is, therefore, possible that $\alpha_5\beta_1$–ligand interaction is a feature of bone formation during development or repair and may not play a prominent role in the turnover and maintenance of mature lamellar bone. There is also some evidence for the involvement of the $\alpha_5\beta_1$ integrin in mechanical sensing by osteoblasts, at least *in vitro* (Salter *et al.,* 1997).

Integrins and Mesenchymal Precursor Cells

$\alpha_1\beta_1$ and $\alpha_2\beta_1$ integrins are both collagen receptors, with $\alpha_1\beta_1$ showing higher affinity for type IV over type I collagen (Kern *et al.,* 1993). Type IV collagen is a feature of the endothelial basal lamina, and the α_1 integrin has been reported in mesenchymal stem cells (Owen, 1998) with osteogenic potential (Bruder *et al.,* 1998a). In addition, both type IV collagen and laminin are synthesized by pericytes (Doherty *et al.,* 1998), which have been suggested as putative osteogenic precursor cells, and expression of these proteins is lost as cells mature. It is possible, therefore, that the $\alpha_1\beta_1$ heterodimer has a role in cell–matrix interactions involving mesenchymal precursor cells associated with small blood vessels in the bone/bone marrow microenvironment. Support for this also comes from the finding that osteoprogenitors, in contrast to more mature calvarial-derived cells, showed preferential binding to laminin, a component of the endothelial basement membrane (Roche *et al.,* 1999). Furthermore, mesenchymal precursor cells express the α_6 integrin (Bruder *et al.,* 1998a), which binds laminin, a major component of the basement membrane.

α_v Integrins

Several studies report expression of α_v in cells of the osteoblast lineage. However, the published literature varies with regard to which β subunit is utilized (the balance of data favoring $\alpha_v\beta_5$ expression), and staining appears more prominent in osteoblasts than osteocytes (Hughes *et al.,* 1993; Grzesik and Robey, 1994).

Nonintegrin Cell Adhesion Molecules in Osteoblasts

Cadherins

Osteoblasts and bone-lining cells form gap and adherens type cell junctions with each other and with the osteocytes (Palumbo *et al.,* 1990, Doty, 1981). Cadherins are among the best characterized cell–cell adhesion molecules (Isacke and Horton, 2000), localizing to sites of intercellular attachment. The expression pattern and function in osteoblasts of cadherins are covered in depth in Chapter 18 and is only reviewed briefly herein. Cells of the osteoblast lineage express a limited repertoire of cadherins, including N-cadherin, cadherin-4, cadherin-6, and cadherin-11 (Okazaki *et al.,* 1994; Babich and Foti 1994; Cheng *et al.,* 1998; Mbalaviele *et al.,* 1998; Ferrari *et al.,* 2000). N-cadherin has been histochemically localized to well-differentiated osteoblasts lining the bone surface, but not osteocytes, in fetal rat calvaria and blocking N-cadherin binding decreased bone nodule formation *in vitro* (Ferrari *et al.,* 2000).

The biological significance of cadherin-mediated cell–cell interactions in bone remains largely unexplored. However, evidence shows that cadherins function synergistically with other cell adhesion molecules to influence cell behavior. They may, for example, modulate the function of connexins, proteins associated with gap junction function, and osteoblasts are known to communicate via such mechanisms (Yellowley *et al.,* 2000) (see Chapter 18). In common with other tissues, variations in cadherin expression have been observed in association with malignancy. Reduced N-cadherin and anomalous cadherin-11 expression have been associated with high-grade metastatic osteosarcomas (Kashima *et al.,* 1999), suggesting an important role for these molecules in intercellular adhesion.

CD44

Immunohistochemical studies of human tissues showed CD44 expression in osteocytes, but not osteoblasts or bone-lining cells (Hughes *et al.,* 1994). This is consistent with other mammalian models in which strong expression has been observed in osteocytes, with weaker staining in cells earlier in the osteoblast lineage (Jamal and Aubin, 1996; Nakamura *et al.,* 1995; Nakamura and Ozawa, 1996; Noonan *et al.,* 1996). The functional significance of CD44 expression is unknown. *In vitro,* osteoblastic cells have, indeed, been shown to be able to bind to, and degrade, hyaluronate in the transition zone from cartilage to bone in the growth plate and utilize a CD44-dependent mechanism (Pavasant *et al.,* 1994). There are a variety of other known ligands for CD44, e.g., type I collagen, fibronectin, laminin, and osteopontin, and these are also produced by both osteoblasts and osteocytes (Aarden *et al.,* 1996) and colocalize with CD44, indicating that a much wider range of functions for this molecule may exist.

Immunoglobulin Superfamily

Although sparse, there are data relating to the expression of members of this family by osteoblasts and related cells. ICAM-1 and -2, VCAM-1, and LFA-3 expression has been reported in human bone cells (Tanaka *et al.,* 1995b; Bruder *et al.,* 1998a) and they may play a role in the interaction of osteoclast precursors with stromal cells in the bone/bone marrow microenvironment (Tanaka *et al.,* 2000). Expression of the activated leukocyte cell adhesion molecule (ALCAM) has been reported in undifferentiated human mesenchymal cells and may have a functional role in osteoblast differentiation (Bruder *et al.,* 1998a,b); likewise, NCAM is expressed transiently during ossification (Lee and Chuong, 1992).

Selectins

There is, as yet, little information on the expression of members of the selectin family in osteoblasts. However, there is evidence for L-selectin expression by human mesenchymal stem cells (Bruder *et al.,* 1998a), but not E- or P-selectin. These molecules are normally associated with leukocyte trafficking across endothelia, but the function of L-selectin in osteoblasts is unknown.

SYNDECANS

Syndecans -1, -2, and -4 have been identified in human marrow stromal and osteoblast-like cells *in vivo* and *in vitro* (Schofield *et al.,* 1999; Birch and Skerry, 1999), and syndecan-3 is expressed during periosteal development (Koyama *et al.,* 1996). Studies using a rat organ culture model demonstrated coincident expression of syndecan-2 and -4 with fibroblast growth factor receptors *in vitro* and a similar spatiotemporal expression *in vivo* (Molteni *et al.,* 1999). This suggests that members of the syndecan family have a role in presentating growth factors during skeletal development, but this remains to be investigated.

Adhesion Receptors in Cartilage

The role of cell adhesion molecules in cartilage is relatively unclear, although some of their putative functions are summarized in Table I. These may include roles in chondrocyte proliferation and cartilage differentiation during fetal development (see Chapter 3); responses to mechanical forces (e.g., in articular cartilage or menisci); maintenance of tissue architecture and integrity, including matrix synthesis and assembly; or cell adhesion, regulation of chondrocyte gene expression, and cell survival. Additionally, there is likely to be a role for cell adhesion molecules in the response in cartilage to injury and disease (Forster *et al.,* 1996; Lapadula *et al.,* 1997; Millward-Sadler *et al.,* 2000; Ostergaard *et al.,* 1998). The differing distribution of both integrin and matrix proteins (Salter *et al.,* 1995) in the zones of cartilage suggests a role in chondrocyte differentiation from mesenchymal precursors (Hirsch and Svoboda, 1996; Tavella *et al.,* 1997; Shakibaei *et al.,* 1995) and/or interaction with matrix, or a specialized function such as response to mechanical stresses. There have been few studies to investigate these possibilities.

Integrins in Chondrocytes

As with the osteoblast lineage, the reported integrin phenotype of chondrocytes is complex, with additional inconsistency between publications (Durr *et al.,* 1993; Enomoto *et al.,* 1993; Loeser *et al.,* 1995; Salter *et al.,* 1992, 1995; Woods *et al.,* 1994; Ostergaard *et al.,* 1998; reviewed in Helfrich and Horton, 1999). A synthesis of the literature suggests that human chondrocytes express the β_1 integrins α_1, α_2, α_3, α_5, and α_6, but not α_4; β_2, β_4, and β_6 are absent, and analysis of β_{7-9} and CD11 has not been reported. Some studies have shown high expression of α_v integrin; as in osteoblasts, this is mainly as $\alpha_v\beta_5$ and not the $\alpha_v\beta_3$ dimer seen in osteoclasts, although a subpopulation of superficial articular chondrocytes has been found to be $\alpha_v\beta_3$ positive (Woods *et al.,* 1994). A new collagen type II-binding integrin, first identified in chondrocytes, $\alpha_{10}\beta_1$, has been reported (Camper *et al.,* 1998). Differences in reported integrin expression patterns could well relate, in part, to a variation in sampling site, use of fetal versus adult material, species differences, or influences of disease on phenotypes; indeed the first possibility is born out by the study of Salter *et al.* (1995) where the distribution of integrin clearly differs by site (human articular, epiphyseal, and growth plate chondrocytes were studied). Likewise, changes have been reported in *in vitro*-cultured chondrocytes (Loeser *et al.,* 1995; Shakibaei *et al.,* 1993).

Extensive studies have, though, been performed to address the role of $\alpha_5\beta_1$ in chondrocyte interaction with fibronectin (Durr *et al.,* 1993; Enomoto *et al.,* 1993; Shimizu *et al.,* 1997; Enomoto-Iwamoto *et al.,* 1997; Homandberg and Hui, 1994; Xie and Homandberg, 1993). Function-blocking antibodies and RGD peptides have been shown to inhibit cell adhesion to fibronectin and its fragments, thus modifying chondrocyte behavior and cartilage function. Likewise, chondrocyte recognition of collagen, including types I, II, and VI collagen, has been studied *in vitro* (Durr *et al.,* 1993; Enomoto *et al.,* 1993; Shimizu *et al.,* 1997; Enomoto-Iwamoto *et al.,* 1997; Holmvall *et al.,* 1995) and shown to be mediated via several β_1 integrins: $\alpha_1\beta_1$, $\alpha_2\beta_1$, and $\alpha_3\beta_1$ (Shakibaei, *et al.,* 1993; Loeser, 1997; Holmvall *et al.,* 1995).

Data have highlighted the functional interaction between integrins and mechanical strain in cartilage, although the mechanisms are likely to differ considerably from those obtained in osteoblasts due to the major differences in strain magnitude and exposure frequency to which joint cartilage is exposed. Thus, Salter and colleagues (Wright *et al.,* 1997; Millward-Sadler *et al.,* 1999; Lee *et al.,* 2000) have shown that integrin $\alpha_5\beta_1$ acts as a mechanoreceptor in chondrocytes, with strain inducing a variety of downstream signaling events and cytokine secretion. Differences were, additionally, observed in osteoarthritic versus normal cartilage (Millward-Sadler *et al.,* 2000).

There is also increasing evidence for a connection between chondrocyte adhesion to extracellular matrix proteins, especially fibronectin, and chondrocyte–synovial cell interaction (Ramachandrula *et al.,* 1992). Here, integrin expression and function are regulated by inflammatory cytokines and growth factors, resulting in the release of matrix metalloproteinases (Arner *et al.,* 1995) and hence cartilage breakdown (Xie and Homandberg, 1993; Yonezawa *et al.,* 1996). Such events are likely to be involved in the pathogenesis of the cartilage destruction seen in osteoarthritis and rheumatoid arthritis.

Nonintegrin Cell Adhesion Molecules of Cartilage

CADHERINS

There is some evidence for differential expression of cadherins (N-cadherin and cadherin-11) in prechondrocytic cells of developing limb primordia, but cadherins appear not to be found in mature cartilage (Simonneau *et al.,* 1995; Oberlender and Tuann, 1994; Tavella *et al.,* 1994). There is no published literature on cadherin in human cartilage development.

CD44

CD44 is expressed by cartilage and has been studied for a variety of sites and species (Hughes *et al.,* 1994; Noonan *et al.,* 1996; Stevens *et al.,* 1996). The predominant isoform detected is the standard CD44H variant (Salter *et al.,* 1996). There is some evidence from the use of function-blocking antibodies showing that CD44 is involved in chondrocyte pericellular matrix assembly (Knudson, 1993). The range of extracellular matrix molecules recognized by CD44 in cartilage is unclear, although interaction with hyaluronan is likely. CD44 is upregulated during cartilage catabolism (Chow *et al.,* 1995) induced by inflammatory cytokines, and chondrocytes have been shown to actively take up hyaluronan via CD44-mediated endocytosis (Hua *et al.,* 1993). Thus, it is reasonable to speculate that this molecule plays a regulatory role in cartilage matrix turnover in health and disease (Neidhart *et al.,* 2000).

IG FAMILY MEMBERS

N-CAM is distributed similarly to N-cadherin in early cartilage development (Tavella *et al.,* 1994; Hitselberger Kanitz *et al.,* 1993); again, there are no data for mature human cartilage. A further Ig superfamily molecule, ICAM-1, is expressed by chondrocytes, particularly after activation by inflammatory cytokines (Bujia *et al.,* 1996; Davies *et al.,* 1991), which may play a role in mediating

Table V Key Roles for Cell Adhesion Molecule Interactions in Bone

Receptor	Cell type	Ligand(s) bound[a]	Known/potential functions
Integrins			
$\alpha_v\beta_3$	Osteoclast	Vitronectin, osteopontin, bone sialoprotein, fibronectin, fibrinogen, denatured collagen, etc.	Matrix adhesion Signal transduction Osteoclast polarization ? cessation of resorption
$\alpha_2\beta_1$	Osteoclast	Native collagens	Matrix adhesion
	Osteoblast	Native collagens	Matrix adhesion Osteoblast differentiation
	Chondrocytes	Type II collagen	Matrix adhesion
$\alpha_5\beta_1$	Osteoblast	Fibronectin (RGD)	Osteoblast differentiation
	Chondrocyte	Fibronectin (RGD)	Cartilage breakdown
Cadherins			
N- and other cadherins	Osteoblasts	N-cadherin, etc.	Osteoblast development
	Chondrocyte	N-cadherin, etc.	Cartilage development
E-cadherin	Osteoclast	E-cadherin	? Osteoclast differentiation
Ig superfamily			
ICAM-1	Osteoblast	LFA-1 on leukocytes	Osteoblast differentiation Production of cytokines
	Chondrocyte	LFA-1 on leukocytes	Cartilage breakdown
VCAM-1	Osteoblast	α_4 integrins on leukocytes	Osteoblast differentiation Production of cytokines
Cell surface proteoglycans			
Syndecan-1	Osteoblast, osteocyte	Type I collagen, tenascin-C	? Matrix adhesion ? Osteoblast differentiation ? Role in mechanosensing
Syndecan-3	Chondrocyte	Tenascin-C	Cartilage development
CD44	Osteoclast	? Hyaluronate, ? osteopontin, ? type I collagen, ? fibronectin	Osteoclast formation ? Osteoclast migration ? Osteoclast–osteoblast interaction
	Osteoblast	Hyaluronate	Hyaluronate degradation
	Osteocyte	? Hyaluronate, ? osteopontin, ? type I collagen, ? fibronectin	? Matrix adhesion ? Role in mechanosensing
	Chondrocyte	Hyaluronate	Pericellular matrix assembly

[a] There is no definitive information on the natural ligands in bone or cartilage for these molecules. The range of ligands demonstrated to be bound in *in vitro* adhesion assays is shown.

T-cell–chondrocyte interactions at sites of inflammatory joint destruction (Horner *et al.,* 1995; Seidel *et al.,* 1997).

SYNDECANS

Syndecan-3 is highly expressed in proliferating chondrocytes, below the tenascin-C-rich layer of articular chondrocytes; decreased levels are found in hypertrophic cartilage (Shimazu *et al.,* 1996). High levels are also found in forming perichondrium (and later in periosteum) in the developing avian limb (Seghatoleslami *et al.,* 1996) and it has been suggested that syndecan-3 is involved with tenascin-C in establishing, or maintaining, boundaries during skeletogenesis (Koyama *et al.,* 1995).

Concluding Remarks: Modulation of Integrin Function in Bone—New Therapeutic Possibilities for Bone Disease

Bone and cartilage cells express a wide variety of adhesion molecules (summarized with their known and potential functions in Table V). Integrin expression has been studied extensively, but, generally, there is less information on expression of other adhesion molecule family members. There is also little information on the expression and function of adhesion molecules of all classes during skeletal cell development, largely because we currently lack adequate markers to identify immature bone cells. Adhesion receptors fulfill many functions in the skeleton, and these are frequently linked to a variety of intracellular signaling pathways, leading to a central regulatory role for this class of molecules in bone metabolism. Knowledge of their role in bone resorption and cartilage integrity is extensive, although a function for cell adhesion receptors in bone formation has only been defined recently. Although no unique osteoblast, osteoclast, or chondrocyte adhesion molecule has been identified to date, therapeutic strategies based on selectively inhibiting highly expressed receptors, such as the $\alpha_v\beta_3$ integrin in osteoclasts, have proved to be successful in regulating excessive bone resorption. Better knowledge of the expression of adhesion molecules in bone and cartilage pathology is required, and elucidation of the role of cell–matrix interactions in the aetiology of skeletal disease will, therefore, remain a research challenge for the foreseeable future.

CHAPTER 18

Intercellular Junctions and Cell–Cell Communication in Bone

Roberto Civitelli,[*] Fernando Lecanda,[†] Niklas R. Jørgensen,[‡] and Thomas H. Steinberg[*]

Introduction

The organization of cells in tissues and organs is controlled by molecular programs that afford cells the ability to recognize other cells and the extracellular matrix and to communicate with their neighbors. Adhesive interactions are essential not only in embryonic development, but also in a variety of other biologic processes, including the differentiation and maintenance of tissue architecture and cell polarity, the immune response and the inflammatory process, cell division and death, tumor progression and metastases (Takeichi, 1993; Goodenough *et al.,* 1996). Cell–cell and cell–matrix adhesion are mediated by four major groups of molecules: cadherins, immunoglobulin-like molecules, integrins, and selectins (Hynes *et al.,* 1992; Gumbiner, 1996). Cadherins are an integral part of *adherens junctions,* which along with tight junctions and desmosomes, constitute the so-called anchoring junctions, which join cells by anchorage through their cytoskeletons (Alberts *et al.,* 1994). A special type of intercellular junction are *gap junctions,* which do not provide cell anchorage but allow direct communication via specialized intercellular channels, and thus they are defined as communicating junctions (Lowenstein, 1981). Recent findings of naturally occurring mutations of gap junction proteins in several pathologic conditions (Paul, 1995) and the development of mouse models with disrupted gap junctional communication indicate that gap junctions are critical for cell fate specification, migration, differentiation, and tissue morphogenesis. In addition to cell–cell adhesion molecules and gap junctional communication, mechanically induced "calcium waves" represent a short-range signaling system that allows cell-to-cell propagation of locally generated signals that diffuse through cell networks.

Bone development occurs by aggregation and condensation of immature osteoprogenitor cells in specific areas to form cartilaginous scaffolds and in the adult skeleton bone remodels via repeated sequences of bone resorptive and formative cycles, which in turn requires a coordinated cellular activity among osteoblasts, osteoclasts, and osteocytes. The cooperative nature of bone modeling and remodeling requires efficient means of intercellular recognition and communication that allow cells to sort and migrate, synchronize their activity, equalize hormonal responses, and diffuse locally generated signals. Thus, as differentiated osteoclasts represent a real syncytium, the result of mononuclear precursor fusion, osteoblasts and osteocytes are interconnected in a "functional syncytium" via intercellular adhesive and communicating junctions. This chapter reviews current knowledge about the role of direct cell–cell interactions in the development and remodeling of the skeletal tissue, focusing on cell–cell adhesion via cadherins and other cell adhesion molecules, cell–cell communication via gap junctions, and short-range calcium signals, or calcium waves.

Cell–Cell Contact via Cell Adhesion Molecules

Adherens Junctions and the Cadherin Superfamily

Cadherins are single chain integral membrane glycoproteins that mediate calcium-dependent cell–cell adhesion (Kemler, 1992; Takeichi, 1995). About 30 members of this large superfamily of cell adhesion molecules have been cloned (Tanihara *et al.,* 1994; Takeichi, 1995; Gumbiner, 1996). Although cadherins were originally named after their tissue of origin—N-cadherin (Ncad) from the nervous system, E-cadherin (Ecad) from epithelial cells, etc.—new family members are identified sequentially as cadherin-4 (cad4) through cadherin-14 (Suzuki *et al.,* 1991). Cadherins have a molecular mass of about 120 kDa and are composed of a long extracellular domain (EC), a single transmembrane-spanning domain, and a relatively small intracellular (IC) C-terminus tail. Calcium-binding sites are located in the EC, which is composed of five repeats (EC1 through EC5), and confer the ability to bind to the same cadherin on neighboring cells. A further classification into two cadherin types has been proposed based on relatively minor structural differences (Tanihara *et al.,* 1994): type I, which includes, among others, Ncad, Ecad, Mcad, and cad4 (the human homologue of mouse Rcad), and type II, comprising cad5 through cad12. Another group of cadherins includes those lacking the intracellular tail, i.e., Tcad and cad13, whose function is still obscure. This now large family of molecules is sometimes referred to as "classical" cadherins to distinguish them from protocadherins, also members of this superfamily, perhaps representing ancestor molecules (Sano *et al.,* 1993; Suzuki, 1996), and from desmocollins and desmogleins, which also differ from the typical cadherins in their cytoplasmic domain (Buxton *et al.,* 1992).

Crystallographic analysis has provided mechanistic insights into the steric arrangement and Ca^{2+} dependency of the adhesion structure formed by cadherins (Shapiro *et al.,* 1995; Pertz *et al.,* 1999). The most recent model derived from the crystallization of Ecad ectodomains envisages the formation of *cis* homodimers as Ca^{2+} concentration increases to > 1 m*M*. Upon Ca^{2+} binding and dimerization, the two cadherins participating in the dimer become rigid and form an X-shaped assembly, interfacing through their EC1 and EC2 domains. Further steric rearrangement at higher Ca^{2+} concentration allows Trp2 to dock into the hydrophobic pocket formed in part by the His-Ala-Val (HAV) domain—thought to be critical for cell adhesion (Blaschuk *et al.,* 1990)—of an opposing cadherin, thus forming a *trans* homodimer and generating a "zipper" structure of multiple *cis* dimers on opposing membranes (Fig. 1). It is unclear whether the same domain mediates adhesion among type II cadherins, where the motif is changed to QAV (cad11) or QAI (cad6) (Suzuki *et al.,* 1991). The cytoplasmic tail, highly conserved among cadherins, is associated with specific proteins, β-catenin and plakoglobin, which connect the cadherin molecule to the actin cytoskeleton either directly or via α-catenin. The latter in turn interacts with a number of proteins, such as α-actinin, ZO-1, vinculin, and other molecules (Yamada *et al.,* 1997) (Fig. 1). The assembly of cadherins and their associated cytoskeletal elements form the junctional structures known as *adherens junctions.* Both β-catenin and plakoglobin are targets of tyrosine kinases that regulate their phosphorylation state, leading to inhibition or strengthening of the adhesion complex, respectively (Grunwald, 1993). Regulation of adhesion is also controlled by cadherin binding to other proteins, most importantly, $p120^{ctn}$ and IQGAP1. The former is a member of the armadillo family of proteins, which also includes β-catenin and plakoglobin (Hatzfeld, 1999). The other interacting protein, IQGAP1, mediates regulatory signals from the Rho family of small GTPases, particularly Rac1 and Cdc42 (Kaibuchi *et al.,* 1999). Cadherins are not only part of adhesion structures, they can also function as signaling molecules. One mechanism of cadherin-mediated signaling is via β-catenin, which can translocate to the nucleus where it functions as a transcriptional activator through interaction with lymphoid enhancer factor-1 and T-cell factor-1,3,4, all part of the *Wnt* signaling cascade (Ben Ze'ev *et al.,* 1998).

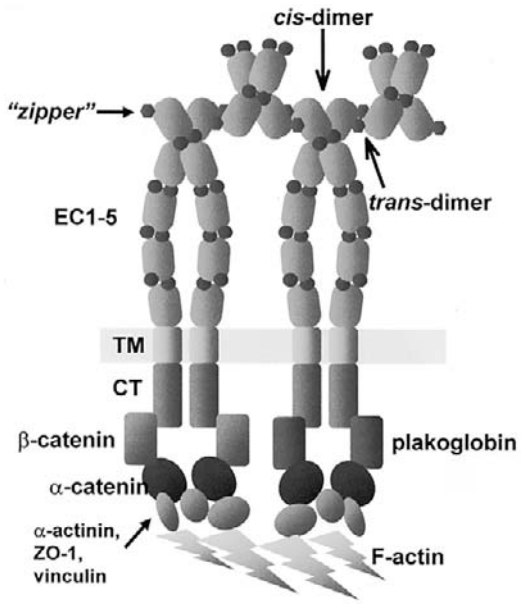

Figure 1 Schematic representation of the cadherin adhesion complex. Two complete cadherin *cis* dimers side by side, forming *trans* dimers with cadherins on the opposing side (partially represented), are illustrated. Each cadherin is shown with its five extracellular domains (EC1–5), as well as their transmembrane (TM) and cytoplasmic (CT) domains. Small circles between the EC domains symbolize calcium ions, and the small hexagons in EC1 represent Trp2, thought to be critical for *trans* dimerization. The alignment of EC1 domains forms the so-called "zipper" structure of the adhesion complex.

Cadherins in Skeletal Development

Molecular cloning from osteoblastic cells of different species has established that Ncad and cad11 are the major cadherins present in bone-forming cells (Okazaki *et al.,* 1994; Cheng *et al.,* 1998; Ferrari *et al.,* 2000), although the

degree of expression and their distribution are not identical in cartilage and bone. Ncad is abundant in mesenchymal cells undergoing cartilage nodule condensation (Tsonis *et al.,* 1994) and it is required for chondrogenesis in the early phases of embryonic limb bud development (Oberlender *et al.,* 1994; Tavella *et al.,* 1994). In fact, perturbation of cadherin-mediated interactions disrupts mesenchymal cell condensation and chondrogenic differentiation (Woodward *et al.,* 1999; Haas *et al.,* 1999). Therefore, Ncad provides a molecular cue for development of the cartilaginous scaffolding of bone rudiments, and while not present in mature cartilage, Ncad expression clearly persists in mature and adult bone (Ferrari *et al.,* 2000). Conversely, cad11 is found primarily in mesenchymal cells and has been considered crucial for mesenchymal organization (Hoffmann *et al.,* 1995; Simonneau *et al.,* 1995). Cad11 is expressed transiently in the cephalic mesoderm and then in the paraxial mesoderm of the trunk during early development, where it participates in cell condensation and segregation in the head, somites, and limb buds (Kimura *et al.,* 1995; Hoffmann *et al.,* 1995). However, at later developmental stages, a wide variety of mesenchymal tissues in both mesodermal and neural crest derivatives express cad11 (Simonneau *et al.,* 1995). Thus, both Ncad and cad11 are present in mesenchymal cells, but with distinct expression patterns; Ncad is less abundant than cad11 in the head and it is absent in branchial arches, in sharp contrast with the abundant presence of cad11 (Kimura *et al.,* 1995) Furthermore, while Ncad is present in the perichondrium (Oberlender *et al.,* 1994; Kimura *et al.,* 1995), cad11 appears only in the primary spongiosa but not in condensing or proliferating chondrocytes of the growth plate, where Ncad is abundant (unpublished observations).

Role of Cadherins in Osteogenic Cells

N-Cadherin and Cadherin-11 Define the Osteogenic Lineage

The presence of multiple cadherins in the same cell type is not an uncommon finding. In general, expression of a certain cadherin is linked to differentiation or commitment to a specific cell phenotype, but terminal differentiation of many specialized tissues is associated with coexpression of others, usually type II cadherins. For example, while Ncad is present in most neural cells, cad6 expression is restricted to synaptic connections between neurons driving their formation (Inoue *et al.,* 1998); similarly, whereas N-cadherin is important for myogenic commitment, it is not required for myoblast fusion (Charlton *et al.,* 1997). In uncommitted mesenchymal cells, such as the embryonic mouse cell line C3H10T1/2, expression of Ncad is increased by bone morphogenetic protein-2 (BMP-2), presumably reflecting the transition to a chondroosteogenic phenotype (Shin *et al.,* 2000). Likewise, cad11 is upregulated in immature mesenchymal cells under stimulation by osteogenic factors, such as BMP-2, whereas it is downregulated when cells undergo adipogenic or myogenic differentiation (Shin *et al.,* 2000; Kawaguchi *et al.,* 2001b) and it disappears in adipocytes (Shin *et al.,* 2000; Kawaguchi *et al.,* 2001b). Similarly, the uncommitted C2C12 cells lose Rcad/cad4 upon osteogenic differentiation, whereas cad11 abundance increases. These cells also express Mcad, indicative of their myogenic potential, but transdifferentiation from myogenic to osteogenic cell phenotypes is associated with a Mcad to cad11 transition (Kawaguchi *et al.,* 2001b). Therefore, it is conceivable that coexpression of cad11 and Ncad may allow sorting and segregation of mesenchymal progenitors committing to osteogenic differentiation from those entering the adipogenic pathway. Interestingly, cad11 abundance decreases with aging in rat bone marrow stromal cells (Goomer *et al.,* 1998), raising the possibility that loss of cad11 and Ncad may be involved in determining a reduced osteogenic potential in the aging skeleton. Based on the accumulated results, a model of "cadherin switch" during mesenchymal cell differentiation has been proposed (Fig. 2). This model predicts that uncommitted precursors express low levels of all mesenchymal cadherins (Ncad, cad11, cad4/Rcad, and perhaps others), and upon commitment to a certain pathway, both Ncad and a second "tissue-defining" cadherin (cad11 for osteoblasts, Mcad for myoblasts) are upregulated, whereas cad4/Rcad is shut off. Whether a second cadherin exists for chondrocytes or adipocytes remains unknown. In their terminally differentiated state, adipocytes, myotubes, and chondrocytes lose their cadherin fingerprinting, whereas osteoblasts do not, perhaps reflecting their active role in a high remodeling tissue. The chondrocyte-to-osteoblast transition during endochondral ossification is marked by cad11 induction.

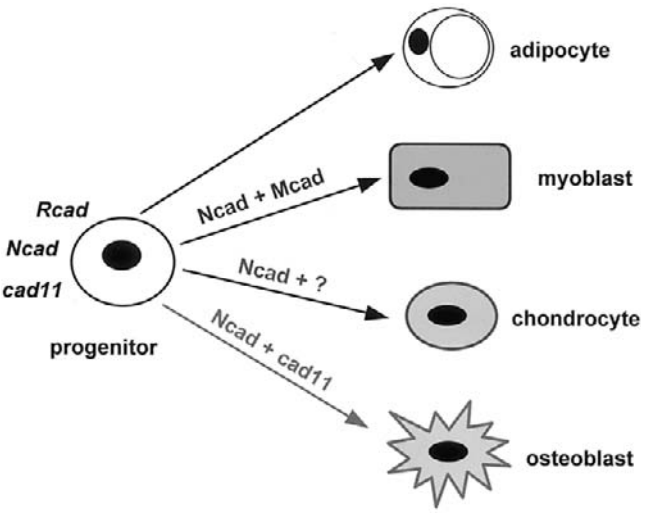

Figure 2 The "cadherin switch" model during mesenchymal cell differentiation. Uncommitted precursors express low levels of all mesenchymal cadherins (Ncad, cad11, and Rcad/cad4). Upon commitment to a certain lineage, both Ncad and a "tissue-defining," usually type II cadherin (cad11 for osteoblasts, M-cad for myoblasts, an unknown cadherin for chondrocytes) are upregulated, whereas Rcad/cad4 is shut off. In their terminally differentiated state, adipocytes, myotubes, and chondrocytes lose their cadherin fingerprinting, whereas osteoblasts do not, perhaps reflecting their active role in a high remodeling tissue.

Regulation of Cadherins in Bone-Forming Cells

In cells already committed to the osteogenic pathway, expression of cad11 does not change substantially with differentiation (Kawaguchi *et al.,* 1999; Tsutsumimoto *et al.,* 1999). A splice variant of cad11 lacking the IC domain has also been described on the surface of osteoblasts, but its function remains uncertain (Kawaguchi *et al.,* 1999). Aside from a modest downregulation by dexamethasone (Lecanda *et al.,* 2000a), cad11 does not appear to be heavily affected by BMP-2 (Cheng *et al.,* 1998). However, Ncad mRNA is sharply downregulated by dexamethasone (Lecanda *et al.,* 2000a) and by IL-1 or TNF-α (Tsutsumimoto *et al.,* 1999), whereas it is upregulated by a constitutively active, mutated FGFR-2 receptor (Lemonnier *et al.,* 1998). Ecad reactivity has been observed in UMR 106–01 cells using an anti-Ecad antibody (Babich *et al.,* 1994). Because both Ncad and Ecad are stimulated rapidly by BMP-2 in calvaria cells and neutralizing antibodies against either Ncad or Ecad prevent BMP-2 stimulation of alkaline phosphatase (Hay *et al.,* 2000), Ecad may also be functionally important in bone. However, one must consider that antibodies are not absolutely specific for a single cadherin isotype, and the presence of Ecad in calvaria cells may reflect their heterogeneous nature, encompassing neural, vascular endothelial and perhaps epithelial cells, in addition to osteoblasts. In fact, a low abundance of Pcad, VEcad, and cad8 has also been detected in mouse calvaria cells (Kawaguchi *et al.,* 2001b), whereas osteoblastic cells isolated from human trabecular bone do not express any of these cadherins (Cheng *et al.,* 1998). Whether the cadherin repertoire changes with terminal differentiation into osteocytes has not been investigated thoroughly, although neither cad11 nor other cadherins have been detected in the osteocyte-like cell line MLO-Y4 (Kawaguchi *et al.,* 2001b).

Function of Cadherins in Bone-Forming Cells

Synthetic peptides containing the HAV adhesion recognition motif (see earlier discussion) have been used to inhibit cadherin-mediated adhesion. Such inhibitory peptides prevent the development of alkaline phosphatase activity in both human bone marrow stromal cells under BMP-2 stimulation (Cheng *et al.,* 1998) and the osteogenic sarcoma cell line SaOS-2 (Ferrari *et al.,* 2000). Exposure to HAV peptides also decreases osteocalcin and immediate early gene *zif* 268 expression by SaOS-2 cells and inhibits bone nodule formation by calvaria cell cultures (Ferrari *et al.,* 2000). A more selective and controlled antagonism of cadherin-mediated adhesion can be obtained by overexpressing cadherin mutants with dominant-negative action. One such molecule, NCadΔC, has been used successfully to disrupt cadherin-mediated cell–cell adhesion (Kintner, 1992; Hermiston *et al.,* 1995; Haas *et al.,* 1999). Accordingly, NcadΔC transfection significantly reduces calcium-dependent cell–cell adhesion between MC3T3-E1 cells, altering their development into fully mature osteoblasts (Cheng *et al.,* 2000), and it inhibits cell–cell aggregation and morphological differentiation by SaOS-2 cells (Ferrari *et al.,* 2000).

Although these data strongly suggest that cadherin-mediated adhesion is required for osteoblast function, peptide inhibitors and dominant-negative cadherin mutants are not specific inhibitors of individual cadherins. Targeted gene deletion should afford a more precise definition of the function of each cadherin isotype in bone. Unfortunately, homozygous loss of the N-cad gene is lethal at early stages of embryogenesis (Radice *et al.,* 1997), making this model unsuitable for studies on bone cell differentiation. However, mice genetically deficient in cad11 are viable and have mildly decreased trabecular bone density and skull abnormalities with reduced diploic space. In addition, calvaria cells isolated from cad11–null mice exhibit stunted mineralization potential *in vitro* (Kawaguchi *et al.,* 2001a). This mild but clear skeletal phenotype demonstrates that cadherins are indeed important for the skeletal system *in vivo.* It also suggests that other cadherins, possibly Ncad, may compensate for the loss of cad11, thus serving partially overlapping roles.

Other Cell Adhesion Molecules in Bone and Cartilage

Neural cell adhesion molecule (N-CAM), a member of the immunoglobulin superfamily, is present in chick limb buds before mesenchymal cell condensation and its abundance increases during cell aggregation in a pattern similar to that of Ncad (Tavella *et al.,* 1994). Both adhesion molecules are undetectable in hypertrophic chondrocytes, but are reexpressed in preosteoblastic cells (Lee *et al.,* 1992; Tavella *et al.,* 1994). Although N-CAM and Ncad are present during chondrogenesis, subtle differences in the timing of expression suggest that Ncad may initiate cell–cell aggregation while N-CAM stabilizes the aggregates, although such hypothesis has not been proven in a more mechanistic fashion. While disappearing in differentiated cartilage, N-CAM persists in the perichondrium of long bones and sclerotomes, and it is present in the calvarium during mesenchymal cell aggregation (Lee *et al.,* 1992). N-CAM is not present homogeneously in osteoblasts, its expression apparently declining with osteogenic differentiation (Lee *et al.,* 1992), and is not regulated by BMP-2 (Hay *et al.,* 2000).

Cell Adhesion Molecules in Osteoclast Development and Function

The physiologic importance of direct cell–cell contact is not limited to homotypic interactions among osteoblasts. Two critical steps of osteoclastogenesis, i.e., heterotypic interactions between hematopoietic osteoclast precursors and stromal/osteoblastic cells and osteoclast precursor fusion, are both dependent on cell–cell adhesion. Osteoblast/stromal cell support of osteoclastogenesis is mediated by the interaction of RANKL on the surface of osteoblasts and stromal cells and its receptor, RANK, present on osteoclast precursors (see Chapter 7). Although soluble RANKL is sufficient to induce osteoclastogenesis *in vitro,* direct contact between

cells of the two lineages seems to be required *in vivo* (Suda *et al.,* 1999). A type II cadherin, cad6 (the murine homologue of human Kcad), and a splice variant of cad6, named cad6/2, are present on the surface of both hematopoietic osteoclast precursors and stromal or osteoblastic cells, and inhibition of cad6/2 expression severely impairs the support of osteoclast differentiation by ST2 cells (Mbalaviele *et al.,* 1998), indicating that cad6 isoforms may be key mediators of heterotypic contact between cells of the two lineages. In contrast, Ecad seems to be important in the fusion of mononuclear precursors, as interference with Ecad adhesion prevents the formation of multinucleated bone-resorbing osteoclasts (Mbalaviele *et al.,* 1995). Interestingly, colocalization of cadherins with vinculin at the sealing zone of the osteoclast suggests that cadherins may be involved in the formation or maintenance of the actin ring in the sealing zone and thus osteoclast attachment to the matrix (Ilvesaro *et al.,* 1998). In any case, cadherin participation to osteoclast–matrix adhesion is likely to be indirect, as cadherins do not bind matrix components, whereas cell–cell and cell–matrix adhesion are coordinated by shared signaling mechanisms (Monier-Gavelle *et al.,* 1997).

Other cell adhesion molecules, particularly, intercellular adhesion molecule-1 (ICAM-1) and vascular adhesion molecule-1 (VCAM-1), members of the immunoglobulin superfamily, play a role in osteoclastogenesis by stimulating cytokine production upon homophilic cell–cell adhesion (Tanaka *et al.,* 1995). Intriguingly, ICAM-1-positive stromal cells are able to support osteoclastogenesis in a far larger degree than ICAM-1-negative cells, and interruption of ICAM-1 or VCAM-1 adhesion to cognate receptors (leukocyte function-dependent antigen-1; LFA-1) dramatically decreases human osteoblast support of osteoclastic cell formation with or without hormonal stimulation (Tanaka *et al.,* 2000). As one would expect, anti-ICAM-1 or anti-VCAM-1 antibodies inhibit osteoblast adhesion to peripheral monocytes, whereas anti-RANKL antibodies do not, implying that RANKL–RANK interaction does not provide cell–cell adhesion (Tanaka *et al.,* 2000). Thus, it is likely that higher affinity cell–cell adhesion and anchorage are required to allow efficient presentation and engagement of membrane-bound RANKL to its receptor and attendant generation of osteoclastogenic signals. These new and intriguing data greatly expand the physiologic role of cadherins and other cell adhesion molecules from morphogenic regulators during organism development to essential regulators of bone cell function during both phases of the bone-remodeling cycle in the adult skeleton.

Direct Cell–Cell Communication via Gap Junctions

Gap Junctions as Intercellular Channels

Gap junctions are transcellular channels that provide aqueous continuity between two cytoplasms. They are composed by juxtaposition of two hemichannels (Li *et al.,* 1996), called

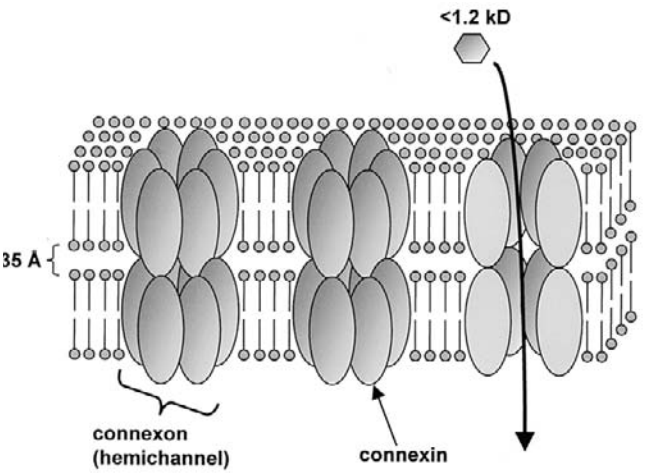

Figure 3 Schematic diagram of gap junctions. One connexon, or hemichannel, is a transmembrane hexamer formed by gap junction proteins, connexins. Two connexons in register on opposing membranes (represented as lipid bilayers) form a gap junction channel, leaving a 35-Å gap between the two cell membranes. The gap junction pore provides aqueous continuity between the two cytoplasms, allowing small molecules of up to 1.2 kDa and ions to pass from one cell to the other.

connexons, to form a complete intercellular channel (Fig. 3). Each connexon is formed by a hexameric array of protein subunits, called connexins (Revel *et al.,* 1967; Goodenough *et al.,* 1996; Kumar *et al.,* 1996). The connexin family is composed of at least 13 genes in rodents, with many homologues in other species (White *et al.,* 1995; Goodenough *et al.,* 1996; Kumar *et al.,* 1996). A widely used nomenclature identifies each connexin by their predicted molecular mass. Thus, the most common connexin in the heart and bone is a 43,036 Da protein, called connexin43 (Cx43) (Beyer *et al.,* 1987). Connexins are integral membrane proteins with four transmembrane-spanning domains, two extracellular loops, one intracellular loop, and both carboxyl and amino termini inside the cell (Fig. 4). The intracellular loop and the

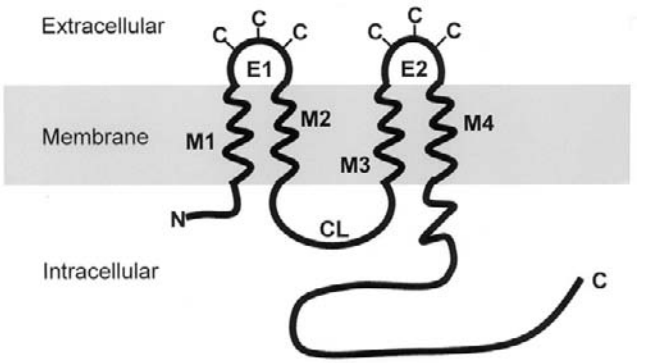

Figure 4 Structure of a connexin. Connexins are integral membrane proteins, with four transmembrane-spanning domains (M1–M4), two extracellular loops, one intracellular loop and both carboxyl and amino-termini inside the cell. The intracellular loop and the long carboxyl-terminal intracellular tail differ widely between the various connexins, both in sequence and in length. Each of the two extracellular loops contains three conserved cysteines, which are required for proper orientation of the extracellular loops and docking to connexins on the adjoining membrane.

long carboxyl-terminal intracellular tail differ widely between the various connexins, both in sequence and in length. Each of the two extracellular loops contains three conserved cysteines, which are required for proper orientation of the extracellular loops and docking to connexins on the adjoining membrane. Although in most circumstances, connexons formed by a certain connexin pair with like connexons on the opposing membrane, heterotypic channels are possible, depending on the compatibility of the extracellular loops (White *et al.,* 1994). Likewise, co-oligomerization into heteromeric connexons may occur when more than one connexin is present in the same cell (Kumar *et al.,* 1996). The phosphorylation state of connexins controls the assembly and degradation of the protein, as well as the functionality of the gap junction pore (Musil *et al.,* 1991; Sàez *et al.,* 1993; Laird *et al.,* 1995). Three-dimensional maps of a recombinant gap junction formed by a truncated Cx43 offer a spectacular confirmation of the predicted hexameric structure of the gap junction channel, with rings of α helices delimiting the pore crossing two plasma membranes and the intercellular gap (Unger *et al.,* 1997; Unger *et al.,* 1999).

The gap junction channel is permeable to ions as well as small molecules, and the size and charge selectivity depend on the connexin isotype that forms the channel. For example, Cx43 assembles in gap junctions with relatively large pores, allowing molecules of up to ~1200 Da of molecular mass and of negative charge to pass through the pore. In contrast, gap junctions formed by Cx45 have smaller pores and favor positively charged ions (Elfgang *et al.,* 1995; White *et al.,* 1995). Thus, signaling molecules such as cAMP, inositol derivatives, nucleotides, and ions such as Ca^{2+}, Zn^{2+}, and Mg^{2+} can travel across the intercellular channels, although the nature of the molecules that are exchanged by cells through gap junctions in physiologic conditions has not been fully established. The functionality of the channels is assessed by two types of tests: those that monitor cell-to-cell diffusion of molecules between cells (chemical coupling) and those that measure electrical currents carried by intracellular ions (electric coupling). The former methods are based on monitoring cell-to-cell diffusion of a membrane-impermeant fluorescent dye that is either microinjected into single cells (Stewart, 1978) or preloaded in "donor" cells that are put in direct contact with "acceptor" cells (Goldberg *et al.,* 1995; Ziambaras *et al.,* 1998). Transjunctional ion currents and unitary channel conductance can be measured using electrophysiological methods based on a double whole cell configuration of the patch-clamp technique (Veenstra and Brink, 1992).

Diversity of Connexin Expression and Distribution in Bone and Cartilage

Multiple Connexins in Osteoblastic Cells

Gap junctions were first identified in bone by electron microscopy in the early 1970s (Doty *et al.,* 1972; Stanka, 1975). In these studies, gap junctions were consistently observed among adjacent osteoblasts, osteocytes, and periosteal fibroblasts (Doty, 1981). Such abundant distribution of gap junctions among cells of the osteoblastic lineage has since been confirmed by a number of ultrastructural studies in histological sections of bone (Palumbo *et al.,* 1990; Jones *et al.,* 1993; Shapiro, 1997). Numerous *in vitro* studies have demonstrated the presence of functional gap junctions among murine calvaria osteoblasts (Jeasonne *et al.,* 1979), odontoblasts (Ushiyama, 1989), human bone cells (Civitelli *et al.,* 1993) and a variety of cell lines (Schiller *et al.,* 1992; Yamaguchi *et al.,* 1994; Donahue *et al.,* 1995b). Heterotypic communication between osteoblasts and epithelial cells has also been demonstrated (Melchiore *et al.,* 1994). The most abundant gap junction protein expressed in primary cultures of osteoblastic cells and in immortalized cell lines, i.e., MC3T3-E1 and hFOB, is Cx43. Although less abundant than Cx43 in these cell models, Cx45 is also present at appositional membranes and occasionally in cytoplasmic areas, suggesting that both connexins may interact in forming gap junctions among osteoblasts (Civitelli *et al.,* 1993; Donahue *et al.,* 2000).

In contrast, the relative abundance of the two connexins, and the resulting gap junctional communication, is highly heterogeneous among transformed cell lines. For instance, human SaOS-2 and rat UMR 106 cell lines express primarily Cx45, whereas ROS 17/2.8 cells only express Cx43 (Steinberg *et al.,* 1994; Donahue *et al.,* 1995b). Consistent with the different molecular permabilities of gap junctions formed by Cx43 and Cx45 (Veenstra *et al.,* 1992), cells that express primarily Cx45 exhibit poor cell-to-cell diffusion of negatively charged molecules the size of Lucifer yellow or calcein (~600 Da), but they are coupled electrically (Steinberg *et al.,* 1994). In contrast, cells that express abundant Cx43 are coupled chemically and electrically, and overexpression of Cx43 in UMR 106–01 cells increases dye coupling, indicating that Cx45 and Cx43 interact in forming gap junctions when coexpressed in the same cells (Steinberg *et al.,* 1994). Conversely, transfection of Cx45 in ROS 17/2.8 cells reduces both intercellular diffusion of Lucifer yellow and transjunctional conductance compared to parent ROS 17/2.8 cells (Koval *et al.,* 1995). However, transfer of smaller fluorescent molecules, such as hydroxycoumarin (~350 Da) is reduced only slightly, demonstrating that Cx45 reduces the pore size of gap junctions in a mixed Cx43/Cx45 background and that the gating properties of Cx45 prevail in the resulting channels (Koval *et al.,* 1995).

While several investigators have consistently failed to detect other connexins, such as Cx26, Cx32, Cx40, or Cx47 (Schirrmacher *et al.,* 1992; Schiller *et al.,* 1992; Civitelli *et al.,* 1993), Cx46 is present in murine osteoblastic cells. However, this connexin is never found on the cell surface, is localized exclusively within intracellular compartments, and does not oligomerize to form gap junctions in these cells (Koval *et al.,* 1997), thus the function of Cx46 in bone remains elusive.

Gap Junctions in Other Skeletal Cells

Although most of the progress on gap junctional communication in bone has been made using osteoblasts as cell

models, chondrocytes, osteocytes, and cells of the osteoclast lineage also express connexins. As mentioned previously, Cx43 is present in osteoblasts, osteocytes, and chondrocytes in rat calvaria (Jones *et al.,* 1993; Shapiro, 1997). In principle, direct communication via gap junctions is particularly important for osteocytes, as it may provide a mechanism of rapid diffusion of signals generated by mechanical forces or chemical stimuli through the osteocytic network and to the cells on the endosteal and periosteal surface. Support for this hypothesis comes from data in the mouse osteocytic cell line MLO-Y4, which expresses abundant Cx43, can diffuse negatively charged dyes, and can engage in heterotypic coupling with osteoblastic cells (Yellowley *et al.,* 2000). Similarly, the presence of Cx43 in osteoclasts at sites of active bone resorption (Jones *et al.,* 1993; Su *et al.,* 1997), primarily at contact sites between osteoclasts and overlying marrow mononuclear cells (Jones *et al.,* 1993; Ilvesaro *et al.,* 2000), suggests that functional coupling between the two cell lineages may occur *in vivo.* These observations are consistent with the presence of Cx43 in macrophages (Beyer *et al.,* 1991), although the exact role of gap junction proteins in cells, i.e., macrophages and osteoclasts, that can function effectively without contact with other cells remains unclear.

Cartilage may seem an unlikely tissue for the presence of intercellular junctions, simply because chondrocytes in mature cartilage are isolated and embedded in the matrix. However, during development, mesenchymal chondrogenic precursors must condense, and adherens and gap junctions appear between adjacent cells (Minkoff *et al.,* 1994; Langille, 1994). Therefore, cell–cell adhesion and direct intercellular communication are important during these early steps of cartilage development, when recruitment, proliferation, and differentiation of precursors occur. Importantly, Cx43 is also expressed and is functional in adult bovine articular chondrocytes when these cells are grown in tissue cultures (Donahue *et al.,* 1995a), suggesting that gap junctional communication can be reëstablished in mature cartilage in conditions that lead to cell proliferation and tissue repair, as it occurs, for example, in osteoarthritis (Hamerman, 1989).

Connexins in Skeletal Development

Earlier immunohistochemical studies in chick embryos demonstrated the presence of connexins in developing teeth and bone. Cx43 is expressed in tooth germs of neonatal rats (Pinero *et al.,* 1994) and is concentrated on mesenchymal cells at early stages of intramembranous bone formation in chick mandible, preceding the appearance of osteogenic cells (Minkoff *et al.,* 1994). In this model, Cx43 is present throughout the entire bone development process and its expression is not altered appreciably with differentiation. Conversely, Cx45 distribution seems to be more restricted to areas of active bone formation, gradually increasing in abundance at successive stages of development (Minkoff *et al.,* 1994). More mechanistic information on the physiologic role of Cx43 in skeletal development has emerged from the analysis of mice genetically deficient of Cx43. Underlining its importance in the heart, targeted deletion of the Cx43 gene in the mouse causes severe conotruncal malformations incompatible with postnatal life (Reaume *et al.,* 1995). The skeleton of homozygous Cx43-null mutants at birth reveals delayed intramembranous and endochondral ossification and clear skull abnormalities, with brittle, misshapen ribs and hypoplastic skull (Lecanda *et al.,* 2000b). As a consequence of the delayed development of all the cranial vault elements, an open foramen remains in the roof of the skull at birth (Lecanda *et al.,* 2000b). Similar abnormalities in craniofacial development have been produced by Cx43 "knock down" using antisense oligonucleotides in developing chick embryos (Becker *et al.,* 1999). Although the precise cellular bases of these defects remain to be elucidated, osteoblasts lacking Cx43 are dysfunctional as bone-forming cells, and it is likely that the delayed ossification of most skeletal elements in Cx43-null mice is related to this cell autonomous defect, regardless of the ontogeny or mode of ossification of each bone (Lecanda *et al.,* 2000b). Thus, Cx43 is functionally involved in skeletogenesis, while the contribution of Cx45 to skeletal development and its potential compensatory function in the absence of Cx43 are still unknown. Unfortunately, ablation of Cx45 is embryonically lethal, precluding the analysis of even the early stages of skeletal development (Kruger *et al.,* 2000).

Regulation of Connexin Expression and Function in Bone Cells

Regulation by Hormones and Local Factors

Prostaglandin E_2 enhances cell coupling in rat calvaria cells (Shen *et al.,* 1986) and in osteosarcoma cell lines, probably by interference with the posttranslational processing of Cx43, resulting in an increased assembly of preformed connexins into gap junction channels (Civitelli *et al.,* 1998). Parathyroid hormone (PTH) also stimulates gap junctional communication among osteoblasts, although this action seems to be dependent on the cell type (Schiller *et al.,* 1992; Donahue *et al.,* 1995b; Civitelli *et al.,* 1998). The hormonal effect on cell coupling is paralleled by a time- and dose-dependent increase of steady-state Cx43 mRNA (Civitelli *et al.,* 1998), is mediated by cAMP production (Schiller *et al.,* 1992; Civitelli *et al.,* 1998), and is prevented by PTH antagonists (Donahue *et al.,* 1995b). Thus, both PTH and prostaglandin E_2, important regulators of bone remodeling, increase gap junctional communication between osteoblasts by modulating Cx43 expression or function via different mechanisms. Both BMP-2 and TGF-β can also enhance gap junctional communication (Rudkin *et al.,* 1996). The effect of BMP-2 is associated with increased cell coupling and Cx43 abundance. In contrast, retinoic acid (Chiba *et al.,* 1994) and cytoplasmic acidification (Yamaguchi *et al.,* 1995) decrease gap junctional communication and Cx43 expression, whereas alkalinization increases gap junctional communication. Changes in cytoplasmic pH have rapid effects on channel permeability, and

prolonged exposures to a low ambient pH decrease Cx43 expression (Yamaguchi *et al.,* 1995).

Regulation by Physical Factors

Intercellular communication is important for mechanotransduction, not only because mechanical and physical factors can modulate gap junctional communication, but also because gap junctions may provide the means by which osteocytes, embedded within the calcified tissue, can transmit mechanical signals to cells on the surface, thus regulating their activity (Donahue, 2000). The number of gap junctions declines in weightlessness conditions (Doty *et al.,* 1982), and application of cyclical stretch increases the number of gap junctions in osteocytes (Lozupone *et al.,* 1996). Furthermore, Cx43 expression is increased in periodontal ligament after experimental tooth movement and in osteocytes after tooth extraction (Su *et al.,* 1997). Thus, cell-cell communication via gap junction is modulated by mechanical load to skeletal structures. At the cellular level, application of cyclical stretch by deformation of the tissue culture substrate leads to a rapid and prolonged increase of intercellular communication among osteoblastic cells, associated with increased abundance of Cx43 on the cell surface, presumably the result of decreased Cx43 turnover (Ziambaras *et al.,* 1998). Data in osteocytic MLO-Y4 cells demonstrate that gap junctional communication is also stimulated by fluid flow-induced shear stress, which causes rapid redistribution of Cx43 to the osteocytic dendritic processes and delayed stimulation of Cx43 expression (Cheng *et al.,* 2001), lending support to the notion that gap junction channels may propagate signals generated by osteocytes in response to mechanical stimuli.

Role of Gap Junctions in Bone Remodeling

Role of Connexin43 Gap Junctions in Bone-Forming Cells

While data on gap junctions and connexin expression in osteoblasts are abundant, evidence for their role in physiologic regulation of bone formation has accumulated only recently. Cx43 abundance increases upon osteoblast differentiation (Chiba *et al.,* 1993; Donahue *et al.,* 2000; Schiller *et al.,* 2001), and this increase correlates with enhanced cell–cell communication (Donahue *et al.,* 2000; Schiller *et al.,* 2001). Conversely, Cx45 abundance does not change during osteoblast differentiation (Donahue *et al.,* 2000). The increased Cx43 expression appears to be related inversely to cell proliferation, reinforcing the idea that gap junctional communication is a feature of postproliferative osteoblasts (Donahue *et al.,* 2000). Importantly, chemical inhibition of gap junctional communication leads to delayed bone nodule formation and disruption of osteoblast gene expression in human osteoblasts (Donahue *et al.,* 2000) and MC3T3-E1 cells (Schiller *et al.,* 2001), and osteoblastic cells isolated from either calvaria or bone marrow of Cx43-null mice are dysfunctional, exhibiting a severely impaired capacity to form mineralized nodules *in vitro* and reduced expression of a differentiated osteoblastic phenotype (Lecanda *et al.,* 2000b). Interestingly, Cx45 abundance is increased in Cx43-null osteoblasts, perhaps reflecting a compensatory mechanism (Lecanda *et al.,* 2000b), however, the increased Cx45 does not effectively compensate for the lack of Cx43, neither in terms of cell coupling nor of differentiation potential.

The presence of Cx43 gap junctions is also permissive for normal cell responsiveness to hormonal and physical stimuli. Rat osteogenic sarcoma cells rendered communication deficient by expression of a Cx43 antisense construct display a reduced cAMP response to parathyroid hormone (Van der Molen *et al.,* 1996), impaired contraction of osteoblast populated collagen lattices (Bowman *et al.,* 1998), and reduced alkaline phosphatase induction in response to electromagnetic fields (Van der Molen *et al.,* 2000). The reduced hormonal response of communication-deficient cells occurs despite a normal adenylate cyclase system, indicating that Cx43 gap junctions amplify the signals generated by local receptor activation, perhaps by allowing diffusion of signaling molecules or ions from responsive to nonresponsive cells, thus equalizing differences in receptor distribution and hormonal responses in osteooblastic populations (Civitelli *et al.,* 1994).

Modulation of Osteoblast Gene Expression by Gap Junctional Communication

The finding that Cx43 and Cx45 interact in forming gap junctions when expressed in the same cells (Koval *et al.,* 1995) offered a powerful strategy to study the consequences of changing intercellular communication on the phenotypic profile and gene expression in osteoblastic cell lines. Steady-state levels of osteocalcin, bone sialoprotein, alkaline phosphatase, and type I collagen are reduced significantly in ROS 17/2.8 cells transfected with Cx45, whereas osteopontin and osteonectin are not appreciably altered (Lecanda *et al.,* 1998). Reduced osteocalcin and bone sialoprotein expression in either ROS 17/2.8 or MC3T3–E1 cells transfected with Cx45 is associated with transcriptional downregulation of the respective gene promoters relative to parent cells and decreased dye coupling. In contrast, transfection of Cx43 in UMR 106–01 (they express more Cx45 than Cx43 and are poorly coupled) is followed by upregulation of both osteocalcin and bone sialoprotein mRNA abundance and promoter activity, in parallel with increased gap junctional permeability (Lecanda *et al.,* 1998). Thus, the relative expression of Cx43 and Cx45 regulates the transcriptional activity of osteoblasts-specific genes in a reciprocal fashion (Fig. 5). This new regulatory function of gap junctional communication is not restricted to bone, as gap junction-dependent gene expression and regulation have been observed in insulin-producing cells (Vozzi *et al.,* 1995), thyrocytes (Statuto *et al.,* 1997), and chromaffin cells (Munari-Silem *et al.,* 1995).

Interestingly, suppression of Cx43 expression by antisense strategies also causes reduced expression of alkaline phosphatase and osteocalcin (Li *et al.,* 1999). Such observations would imply that it is the loss of Cx43 more than the change to a Cx45-mediated intercellular communication that affects osteoblast gene expression. In fact, calvaria or bone marrow stromal cells genetically deficient of Cx43 exhibit

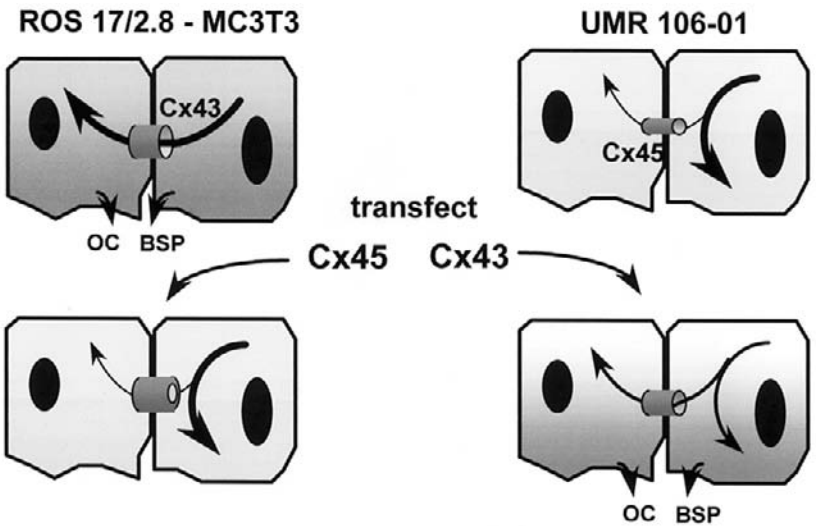

Figure 5 Model of connexin-43 (Cx43)/connexin-45 (Cx45) interactions and osteoblast gene expression regulation. The highly coupled ROS 17/2.8 and the MC3T3-E1 cells (as well as primary murine and human osteoblastic cells) express primarily endogenous Cx43 and are able to constitutively produce matrix proteins, including bone sialoprotein (BSP) and osteocalcin (OC). The poorly coupled UMR 106–01 cells express prevalently Cx45 and are poor producers of BSP or OC. Upon transfection of Cx45 in ROS 17/2.8 and MC3T3–E1 cells, gap junctions are formed by a mix of Cx45 and endogenous Cx43, resulting in channels of lower molecular permeability relative to the parent clones. This is associated with a dramatic reduction of BSP and OC gene transcription. Conversely, transfection of Cx43 in UMR 106–01 cells results in an increased Cx43/Cx45 ratio, increased gap junctional communication, and increased transcription of BSP and OC genes. Presumably, the transfected connexin can form either heteromeric connexons or homomeric, heterotypic gap junctional channels (Kumar *et al.*, 1996). In either case, Cx45 prevails in determining the permeability of the resulting channel (Koval *et al.,* 1995).

reduced osteocalcin and collagen type I expression during *in vitro* differentiation (Lecanda *et al.,* 2000b). The mechanism that links gap junctional communication to gene expression remains elusive, but it certainly depends on the type of signals that permeate the junctional channel. Based on the pore size selectivity of Cx43 and Cx45 gap junctions (Veenstra *et al.,* 1992), one could predict that the intercellular diffusion of signaling molecules, such as cyclic nucleotides or inositol phosphates, may be impaired when Cx43 permeability is decreased by interaction with Cx45. Alternatively, oscillations in intracellular-free calcium concentration or in membrane polarity may be affected by a changed connexin environment. Thus, the type of gap junctional communication provided by Cx43 is necessary for the full development of a differentiated osteoblast phenotype.

CONNEXIN43 IN OSTEOCLASTOGENESIS

As already noted, Cx43 is present in osteoclasts both *in vivo* and in cell cultures (Jones *et al.,* 1993; Su *et al.,* 1997; Ilvesaro *et al.,* 2000). Importantly, chemical inhibition of gap junctional communication leads to decreased number of bone-resorbing, multinucleated, TRAP-positive cells, but the average size of resorption pits may actually increase (Ilvesaro *et al.,* 2000). These intriguing observations would suggest that Cx43 gap junctions may serve a permissive role in mononuclear cell fusion, but once active osteoclasts are formed, Cx43 may function as an inhibitor. One possible scenario is that Cx43 forms hemichannels, which, if open for a long time, would permeabilize the cells with negative consequences, such as an increased rate of apoptosis (Ilvesaro *et al.,* 2000). In support of a role for Cx43 in osteoclastogenesis, we found that the ability of osteoblastic cells derived from Cx43-null mice has a reduced potential to support osteoclast differentiation when cocultured with wild-type mononuclear osteoclast precursors (Furlan *et al.,* 2000). Although these data are still preliminary, they are consistent with the reported failure of Cx43-null marrow stromal cells to support hematopoietic cell differentiation (Cancelas *et al.,* 2000) and indicate that loss of Cx43 impairs both arms of bone remodeling.

Intercellular Communication via Short-Range Calcium Signals

Intercellular Calcium Signaling

Transient and oscillatory elevations of cytosolic-free calcium concentration ($[Ca^{2+}]_i$) initiate or modulate a large number of cellular activities, including cell growth, motility, and secretion. Many studies have helped define cellular calcium homeostasis and the mechanisms by which extracellular signals are translated into intracellular calcium transients, but relatively scant attention has been paid to the mechanisms by

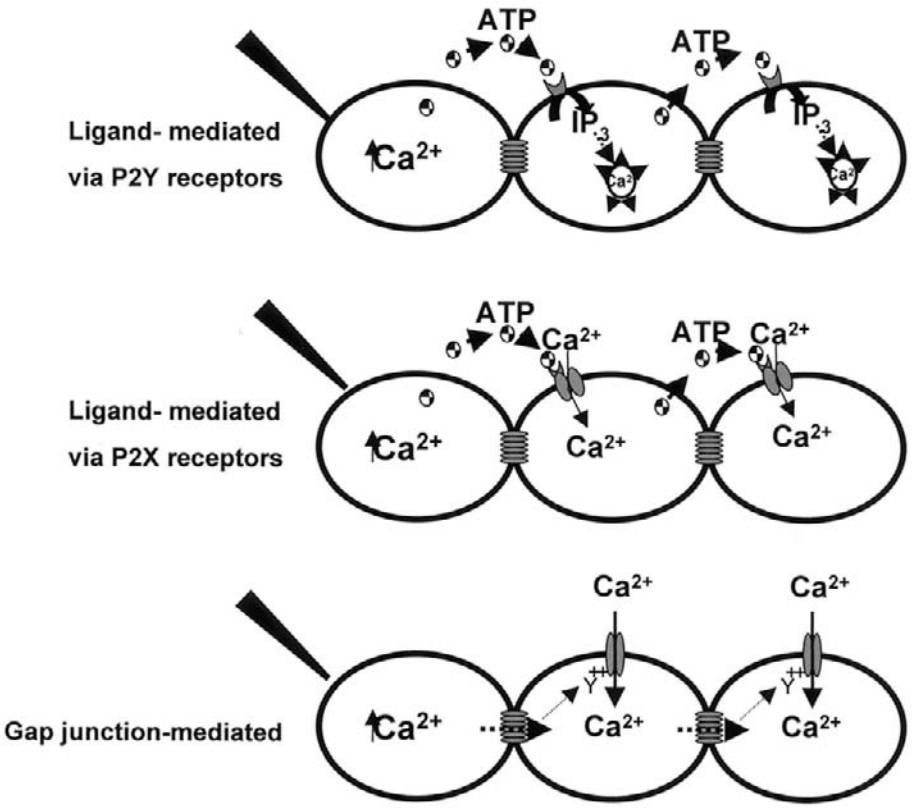

Figure 6 Mechanisms for the propagation of intercellular calcium signals. Ligand-mediated calcium waves: mechanical stimulation increases intracellular-free calcium concentration in the stimulated cell. As a consequence, ATP or a related nucleotide is released to the extracellular space and binds to surface receptors on neighboring cells. If ATP binds to P2Y receptors (top), inositol triphosphate (IP_3) is generated, inducing the release of calcium from IP_3-sensitive intracellular calcium stores. If ATP binds to P2X receptors (middle), conformational changes of the receptor/channel are induced, resulting in the opening of the channel, with a subsequent influx of extracellular calcium. In both cases, a calcium wave is generated by successive activation of P2 receptors in neighboring cells. Gap junction-mediated calcium waves (bottom): the increase in intracellular-free calcium concentration caused by mechanical stimulation produces a signaling molecule (IP_3?) that passes through the gap junction channel into adjacent cells where it induces depolarization of the plasma membrane and the subsequent opening of voltage-operated calcium channels with an influx of calcium from the extracellular space. The intracellular calcium increase is then propagated to the next cell through the same mechanism, thus producing a calcium wave.

which groups of cells propagate calcium signals among themselves and coordinate calcium responses. Two mechanisms of intercellular calcium signaling have been identified: gap junctional communication and release of soluble mediators that act on nearby cells (Fig. 6). Gap junctional communication propagates calcium signals either by allowing the passage of inositol trisphosphate and potentially other small soluble messengers between cells or by allowing electrical coupling of cells and subsequent activation of voltage-sensitive calcium channels (Sanderson *et al.,* 1994). Intercellular calcium signaling by released soluble mediators frequently involves activation of P2 ("purinergic") receptors by extracellular nucleotides such as adenosine triphosphate (ATP) (Osipchuk *et al.,* 1992; Schlosser *et al.,* 1996; Brake *et al.,* 1996).

Purinergic Receptors in Bone

Specific receptors for extracellular ATP that recognize the nucleoside triphosphate, but not adenosine, are termed P2 purinoceptors and are distinct from the P1 purinoceptors that bind adenosine. Two different families of P2 purinergic receptors exist, P2X and P2Y, which differ in structure and sensitivity to nucleotides (Brake *et al.,* 1996). Receptors of the P2X type are ligand-gated ion channel receptors. Binding of the ligand induces a rapid depolarization of the target cell followed by a rapid increase in cytosolic calcium concentration via an influx of calcium ions through the channel. Conversely, P2Y receptors belong to the seven transmembrane domain, G protein-coupled receptor superfamily (Dubyak *et al.,* 1993) and are distributed more diffusely than P2X receptors. Binding of a ligand to a P2Y receptor activates the phospholipase C (PLC) system, with production of IP_3 and subsequent release of intracellular calcium from IP_3-sensitive stores.

It has been known for at least a decade that ATP and ADP can induce transient increases in intracellular calcium concentrations in osteoblastic cells (Kumagai *et al.,* 1991), and there are now many functional studies indicating the presence of P2 receptors in cell lines (Reimer *et al.,* 1992;

Table I P2 Receptors in Bone Cells[a]

P2 receptor subtype	Cell type	Relative agonist potency
P2X2	OC	ATP = 2-MeSATP = ATP-γ-S
P2X4	OC	ATP > 2-MeSATP >> α,β-MeATP
P2X5	OB	ATP > 2-MeSATP > ADP
P2X7	OC	BzATP >> ATP > 2-MeSATP > ATP-γ-S >> ADP
P2Y1	OB/OC	2-MeSATP > ATP = ADP
P2Y2	OB/OC	ATP = UTP > ATP-γ-S >> 2-MeSATP
P2Y4	OB	ATP = UTP = ADP = ATP-γ-S = 2-MeSATP > UDP
P2Y6	OB	UDP > UTP > ADP > 2-MeSATP >> ATP

[a]OC, osteoclasts; OB, osteoblasts; ATP, adenosine 5′-triphosphate; 2-MeSATP, 2-methylthio-ATP; ATP-γ-S, adenosine 5′-*O*-(3-thiotriphosphate); α,β-MeATP, α,β-methyl-ATP; ADP, adenosine 5′-diphosphate; BzATP, 2′,3′-*O*-(4-benzoylbenzoyl)ATP; UTP, uridine 5′-triphosphate; UDP, uridine 5′-diphosphate.

Schofl *et al.,* 1992; Yu *et al.,* 1993), rat primary osteoblasts (Gallinaro *et al.,* 1995), and primary cultures of human osteoblasts (Schofl *et al.,* 1992; Dixon *et al.,* 1997). In human osteoblasts, responses to ATP and ADP may be heterogeneous, perhaps reflecting regulated P2 gene expression during osteoblast differentiation or specific roles of different receptors at various stages of differentiation (Dixon *et al.,* 1997). Indeed, several members of both P2X and P2Y classes are present on the surface of human and rat osteoblastic cells, particularly P2Y2, P2X2, and P2X5 (Bowler *et al.,* 1995; Hoebertz *et al.,* 2000; Jørgensen *et al.,* 1997). Osteoclasts also respond to extracellular nucleotides by increasing intracellular calcium concentrations. Because both extracellular calcium influx and calcium release from intracellular stores are involved in the osteoclast response to ATP (Yu *et al.,* 1993; Weidema *et al.,* 1997; Wiebe *et al.,* 1999), both the P2X and P2Y families of receptors seem to be functional in these cells. However, while P2X2 (Hoebertz *et al.,* 2000), P2X4 (Naemsch *et al.,* 1999; Hoebertz *et al.,* 2000), and P2X7 (Hoebertz *et al.,* 2000) have been identified in rat osteoclasts, P2Y2 is expressed but it does not localize to the cell surface (Bowler *et al.,* 1995). Table I summarizes the currently know P2 receptors identified in bone cells [see also Dixon *et al.* (2000) for a review].

Intercellular Calcium Signaling in Skeletal Tissue

Intercellular Calcium Signaling among Osteoblasts and Osteoclasts

As it occurs in other tissues, one of the functions of P2 receptors in bone cells is to propagate calcium signals from cell to cell. Intercellular calcium waves in response to mechanical stimulation of a single cell can be generated in osteoblastic cell cultures. These calcium waves were first observed in the osteogenic sarcoma cell line ROS 17/2.8 and in osteoblasts derived from rat calvaria (Xia *et al.,* 1992). Propagation of intercellular calcium waves was found to be dependent on the passage of an unknown signaling molecule(s) through gap junctions and regeneration of the calcium transient in neighboring cells by calcium-induced calcium release. In striking contrast with the ROS 17/2.8, cells of another osteoblastic cell line, UMR 106–01, respond to mechanical perturbation with a similar rapid calcium transient, which is followed by a calcium wave of very different kinetics. While ROS 17/2.8 cells propagate a slow wave extending to 5–15 cells over several minutes, calcium waves in UMR 106–01 cultures spread very rapidly, extending to more than 50 cells in less than 30 sec (Jørgensen *et al.,* 1997). The difference in kinetics reflects different mechanisms of intercellular signal diffusion, as ROS 17/2.8 and UMR 106–01 cells follow the two fundamental mechanisms of calcium wave propagation (see Fig. 6): signal diffusion through gap junctional communication among ROS 17/2.8 cells and autocrine release of nucleotides (most probably ATP) with activation of P2 receptors in UMR 106–01 cells.

The strikingly different mechanisms of wave propagation observed in two distinct but phenotypically similar cell lines raise the question as to the physiologic meaning of these short-range intercellular calcium signals. Studies in human bone marrow-derived stromal cells demonstrated that both mechanisms of intercellular wave diffusion are present in normal cells. Upon mechanical stimulation, human osteoblast-like cells propagate a fast wave mediated by P2 receptor activation, thus very similar to that observed in UMR 106–01 cells. However, after desensitization with ATP, the fast nucleotide-mediated wave disappears, and a slow wave is uncovered. This slow wave is very similar to a "ROS 17/2.8 wave" and is likewise mediated by gap junctional communication (Jørgensen *et al.,* 2000). In addition to secretion of paracrine factors and direct cell–cell contact, short-range calcium signals offer alternative mechanisms for the cross-talk between osteogenic and osteoclastogenic lineages in local control of bone remodeling. Because P2 receptors are present in both osteoblasts and osteoclasts, it is logical to ask whether calcium signals can

be transmitted from one cell type to another. Preliminary results obtained in our laboratory show that mechanical stimulation of a single osteoblast generates a signal that is propagated not only to surrounding osteoblasts, but also to nearby osteoclasts. Intriguingly, the signal can go both ways, as mechanical perturbation of an osteoclast induces a calcium wave that propagates to both osteoblasts and other osteoclasts. This type of heterotypic intercellular signaling seems to be entirely dependent on P2 receptor activation, with P2Y receptors responsible for signaling in osteoblasts and P2X receptors mediating calcium signaling in osteoclasts (Jørgensen *et al.,* 1999).

Intercellular Calcium Signaling in Chondrocyte Cultures

As noted earlier, articular chondrocytes can establish direct contact and gap junctional communication when they are allowed to proliferate and grow in tissue cultures. Exposure to extracellular ATP induces trains of repetitive short-lasting calcium spikes in articular chondrocytes followed by initiation of calcium waves affecting neighboring cells (D'Andrea and Vittur, 1996a,b). Likewise, mechanical stimulation of one chondrocyte induces calcium transients that propagate from cell to cell (Guilak *et al.,* 1999; D'Andrea *et al.,* 2000). Wave propagation in these articular chondrocyte cultures seems to be highly dependent on signal diffusion through gap junctions (D'Andrea and Vittur, 1996a; D'Andrea *et al.,* 2000; Donahue *et al.,* 1995a). However, chondrocytes are also responsive to ATP, and it is quite conceivable that a P2-mediated mechanism of intercellular calcium signal diffusion exists in these cells but that in resting conditions the alternative mechanism prevails, in contrast to human osteoblasts. Interestingly, mechanically induced calcium waves can propagate from chondrocytes to sinovial cells in culture via mechanisms involving both extracellular ATP release and gap junctions (D'Andrea *et al.,* 1998; Grandolfo *et al.,* 1998). Thus, heterotypic intercellular communication is possible in cartilage via cell–cell propagation of locally generated calcium signals.

Cell–Cell Adhesion and Intercellular Communication: An Integrated View

A hierarchical relationship links cell–cell adhesion and direct intercellular communication via gap junctions. Gap junctional channels form by weak, non-covalent interactions between connexins on opposite cell membranes, thus the integrity of the channel and its functionality require a stable contact between the two cells. However, connexins assembled into gap junctions are not linked directly to any cytoskeletal structure that may stabilize the transjunctional pores (Goodenough *et al.,* 1996). Therefore, it is commonly believed that cells must first adhere to each other via anchoring junctions, then they can form gap junctions (Singer, 1992); in fact, cell–cell communication and neural differentiation can be inhibited by neutralizing antibodies against N-CAM (Keane *et al.,* 1988), and anti-Ncad antibodies prevent gap junction formation (Meyer *et al.,* 1992; Frenzel *et al.,* 1996). Conversely, transfection of Ecad in communication-deficient cell lines restores gap junctional communication and alters the pattern of Cx43 expression (Musil *et al.,* 1990; Jongen *et al.,* 1991). In addition, by providing specificity for cell sorting, different cadherins may compartmentalize gap junctional communication within separate domains of different cells or allow hetorologous communication between cells on different compartments (Prowse *et al.,* 1997; Woodward *et al.,* 1998). There is virtually no information about the relationships between cadherins and connexins in bone cells, except the observation of Ncad and Cx43 colocalization in developing avian mandibles (Minkoff *et al.,* 1994). It is highly likely that cell–cell adhesion precedes and initiates intercellular communication, perhaps by modulating the synthesis and/or assembly of connexins in gap junctions in osteoblasts and osteoclastic cells. Cell–cell contact and communication represent two aspects of an integrated mechanism that allow cells to develop and work in a social context.

Acknowledgments

The authors thank Drs. Pierre Marie, Akira Kudo, Henry Donahue, and Paul Schiller for their support and sharing of the latest data from their respective laboratories. CHAPTER 19

Histomorphometric Analysis of Bone Remodeling

Susan M. Ott
Department of Medicine, University of Washington, Seattle, Washington 98195

Introduction

Purpose of Remodeling

The skeleton has two major functions. It serves as a reservoir for minerals and as a structural framework to support the muscles and protect vital organs. Once growth and modeling of the skeleton have been completed, the bones continually alter their internal structure by remodeling, which is the localized removal of old bone and replacement with newly formed bone. The process is complex, requiring interactive cellular activity, and is regulated by a variety of biochemical and mechanical factors. It is likely that the major reason for remodeling is to enable the bones to adapt to mechanical stresses. Remodeling also allows the bone to repair microdamage and thus maintain its strength. Finally, remodeling is an important component of mineral metabolism. Alterations in remodeling are responsible for most metabolic bone diseases, and interpretation of pharmacological interventions must be done in the context of the remodeling sequence.

Bone as a material compares poorly with other engineering materials. At repetitive loading equal to 100 miles of running, fatigue damage will occur (Marcus, 1987). However, unlike the other materials, bone can repair itself by directing remodeling to the damaged site. In some situations, such as military training, the rate of repair cannot keep up with the rate of damage and the material fractures (Casez *et al.,* 1995; Margulies *et al.,* 1986). In addition to directed remodeling, which repairs cracks and fatigue damage, there is apparently random (Parfitt terms this stochastic) remodeling, which may act to continually renew bone. This prevents accumulation of older, densely mineralized bone, which is more brittle.

Although bone remodeling affects the serum levels of minerals, the minute-to-minute regulation of minerals does not depend on bone remodeling. The strongest evidence for this comes from studies of potent bisphosphonates, which can reduce bone remodeling by up to 98% when evaluated by histologic endpoints, but which have only transient, asymptomatic effects on the serum calcium concentration (Vasikaran *et al.,* 1995; Chavassieux *et al.,* 1997). The time course of remodeling also argues against its function to acutely control calcium concentration. If serum calcium drops, the parathyroid hormone (PTH) increases and serum calcium rises immediately. It takes more time, however, for origination of a basic multicellular unit (BMU) and activation of osteoclasts. The acute release of calcium is a function that is probably performed by lining cells in response to changes in endocrine hormones.

Bone remodeling activity does affect chronic serum mineral levels. For example, when there is a pathological increase in bone resorption, as seen in hyperparathyroidism or malignancy, the serum calcium is increased. In patients with renal failure and adynamic bone disease, decreased bone remodeling results in more brittle control of serum calcium: an increase in calcium intake causes greater increases in serum calcium and chelation or dialysis with low calcium causes a greater fall than in patients with normal bone remodeling rates (Kurz *et al.,* 1998).

Dynamics of Bone Physiology

Bone is not usually considered in classic physiological terms because the events are so slow. Whereas the heart contracts every second and the kidney filters 180 liters each day,

it takes 4 or 5 years for an area on the bone surface to complete one bone remodeling cycle. A time-lapse movie of the trabecular bone, played sufficiently fast, would show quivering at the surfaces, while entire trabeculae would drift, enlarge, or dissolve. An animation demonstrating this movement is available on the internet ("Osteoporosis and Bone Physiology," http://courses.washington.edu/bonephys).

Although the dynamics of bone physiology are slower than other organs, many of the same principles apply. Bone senses and then responds to external forces or stimuli, and it adjusts to different environments. An inability to perform these functions results in diseases, and the knowledge of this physiology is important so that it can be manipulated to treat or prevent the disease.

A fundamental property of bone remodeling is that it occurs in discrete locations and involves a group of different kinds of cells. This secondary level of organization, analogous to the nephron, was named the basic multicellular unit by Frost (1969). Unlike the nephron, the BMU is not a permanent structure. It forms in response to signal or stimulus, performs its function, and disbands, leaving a few residual lining cells and osteocytes. Each BMU undergoes its functions in the same sequence: origination and organization of the BMU, activation of osteoclasts, resorption of old bone, recruitment of osteoblasts, formation of new bone matrix, and mineralization [Figs. 1 and 2 (Fig. 2, see also color plate)]. A major goal of histomorphometric research has been to determine the dynamics of these sequences of bone events.

Methodology

Most of the physiology of bone remodeling has been defined from undecalcified tetracycline-labeled bone biopsies (Fig. 3, see also color plate). Details of bone biopsy technique and histomorphometric measurements are covered in Chapter 94. Insights by Frost and Parfitt are responsible for much of our current interpretation of these measurements (Frost, 1969, 1989; Parfitt *et al.,* 1996). They observed that bone remodeling activity occured in localized areas on the bone surface. The spatial relationships between osteoclastic bone resorption and osteoblastic bone formation gave clues to the temporal sequence of these events. Measuring the distance between two tetracycline labels given over a known interval allows conversion of distance measurements to time intervals. The proportion of the bone surface that is covered with tetracycline labels is the same as the proportion of time spent forming bone at a point on the surface. Newly formed bone has a different orientation from older bone; at the nonconformity is a cement line (Fig. 4, see also color plate). If the surface is quiescent, the distance between the cement line and the bone surface (wall thickness) represents the total cross-sectional thickness of bone formed by that BMU. In osteoid-covered surfaces, those sites closest to a cement line are younger than those farther away. Measurements from the cement lines to the surface can be used to determine the duration of formation at that location. Eriksen *et al.* (1984) made extensive measurements on individual BMUs and reconstructed the entire formation sequence.

Other methods have aided the study of bone remodeling. Stains for acid phosphatase (Fig. 5, see also color plate) identify osteoclasts, and stains for alkaline phosphatase identify active osteoblasts (Bradbeer *et al.,* 1992). The TUNEL stain, which identifies apoptotic cells, has been applied to bone (Weinstein *et al.,* 2000; Verborgt *et al.,* 2000). Immunohistochemical techniques (Derkx *et al.,* 1998) are emerging; these are important in understanding how new *in vitro* molecular biological findings actually work in the bone.

Back-scattered electron photomicrographs and radiodensitometry are the only methods that show the differential mineralization as bone ages (Fig. 6) (Boyde *et al.,* 1993; Jowsey, 1960; Reid and Boyde, 1987)

Other techniques, such as scanning electron microscopy, allow further examination of the three-dimensional structure of bone (Fig. 7) (Dempster *et al.,* 1986; Hahn *et al.,* 1995; Jayasinghe *et al.,* 1993; Moskilde, 1993). Hahn *et al.* (1995) have developed a technique of simultaneously examining the surface and structure of trabecular bone. They cut thick sections and stain only the surface; using reflective light, the surface looks like an ordinary thin section and can be measured. However, using back lighting, the three-dimensional connections can be appreciated. A similar approach by Aaron (2000) was applied to bone biopsies from patients with osteoporosis, allowing differentiation between real and apparent free ends. Another new technique for examining the three-dimensional structure is microcomputed tomorgraphy (Chapter 93).

Reeve *et al.* (1987) used whole body ^{85}Sr kinetics to measure mineral retention and accretion. These showed correlations with histological techniques that used tetracycline labeling. Similarly, Charles *et al.* (1987) and Eastell *et al.* (1988) have shown correlations between histomorphometry and kinetics using ^{47}Ca.

Changes in bone mass and in biochemical markers have added to the understanding of bone remodeling. Bone densitometry, using methods such as dual-energy X-ray absorptiometry, allows an integrated view of remodeling effects, although it cannot predict the microstructure of the bone or differentiate between increased formation and decreased resorption. Because resorption rates cannot be measured accurately on bone biopsies, the combination of bone formation rates and bone mass changes can provide an estimate of net resorption. The role of biochemical markers is discussed in Chapter 90.

Remodeling at the BMU Level

Origination

At any one time, ~20% of the cancellous bone surface is undergoing remodeling, and at any one surface location, remodeling will occur on average every 2–years. This is known as the activation frequency (Parfitt *et al.,* 1987). The skeleton contains millions of BMUs, all at different stages.

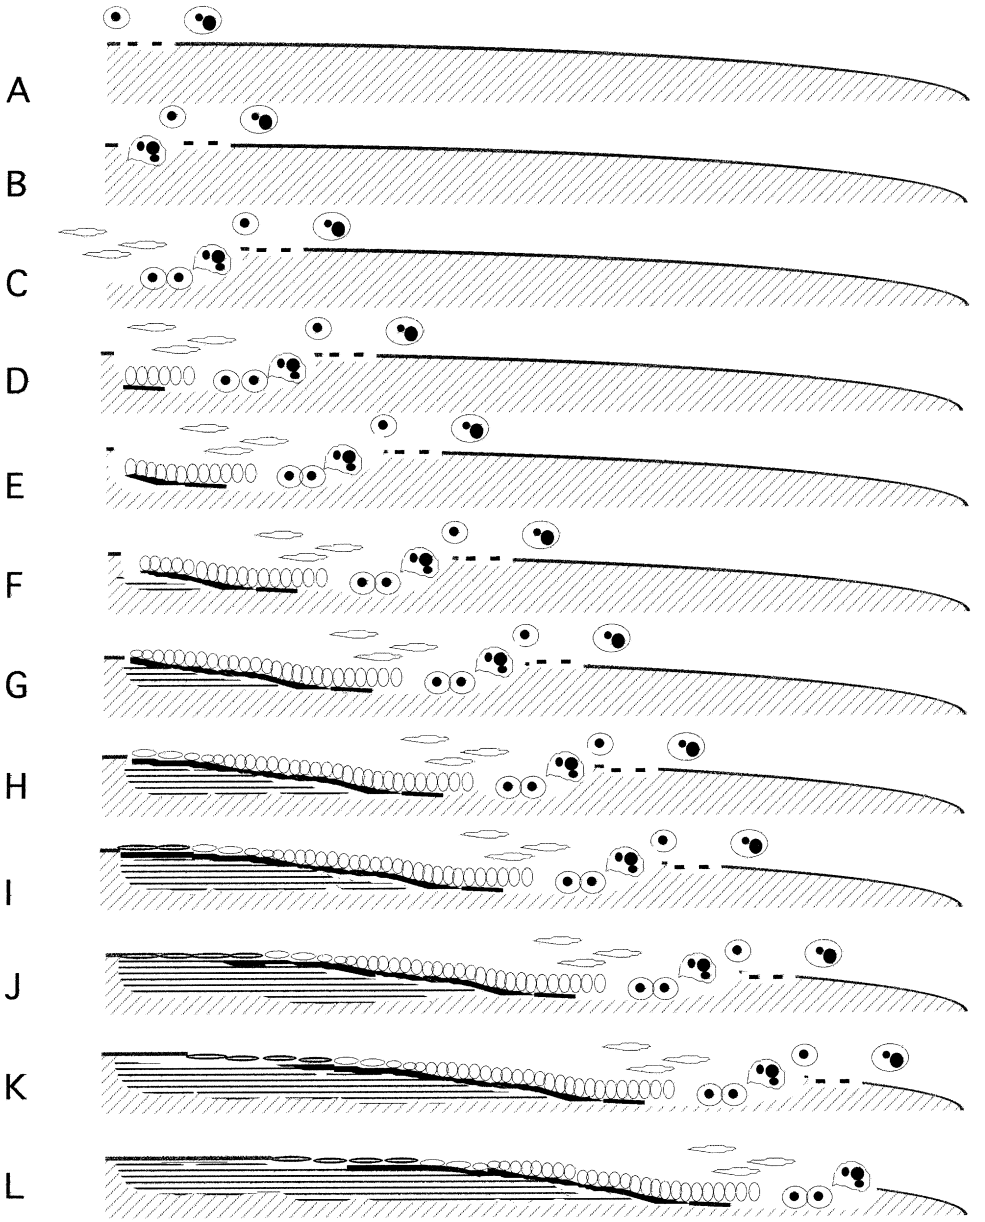

Figure 1 The basic multicellular unit moving along a cancellous surface. Each step represents ~10 days, and the BMU moves at about 10 μg each day. (A) Origination of BMU; lining cells contract to expose collagen and attract preosteoclasts. (B) Osteoclasts fuse into multinucleated cells, which resorb cavity. (C) Mononuclear cells continue resorption, and preosteoblasts are stimulated to proliferate. (D) The osteoblast team forms at the bottom of the cavity and starts forming osteoid. (E) Osteoblasts continue forming osteoid (black) and previous osteoid starts to mineralize (horizontal lines). (F–H) Osteoblasts continue formation and mineralization. (I and J) Osteoblasts begin to flatten. (K and L) Osteoblasts turn into lining cells; bone remodeling at initial surface (left of drawing) is now complete, but BMU is still advancing (to the right).

What initiates the organization of a new BMU? This question has not yet been answered, but evidence shows that mechanical stress can be sensed by osteocytes that can signal lining cells to form a new BMU at either cortical or cancellous surfaces. The osteocytes excrete paracrine factors when subjected to mechanical stimuli, e.g., IGF I expression increases 6 hr after mechanical loading (Turner and Forwood, 1995). Following fatigue loading, osteocyte apoptosis is seen in association with microdamage as well as resorption (Verborgt *et al.,* 2000). Martin (2000) hypothesized that the osteocytes chronically inhibit lining cells so that the origination of a BMU is caused by release of the inhibition. Lining cells themselves may also detect the mechanical strains; when grown *in vitro,* these cells respond to either str in or estrogen via an estrogen receptor (Zaman *et al.,* 2000). Local and circulating hormones cytokines, and growth factors certainly influence the origination of BMUs but it is not clear which ones, if any, actually set one off. Mori and Burr (1993)

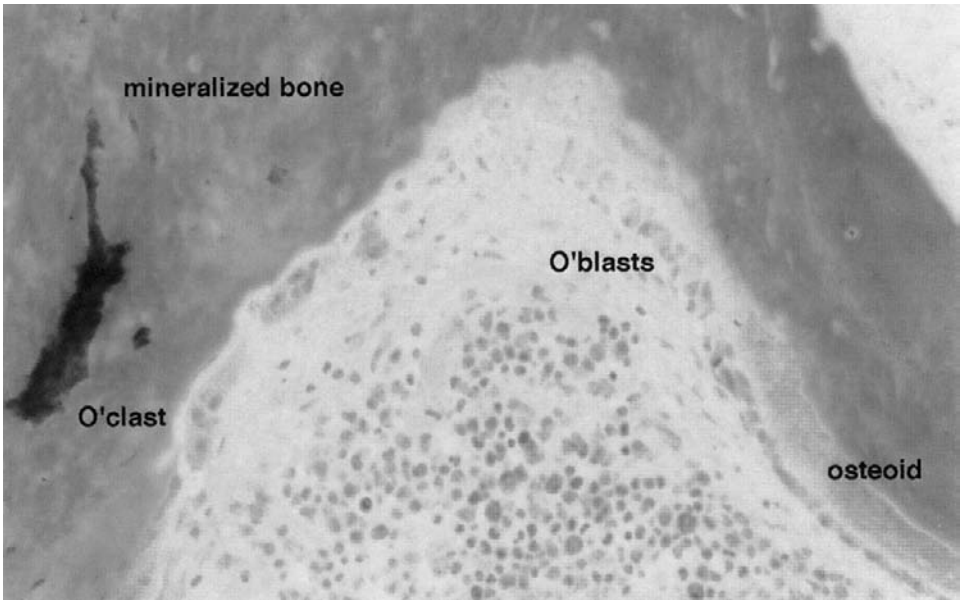

Figure 2 Photomicrograph showing BMU along a trabecular surface from a patient with renal failure. At left is osteoclastic resorption ("cutting edge") and at the right are osteoblasts and osteoid. (See also color plate.)

demonstrated an association between fatigue damage and intracortical remodeling. They anesthetized mature dogs and applied a cyclic load to the radius, which did not cause the animals to limp but did cause microscopic cracks. Eight days later an identical load was applied to the opposite radius and the animals were sacrificed. Histologic sections showed an equal number of cracks on each side. However, at the site with the earlier load, there was a significant increase in resorption cavities that were adjacent to the cracks. The temporal design of the study demonstrated that the resorption occurred after the fatigue damage.

Origination is the first step in organizing a BMU, and thus it must involve gathering of the initial cells that will form the new BMU. Precursor cells must proliferate and be available. A host of hormones and cytokines that have attracted the attention of molecular biologists probably exert most of their influence at this step. These include parathyroid hormone, 1,25-dihydroxyvitamin D, interleukins 6 and

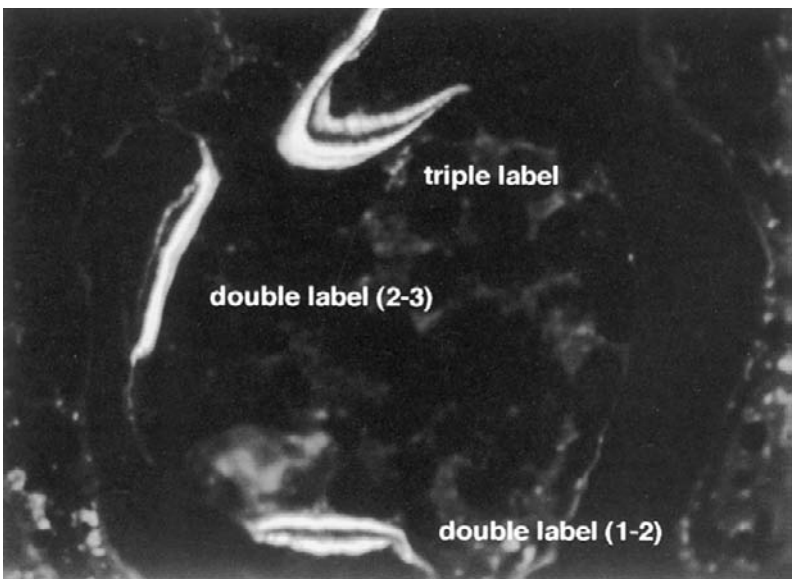

Figure 3 Photomicrograph of tetracycline labeling in an unstained section under fluorescent light. The patient was given three labels, and some BMUs show all three; others demonstrate label escape, and only the first two or last two are seen. (See also color plate.)

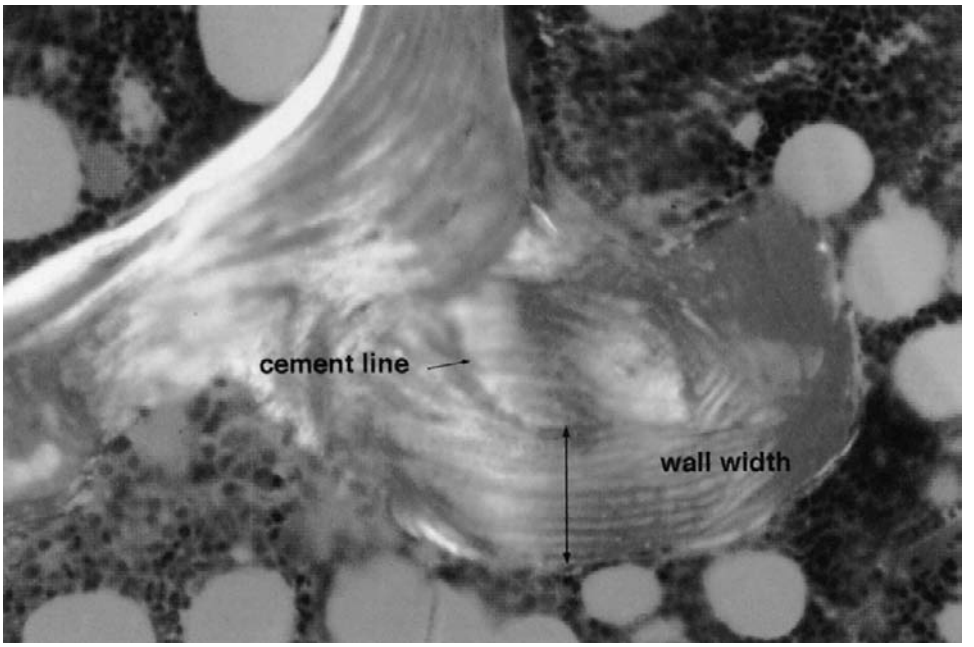

Figure 4 Photomicrograph demonstrating wall thickness; the stained section viewed under polarized light shows a change in the orientation of bone lamella. (See also color plate.)

11, estrogens, androgens, and prostaglandins. To complicate matters, factors that can originate BMUs during disease or in tissue culture are not necessarily important regulators in normal physiology. This is an exciting area of current research.

The life span of a BMU is not well defined. Cortical BMUs can wander for months, usually in a straight line. Parfitt (1994) estimates that the duration is 2–8 months. This is harder to measure in cancellous bone because the two-dimensional sections do not capture the entire serpentine course of the BMU. More research is needed to understand the life span of a BMU and what controls its journey.

Activation

The life span of individual cells in a BMU is much shorter than that of a BMU. As the BMU progresses, new cells must be recruited, continually, which is the essence of activation. Activation frequency can be calculated from two-dimensional histomorphometric measurements, and it represents the probability that remodeling activity will begin at any point on the surface (Parfitt *et al.,* 1987). It is important to distinguish between origination and activation. The former occurs only once for each BMU at a quiescent surface of the cancellous bone or on a surface nearest a crack in the cortical bone. Activation is a continuing process that occurs at the cutting edge of the BMU, and as the BMU spreads, new surfaces undergo activation. The BMU "front" travels at a rate of about 10 μm/day. In the cortical bone, the BMU progresses into solid bone so there are no lining cells to participate in activation or recruitment. The signal comes from existing BMU cells, although nearby osteocytes could play a role. Replacement osteoclasts must come from the capillaries that are formed within the BMU. By analogy, the cancellous bone may also rely on signals from BMU cells and osteoclasts may interact with the new capillaries. In addition, lining cells of osteoblastic lineage are available on the cancellous surfaces.

When exposed to hormones, lining cells change their shape from flat epithelial-like cells to rounded cells, thereby exposing some of the collagen matrix. They also secrete collagenase to expose the bone mineral. These activated cells then produce RANK ligand, which binds to receptors on preosteoclasts and causes them to fuse and become mature osteoclasts. Where do the preosteoclasts come from?

Systemic hormones, growth factors, and interleukins play a role at this step, helping to recruit new osteoclasts by enlarging the precursor pool. Some of these may also have played a role in origination of the BMU, but systemic factors cannot localize the osteoclasts to the cutting edge. As the BMU progresses, new osteoclasts are required at shifting locations. Most research on osteoclast recruitment has focused on differentiation and proliferation and not on localization to the precise site of resorption, but as Parfitt (1996) said, "the manufacture and packaging of a product is of little use if it is not delivered to the right address." This function is probably the responsibility of cells within the BMU.

Resorption

There are two phases of resorption. The first is the most rapid, carried out by multinucleated osteoclasts, and lasts ~8 days. Then comes a slower phase, involving mononuclear cells, which lasts ~34 days (Ericksen *et al.,* 1984).

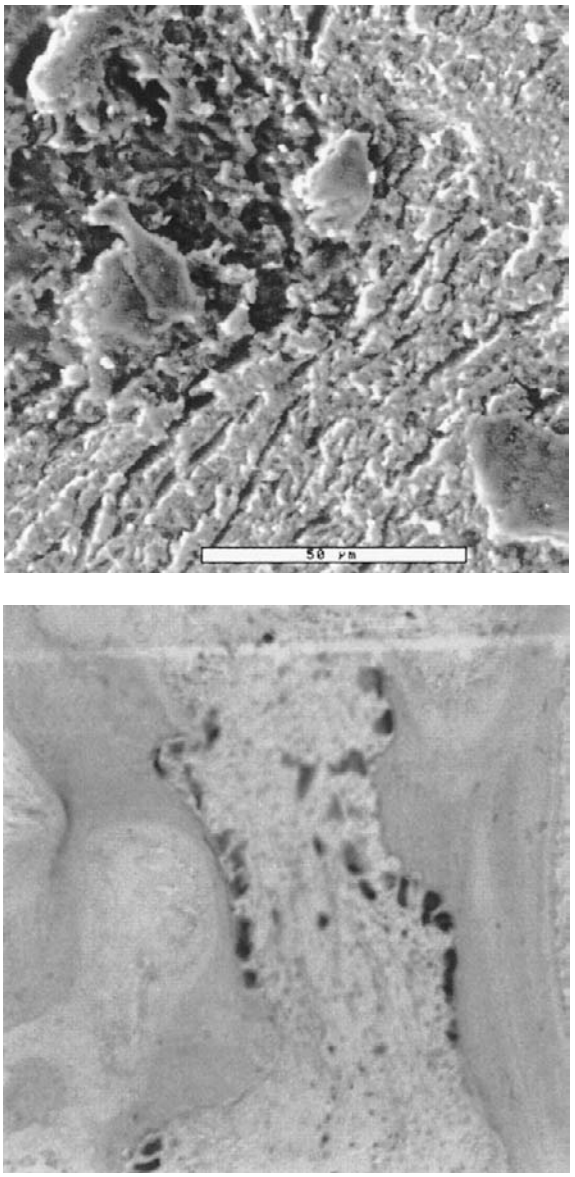

Figure 5 (Top) Environmental scanning electron micrograph of osteoclasts from the same patient shown in the bottom half of the figure. This new technique allows scanning of unstained bone. This sample was embedded in methacrylate. Photograph courtesy of Lara Touryan. (Bottom) Acid phosphatase stain of osteoclasts, which appear red, from a patient with secondary hyperparathyroidism and renal failure. (See also color plate.)

In cortical bone, two types of eroded surfaces are seen (Jaworski *et al.,* 1972). One is a cutting cone, with osteoclasts at the surface; the other is sausage-shaped, more shallow, and lacking in osteoclasts. These might represent surfaces in which resorption had been aborted (Parfitt, 1994). Croucher *et al.* (1995) have measured resorption depths in cancellous bone with analogous findings. The frequency distribution of depths shows greater numbers of shallow cavities than would be expected for a model of continuous resorption. They concluded that bone resorption is interrupted or permanently arrested.

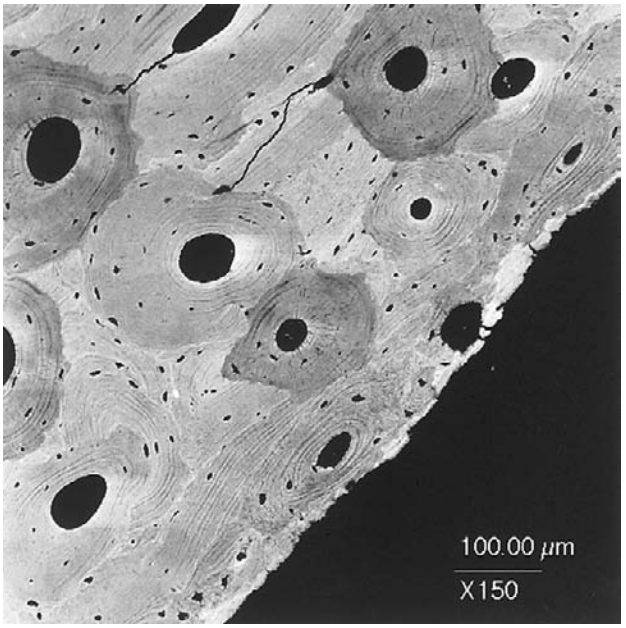

Figure 6 Back-scattered electron micrograph of bone from a 72-year-old woman showing different densities of BMUs. The crack, which occurred during preparation, is characteristically through older, interstitial bone. Courtesy of Barbara Carter.

Multinucleated osteoclasts are active for ~12 day (Parfitt *et al.,* 1996) and then undergo apoptosis. This process may be promoted by TGFβ. Cells undergoing apoptosis have been located at the junction between the resorbing surface and the reversal surface, which suggests that the process might also be involved in signalling new osteoblasts. Osteoclasts have been shown to excrete interleukin 6 and annexin-II, both of which could signal new osteoblasts. The depth of the eroded cavity is also linked to the life span of the active osteoclasts so that early apoptosis would result in a more shallow eroded cavity.

During resorption, bone-derived growth factors are released. These include transforming growth factor-β (TGFβ), insulin-like growth factor (IGF), and fibroblastic growth factor (FGF), which were deposited into the matrix by the previous generation of osteoblasts. Some, like TGFβ, may be activated by the acid environment caused by osteoclastic proton secretion. These growth factors (delayed autocrine factors) might account for the coupling between resorption and formation that is seen in normal situations. Direct evidence for this theory is lacking; possibly the proteolytic milieu in the resorption cavity inactivates these factors before they can recruit osteoblasts (Parfitt, 2000). Certain pathological conditions, such as Paget's disease and postmenopausal osteoporosis, also demonstrate coupling. High correlations between total skeletal resorption and formation could be seen if biochemical stimuli (e.g., interleukin 6) for origination of BMUs also participated in the recruitment of osteoblasts. Which mechanisms predominate in normal physiology and which are involved in pathophysiology are not yet known. Parfitt (2000) has proposed that vascular

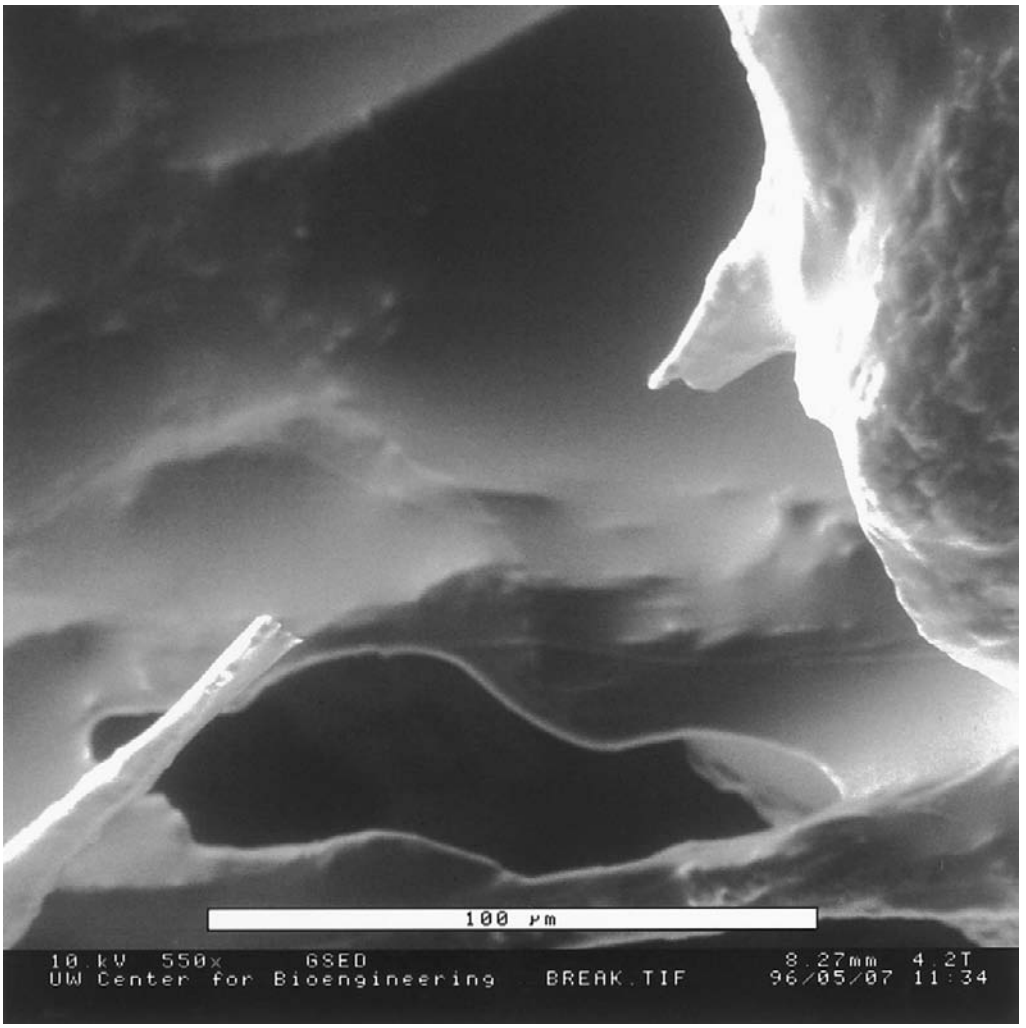

Figure 7 Environmental scanning electron micrograph of trabecula. The sample had been removed from a patient in the operating room minutes before the photograph was taken; the only preparation was rinsing with water. Broken trabecular bridging can be seen. Photograph courtesy of Lara Touryan.

endothelial cells are responsible for the coupling between bone formation and resorption (discussed later).

During resorption, collagen is digested. Some fragments can be used as biochemical markers for overall bone resorption as discussed in Chapter 90.

Formation

After the maximum eroded depth has been achieved, there is a reversal phase that lasts ~9 days (Eriksen *et al.,* 1984). During this phase, the osteoblasts converge at the bottom of the cavity. The team of osteoblasts then begins to form the osteoid. After 15 days, the osteoid begins to mineralize. The osteoblasts continue to form and to mineralize the osteoid until the cavity is filled or nearly filled. The time to fill in the cavity at any given point on the surface is 124–168 days in normal individuals (Erickson *et al.,* 1984).

The apposition rate of matrix and of mineral is most rapid initially, as determined by measurements of osteoid seams that are very close to the cement lines. The initial rate is 1.2 μm/day, which gradually decreases to zero as the cavity is filled. The delay between osteoid formation and mineralization is 15 days initially, with an increase to 27 days, then a gradual decrease (Erikson *et al.,* 1984). These rates were determined using reconstructive techniques. It is easier to measure the average mineral apposition rate and calculate the average osteoid maturation time, which is the mean time interval between the onset of matrix depostion and the onset of mineralization (Parfitt *et al.,* 1987). The average normal adult osteoid maturation time is 17–20 days (Parfitt *et al.,* 1997; Recker *et al.,* 1988; Vedi, *et al.,* 1983).

At the bottom of the cavity, the new osteoblasts are plump and vigorous, they have tall nuclei, and they make a thick layer of osteoid. The cells then gradually flatten as they slow production, and finally they become quiescent lining cells. Some of the osteoblasts differentiate into osteocytes and remain in the matrix. The osteocytes may secrete inhibitory factors that slow the rate of bone formation as the resorbed cavity is nearly filled (Martin, 2000). Adjacent osteoblasts appear to be the same age; plump and flat cells

are not intermixed. This suggests that there are no replacement osteoblasts that join a team that is already filling the resorption space. Autoradiographic studies showing osteoblastic cells in teams of the same age confirm these observations (Parfitt *et al.,* 1996). As the BMU progresses, new osteoblasts are added, but only at the edge of the formation site.

The density of the osteoblasts at the formation site may vary. When the cells are more crowded they are taller and narrower, and they collectively can make more osteoid than when there are fewer cells. Parfitt *et al.* (1995) have shown that osteoporotic patients have the same rate of osteoid production per cell, but overall the wall thickness is decreased and the amount of newly formed bone is inadequate to fill the resorbed cavity. They suggests that when there are not enough osteoblasts, they must flatten out sooner to cover the bone.

The percentage of the cancellous bone as measured in surface that is mineralizing (shows tetracycline labels), different studies, is shown in Fig. 8.

A high proportion (40–60%) of osteoid surfaces do not have associated tetracycline labels. Some osteoid that does not take tetracycline is newly formed and has not yet begun mineralization; this accounts for only ~7% of the osteoid (Ott, 1993). Two theories have been proposed to account for the unlabeled osteoid surface. One explanation is that the bone formation is not continuous; in other words, there are active "on" periods where osteoid is made and mineralized followed by inactive "off" periods where the osteoblasts rest (Frost 1980). The other theory is that tetracycline-free osteoid represents terminal osteoid, which persists at the end of formation, mineralizing too slowly to be measured. It is possible that both mechanisms are operative.

An indirect way to assess the presence of "off" periods is to calculate the label escape, which is the amount of single tetracycline label seen when two labels were given. During the interval between the two tetracycline labels, some osteoid surfaces will have finished formation and others will have started. A single first label is seen when the osteoid finished mineralization before the next label was given, and a single second label is seen when the osteoid starts after the first label was given. The proportion of double labels to single labels depends on the days in the labeling interval as well as the formation period. The shorter the interval or the longer the formation period, the higher the proportion of double labels compared to single labels (Keshawarz and Recker, 1986; Martin, 1989). Therefore, if the formation period and label interval are known, the amount of expected label escape can be calculated. When the observed measurements are different from the expected ones, it suggests that there could be off periods during the formation. Several studies in humans and animals have shown too much label escape, which supports the idea of discontinuous formation.

Other findings are more consistent with the theory of slow terminal mineralization. Keshawarz and Recker (1986)

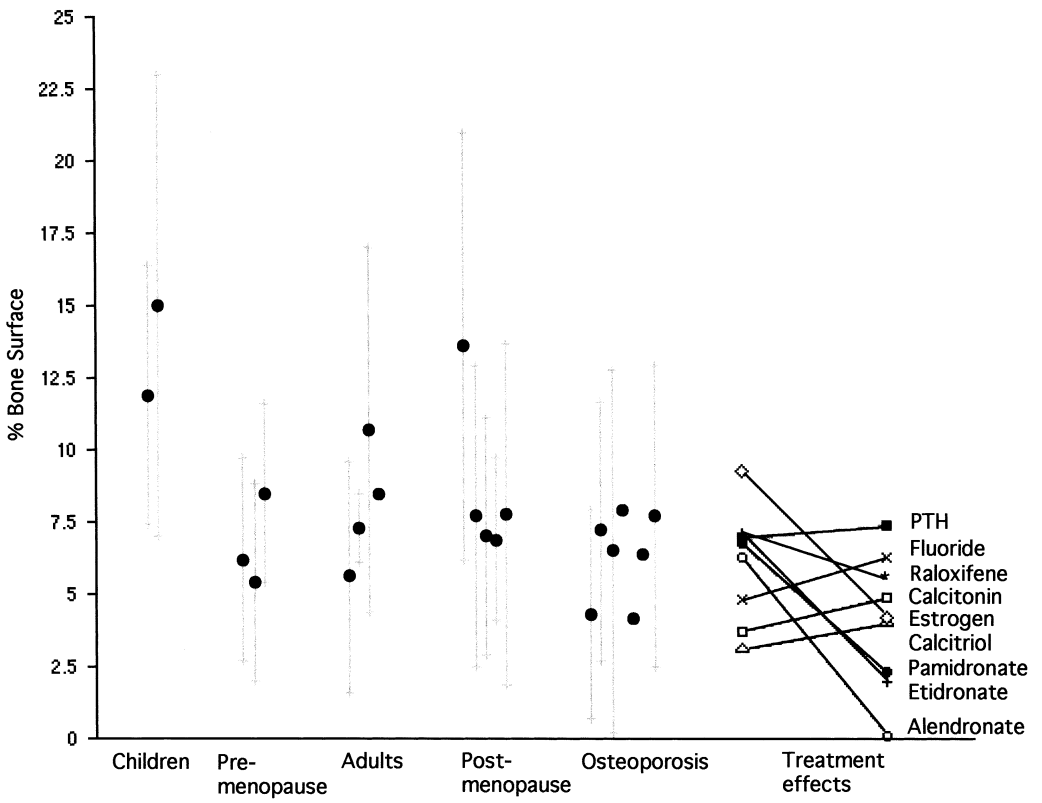

Figure 8 Mineralizing surface per bone surface in normal individuals and patients with osteoporosis. Also shown are effects of treatment in women with osteoporosis. Error bars are 1 SD. Points represent double plus 1/2 single label, and points without error bars were calculated from available data.

found less label escape in women with osteoporosis than in normal controls. Ott (1993) found that osteoporotic women had somewhat higher label escape than expected from calculations of the formation period (which involve measurements of wall thickness that may not be current). However, use of triple tetracycline labeling failed to demonstrated any discontinuations in bone formation between 3 and 35 days of observation. There were no first and third labels without a second label. Patel and colleagues (1999) administered quadruple tetracycline labels to postmenopausal women before and after commencing estrogen therapy; they did not see any BMUs with a missing label. Parfitt (1997) studied differences between ethnic groups and found that 40% of osteoid surface in blacks had labels compared to 53% in whites. The blacks appeared to have slower terminal mineralization, and the authors suggested that this could be due to lower bone blood flow. More studies in normals and patients with other diseases need to be done to clarify this issue.

During formation, osteoblasts make osteocalcin and bone-specific alkaline phosphatase, which can be used as serum biochemical markers of formation (see Chapter 90).

Mineralization

Mineralization begins ~15 days after osteoid has been formed. In most situations (except osteomalacia), the average rate of osteoid formation and the rate of mineralization are the same and are measured by tetracycline labels.

After the BMU has completely restored the bone volume, mineralization continues to increase. Older bone has more densely packed crystals, and microradiographic studies have shown that newly formed bone may be 25% less dense than older bone (Jowsey, 1960). The length of time for this increased mineralization is uncertain. If the bone turnover is decreased, then gradually the mean age of the remodeled bone will increase, and the bone will become denser. As individuals age, the interstitial bone (bone between newly remodeled osteons) becomes older and more densely mineralized (Boyde *et al.,* 1993; Reid and Boyde, 1987). The increased mineralization seen with more densely packed crystals or with change in the crystal structure itself may have several consequences. Schaffler *et al.* (1995) reported observations of microcracks, which increased exponentially with aging. The overwhelming majority of microcracks (87%) were observed within the interstitial bone. Another consequence of aging mineral is that it has less water and the minerals are less able to exchange with extracellular fluid (Parfitt, 1994).

Potential Roles of Local Environmental Factors in Bone Remodeling

Vasculature

Each BMU is associated with a capillary. In cortical bone, the capillary grows along the excavated tunnel. On trabecular surfaces, small capillaries are frequently seen adjacent to osteoblasts. It is interesting to note that ^{85}Sr kinetic studies have shown correlations between the blood flow and the work rate of osteoblasts, as well as biochemical indices of bone formation and resorption (Reeve *et al.,* 1988).

These have not been well characterized, and most investigators, if they considered the capillaries at all, thought their role was to provide nutrients and a source of precursor bone cells. Parfitt (2000) theorized that vascular endothelial cells could also provide a mechanism for the coupling of formation to resorption. These cells are stategically located to sense growth factors derived from the resorption of bone; in turn they secrete several types of growth factors that can be mitogenic for osteoblasts

Nervous system

Anatomic studies have documented a dense and intimate innervation of bone tissue, but the function of the nervous system is not clear. Serre and colleagues (1999) have demonstrated the presence of fibers that run along vessels adjacent to bone trabeculae.

Immunocytochemical studies showed that the fibers contained three different markers for neural tissue and that some were sensory fibers and other sympathetic fibers. Nerve endings were seen in contact with bone cells. Glutamate was expressed in fibers that were in proximity to bone cells, suggesting a potential role of glutamatergic innervation in the bone remodeling process.

Evidence has shown a role for the central nervous system in the control of bone formation rates. Leptin injected into brains of mice causes a substantial decrease in bone formation rates at doses that do not affect the body weight. The leptin does not have this effect when administrered intravascularly. The mechanism of this effect remains unknown (Ducy *et al.,* 2000).

Bone Marrow Cells

Bone stromal cells secrete a variety of cytokines that can stimulate the proliferation of osteoblasts and osteoclasts. These are discussed in detail in other chapters of this text. Bone remodeling is higher in areas with more red marrow, possibly because these areas have more cytokine and interleukin activity.

Adipocytes

Adipocytes and osteoblasts derive from the same precursors, which are multipotential stromal cells. Studies have suggested that oxidized lipids promote the adipogenic differentiation of these precursors (Parhami *et al.,* 2000). Histologic studies have shown that the area occupied by fat cells increases as bone volume decreases (Meunier *et al.,* 1971). *In vitro* experiments have shown that mature adipocytes inhibit osteoblast proliferation (Maurin *et al.,* 2000).

How Remodeling Affects the Three-Dimensional Structure of Bone

Conversion of Plates to Rods

Young healthy cancellous bone forms a well-connected lattice, with plate-shaped trabeculae. Remodeling does not necessarily change this overall structure, but when resorption exceeds formation, the bone loss leads to thinning of the trabecular plates and/or to perforations (Fig. 9). For the same amount of bone loss, the mechanical strength of the bone is impaired to a greater extent if the plates are perforated.

Plates can perforate if the resorption depth of one BMU is deeper than the thickness of the plate or if two BMUs on opposite sides of the plate resorb bone at the same time. In any case, once the bone has perforated, further bone loss will be amplified (Fig. 10) because there is no more scaffolding to support a team of osteoblasts. Instead of a cement line, there is empty marrow space. By this process, the plate-shaped trabecular bone is converted into a rod-shaped structure with loss of surface available for formation (Parfitt *et al.,* 1983).

Once the plates have become rods, they may become disconnected. This has been demonstrated by scanning electon micrographs (Dempster, 2000) and by examination of thick, superficially stained bone sections (Aaron *et al.,* 2000). The isolated trabecular rods have no mechanical stimuli and are severed from the osteocyte network and are resorbed rapidly (Mosekilde, 1993).

Several kinds of measurements from bone biopsies can estimate the degree of connectivity, the thickness of trabeculae, the volume of the marrow spaces, or the extent of perforated or isolated rods (Croucher *et al.,* 1996). Patients with osteoporotic fractures have more structural abnormalities than those without fractures, even when the total bone volume is taken into account. Bone biopsies from patients with similar bone mass (Kleerekoper *et al.,* 1985) show that patients with fractures have fewer trabecula but greater trabecular width than those without fracture. In subjects with and without fractures, Recker (1993) matched bone biopsies according to bone volumes: those from women with fracture had poor measures of connectivity. Legrand *et al.* (2000) found increased values of interconnectivity index, free end to free end stuts, and trabecular spacing were greater in men with fractures than in men without fractures after adjusting for age and bone density. Oleksik *et al.* (2000) found that structural measurements indicating disruption of the trabecular lattice were different in postmenopausal osteoporotic women with fractures than in those without fractures after adjustment for bone mass.

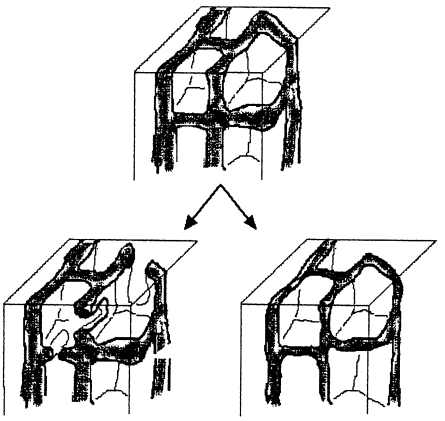

Figure 9 Diagram depicting two possible methods of losing bone with aging. Trabeculae could thin without loss of structure or could be perforated with structural damage.

Measurements from usual bone sections are two dimensional and may not reflect the three-dimensional reality of the bone accurately. A group of postmenopausal women with or without vertebral fractures was matched for trabecular bone mass. The two-dimensional measurements of bone histology and trabecular width, including plate density, star volume, and node:terminus ratio, were not significantly different between those with and without a fracture (Hordon *et al.,* 2000).

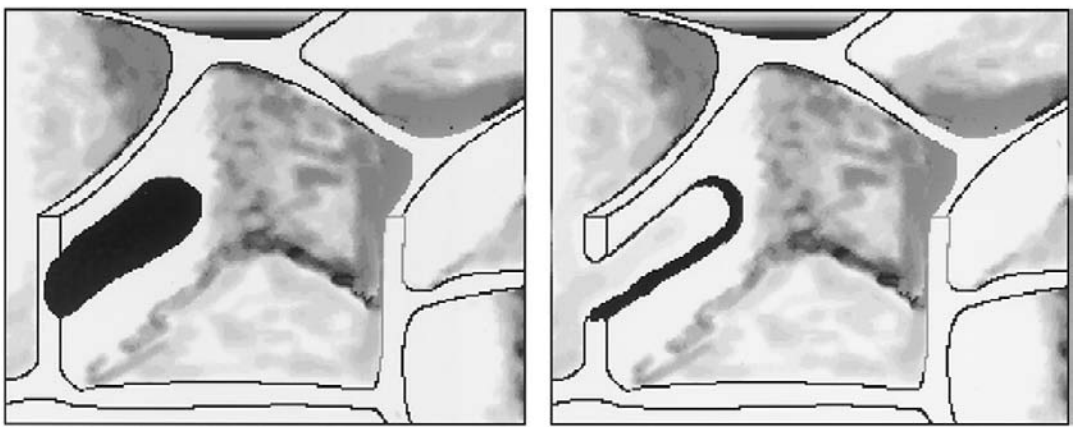

Figure 10 Diagram of loss of surface space by deep resorption. (Left) Cancellous surfaces just after resorption; available surface for formation of new bone is shown in black. (Right) If resorption is slightly deeper, the plate will be perforated, and the only available surface is around the edge of the hole. The plate is being converted to a rod.

Three-dimensional analysis, however, showed that the fracture group had almost four times as many "real" trabecular termini as the group without fractures (Aaron *et al.,* 2000).

Cortical versus Cancellous Bone

The overall surface of cancellous bone is much higher than cortical bone. In the entire skeleton, however, ~80% of bone is composed of cortical bone and only 20% is cancellous bone. The surface/volume relationships are much greater in the cancellous bone. Thus it is metabolically more active. This is the usual explanation for differences between remodeling activity in the two types of bone, but other important differences are also seen. Cortical bone and cancellous bone share many features of remodeling, particularly in the sequence of origination, activation, resorption, formation, and mineralization. Whereas BMUs in the cancellous bone lie along the surface, those in the cortex burrow through the bone. Intracortical BMUs form a tunnel, but cancellous BMUs either form a trench (half-tunnel) or spread out over an area (Hahn *et al.,* 1995; Jayasinghe *et al.,* 1993; Parfitt, 1994) (Fig. 11). Thus, intracortical bone remodeling could not possibly result in increased bone volume, whereas remodeling on exterior or cancellous surfaces could potentially increase bone volume.

Endocortical bone is a special surface that may react differently than either cortical or cancellous. In postmenopausal osteoporosis, for example, this surface shows more formation (Arlot *et al.,* 1990; Brown *et al.,* 1987; Parfitt *et al.,* 1996) and resorption (Keshawarz and Recker, 1984) than other areas, with a net result of "trabecularization" of the interior surface of the cortical bone.

The cortical bone of the femoral neck has been studied using sections that contain the entire cross-sectional area in a group of patients who fractured the femoral neck. Compared to cadaveric control samples, cortical bone had greater porosity in the inferoanterior and superoposterior regions, there were more giant Haversian canals in those regions, and those canals were more likely to be composite osteons. Although most osteons had remodeling measurements that were similar in controls and fracture cases, the giant, composite osteons had significantly lower wall thickness. The authors suggest that in some cortical BMUs, there is failure to recruit osteoblasts or that osteoblasts cease bone deposition prematurely (Bell *et al.,* 1999, 2000).

Cancellous bone can also form microcalluses, for which there is no room in cortical bone. However, the periosteal surface of cortical bone can add woven bone in response to mechanical loading; this is not observed in cancellous bone. Another difference is that cancellous bone BMUs proceed along a surface lined with lining cells, which could participate in remodeling, whereas there are no lining bone cells within the cortex. Cancellous bone has also a more ready access to marrow cells than cortical bone.

Sometimes in cancellous bone a trabecula can become isolated, and the lack of continuity will remove both the ability to sense mechanical forces and the structural function of the segment of bone. These fragments are then prey to rapid resorption and virtually disappear, enhancing loss of bone mass. This does not occur in cortical bone.

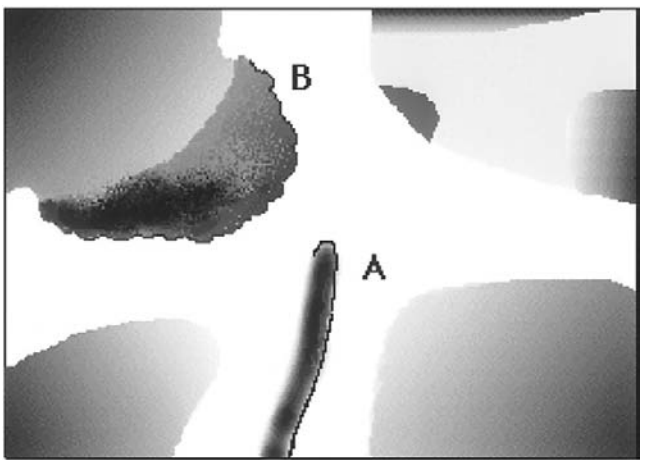

Figure 11 Remodeling on cancellous surfaces showing resorption in the trench (A) or along the surface (B).

Remodeling in Osteoporosis

The Trouble with "Turnover"

Frequently, metabolic bone diseases are described using the term "turnover." The increased use of biochemical markers has resulted in an even greater use of the term, which is often ambiguous or misleading. Turnover is an appropriate description only when both bone formation and bone resorption rates are similar. Thus, "high turnover" is seen in hyperparathyroidism and acute estrogen deficiency; "low turnover" is seen in hypoparathyroidism. In growing children, both bone formation and resorption rates are high, but the bone is not really turning over, it is modeling. In many conditions, the formation rate is different from the resorption rate. For example, in corticosteroid-induced osteoporosis, early pregnancy, or space travel, the bone formation rate is decreased while the bone resorption rate is increased. These situations have been called "low turnover" based on the markers of bone formation; others have called them "high turnover" based on the bone resorption markers. Furthermore, "high turnover" is used frequently as a synonymn for "negative bone balance." This is not always true; e.g., intermittent injections of PTH increase bone formation and resorption but result in a net gain of bone volume.

Biochemical markers in serum and urine correlate to tetracycline-measured bone formation rates and to calcium kineteics determined using radioactive calcium isotopes. These methods show correlations with each other, but the slopes of the regression lines between accretion and biochemical markers change with age (Eastell *et al.,* 1988). The markers also do not always reflect the changes in the bone formation rates with therapy. For example, after treatment with

alendronate, biochemical markers decrease by about 50%, but the tetracycline-based measurements show decreases of 95 to 98% (Chavassieux *et al.,* 1997).

Changes Seen in Osteoporosis

Postmenopausal osteoporosis is a heterogeneous disorder, and several kinds of bone remodeling abnormalities have been described. Menopause itself is associated with an increase in the origination of BMUs, possibly because estrogen deficiency results in increases of interleukin 6 and other cytokines, which are potent factors involved in the proliferation of both osteoclasts and osteoblasts (Manolagas and Jilka, 1995). This alone would not necessarily cause loss of bone mass, but each BMU does not completely replace as much bone as was resorbed. Therefore, if there are more BMUs, there will be greater bone loss. In the cortical bone, more BMUs will result in more cement lines, which can lead to decreased strength of the bone because cement lines are weaker than other bone.

In addition, there may be abnormalities in the BMUs themselves. Menopause causes an increased depth of resorption, perhaps because of a longer osteoclast life span (Eriksen *et al.,* 1999) or decreased osteoclast apoptosis (Kameda *et al.,* 1997) These changes can result in loss of structural integrity as discussed earlier.

With aging, osteoblasts lose their ability to fill the resorbed spaces. This is shown by age-related decreases in the wall thickness (Arlot *et al.,* 1990; Lips and Meunier, 1978; Parfitt *et al.,* 1995). This results in a gradual loss of bone volume and senile osteoporosis. Parfitt *et al.* (1995) have shown that women with postmenopausal osteoporosis have a lower ratio of osteoblastic surface to osteoid surface than normal postmenopausal women. They also have a lower mineral apposition rate (Arlot *et al.,* 1990). These findings can be explained by insufficient numbers of osteoblasts. In addition, the findings suggested that women with osteoporosis had fewer active BMUs than normal postmenopausal women. Scanning electron micrographs of patients with osteoporosis show a high percentage of surface with unmineralized matrix (Jayasinghe *et al.,* 1993), suggesting that formation at these sites is incomplete. This may account for the findings of a low percentage of osteoid that has tetracycline labels (Ott, 1993).

When bone porosity increases, the remaining bone accumulates microdamage at an exponential rate, whereas osteocyte lacunar density decreases (Vashishth *et al.,* 2000). A viscious cycle is begun; bone mass decreases, so the remaining bone is subject to more fatigue damage, which increases bone resorption, which may further weaken the bone and disrupt the osteocyte network.

Corticosteroid-Induced Osteoporosis

The worst case scenario is when increased resorption is combined with decreased formation, which is seen with high doses of corticosteroids. The resorption surfaces are increased and wall thickness is decreased (Dempster, 1989; Dempster *et al.,* 1983). The effect is more prominent in cancellous bone. In addition to an imbalance at each BMU, steroids increase activation frequency, which further enhances bone loss.

Corticosteroids also increase apoptosis of osteocytes. In femoral heads of patients with osteonecrosis of the hip, Weinstein *et al.* (2000) demonstrated many apoptotic cells; thus, the bone was not really necrotic, but was suffering the consequences of apoptosis and the disruption of the osteocyte network. Apoptotic osteoblasts were also seen in rats treated with high doses of glucocorticoids (Silvestrini *et al.,* 2000).

Consequences of Pharmacological Agents That Affect Remodeling

Understanding bone remodeling is important for prediction of the response to therapeutic agents used in osteoporosis. The effects on bone formation, as measured by tetracycline-labeled surfaces on bone biopsies, are shown in Fig. 8. Currently approved therapies (estrogen, bisphosphonates, risedronate, calcitonin) all decrease the bone formation. Most of these drugs inhibit BMU origination or activation, but because they increase bone mass, many physicians believe they promote bone formation. However, antiresorptive drugs eventually inhibit bone formation, although this is not necessarily a direct effect. Bone volume will increase as long as the formation period if the drug blocked activation or as long as the BMU life span if the drug blocked only origination (Fig. 12). Thus, some increase in bone volume could occur for 8 months or even longer if there were inactive formation phases that resumed activity. Eventually a new steady-state bone volume is reached. The total amount of gain in bone mass depends on the remodeling rate, and once the resorption cavities are filled, there can be no further gain in bone volume. The plateau reached could be termed the "remodeling barrier." Any further increases in bone volume would have to occur by nonremodeling mechanisms or by agents that had direct anabolic effects on the osteoblasts.

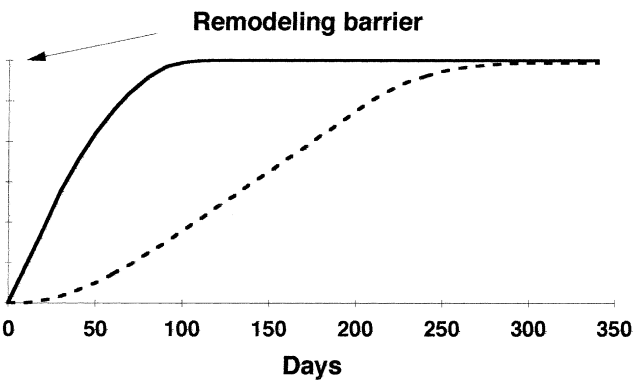

Figure 12 Plot from a computer model of bone loss following a sudden block in origination (dashed line) or activation (solid line), assuming no direct effect on formation.

Bone *density* will increase even after bone *volume* has reached a steady state, as the newly formed bone becomes more mineralized. The duration of mineralization is not precisely known. In a report of 7 years continuous treatment with alendronate, hip bone density measured by dual-energy X-ray absorptiometry rose rapidly during the first 6 months (corresponding to increases in bone volume from refilling resorption cavities), rose more gradually until 36 months (corresponding to increasing mineralization), and did not change significantly thereafter. This suggests that mineralization reaches maximal levels after 3 years (Tonino *et al.,* 2000). At the spine, bone density showed slight increases even during the sixth and seventh years, but arthritic changes and soft tissue calcifications may falsely increase the spine measurements.

Bisphosphonates have been reported to affect various steps of the remodeling process (Parfitt *et al.,* 1996). They could affect lining cells, inhibit IL-6 production, affect osteoclast action directly, or promote early apoposis. Aminobisphosphonates inhibit an enzyme in the cholesterol synthesis pathway resulting in low levels of geranylgeranyl diphosphate. This results in inhibition of rho21, a GTP-binding protein, which results in an inability of osteoclasts to form ruffled borders. Thus, osteoclastic resorption is directly inhibited. With no prior resorption to signal osteoblasts, there is a secondary inhibition of bone formation. The histology of human subjects treated with these agents documents very low tetracycline-labeled bone formation rates and decreased activation frequency (Ott *et al.,* 1994)(Chavassieux *et al.,* 1997). Backscattered electron images demonstrate higher mineralization levels with alendronate treatment (Roschger *et al.,* 1997). Some studies have found increased wall thickness, leading to speculation that bisphosphonates can increase bone formation in the few remaining BMUs (Balena *et al.,* 1993). It is not clear, however, that walls with increased thickness represent those formed at the time of measurement.

With inhibition of origination or of activation, the initial gain in bone volume will increase bone strength, which appears to be the predominant effect of many pharmacological agents. Furthermore, the decrease in bone resorption will prevent some of the architectural deterioration that would have occurred without therapy. Clinical studies of up to 3 years duration in women with established osteoporosis have shown significant reductions in fracture rates in those treated with bisphosphonates compared to those treated with placebo (Black *et al.,* 1996; McClung *et al.,* 2001.)

Newer bisphosphonates are deposited in bone with a half-life of greater than 10 years (Gertz *et al.,* 1993) so the drugs will accumulate with continuing use. There has been concern that long-term 95% suppression of bone formation could result in adverse effects on bone strength due to a failure to repair microdamage or to increased brittleness from hypermineralized bone (Boyce and Bloemaum, 1993). Beagles were treated with high doses of risedronate or alendronate for a year, resulting in suppressed bone formation rates and increased microdamage accumulation. Biomechanical studies showed no significant effect on bone strength, but there was reduced toughness of the ribs (Mashiba *et al.,* 2000). It is not yet clear if prolonged use of usual doses of these drugs will reduce bone strength. A 7-year study of continuous alendronate has been reported (Tonino *et al.,* 2000), but the fracture rates during years 6 and 7 were not reported using the same criteria as during the first 3 years. Investigations on the long-term safety of potent inhibitors of bone formation are needed, especially since they are prescribed to women in their 50's for the prevention of osteoporotic fractures, which are not expected to occur for at least 15 years.

Estrogen also decreases activation frequency, which is consistent with the theory that estrogen prevents increased IL-6 production. The decrease in bone formation rate is not as great as with aminobisphosphonates. (Steiniche *et al.,* 1989). Raloxifene also decreases bone formation, similar to estrogen (Ott *et al.,* 2000).

Calcitonin acts directly on osteoclasts, and bone biopsies from patients treated with the drug show no effects on bone formation rate or activation frequencies (Thamsborg *et al.,* 1996).

Parathyroid hormone (1-34) has been investigated in clinical trials but is not available for clinical use. Daily injections result in large increases of bone density. Bone histomorphometric studies document increased bone resorption and bone formation rates. The bone volume does not increase, and trabecular architecture does not show reconnection. Wall thickness is increased, suggesting an anabolic effect. Of interest, increases in the bone formation rate are largely due to increases in the mineral apposition rate, with only modest increases in the percentage of surface undergoing mineralization. (Hodsman *et al.,* 2000).

Fluoride treatment appears to bypass the remodelling system, causing markedly enhanced bone formation without previous bone resorption (Balena *et al.,* 1998). This is discussed further in the next section.

Other Mechanisms of Altering Bone Structure

Microcallus Formation

Hahn *et al.* (1995) carefully examined sections of human spine from normal men and women and from patients with osteoporosis. They observed that microcallus formations in spine sections increase after age 50. There are more in females than in males and even more in osteoporotic persons. These are mostly seen in the lower thoracic and lumbar spine near the end plates. They are found in only 1.4% of iliac crest biopsies. In those with osteoporosis, the number of microcallus formations correlates with the trabecular bone pattern factor, which measures intertrabecular connection ($r = 0.75$) and trabecular thickness ($r = 0.45$) but not bone volume or age.

Microcallus formations can allow formation of new trabeculae by forming bridges between existing trabecula. These formations can account for up to 10% of the trabecular bone volume. They undergo resorption and modeling,

eventually becoming mineralized and indistinguishable from trabecular bone. Hansson and Roos (1981) also described microcallus formation in the spine, which increased as bone mineral content decreased. This mechanism of altering trabecular structure could be relatively important in patients with osteoporosis.

Back-scattered electron images also show microcallus formation. These are less well mineralized than normal bone, and a gap remains between the microcallus and the original trabecular bone (Boyce, 1993)

Direct Activation

Bone formation also can, in some situations, take place along surfaces in the absence of previous resorption. With fluoride therapy, bone formation surfaces increase markedly, but the bone is woven and not normal lamellar bone (Kleerekoper and Balena, 1991). After 5 years of fluoride, there is little residual woven bone, but mineralization defects are seen despite calcium and vitamin D treatment; the wall thickness is greater than the resorption depth, and the formation period is prolonged (Eriksen *et al.,* 1985). Beagles treated with aluminum show new bone formation in some, but not all, experimental conditions (Galceran *et al.,* 1987; Quarles *et al.,* 1988), but this phenomenon is not seen in humans, who develop osteomalacia when exposed to parenteral aluminum (Ott *et al.,* 1983).

Bone Arising from Marrow Spaces

Metastatic prostate cancer causes several types of bone lesions. Unlike most metastatic lesions, which are osteolytic, prostate cancer can form blastic lesions. In some areas that have prostate cancer cells in the marrow, spindle-shaped cells in the marrow spaces are adjacent to extracellular tissue, which shows early mineralization. In other areas, woven bone is found inside the marrow spaces, suggesting progression. Osteosclerotic lesions appear to be the end result of this process (Roudier *et al.,* 2000).

Woven versus Remodeled Bone

Woven bone, seen in response to injury, may be an important adaptation, which may involve positive feedback loops with osteoblasts stimulating further osteoblast action (Turner, 1992). Severe repetitive stress on cortical bone can lead to rapid increases in bone formation that cannot be accounted for by the remodeling process. Animal studies of increased load frequency show that the periosteal surface makes new woven bone (Burr *et al.,* 1989; Lanyon, 1989). If the loads are placed so that the endosteal surface is not bent, then there will be periosteal new woven bone without a change in endosteal surfaces (Turner and Forsood, 1995). Studies in military recruits have documented a 7.5% increase in tibial bone mineral density after only 4 months. This was probably also woven bone on the periosteum because the tibial cross-sectional area also increases. Of interest, these same recruits showed a decreased vertebral bone mass, which suggests that the trabecular bone was subject to increased origination and developed an excessive resorption space. After 2 years the vertebral bone density was slightly (nonsignificantly) higher than at baseline (Casez *et al.,* 1995).

The periosteal surfaces of cortical bone can form without previous resorption, and this process may occur throughout life. Boyce *et al.* (1993) observed a zone of hypermineralized bone on the periosteal surface of femoral bone from aged humans. This zone does not have osteonal remodeling, which suggests that it was woven bone that had become highly mineralized. Because this phenomenon was seen only in older subjects who also had decreased cortical thickness, one can speculate that the weakened osteoporotic bone results in excess mechanical stress on these cortical surfaces. Perhaps aged bone can no longer rely on remodeling to increase bone mass and must resort to a secondary method of forming woven bone in calluses and on the periosteum.

CHAPTER 20

Phosphorus Homeostasis and Related Disorders

Marc K. Drezner

Department of Medicine, Section of Endocrinology, Diabetes, and Metabolism, University of Wisconsin, Madison, Wisconsin 53792

Phosphorus plays an important role in cellular physiology and skeletal mineralization, serving as a constituent of nucleic acids and hydroxyapatite, a source of the high-energy phosphate in adenosine triphosphate, an essential element of the phospholipids in cell membranes, and a factor influencing a variety of enzymatic reactions (e.g., glycolysis) and protein functions (e.g., the oxygen-carrying capacity of hemoglobin by regulation of 2,3-diphosphoglycerate synthesis). Indeed, phosphorus is one of the most abundant components of all tissues, and disturbances in phosphate homeostasis can affect almost any organ system. Most phosphorus within the body is in bone (600–700 g), while the remainder is largely distributed in soft tissue (100–200 g). As a consequence, less than 1% of the total is in extracellular fluids. The plasma contains about 12 mg/dl of phosphorus, of which approximately 8 mg is organic and contained in phospholipids, a trace is an anion of pyrophosphoric acid, and the remainder is inorganic phosphate (P_i) (Yanagawa *et al.,* 1994). Inorganic phosphate is present in the circulation as monohyrogen phosphate, which is divalent, and dihydrogen phosphate, which is monovalent. At normal pH, the relative concentrations of monohydrogen and dihydrogen phosphate are 4:1.

The critical role that phosphorus plays in cell physiology has resulted in the development of elaborate mechanisms designed to maintain phosphate balance. These adaptive changes are manifest by a constellation of measurable responses, the severity of which is modified by the difference between metabolic P_i need and exogenous P_i supply. Such regulation maintains plasma and extracellular fluid phosphorus within a relatively narrow range and depends primarily on gastrointestinal absorption and renal excretion as mechanisms to affect homeostasis. Although investigators have recognized a variety of hormones that influence these various processes, in concert with associated changes in other metabolic pathways, the sensory system, the messenger, and the mechanisms underlying discriminant regulation of P_i balance remain incompletely understood.

While long-term changes in phosphate balance depend on these variables, short-term changes in phosphate concentrations can occur due to redistribution of phosphate between the extracellular fluid and either bone or cell constituents. Such redistribution results secondary to various mechanisms, including elevated levels of insulin and/or glucose; increased concentrations of circulating catecholamines; respiratory alkalosis; enhanced cell production or anabolism; and rapid bone remineralization. In many of these circumstances, hypophosphatemia manifests in the absence of phosphorus depletion or deprivation.

Regulation of Phosphate Homeostasis

Phosphate is sufficiently abundant in natural foods that phosphate deficiency is unlikely to develop except under conditions of extreme starvation, as a consequence of administration of phosphate binders, or secondary to renal phosphate wasting. Indeed, the major proportion of ingested phosphate is absorbed in the small intestine, and hormonal regulation of this process plays only a minor role in normal phosphate homeostasis. In contrast, absorbed phosphate, in response to complex regulatory mechanisms, is eliminated by the kidney, incorporated into organic forms in proliferating cells, or deposited as a component of bone mineral (hydroxyapatite). The vast majority of the absorbed phosphate, however, is excreted in the urine. Thus, under

usual conditions, phosphate homeostasis depends for the most part on the renal mechanisms that regulate tubular phosphate transport. Alternatively, during times of severe phosphate deprivation, the phosphate contained in bone mineral provides a source of phosphate for the metabolic needs of the organism. The specific role that the intestine and kidney play in this complex process is discussed below.

Gastrointestinal Absorption of Phosphorus

The average dietary phosphate intake in humans, derived largely from dairy products, meat, and cereals, is 800 to 1600 mg/day, one and one-half to threefold greater than the estimated minimum requirement. This phosphate is in both organic and inorganic forms, but the organic forms, except for phytates, are degraded in the intestinal lumen to inorganic phosphate, which is the form absorbed. Absorption occurs throughout the small intestine with transport greatest in the jejunum and ileum and less in the duodenum. Essentially no absorption occurs in the colon (Walling, 1977).

In normal subjects, net P absorption is a linear function of dietary P intake. Indeed, for a dietary P range of 4 to 30 mg/kg/day, the net P absorption averages 60 to 65% of the intake (Lee *et al.,* 1986). Intestinal P absorption occurs via two routes: a cellularly mediated active transport mechanism and diffusional flux, largely through a paracellular shunt pathway (Cross *et al.,* 1990). Active P transport requires entry of P across the luminal membrane of the intestinal cells, a process mediated by a vitamin D- and Na^+-dependent mechanism. The effects of $1,25(OH)_2D$ on this process are modulated by the calcitriol-induced transcription of messenger RNA. In this regard, much work has variably identified several vitamin D responsive Na^+-dependent phosphate cotransporters in intestinal brush border membranes, which have a high affinity for P binding (Debiec and Lorenc, 1988; Katai *et al.,* 1999; Hilfiker *et al.,* 1998; Bai *et al.,* 2000). Phosphate incorporated into intestinal cells by this mechanism is ferried from the apical pole to the basolateral pole likely through restricted channels such as microtubules. At the basolateral membrane, phosphate is released from intestinal cells by a passive mechanism, which is carrier mediated and occurs in accord with the electrochemical gradient. Although such active transport systems are responsive to 25(OH)D and $1,25(OH)_2D$ (Lee *et al.,* 1986; Rizzoli *et al.,* 1977), these hormones and systems play a relatively minor role in normal phosphate homeostasis. Indeed, during vitamin D deficiency, the percentage of P absorbed from the diet is reduced by only 15%. Moreover, a substantial portion of this decline is secondary to the failure to absorb calcium, which results from vitamin D deficiency and the resultant formation of calcium phosphate that reduces the free phosphate concentration.

The vast majority of phosphate absorption occurs via the process of diffusional absorption. This results as a consequence of the relatively low K_m of the active transport process (2 m*M*) and the luminal P content during feeding, which generally exceeds 5 m*M* throughout the intestine and the occurrence of net diffusional absorption of P whenever luminal P concentration exceeds 1.8 m*M* (a concentration generally exceeded even when fasting) (Karr and Abbott, 1935; Walton and Gray, 1979; Wilkinson, 1976). Given these conditions, the active component of transport becomes important only under unusual circumstances, such as when dietary P is extremely low. Under these conditions, studies suggest that an activator protein for sodium-dependent phosphate transport (P_iUS) and the type III Na/P_i cotransporter P_iT-2 may be important components in the regulation of the intestinal phosphate transport system (Katai *et al.,* 1999). Regardless, the bulk of intestinal P absorption is mediated by a diffusional process, presumably through the paracellular space, and therefore is primarily a function of P intake. Because most diets contain an abundance of P, the quantity of phosphate absorbed always exceeds the need both under normal circumstances and disease states such as uremia. Thus, active, transcellular P absorption becomes predominant only under conditions of low luminal P availability, such as dietary P deprivation and/or excessive luminal P binding (Lee *et al.,* 1979; Kurnik and Hruska, 1984). Factors that may influence the diffusional process adversely are the formation of nonabsorbable calcium, aluminum, or magnesium phosphate salts in the intestine and age, which reduces P absorption by as much as 50%.

Renal Excretion of Phosphorus

The kidney is immediately responsive to changes in serum levels or dietary intake of phosphate. Renal adaptation is determined by the balance between the rates of glomerular filtration and tubular reabsorption (Mizgala and Quamme, 1985).

The concentration of phosphate in the glomerular ultrafiltrate is approximately 90% of that in plasma because not all of the phosphate in plasma is ultrafilterable (Harris *et al.,* 1977). Nondiffusable phosphorus includes plasma P that is protein bound and a small fraction of plasma P that complexes with calcium and magnesium. With increasing serum calcium levels, the calcium–phosphate–protein colloid complex increases, reducing the ultrafilterable plasma P to as little as 75% (Rasmussen and Tenenhouse, 1995). Because the product of the serum phosphorus concentration and the glomerular filtration rate (GFR) approximates the filtered load of phosphate, a change in the GFR may influence phosphate homeostasis if uncompensated by commensurate changes in tubular reabsorption.

Normally, 80 to 90% of the filtered phosphate load is reabsorbed, primarily in proximal tubules, with higher rates at early segments (S_1/S_2 vs S_3) and in deep nephrons (Agus, 1983; Cheng and Jacktor, 1981; Dousa and Kempson, 1982; Suki and Rouse, 1996). The transcellular transport of phosphate is a carrier-mediated, saturable process limited by a transfer maximum or T_{max}. The T_{max} varies considerably as dietary phosphorus changes, and the best method to

approximate this variable is to measure maximum phosphate reabsorption per unit volume of glomerular filtrate (T_mP/GFR) during acute phosphate infusions. Alternatively, the nomogram developed by Bijvoet allows estimation of the T_mP/GFR with measurement of phosphate and creatinine excretion and plasma phosphate concentration (Walton and Bijvoet, 1975).

The major site of phosphate reabsorption is the proximal convoluted tubule, at which 60 to 70% of reabsorption occurs (Fig. 1). Along the proximal convoluted tubule the transport is heterogeneous. In the most proximal portions, the S_1 segment, phosphate reabsorption exceeds that of sodium and water, whereas, more distally, phosphate reabsorption parallels that of fluid and sodium. Additional reabsorption in the proximal straight tubule accounts for 15–20% of phosphate reclamation. In contrast, there is little evidence to suggest net P transport in the thin and thick ascending loops of Henle. However, increasing, but not conclusive, data support the existence of a P reabsorptive mechanism in the distal tubule. Currently, however, definitive proof for tubular secretion of phosphate in humans is lacking (Knox and Haramati, 1981).

	Phosphate Reabsorption	PTH Sensitive Adenylate Cyclase	PTH Inhibited Phosphate Reabsorption	Calcitonin Sensitive Adenylate Cyclase	Calcitonin Inhibited Phosphate Reabsorption
PCT	60–70%	++	++	–	++
PST	15–20%	++	++	–	++
DCT	5–10%	++	++	++	–
CAL	0%	++	–	++	–
MAL	0%	–	–	++	–

Figure 1 Model of the renal tubule and distribution of phosphate reabsorption and hormone-dependent adenylate cyclase activity throughout the structure. The renal tubule consists of a proximal convoluted tubule (PCT), composed of an S_1 and S_2 segment, a proximal straight tubule (PST), also known as the S_3 segment, the loop of Henle, the medullary ascending limb (MAL), the cortical ascending limb (CAL), the distal convoluted tubule (DCT), and three segments of the collecting tubule: the cortical collecting tubule (CCT), the outer medullary collecting tubule (OMCT), and the inner medullary collecting tubule (IMCT). Phosphate reabsorption occurs primarily in the PCT but is maintained in the PST and DCT as well. In general, parathyroid hormone (PTH) influences phosphate reabsorption at sites where PTH-dependent adenylate cyclase is localized. In contrast, calcitonin alters phosphate transport at sites distinct from those where calcitonin-dependent adenylate cyclase is present, suggesting that response to this hormone occurs by a distinctly different mechanism.

At all three sites of phosphate reabsorption—the proximal convoluted tubule, proximal straight tubule, and distal tubule—several investigators have mapped PTH-sensitive adenylate cyclase (Fig. 1) (Knox and Haramati, 1981; Morel, 1981). Not surprisingly, there is clear evidence that PTH decreases phosphate reabsorption at these loci by a cAMP-dependent process, as well as a cAMP-independent signaling mechanism. In contrast, calcitonin-sensitive adenylate cyclase maps to the medullary and cortical thick ascending limbs and the distal tubule (Fig. 1) (Berndt and Knox, 1984). Nevertheless, calcitonin inhibits phosphate reabsorption in the proximal convoluted and proximal straight tubule, certainly by a cAMP-independent mechanism that may be mediated by a rise in intracellular calcium (Murer *et al.,* 2000). An action of calcitonin on the distal tubule is uncertain, despite the abundant calcitonin-sensitive adenylate cyclase.

MECHANISM OF PHOSPHATE TRANSPORT

The most detailed studies of the cellular events involved in P movement from the luminal fluid to the peritubular capillary blood have been performed in proximal tubules and cultured cells derived from them. These investigations indicate that P reabsorption occurs principally by a unidirectional process that proceeds transcellularly with minimal intercellular backflux from the plasma to the lumen. Entry of phosphate into the tubular cell across the luminal membrane proceeds by way of a saturable active transport system that is sodium dependent (analogous to the sodium-dependent cotransport in the intestine) (Fig. 2). With each phosphate transported, two Na^+ ions enter the proximal tubule cell. Because transport of HPO_4^{2-} is electroneutral and $H_2PO_4^-$ electrogenic, the rate of phosphate transport is dependent on the magnitude of the Na^+ gradient maintained across the luminal membrane, which depends on the Na^+/ATPase or sodium pump on the basolateral membrane. Further, the rate-limiting step in transcellular transport is likely the Na^+-dependent entry of phosphate across the luminal membrane, a process with a low K_m for luminal phosphate (~0.43 M), which permits highly efficient phosphate transport. However, several studies in proximal convoluted tubules from various species indicate that there are two such Na^+-dependent phosphate transport systems: one of low affinity and high capacity, responsible for the majority of phosphate reabsorption, and a high-affinity, low-capacity system, accountable for the remainder (Brunette *et al.,* 1984). In contrast, a single high-affinity system operates in the proximal straight tubule.

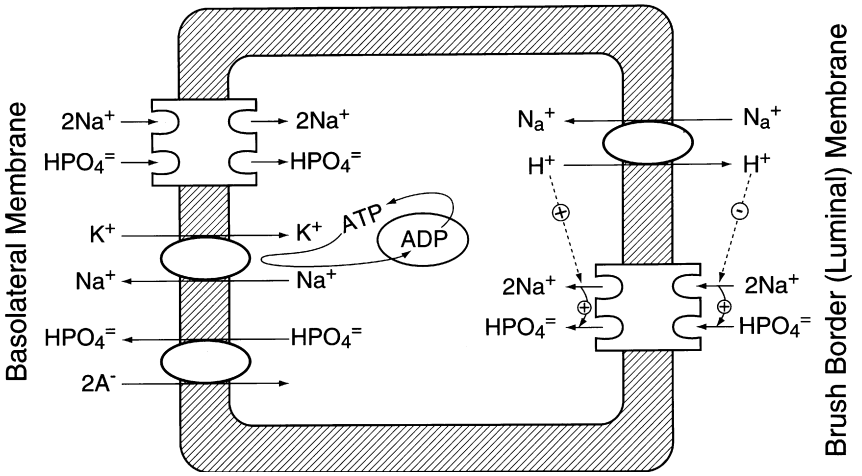

Figure 2 Model of inorganic phosphate ($HPO_4^=$) transcellular transport in the proximal convoluted tubule of the mammalian kidney. On the brush border or luminal membrane, a Na^+/H^+ exchanger and a $2Na/HPO_4^=$ cotransporter operate. $HPO_4^=$ that enters the cell across the luminal surface mixes with the intracellular metabolic pool of phosphate and is eventually transported out of the cell across the basolateral membrane via an anion (A-) exchange mechanism. On the basolateral membrane there is also a $2Na/HPO_4^=$ cotransporter and a Na^+/K^+-ATPase system. The ATPase transports the Na^+ out of the cell, maintaining the Na^+ gradient-driving force for luminal phosphate entry.

The phosphate that enters the tubule cell plays a major role in governing various aspects of cell metabolism and function and is in rapid exchange with intracellular phosphate. Under these conditions, the relatively stable-free P_i concentration in the cytosol implies that P_i entry into the cell across the brush border membrane must be tightly coupled with its exit across the basolateral membrane (Fig. 2). The transport of phosphate across the basolateral membrane is apparently a passive process driven by an electrical gradient secondary to an anion-exchange mechanism. However, several P_i transport pathways have been postulated, including Na^+-P_i cotransport and an unspecific P_i leak, as well as anion exchange. In any case, basolateral P_i transport serves at least two functions: (1) complete transcellular P_i reabsorption when luminal P_i entry exceeds the cellular P_i requirments and (2) guaranteed basolateral P_i influx if apical P_i entry is insufficient to satisfy cellular requirements (Schwab *et al.,* 1984).

Until recently there was very little information about the molecular structure of the phosphate transporters. However, the cellular scheme for proximal tubular P_i reabsorption currently includes three Na^+-P_i cotransporters (Helps *et al.,* 1995; Verri *et al.,* 1995; Sorribas *et al.,* 1994; Werner *et al.,* 1994; Magagnin *et al.,* 1993), which have been identified molecularly and named type I, type II, and type III Na^+-P_i cotransporters. The three families of Na^+-P_i cotransporters share no significant homology in their primary amino acid sequence and exhibit substantial variability in substrate affinity, pH dependence, and tissue expression (Table I). Tissue expression, relative renal abundance, and overall transport characteristics of type I, II (IIa), and III $Na-P_i$ cotransporters suggest that the type IIa transporter plays a key role in brush border membrane P_i flux. Indeed, changes in expression of the type IIa Na^+-P_i cotransporter protein parallel alterations in proximal tubular P_i handling, documenting its physiological imporance (Murer *et al.,* 1998, 1999). In addition, molecular and/or genetic suppression of the type IIa Na^+-P_i cotransporter support its role in mediating brush border membrane Na^+-P_i cotransport. Thus, intravenous injection of specific antisense oligonucleotides reduces brush border membrane Na^+-P_i cotransport activity in accord with a decrease in type IIa cotransporter protein (Oberbauer *et al.,* 1996). In addition, disruption of the type IIa Na^+-P_i cotransporter gene (*Npt2*) in mice leads to a 70% reduction in brush border Na^+-P_i cotransport rate and complete loss of the protein (Beck *et al.,* 1998; Hoag *et al.,* 1999). Although the molecular basis for the brush border membrane Na^+-P_i cotransport remaining after *Npt2* gene disruption is unclear, residual transport activity may depend on the type I transporter protein or another yet unidentified Na^+-P_i cotransporter.

HORMONAL/METABOLIC REGULATION OF PHOSPHATE TRANSPORT

Several hormones and metabolic pertubations modulate phosphate reabsorption by the kidney. Among these, PTH, PTHrP, calcitonin, transforming growth factor-α (TGFα), glucocorticoids, and phosphate loading inhibit renal phosphate reclamation. In contrast, IGF-1, insulin, thyroid hormone, $1,25(OH)_2D$, epidermal growth factor (EGF), and phosphate deprivation (depletion) stimulate renal phosphate

Table I Characteristics of Na–P_i Cotransporters

	Type I	Type II		Type III
		Type IIa	Type IIb	
Chromosomal location (human)	6	5	4	2 (P_iT-1) 8 (P_iT-2)

reabsorption. The diversity of these factors indicates that the mechanisms by which modulation of phosphate transport occurs are widely varied. However, the common target for regulation is the renal proximal tubular cell.

Insight to the molecular mechanisms that regulate phosphate transport has resulted predominantly from studies of PTH effects on this physiological process. These investigations indicate that both the cAMP–protein kinase A and the phospholipase C–protein kinase C signal transduction pathways modulate proximal tubule phosphate transport. In this regard, PTH-mediated inhibition of phosphate reabsorption operates through the protein kinase C system at low hormone concentrations (10^{-8} to 10^{-10} *M*) and via protein kinase A at higher concentrations. Consistent with this hypothesis is the demonstration that the pattern of apical membrane protein phosphorylation in response to PMA, an activator of protein kinase C, resembles that obtained with low concentrations of PTH, whereas the phosphorylation pattern in response to 8-bromo-cAMP resembles that obtained with high concentrations of PTH. More recently, the mechanism by which these second messenger systems alter phosphate transport has become apparent. In this regard, several investigators have shown that endocytosis and subsequent lysosomal degradation of the phosphate transporters is central to PTH effects on phosphate reabsorption. Thus, interference with the endocytotic pathway, either by the microtubule-disrupting agent colchicine or high-medium osmolarity, reduces PTH inhibition of phosphate transport in OK cells. Further, recovery of Na^+–P_i cotransport activity following PTH inhibition requires protein synthesis, consistent with degradation of the receptors. In any case, the reputed PTH effect on membrane recycling is consistent with the change in the V_{max} for P transport observed secondary to hormonal stimulation. In concert with these findings, studies indicate that expression of the NPT-2 protein at renal tubular sites is increased in parathyroidectomized rats and decreased after PTH treatment. In addition, Northern blot analysis of total RNA shows that the abundance of NPT-2-specific mRNA is not changed by parathyroidectomy, but is decreased minimally in response to the administration of parathyroid hormone. These data indicate that parathyroid hormone regulation of renal Na^+–P_i cotransport is determined by changes in expression of NPT-2 protein in the renal brush border membrane (Kempson *et al.,* 1995).

Although it is generally accepted that PTH is the most important physiologic influence on renal P excretion and is the major determinant of plasma P concentrations through its effect on T_mP/GFR, there is no compelling evidence supporting the importance of this hormone in overall P balance. Indeed, repeated observations have confirmed that the balance between urinary excretion and dietary input of P is maintained not only in normal humans but in patients with hyper- and hypoparathyroidism. In fact, the renal tubule has a seemingly intrinsic ability to adjust the reabsorption rate of P according to dietary P_i intake and the need and availability of P to the body (Levi *et al.,* 1994). Thus P reabsorption is increased under conditions of greater P need, such as rapid growth, pregnancy, lactation, and dietary restriction. Conversely, in times of surfeit, such as slow growth, chronic renal failure, or dietary excess, renal P reabsorption is curtailed. This adaptive response is localized in the proximal convoluted tubule and involves an alteration in the apparent V_{max} of both the high-capacity, low-affinity and the low-capacity, high-affinity Na^+–phosphate cotransport systems independent of any change in affinity. Such changes in response to chronic changes in P_i availability are characterized by parallel changes in Na^+–phosphate

cotransport activity, the NPT-2 mRNA level, and NPT-2 protein abundance. In contrast, the acute adaptation to altered dietary P is marked by parallel changes in Na^+–phosphate cotransporter activity and NPT-2 protein abundance in the absence of a change in NPT-2 mRNA. Thus, in response to chronic conditions, protein synthesis is requisite in the adaptive response, whereas under acute conditions, the number of NPT-2 cotransporters is changed rapidly by mechanisms independent of *de novo* protein synthesis, such as insertion of existing transporters into the apical membrane or internalization of existing transporters.

Although the signal for the adaptive alteration in phosphate transport is not yet known, several possibilities are evident. Studies using MRI spectroscopy indicate a reciprocal relationship between intracellular phosphate concentration and brush border membrane phosphate transport, suggesting that cytosolic phosphate may serve as an important cellular signal mediating the transport response. Alternatively, experiments in OK cell monolayers suggest that apical Na^+-dependent phosphate influx may also play a role in triggering the adaptive response to altered extracellular phosphate. In this regard, depletion of P_i at the apical site is sufficient to provoke an adaptive increase of the apical $Na-P_i$ cotransport rate, whereas removal of P_i only from the basolateral cell surface is without effect. Thus, there is the possibility of a P_i-sensing mechanism at the apical surface or the rate of P_i entry at the apical cell surface contributes to P_i sensing. In addition, alterations in cytosolic Ca^{2+} concentrations may be part of the P_i-sensing mechanism.

Clinical Disorders of Phosphate Homeostasis

The variety of diseases, therapeutic agents, and physiological states that affect phosphate homeostasis are numerous and reflect a diverse pathophysiology. Indeed, rational choice of an appropriate treatment for many of these disorders depends on determining the precise cause for the abnormality. The remainder of this chapter discusses several clinical states that represent primary disorders of phosphate homeostasis. These include X-linked hypophosphatemic rickets/osteomalacia (XLH); autosomal-dominant hypophosphatemic rickets (ADHR); tumor-induced osteomalacia (TIO); hereditary hypophosphatemic rickets with hypercalciuria (HHRH); Dent's disease; Fanconi's syndrome (FS), types I and II; and tumoral calcinosis (TC). Table II documents the full spectrum of diseases in which disordered phosphate homeostasis occurs. Many of these are discussed in other chapters.

Table II Diseases of Disordered Phosphate Homeostasis

- Increased phosphate
  - Reduced renal phosphate excretion
    - Renal failure
    - Hypoparathyroidism
    - Tumoral calcinosis[a]
    - Hyperthyroidism
    - Acromegaly
    - Diphosphonate therapy
  - Increased phosphate load
    - Vitamin D intoxication
    - Rhabdomyolysis
    - Cytotoxic therapy
    - Malignant hyperthermia
- Decreased phosphate
  - Decreased gastrointestinal absorption
    - Phosphate deprivation[a]
    - Gastrointestinal malabsorption
  - Increased renal phosphate excretion
    - Hyperparathyroidism
    - X-linked hypophosphatemic rickets/osteomalacia[a]
    - Fanconi's syndrome, type I[a]
      - Familial idiopathic
      - Cystinosis (Lignac–Fanconi disease)
      - Hereditary fructose intolerance
      - Tyrosinemia
      - Galactosemia
      - Glycogen storage disease
      - Wilson's disease
      - Lowe's syndrome
    - Fanconi's syndrome, type II[a]
    - Vitamin D-dependent rickets
    - Autosomal-dominant hypophosphatemic rickets[a]
    - Dent's disease (X-linked recessive hypophosphatemic rickets)[a]
    - Tumor-induced osteomalacia[a]
    - Hereditary hypophosphatemic rickets with hypercalciuria[a]
  - Transcellular shift
    - Alkalosis
    - Glucose administration
  - Combined mechanisms

    - Burns
    - Nutritional recovery syndrome
    - Diabetic ketoacidosis

[a]Primary disturbance of phosphate homeostasis.

Impaired Renal Tubular Phosphate Reabsorption

X-Linked Hypophosphatemic Rickets

X-linked hypophosphatemic rickets/osteomalacia is the archetypal phosphate-wasting disorder, characterized in general by progressively severe skeletal abnormalities and growth retardation. The syndrome occurs as an X-linked dominant disorder with complete penetrance of a renal tubular abnormality resulting in phosphate wasting and consequent hypophosphaemia (Table III). The clinical expression of the disease is widely variable even in members of the same family, ranging from a mild abnormality, the apparent isolated occurrence of hypophosphatemia, to severe bone disease (Lobaugh *et al.,* 1984). On average, disease severity is similar in males and females, indicating minimal, if any, gene dosage effect (Whyte *et al.,* 1996). The most common clinically evident manifestation is short stature. This height deficiency is a consequence of abnormal lower extremity growth, averaging 15% below normal. In contrast, upper segment growth is not affected. The

majority of children with the disease exhibit enlargement of the wrists and/or knees secondary to rickets, as well as bowing of the lower extremeties. Additional signs of the disease may include late dentition, tooth abscesses secondary to poor mineralization of the interglobular dentine, enthesopathy (calcification of tendons, ligaments, and joint capsules), and premature cranial synostosis. However, many of these features may not become apparent until age 6 to 12 months or older (Harrison *et al.,* 1966). Despite marked variability in the clinical presentation, bone biopsies in affected children and adults invariably reveal osteomalacia, the severity of which has no relationship to sex, the extent of the biochemical abnormalities, or the severity of the clinical disability. In untreated youths and adults, serum 25(OH)D levels are normal and the concentration of $1,25(OH)_2D$ is in the low-normal range (Haddad *et al.,* 1973; Lyles *et al.,* 1982). The paradoxical occurrence of hypophosphatemia and normal serum calcitriol levels is due to the aberrant regulation of renal 25(OH)D-1 α-hydroxylase activity due most likely to abnormal phosphate transport. Indeed, studies in *hyp*-mice, the murine homologue of the human disease, have established that defective regulation is confined to enzyme localized in the proximal convoluted tubule, the site of the abnormal phosphate transport (Lobaugh and Drezner, 1983; Nesbitt *et al.,* 1986, 1987; Nesbitt and Drezner, 1990).

Pathophysiology Investigators generally agree that the primary inborn error in XLH results in an expressed abnormality of the renal proximal tubule that impairs P_i reabsorption. This defect has been indirectly identified in affected patients and directly demonstrated in the brush border membranes of the proximal nephron in *hyp*-mice. Until recently, whether this renal abnormality is primary or secondary to the elaboration of a humoral factor has been controversial. In this regard, demonstration that renal tubule cells from *hyp*-mice maintained in primary culture exhibit a persistent defect in renal P_i transport (Bell *et al.,* 1988; Dobre *et al.,* 1990), likely due to decreased expression of the Na^+–phosphate cotransporter (NPT-2) mRNA and immunoreactive protein (Tenenhouse *et al.,* 1994, 1995; Collins and Ghishan, 1994), supported the presence of a primary renal abnormality. In contrast, transfer of the defect in renal P_i transport to normal and/or parathyroidectomized normal mice parabiosed to *hyp*-mice implicated a humoral factor in the pathogenesis of the disease (Meyer *et al.,* 1989a,b). Current studies, however, have provided compelling evidence that the defect in renal P_i transport in XLH is secondary to the effects of a circulating hormone or metabolic factor. In this regard, immortalized cell cultures from the renal tubules of *hyp*-mice exhibit normal Na^+–phosphate transport, suggesting that the paradoxical effects observed in primary cultures may represent the effects of impressed memory and not an intrinsic abnormality (Nesbitt *et al.,* 1995, 1996). Moreover, the report that cross-transplantation of kidneys in normal and *hyp*-mice results in neither transfer of the mutant phenotype nor its correction unequivocally established the humoral basis for XLH (Nesbitt *et al.,* 1992). Subsequent efforts, which resulted in localization of the gene encoding the Na^+–phosphate cotransportor to chromosome 5, further substantiated the conclusion that the renal defect in brush border membrane phosphate transport is not intrinsic to the kidney (Kos *et al.,* 1994). While these data establish the presence of a humoral abnormality in XLH, the identity of the putative factor, the spectrum of its activity, and the cells producing it have not been definitively elucidated. Indeed, to date, such a hormone has not been isolated or cloned, but several groups have measured phosphaturic and bone mineralization inhibitory activity in the serum and conditioned medium from osteoblasts of affected patients and/or

hyp-mice (Xiao *et al.,* 1998; Lajeunesse *et al.,* 1996; Nesbitt *et al.,* 1999). Moreover, several investigators have identified the presence and partially characterized phosphaturic factors (inhibitors of Na^+–dependent phosphate transport) in patients with tumor-induced osteomalacia (see later) (Cai *et al.,* 1994; Wilkins *et al.,* 1995) and in patients with end-stage renal disease (Kumar *et al.,* 1995). Whether any one of these factors is increased in patients with XLH remains unknown. Regardless, additional investigation is essential to fully understand the precise physiologic derangement underlying this X-linked hypophosphatemic disorder.

Genetic Defect Efforts to better understand XLH have more recently included attempts to identify with certainty the genetic defect underlying this disease. In 1986, Read and co-workers and Machler and colleagues reported linkage of the DNA probes DXS41 and DXS43, which had been previously mapped to Xp22.31–p21.3, to the *HYP* gene locus. In subsequent studies, Thacker *et al.* (1987) and Albersten *et al.* (1987) reported linkage to the *HYP* locus of additional polymorphic DNA, DXS197, and DXS207 and, using multipoint mapping techniques, determined the most likely order of the markers as Xpter-DXS85-(DXS43/-DXS197)-*HYP*-DXS41-Xcen and Xpter-DXS43-*HYP*-(DXS207/DXS41)-Xcen, respectively. The relatively small number of informative pedigrees available for these studies prevented definitive determination of the genetic map along the Xp22–p21 region of the X chromosome and only allowed identification of flanking markers for the *HYP* locus 20 c*M* apart. More recently, the HYP consortium, in a study of some 20 multigenerational pedigrees, used a positional cloning approach to refine mapping of the Xp22.1–p21 region of the X chromosome, identify tightly linked flanking markers for the *HYP* locus, construct a YAC contig spanning the *HYP* gene region, and eventually clone and identify the disease gene as PHEX, a phosphate-regulating gene with homologies to endopeptidases located on the X chromosome. In brief, these studies ascertained a locus order on Xp22.1 of

Xcen-DXS451-(DXS41/DXS92)-DXS274-DXS1052-DXS1683-*HYP*-DXS7474-DXS365-(DXS443/DXS3424)-DXS257-(GLR/DXS43)-DXS315-Xtel.

Moreover, the physical distance between the flanking markers, DXS1683 and DXS7474, was determined as 350 kb and their location on a single YAC ascertained. Subsequently, a cosmid contig spanning the *HYP* gene region was constructed and efforts were directed at discovery of deletions within the *HYP* region. Identification of several such deletions permitted characterization of cDNA clones that mapped to cosmid fragments in the vicinity of the deletions. Database searches with these cDNAs detected homologies at the peptide level to a family of endopeptidase genes, which includes neutral endopeptidase (NEP), endothelin-converting enzymes 1 and 2 (ECE-1 and ECE-2), soluble secreted endopeptidase (SEP), the "orphan" peptidase X chromosome controlling element (XCE), and the Kell blood group antigen (KELL). These efforts clearly established PHEX as the candidate gene responsible for XLH (Econs *et al.,* 1993, 1994a,b; Francis *et al.,* 1994; Rowe *et al.,* 1996; The Hyp Consortium, 1995), a conclusion confirmed by the partial rescue of the phenotype accomplished by using bone marrow transplantation as a means to replace the defective gene product(s) with the normal gene product(s) (Miyamura *et al.,* 2000).

Subsequent studies found that PHEX is expressed predominantly in bones, teeth, and parathyroid glands; mRNA, protein, or both have also been identified in lung, brain, muscles, and gonads. However, the gene is not expressed in kidney and even in bones and teeth PHEX/Phex is a low-abundance transcript. In addition, since discovery of the PHEX gene, approximately 150 different mutations have been identified in patients with XLH (see *http://data.mch.mcgill.ca/phexdb/*), including deletions, frame shifts, exon splice, missense, and nonsense mutations. However, no genotype/phenotype correlations have been recognized, albeit changes in conserved amino acids more often result in clinical disease than changes in nonconserved amino acids (Filisetti *et al.,* 1999).

Unfortunately, the precise role that this gene and its product play in the regulation of phosphate homeostasis and the pathogenesis of the disease remains unknown. However, because NEP, ECE-1, KELL, and SEP are proteolytic enzymes (Florentin *et al.,* 1984; Koehn *et al.,* 1987), it is likely that the PHEX gene product either activates or degrades a peptide hormone (see later). In any case, cloning the human PHEX gene led relatively rapidly to cloning the mouse Phex gene, which has high homology to its human counterpart. Unlike 97% of other known genes, however, neither the human nor the murine PHEX/Phex gene has a classic Kozak sequence, consisting of a purine at the −3 position before the ATG initiation sequence. This suggests that regulation of PHEX gene expression will occur by posttranscriptional mechanisms, as occurs in genes that do not have such Kozak sequences.

Pathogenesis Despite the remarkable advances that have been made in understanding the genetic abnormality and pathophysiology of XLH, the detailed pathogenetic mechanism underlying this disease remains unknown. Nevertheless, several observations suggest the likely cascade of events that result in the primary abnormalities characteristic of the syndrome. In this regard, the X-linked dominant expression of the disorder with little, if any, gene dosage effect likely results from PHEX mutations that result in an haploinsufficiency defect, in which one-half the normal gene product (or null amounts) causes the phenotype. The alternative possibility that the PHEX gene results in a dominant-negative effect is unlikely because, inconsistent with this prospect, several mutations reported in affected humans (Francis *et al.,* 1997) and the murine *Gy* mutation almost certainly result in the lack of message production (Meyer *et al.,* 1998). In any case, it is tempting to speculate that the PHEX gene product acts directly or

indirectly on a phosphaturic factor that regulates renal phosphate handling. Given available data, the PHEX gene product, a putative cell membrane-bound enzyme, may function normally to inactivate "phosphatonin," a phosphaturic hormone. However, data from parabiotic studies of normal and *hyp*-mice argue strongly that extracellular degradation of the phosphaturic factor does not occur. Indeed, such activity would preclude transfer of the *hyp*-mouse phenotype to parabiosed normals. Alternatively, the PHEX gene product may function intracellularly to inactivate "phosphatonin." In this regard, Jalal *et al.* (1991) reported the internalization of neutral endopeptidase and a potential role for this enzyme in intracellular metabolism. In addition, Thompson *et al.* (2001) reported that the PHEX protein in osteoblasts is found predominantly in the Golgi apparatus and the endoplasmic reticulum. Less likely, the PHEX gene product may enzymatically activate a protein that suppresses production of phosphatonin. While this is consistent with all previous data, it is a complex process and requires the production of PHEX, phosphatonin, and the suppressor protein in the same cell in order to accommodate data from the parabiotic studies. Nevertheless, in accord with this possibility, Mari *et al.* (1992) reported that the neutral endopeptidase on human T cells may be involved in the production of lymphokines through the processing of an activating factor at the surface of the lymphocyte. In any of these cases, a defect in the PHEX gene will result in overproduction and circulation of phosphatonin and consequent decreased expression of the renal Na^+–phosphate cotransportor, *Npt2*, the likely scenario in the pathogenesis of XLH. Although such overproduction of phosphatonin is a favored hypothesis based on available data, including identification and isolation of such factors in patients with tumor-induced osteomalacia and detection of biological activity in conditioned medium from *hyp*-mouse osteoblasts (Xiao *et al.,* 1998; Nesbitt *et al.,* 1999), it is possible that XLH results from the inability of mutant PHEX to activate a phosphate-conserving hormone. However, the only known phosphate-conserving hormone, stanniocalcin, is synthesized in active form within the kidney and has little known bioactivity in humans. These features strongly mitigate against a role for stanniocalcin in the pathogenesis of XLH. Nevertheless, it is evident that further information is requisite to enhance our understanding of the pathogenesis of XLH and, in turn, regulation of phosphate homeostasis. Unfortunately, clarifying the role that the PHEX gene product may play in regulating phosphatonin will not completely unravel the role that PHEX has in the genesis of XLH. Indeed, such information will not discriminate if significant elements of the *hyp*-mouse phenotype, including rickets and osteomalacia and aberrantly regulated renal 25(OH)D-1α-hydroxylase activity, are a direct consequence of renal phosphate wasting and hypophosphatemia or result from a separate PHEX gene-mediated pathway(s) of action. At present, however, preliminary studies suggest that PHEX in osteoblasts does play a key role in the regulation of bone mineralization. Such investigations illustrate that *hyp*-mouse osteoblasts *in vitro* exhibit decreased alkaline phosphatase activity, collagen deposition and reduced osteocalcin, bone sialoprotein, and vitronectin at both protein and mRNA levels. Furthermore, conditioned medium from cultures of these cells induce analogous defects in osteoblasts from normal mice. While these data suggest that alterations in the PHEX gene may control bone mineralization, further investigations are critical to understanding the pathogenesis of XLH and the regulation of phosphate and mineral homeostasis, as well as vitamin D metabolism. Such investigations may have significant impact on the determination of optimal treatment strategies for many of the vitamin D-resistant diseases.

Treatment In past years, physicians employed pharmacologic doses of vitamin D as the cornerstone for treatment of XLH. However, long-term observations indicate that this therapy fails to cure the disease and poses the serious problem of recurrent vitamin D intoxication and renal damage. More recently, current treatment strategies for children directly address the combined calcitriol and phosphorus deficiency characteristic of the disease. Generally, the regimen includes a period of titration to achieve a maximum dose of calcitriol, 40–60 ng/kg/day in two divided doses, and phosphorus, 1–2 g/day in four to five divided doses (Friedman *et al.,* 1991, 1993). Such combined therapy often improves growth velocity, normalizes lower extremity deformities, and induces healing of the attendant bone disease. Of course treatment involves a significant risk of toxicity that is generally expressed as abnormalities of calcium homeostasis and/or detrimental effects on renal function secondary to abnormalities such as nephrocalcinosis. In addition, refractoriness to the growth-promoting effects of treatment is often encountered, particularly in youths presenting at $<$5th percentile in height (Friedman *et al.,* 1993). Several studies, however, indicate that the addition of growth hormone to conventional therapy increases growth velocity significantly. Unfortunately, such a benefit is realized more frequently in younger patients, and disproportionate growth of the trunk often continues to manifest. Moreover, the definitive impact of growth hormone treatment on adult height remains unknown (Wilson, 2000)

Therapy in adults is reserved for episodes of intractable bone pain and refractory nonunion bone fractures.

HEREDITARY HYPOPHOSPHATEMIC RICKETS WITH HYPERCALCIURIA

This rare genetic disease is characterized by hypophosphatemic rickets with hypercalciuria (Tieder *et al.,* 1985). The cardinal biochemical features of the disorder include hypophosphatemia due to increased renal phosphate clearance and normocalcemia. In contrast to other diseases in which renal phosphate transport is limited, patients with HHRH exhibit increased $1,25(OH)_2D$ production (Table III). The resultant elevated serum calcitriol levels

enhance gastrointestinal calcium absorption, which in turn increases the filtered renal calcium load and inhibits parathyroid secretion (Tieder *et al.,* 1985). These events cause the hypercalciuria observed in affected patients.

The clinical expression of the disease is heterogeneous, although initial symptoms, evident at 6 months to 7 years of age, generally consist of bone pain and/or deformities of the lower extremities. The bone deformities vary from genu varum or genu valgum to anterior external bowing of the femur and coxa vara. Additional features of the disease include short stature, muscle weakness, and radiographic signs of rickets or osteopenia. These various symptoms and signs may exist separately or in combination and may be present in a mild or severe form. Relatives of patients with evident HHRH may exhibit an additional mode of disease expression. These subjects manifest hypercalciuria and hypophosphatemia, but the abnormalities are less marked and occur in the absence of discernible bone disease (Tieder *et al.,* 1987). Bone biopsies in children with characteristic HHRH exhibit classical osteomalacia, but the mineralization defect appears to vary in severity with the magnitude of the hypophosphatemia. Histological measurements are within the normal range in family members with idiopathic hypercalciuria.

Pathophysiolgy and Genetics Liberman and co-workers (Tieder *et al.,* 1985, 1987; Lieberman, 1988) have presented data that indicate the primary inborn error underlying this disorder is an expressed abnormality in the renal proximal tubule, which impairs phosphate reabsorption. They propose that this pivotal defect results in enhanced renal 25(OH)D-1α-hydroxylase, thus promoting the production of $1,25(OH)_2D$ and increasing its serum and tissue levels. Consequently, intestinal calcium absorption is augmented, resulting in the suppression of parathyroid function and an increase of the renal filtered calcium load. The concomitant prolonged hypophosphatemia diminishes osteoid mineralization and accounts for the ensuing rickets and/or osteomalacia.

The suggestion that abnormal phosphate transport results in increased calcitriol production remains untested. Indeed, the elevation of $1,25(OH)_2D$ in patients with HHRH is a unique phenotypic manifestation of the disease that distinguishes it from other disorders in which abnormal phosphate transport is likewise manifest. Such heterogeneity in the phenotype of these disorders suggests that disease at variable anatomical sites along the proximal convoluted tubule uniformly impairs phosphate transport but not 25(OH)D-1α-hydroxylase activity. Alternatively, the aberrant regulation of vitamin D metabolism in other hypophosphatemic disorders may occur independently (e.g., in XLH secondary to the PHEX gene abnormality) and override the effects of the renal phosphate transport.

Although X-linked transmission of this disease has been ruled out, the mode of genetic transmission for HHRH/hypercalciuria remains uncertain. Indeed, current observations suggest that the mode of inheritance may be heterogenous. However, an autosomal dominant form of disease has been described, with less pronounced clinical and biochemical abnormalities. These observations are consistent with an autosomal codominant pattern of inheritance with high, but incomplete penetrance. Under such circumstances, the variability in this disorder may be explained by assuming that individuals with HHRH or idiopathic hypercalciuria are homozygous and heterozygous, respectively, for the same mutant allele.

Although identification of the gene underlying HHRH has not occurred, a few candidate genes have been proposed and mapped. These include the Na^+-dependent phosphate cotransporter gene 1 (NPT1) and the Na^+-dependent phosphate cotransporter gene 2 (NPT2), which are autosomal and expressed predominantly in the kidney. Interestingly, NPT2 null transgenic mice have a biochemical and physical phenotype that resembles HHRH. In fact, heterozygous mice exhibit urinary phosphate excretion and serum calcium levels intermediate between normal mice and homozygotes, consistent with the supposition that HHRH may represent a codominant disorder. Whether a mutation in NPT2 or inactivating mutations in genes coding for ancillary proteins that regulate NPT2 function underlies HHRH, however, remains unknown.

Treatment In accord with the hypothesis that a singular defect in renal phosphate transport underlies HHRH, affected patients have been treated successfully with high-dose phosphorus (1–2.5 g/day in five divided doses) alone. In response to therapy, bone pain disappears and muscular strength improves substantially. Moreover, the majority of treated subjects exhibit accelerated linear growth and radiologic signs of rickets disappear completely within 4–9 months. Concordantly, serum phosphorus values increase toward normal, the $1,25(OH)_2D$ concentration decreases, and alkaline phosphatase activity declines. Despite this favorable response, limited studies indicate that such treatment does not heal the associated osteomalacia. Therefore, further investigation will be necessary to determine if phosphorus alone is truly sufficient for this disorder.

AUTOSOMAL-DOMINANT HYPOPHOSPHATEMIC RICKETS

Several studies have documented an autosomal-dominant inheritance, with incomplete penetrance, of a hypophosphatemic disorder similar to XLH (Harrison and Harrison, 1979). The phenotypic manifestations of this disorder include lower extremity deformities and rickets/osteomalacia. Indeed, affected patients display biochemical and radiographic abnormalities indistinguishable from those of individuals with XLH. These include hypophosphatemia secondary to renal phosphate wasting and normal levels of parathyroid hormone and 25(OH)D, as well as inappropriately normal (relative to the serum phosphorus concentration) $1,25(OH)_2D$ (Table III). However, unlike patients with XLH, some with ADHR display variable incomplete penetrance and delayed onset of penetrance (Econs and

McEnery, 1997). Thus, long-term studies indicate that a few of the affected female patients exhibit delayed penetrance of clinically apparent disease and an increased tendency for bone fracture, uncommon occurrences in XLH. Moreover, these individuals present in the second through the fourth decade with weakness and bone pain but do not have lower extremity deformities. Further, other patients with the disorder present during childhood with phosphate wasting, rickets and lower extremity deformity but manifest postpubertal loss of the phosphate-wasting defect. Finally, a few apparently unaffected individuals have been identified, who seemingly are carriers for the ADHR mutation.

An apparent forme fruste of this disease, (autosomal-dominant) hypophosphatemic bone disease, has many of the characteristics of XLH and ADHR, but reports indicate that affected children display no evidence of rachitic disease (Scriver *et al.,* 1977, 1981). Because this syndrome is described in only a few small kindreds and radiographically evident rickets is not universal in children with familial hypophosphatemia, these familes may have ADHR. Further observations are necessary to discriminate this possibility.

Pathophysiology and Genetics The primary inborn error in ADHR results in an expressed abnormality of the renal proximal tubule that impairs P_i reabsorption. Until recently, whether this renal abnormality is primary or secondary to the elaboration of a humoral factor has been controversial. However, identification of the genetic defect underlying this disease has established that hormonal dysregulation is the pivotal abnormality in this disorder. In this regard, studies localized the ADHR gene to a 6.5 c*M* interval on chromosome 12p13, flanked distally by D12S1685 and proximally by D12S397 (Econs *et al.,* 1997). Moreover, extending these studies, the ADHR Consortium (2000) used a positional cloning approach to identify 37 genes within 4 Mb of genomic sequence in the 6.5 c*M* interval and identified missense mutations in a gene encoding a new member of the fibroblast growth factor (FGF) family, FGF-23. The FGF-23 gene product not only shares sequence homology with other fibroblast growth factors, but is a secreted protein. Thus, transient transfection of OK-E, COS-7 and HEK293 cells with the plasmid encoding full-length FGF-23 results in secretion of two protein species, 32 and 12 kDA, into the incubation medium, which react with a polyclonal antibody to FGF-23. More recent studies have documented that the biological actions of FGF 23 include induction of renal phosphate wasting, a central defect in the hypophosphatemic rachitic diseases. Nevertheless, the relationship between FGF 23, PHEX, and phosphatonin remains unknown. In this regard, considerable controversy exists regarding whether FGF 23 is a substrate for PHEX and evidence has not been presented to determine if FGF 23 has activating or inactivating mutations. However, further studies will undoubtedly establish the relationship between XLH and ADH.

TUMOR-INDUCED OSTEOMALACIA

Since 1947 there have been reports of approximately 120 patients in whom rickets and/or osteomalacia has been induced by various types of tumors (Drezner, 1996). In at least 58 cases a tumor has been clearly documented as causing the rickets–osteomalacia, as the metabolic disturbances improved or disappeared completely upon removal of the tumor. In the remainder of cases, patients had inoperable lesions, and investigators could not determine the effects of tumor removal on the syndrome or surgery did not result in complete resolution of the evident abnormalities during the period of observation.

Affected patients generally present with bone and muscle pain, muscle weakness, rickets/osteomalacia, and occasionally recurrent fractures of long bones. Additional symptoms common to younger patients are fatigue, gait disturbances, slow growth, and bowing of the lower extremities. Biochemistries include hypophosphatemia secondary to renal phosphate wasting and normal serum levels of calcium and 25(OH)D. Serum $1,25(OH)_2D$ is overtly low in 19/23 patients in whom measurements have been made (Table III). Aminoaciduria, most frequently glycinuria, and glucosuria, is occasionally present. Radiographic abnormalities include generalized osteopenia, pseudofractures, and coarsened trabeculae, as well as widened epiphyseal plates in children. The histologic appearance of trabecular bone in affected subjects most often reflects the presence of low turnover osteomalacia. In contrast, bone biopsies from the few patients who have tumors that secrete a nonparathyroid hormone factor(s), which activates adenylae cyclase, exhibit changes consistent with enhanced bone turnover, including an increase in osteoclast and osteoblast number.

The large majority of patients with this syndrome harbor tumors of mesenchymal origin and include primitive-appearing, mixed connective tissue lesions, osteoblastomas, nonossifying fibromas, and ossifying fibromas. However, the frequent occurrence of Looser zones in the radiographs of moribund patients with carcinomas of epidermal and endodermal derivation indicates that the disease may be secondary to a variety of tumor types. Indeed, the observation of tumor-induced osteomalacia concurrent with breast carcinoma (Dent and Gertner, 1976), prostate carcinoma (Lyles *et al.,* 1980; Murphy *et al.,* 1985; Hosking *et al.,* 1975), oat cell carcinoma (Leehey *et al.,* 1985), small cell carcinoma (Shaker *et al.,* 1995), multiple myeloma, and chronic lymphocytic leukemia (McClure and Smith, 1987) supports this conclusion. In addition, the occurrence of osteomalacia in patients with widespread fibrous dysplasia of bone (Dent and Gertner, 1976; Saville *et al.,* 1955), neurofibromatosis (Weidner and Cruz, 1987; Konishi *et al.,* 1991), and linear nevus sebaceous syndrome (Cary *et al.,* 1986) could also be tumor induced. Although proof of a causal relationship in these disorders has been precluded in general by an inability to excise the multiplicity of lesions surgically, in one case of fibrous dysplasia, removal of virtually all of the abnormal bone did result in appropriate biochemical and radiographic improvement.

Regardless of the tumor cell type, the lesions at fault for the syndrome are often small, difficult to locate, and present in obscure areas, which include the nasopharynx, a sinus, the popliteal region, and the suprapatellar area. In any case, a careful and thorough examination is necessary to document/exclude the presence of such a tumor. Indeed, a CT and/or MRI scan of an clinically suspicious area should be undertaken. In addition, several groups have used octreotide scanning to identify suspected, but nonlocalized, tumors.

Pathophysiology The relatively infrequent occurrence of this disorder has confounded attempts to determine the pathophysiological basis for TIO. Nevertheless, most investigators agree that tumor production of a humoral factor(s) that may affect multiple functions of the proximal renal tubule, particularly phosphate reabsorption, is the probable pathogenesis of the syndrome. This possibility is supported by (1) the presence of phosphaturic activity in tumor extracts from three of four patients with TIO (Aschinberg *et al.,* 1977; Yoshikawa *et al.,* 1977; Lau *et al.,* 1979); (2) the absence of parathyroid hormone and calcitonin from these extracts and the apparent cyclic AMP-independent action of the extracts; (3) the occurrence of hypophosphatemia and increased urinary phosphate excretion in heterotransplanted tumor-bearing athymic nude mice (Miyauchi *et al.,* 1988);. (4) the demonstration that extracts of the heterotransplanted tumor inhibit renal 25-hydroxyvitamin D-1 α-hydroxylase activity in cultured kidney cells (Miyauchi *et al.,* 1988); and (5) the coincidence of aminoaciduria and glycosuria with renal phosphate wasting in some affected subjects, indicative of complex alterations in proxima renal tubular function (Drezner and Feinglos, 1977). Indeed, partial purification of "phosphatonin" from a cell culture derived from a hemangioscleroma causing tumor-induced osteomalacia has reaffirmed this possibility (Cai *et al.,* 1994). These studies reveal that the putative phosphatonin may be a peptide with a molecular mass of 8–2 kDa that does not alter glucose or alanine transport, but inhibits sodium-dependent phosphate transport in a cyclic AMP-independent fashion. However, studies, which document the presence in various disease states of additional phosphate transport inhibitors (and stimulants), indicate that tumor-induced osteomalacia syndrome may be heterogeneous and that "phosphatonin" may be a family of hormones. In this regard, excessive tumor production and secretion of FGF-23 (White *et al.,* 2001) and matrix extracellular phosphoglycoprotein (MEPE) have been identified in large numbers of patients with tumor-induced osteomalacia. In addition, the related finding that PHEX is also present in tumors from patients with tumor-induced osteomalaica adds further complexity to the assumption that overproduction of "phosphatonin" explains this syndrome. Indeed, it seems likely that the putative phosphatonin, underlying TIO, is likely a PHEX substrate. As such, excessive tumor production of phosphatonin must overwhelm the function of normal PHEX in order to alter phosphate homeostasis. Within the context of this model (Quarles and Drezner, 2001), data definitively implicating either FGF-23 or MEPE as the phosphaturic agent in tumor-induced osteomalacia are lacking. Hence, the phosphaturic actions of FGF-23 and/or mutated FGF-23 have not been documented and this factor is not an established substrate for PHEX. Similarly, while several groups have documented unequivocal phosphaturic activity of truncated MEPE, both *in vitro* and *in vivo,* evidence that MEPE is a substrate for PHEX is lacking. The discovery of yet additional hormones that regulate phosphate homeostasis add further doubt to the identity of the phosphaturic factor(s) in TIO. For example, stanniocalcin 1 (STC1) and 2 (STC2), phosphate-regulating hormones cloned from a human osteoblast cDNA library, respectively, stimulate and inhibit renal phosphate reabsorption and are secreted as phosphoproteins from human fibrosarcoma cells. While the existence of these multiple hormonal regulators of phosphate homeostasis cloud the pathophysiology of TIO, the demand that ectopic hormone production by a tumor is commensurate with overproduction of a normally occurring hormone, and the similarities in phenotype between TIO and genetic forms of phosphate wasting, XLH and ADRH, argue for commonality in the pathogenesis of these syndromes. Thus, it remains likely that further advances in our knowledge of the biological function(s) of FGF-23 and MEPE, as well as identification of PHEX substrates, will unravel the pathophysiology of TIO and establish the relationship of this disease with ADHR and XLH.

In contrast to these observations, patients with TIO secondary to hematogenous malignancy manifest abnormalities of the syndrome due to a distinctly different mechanism. In these subjects the nephropathy induced with light chain proteinuria or other immunoglobulin derivatives results in the decreased renal tubular reabsorption of phosphate characteristic of the disease. Thus, light chain nephropathy must be considered a possible mechanism for the TIO syndrome.

Treatment The first and foremost treatment of TIO is complete resection of the tumor. However, recurrence of mesenchymal tumors, such as giant cell tumors of bone, or inability to resect certain malignancies completely, such as prostatic carcinoma, has resulted in the development of alternative therapeutic intervention for the syndrome. In this regard, administration of $1,25(OH)_2D$ alone or in combination with phosphorus supplementation has served as effective therapy for TIO. Doses of calcitriol required range from 1.5 to 3.0 μg/day, whereas those of phosphorus are 2–4 g/day. Although little information is available regarding the long-term consequences of such treatment, the high doses of medicine required raise the possibility that nephrolithiasis, nephrocalcinosis, and hypercalcemia may frequently complicate the therapeutic course. Indeed, hypercalcemia secondary to parathyroid hyperfunction has been documented in at least five treated subjects. All of these patients received phosphorus as part of a combination regimen, which may have stimulated parathyroid hormone secretion and led to parathyroid autonomy. Thus, a careful

assessment of parathyroid function, serum and urinary calcium, and renal function is essential to ensure safe and efficacious therapy.

DENT'S DISEASE (X-LINKED RECESSIVE HYPOPHOSPHATEMIC RICKETS)

In the past several decades, multiple syndromes have been described that are characterized by various combinations of renal proximal tubular dysfunction (including renal phosphate wasting), proteinuria, hypercalciuria, nephrocalcinosis, nephrolithiasis, renal failure, and rickets; these disorders, referred to as Dent's disease, include X-linked recessive hypophosphatemic rickets, X-linked recessive nephrolithiasis with renal failure, and low molecular weight proteinuria with nephrocalcinosis. The spectrum of phenotypic features in these diseases is remarkably similar, except for differences in the severity of bone deformities and renal impairment. The finding that all of these syndromes are caused by mutations affecting a chloride channel has clarified their relationship to one another and established that they are variants of a single disease (Scheinman, 1998).

Urinary loss of low molecular weight proteins is the most consistent abnormality in the disease: it is present in all affected males and in almost all female carriers of the disorder (Wrong *et al.,* 1994; Reinhart *et al.,* 1995). Other signs of impaired solute reabsorption in the proximal tubule, such as renal glycosuria, aminoaciduria, and phosphate wasting, are variable and often intermittent. Hypercalciuria is an early and common feature while hypokalemia occurs in some patients. Urinary acidification is normal in over 80% of affected subjects, and when it is abnormal, the defect has been attributed to hypercalciuria or nephrocalcinosis (Wrong *et al.,* 1994; Reinhart *et al.,* 1995; Buckalew *et al.,* 1974. The disease apparently does not recur after kidney transplantation (Scheinman, 1998).

These phenotypic features indicate the presence of proximal tubular dysfunction but do not suggest its pathophysiologic basis. However, mapping studies have established linkage to the short arm of the X chromosome (Xp11.22) (Scheinman *et al.,* 1997). Moreover, a chromosomal microdeletion detected in one family led to mapping of the region and identification of a gene encoding a voltage-dependent chloride channel, ClC-5, that is expressed predominantly in the kidney. A total of 35 mutations have been identified to date in 46 families (Scheinman, 1998; Lloyd *et al.,* 1996; Hoopes *et al.,* 1998; Igarashi *et al.,* 1998). Expression studies confirm that these mutations inactivate the chloride channel (Lloyd *et al.,* 1996; Hoopes *et al.,* 1998; Igarashi *et al.,* 1998). The gene is a member of a family of genes encoding voltage-gated chloride channels. Impairment of this channel could limit endosomal acidification, thus causing defective reabsorption of proteins, and might also lead to impaired reabsorption of other solutes if membrane protein recycling were altered.

It is not clear how this process leads to the increased intestinal calcium absorption and high serum $1,25(OH)_2D$ levels in this disorder (Reinhart *et al.,* 1995), as the 25(OH)D-1α-hydroxylase that catalyzes its formation is located in the mitochondria of proximal tubular cells, whereas ClC-5 is expressed in the thick ascending limb of Henle's loop (Devuyst *et al.,* 1999), a major site of renal calcium reabsorption. The role of this channel in the reabsorption of calcium in the thick ascending limb remains unknown.

FANCONI'S SYNDROME

Rickets and osteomalacia are frequently associated with Fanconi's syndrome, a disorder characterized by phosphaturia and consequent hypophosphatemia, aminoaciduria, renal glycosuria, albuminuria, and proximal renal tubular acidosis (De Toni, 1933; McCune *et al.,* 1943; Brewer, 1985; Chan and Alon, 1985; Chesney, 1990). Damage to the renal proximal tubule, secondary to genetic disease (Table II) or environmental toxins, represents the common underlying mechanism of this disease. Resultant dysfunction results in renal wasting of those substances primarily reabsorbed at the proximal tubule. The associated bone disease in this disorder is likely secondary to hypophosphatemia and/or acidosis, abnormalities that occur in association with aberrantly (Fanconi's syndrome, type I) or normally regulated (Fanconi's syndrome, type II) vitamin D metabolism.

Type I The type I disease resembles in many respects the more common genetic disease, X-linked hypophosphatemic rickets (Table III). In this regard, the occurrence of abnormal bone mineralization appears dependent on the prevailing renal phosphate wasting and resultant hypophosphatemia. Indeed, disease subtypes in which isolated wasting of amino acids, glucose, or potassium occur are not associated with rickets and/or osteomalacia. Further, in the majority of patients studied, affected subjects exhibit abnormal vitamin D metabolism, characterized by serum $1,25(OH)_2D$ levels that are overtly decreased or abnormally low relative to the prevailing serum phosphorus concentration (Chesney *et al.,* 1984). Although the aberrantly regulated calcitriol biosynthesis may be due to the abnormal renal phosphate transport, proximal tubule damage and acidosis may play important roles.

A notable difference between this syndrome and XLH is a common prevailing acidosis, which may contribute to the bone disease. In this regard, several studies indicate that acidosis may exert multiple deleterious effects on bone. Such negative sequellae may be related to the loss of bone calcium that occurs secondary to calcium release for use in buffering. Alternatively, several investigators have reported that acidosis may impair bone mineralization secondary to the direct inhibition of renal 25(OH)D-1α-hydroxylase activity. Others dispute these findings and claim that acidosis does not cause rickets or osteomalacia in the absence of hypophosphatemia. Most likely, however, hypophosphatemia and abnormally regulated vitamin D metabolism are the primary factors underlying rickets and osteomalacia in this form of the disease.

Type II Tieder *et al.* (1988) have described two siblings (from a consanguineous mating) who presented with classic characteristics of Fanconi's syndrome, including renal phosphate wasting, glycosuria, generalized aminoaciduria, and increased urinary uric acid excretion. However, these patients had appropriately elevated (relative to the decreased serum phosphorus concentration) serum $1,25(OH)_2D$ levels and consequent hypercalciuria (Table III). Moreover, treatment with phosphate reduced the serum calcitriol in these patients into the normal range and normalized the urinary calcium excretion. In many regards, this syndrome resembles HHRH and represents a variant of Fanconi's syndrome, referred to as type II disease. The bone disease in affected subjects is likely due to the effects of hypophosphatemia. In any case, the existence of this variant form of disease is probably the result of renal damage to a unique segment of the proximal tubule. Further studies will be necessary to confirm this possibility.

Treatment Ideal treatment of the bone disease in this disorder is correction of the pathophysiological defect influencing proximal renal tubular function. In many cases, however, the primary abnormality remains unknown. Moreover, efforts to decrease tissue levels of causal toxic metabolites by dietary (such as in fructose intolerance) or pharmacological means (such as in cystinosis and Wilson's syndrome) have met with variable success. Indeed, no evidence exists that indicates if the proximal tubule damage is reversible upon relief of an acute toxicity. Thus, for the most part, therapy of this disorder must be directed at raising the serum phosphorus concentration, replacing calcitriol (in type I disease) and reversing an associated acidosis. However, use of phosphorus and calcitriol in this disease has been limited. In general, such replacement therapy leads to substantial improvement or resolution of the bone disease (Schneider and Schulman, 1983). Unfortunately, growth and developmental abnormalities, more likely associated with the underlying genetic disease, remain substantially impaired. More efficacious therapy, therefore, is dependent on future research into the causes of the multiple disorders that cause this syndrome.

TUMORAL CALCINOSIS

Tumoral calcinosis is a rare genetic disease characterized by periarticular cystic and solid tumorous calcifications. Biochemical markers of the disorder include hyperphosphatemia and a normal or an elevated serum $1,25(OH)_2D$ concentration (Table III). Using these criteria, evidence has been presented for autosomal recessive inheritance of this syndrome. However, an abnormality of dentition, marked by short bulbous roots, pulp stones, and radicular dentin deposited in swirls, is a phenotypic marker of the disease that is variably expressed (Lyles *et al.,* 1985). Thus, this disorder may have multiple formes frustes that could complicate genetic analysis. Indeed, using the dental lesion, as well as the more classic biochemical and clinical hallmarks of the disease, an autosomal dominant pattern of transmission has been documented.

The hyperphosphatemia characteristic of the disease results from an increase in capacity of renal tubular phosphate reabsorption secondary to an unknown defect. Hypocalcemia is not a consequence of this abnormality, however, and the serum parathyroid hormone concentration is normal. Moreover, the phosphaturic and urinary cAMP responses to parathyroid hormone are not disturbed. Thus, the defect does not represent renal insensitivity to hormone, or hypoparathyroidism. Rather, the basis of the disease is probably an innate or hormone/metabolic factor-mediated abnormality of the renal tubule that enhances phosphate reabsorption. Undoubtedly, calcific tumors result from the elevated calcium–phosphorus product. The observation that long-term phosphorus depletion alone or in association with administration of acetazolamide, a phosphaturic agent, leads to resolution of the tumor masses supports this possibility.

An acquired form of this disease is rarely seen in patients with end-stage renal failure. Affected patients manifest hyperphosphatemia in association with either (1) an inappropriately elevated calcitriol level for the degree of renal failure, hyperparathyroidism, or hyperphosphatemia or (2) long-term treatment with calcium carbonate, calcitriol, or high calcium content dialysates. Calcific tumors again likely result from an elevated calcium–phosphorus product. Indeed, complete remission of the tumors occurs on treatment with vinpocetine, a mineral scavenger drug, dialysis with low calcium content dialysate, and renal transplantation.

CHAPTER 21

Magnesium Homeostasis

Robert K. Rude
University of Southern California, School of Medicine, Los Angeles, California 90033

Magnesium (Mg) is the fourth most abundant cation and the second most abundant intracellular cation in vertebrates. Mg is involved in numerous biological processes and is essential for life (Rude, 2000). This mineral has evolved to become a required cofactor in literally hundreds of enzyme systems (Frausta de Silva and Williams, 1991; Rude, 2000). Examples of the physiological role of Mg are shown in Table I. Mg may be required for enzyme substrate formation. For example, enzymes that utilize ATP do so as the metal chelate, MgATP. Free Mg^{2+} also acts as an allosteric activator of numerous enzyme systems, as well as playing a role in ion currents and for membrane stabilization. Mg is therefore critical for a great number of cellular functions, including oxidative phosphorylation, glycolysis, DNA transcription, and protein synthesis.

Magnesium Metabolism

The normal adult total body Mg content is approximately 25 g (2000 mEq or 1 mol) of which 50–60% resides in bone (Elin, 1987; Wallach, 1988). Mg constitutes 0.5–1% of bone ash (200 mmol/kg ash weight). One-third of skeletal Mg is surface limited and exchangeable, and this fraction may serve as a reservoir for maintaining a normal extracellular Mg concentration (Wallach, 1988; Rude, 2000). The remainder of Mg in bone is an integral component of the hydroxyapatite lattice, which may be released during bone resorption. The rest of body Mg is mainly intracellular. The Mg content of soft tissues varies between 6 and 25 mEq/kg wet weight (Elin, 1987; Rude, 2000). In general, the higher the metabolic activity of the cell, the higher the Mg content. The concentration of Mg within cells is in the order of 5–20 mmol/liter, of which 1–5% is ionized or free (Elin, 1987; Romani and Scarpa, 1992; Romani *et al.,* 1993a). The distribution of Mg in the body is shown in Table II and Fig. 1.

Extracellular Mg accounts for about 1% of total body Mg. Mg concentration or content may be reported as mEq/liter, mg/dl, or mmol/liter. Values reported as mEq/liter can be converted to mg/dl by multiplying by 1.2 and to mmol/liter by dividing by 1/2. The normal serum Mg concentration is 1.5–1.9 mEq/liter (0.7–1.0 mmol/liter)(Elin, 1987; Rude, 2000). About 70–75% of plasma Mg is ultrafilterable, of which the major portion (55% of total serum Mg) is ionized or free and the remainder is complexed to citrate, phosphate, and other anions as represented schematically in Fig. 2. The remainder is protein bound; 25% of total serum Mg is bound to albumin and 8% to globulins.

Intestinal Mg Absorption

Intestinal Mg absorption is proportional to the amount ingested (Fine *et al.,* 1991; Schweigel and Martens, 2000). The mechanism(s) for intestinal Mg absorption is unclear but includes passive diffusion, solvent drag, and active transport (Fine *et al.,* 1991; Kayne and Lee, 1993; Bijvelds *et al,* 1998; Schweigel and Martens, 2000). As shown in Fig. 3, rat studies suggest there may be both a saturable active and an unsaturable passive transport system for Mg absorption (Ross, 1962), which may account for the higher fractional absorption at low dietary Mg intakes (Fine *et al.,* 1991; Kayne and Lee, 1993). Others have concluded that intestinal Mg absorption in humans increases linearly with Mg intake (for review, see Schweigel and Martens, 2000). The report of a patient with primary hypomagnesemia who was shown to malabsorb Mg during low Mg concentration in the intestine suggests an active transport process (Milla *et al.,* 1979). This familial defect has been mapped to chromosome 9q (Walder *et al.,* 1997). Under normal dietary conditions in healthy individuals, approximately 30–50% of ingested Mg is absorbed (Brannan *et al.,* 1976; Hardwick *et al.,* 1990; Fine *et al.,* 1991; Kayne and Lee, 1993).

Table I Examples of the Physiological Role of Magnesium

I.	Enzyme substrate (ATP Mg, GTP Mg)
	A. ATPase or GTPase (Na^+, K^+-ATPase, Ca^{2+}-ATPase)
	B. Cyclases (adenylate cyclase, guanylate cyclase)
	C. Kinase (hexokinase, creatine kinase, protein kinase)
II.	Direct enzyme activation
	A. Adenylate cyclase
	B. Phospholipase C
	C. Na^+, K^+-ATPase
	D. Ca^{2+}-ATPase
	E. K^+,H^+-ATPase
	F. G proteins
	G. 5′-Nucleotidase
	H. Creatine kinase
	I. Phosphofructokinase
	J. 5-Phosphoribosyl-pyrophosphate synthetase
	K. Lipoprotein lipase
III.	Influence membrane properties
	A. K^+ channels
	B. Ca^{2+} channels
	C. Nerve conduction

Table II Distribution of Magnesium in Adult Humans[a]

Tissue	Body mass, kg (wet wt)	Mg concentration, mmol/kg (wet wt)	Mg content (mmol)	% of total body Mg
Serum	3.0	0.85	2.6	0.3
Erythrocyte	2.0	2.5	5.0	0.5
Soft tissue	22.7	8.5	193.0	19.3
Muscle	30.0	9.0	270.0	27.0
Bone	12.3	43.2	530.1	52.9
Total	70.0		1000.7	100.0

[a]Adapted from Elin (1987).

Mg is absorbed along the entire intestinal tract, including the large and small bowel, but the sites of maximal Mg absorption appear to be the ilium and distal jejunum (Brannan *et al.,* 1976; Hardwick *et al.,* 1990; Fine *et al.,* 1991; Kayne and Lee, 1993).

The recommended daily allowance for Mg is 420 mg per day for adult males and 320 mg per day for adult females (Institute of Medicine, 1997). The dietary Mg intake in Western culture, however, appears to fall below that in a large section of the population across all ages, ranging from approximately 150 to 350 mg per day, suggesting that occult Mg depletion may be relatively prevalent (Morgan *et al.,* 1985; Marier, 1986). The major sources of Mg are nuts, cereals, green leafy vegetables, and meats.

A principal factor that regulates intestinal Mg transport has not been described. Vitamin D, as well as its metabolites 25-hydroxyvitamin D and 1,25-dihydroxyvitamin D [1,25$(OH)_2$D] have been observed in some studies to enhance intestinal Mg absorption but to a much lesser extent than they do calcium absorption (Brannan *et al.,* 1976; Hodgkinson *et al.,* 1979; Krejs *et al.,* 1983). Although net intestinal calcium absorption in humans correlates with plasma 1,25$(OH)_2$D concentrations, Mg does not (Wilz *et al.,* 1979). A low Mg diet has been shown to increase intestinal calbindin-D_{9k}, suggesting that this vitamin D-dependent calcium binding protein may play a role in intestinal Mg absorption (Hemmingsen *et al.,* 1994).

Bioavailability of Mg may also be a factor in Mg intestinal absorption as other nutrients may affect Mg absorption. Although dietary calcium has been reported to both decrease and increase Mg absorption, human studies have

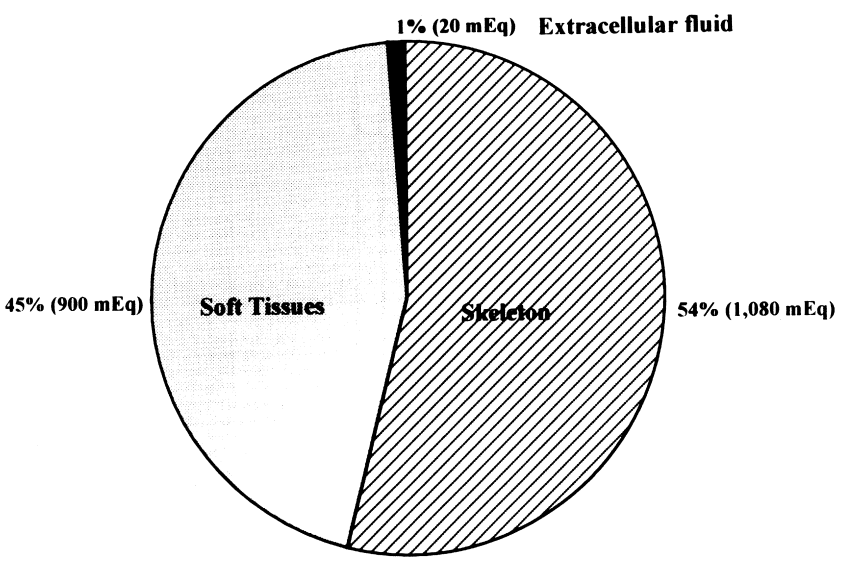

Figure 1 Distribution of magnesium in the body.

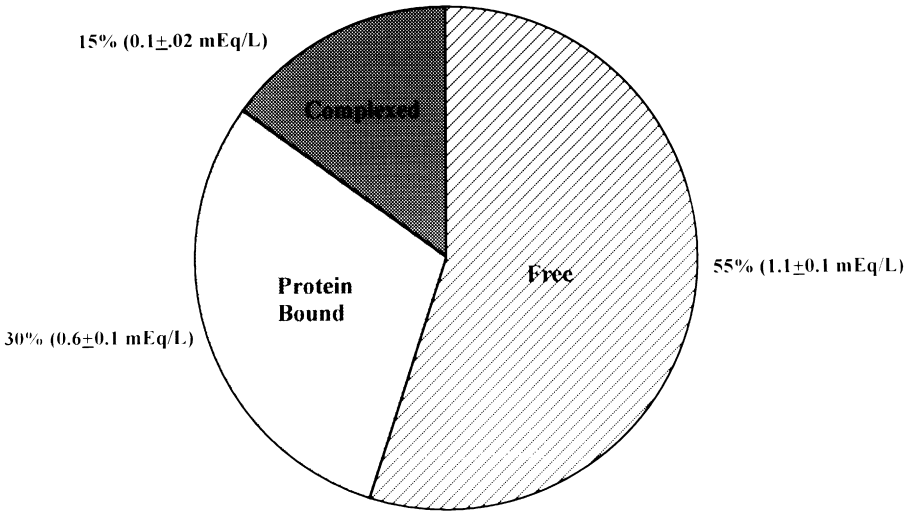

Figure 2 Physicochemical states of magnesium in normal plasma.

shown no effect (Brannan *et al.,* 1976; Fine *et al.,* 1991). The presence of excessive amounts of substances such as free fatty acids, phytate, oxalate, polyphosphates, and fiber may bind Mg and impair absorption (Seelig, 1981; Franz, 1989).

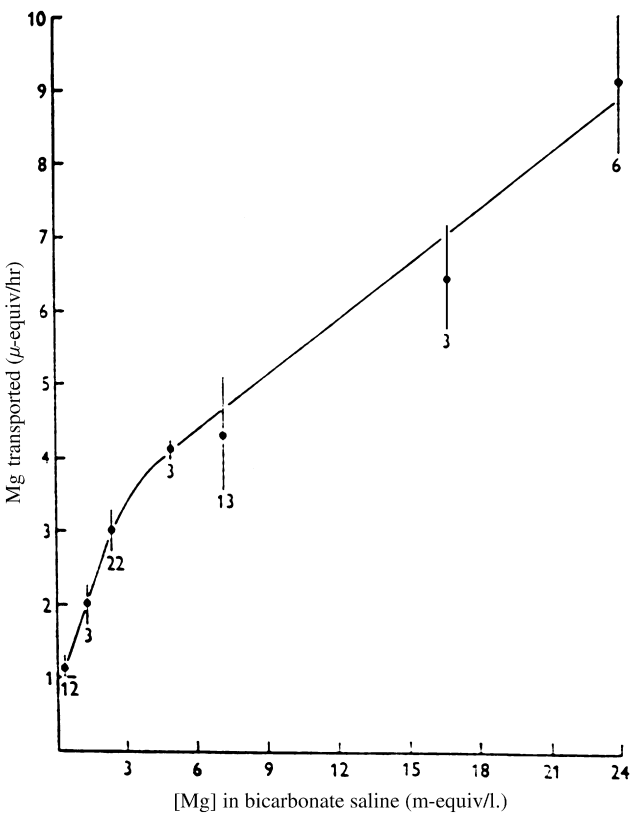

Figure 3 Relation between magnesium transported per hour and circulating luminal fluid magnesium concentration in rats. Values represent mean ± SEM. The number below shows number of experiments in the group (Ross, 1962).

Renal Mg Handling

The kidney is the principal organ involved in Mg homeostasis (Quamme and De Rouffignac, 2000; Cole and Quamme, 2000). During Mg deprivation in normal subjects, the kidney conserves Mg avidly and less than 1–2 mEq is excreted in the urine per day (Barnes *et al.,* 1958). Conversely, when excess Mg is taken, it is excreted into the urine rapidly (Heaton and Parson, 1961). The renal handling of Mg in humans is a filtration–reabsorption process; there appears to be no tubular secretion of Mg. Micropuncture studies of the nephron in several mammalian species have indicated that Mg is absorbed in the proximal tubule, thick ascending limb of Henle, and distal convoluted tubule (Quamme and De Rouffignac, 2000; Cole and Quamme, 2000), as illustrated in Fig. 4.

Approximately 15–20% of filtered Mg is reabsorbed in the proximal convoluted tubule. Current data suggest that Mg transport in this segment is reabsorbed passively through the paracellular pathway (Quamme and De Rouffignac, 2000; Cole and Quamme, 2000). The majority, approximately 65–75%, of filtered Mg is reclaimed in the loop of Henle with the major site at the cortical thick ascending limb. Magnesium transport in this segment appears to be dependent on the transepithelial potential generated by NaCl absorption (Quamme and De Rouffignac, 2000; Cole and Quamme, 2000). Micropuncture studies have also demonstrated that hypermagnesemia or hypercalcemia will decrease Mg reabsorption in this segment independent of NaCl transport (Quamme and De Rouffignac, 2000; Cole and Quamme, 2000). Studies suggest that the concentration of calcium and/or Mg in the extracellular fluid may regulate absorption of Mg in the thick ascending limb of Henle by activation of the Ca^{2+}-sensing receptor in this segment of the nephron (Brown and Hebert, 1995; Quamme and De Rouffignac, 2000; Cole and Quamme, 2000). Approximately 5–10% of Mg is reclaimed in the distal tubule where reabsorption is transcellular and active in

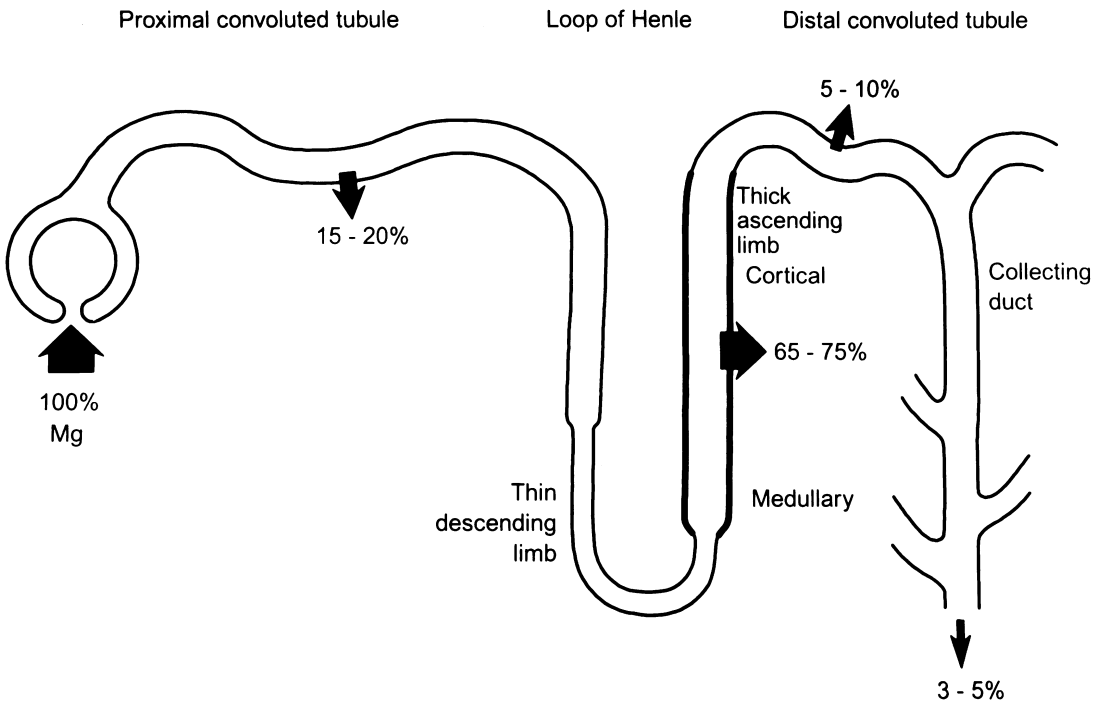

Figure 4 Summary of the tubular handling of magnesium. Schematic illustration of the cellular transport of magnesium within the thick ascending limb of the loop of Henle (Cole and Quamme, 2000).

nature (Quamme and De Rouffignac, 2000; Cole and Quamme, 2000). It is speculated that transport at this site may be regulated hormonally and serve to finely regulate Mg homeostasis.

Micropuncture studies performed during a time in which the concentration of Mg was increased gradually, in either the tubular lumen or in the extracellular fluid, have failed to demonstrate a tubular maximum for Mg (TmMg) in the proximal tubule (De Rouffignac and Quamme, 1994; Quamme, 2000). The rate of Mg reabsorption is dependent on the concentration of Mg in the tubule lumen. Similarly, a TmMg was not reached in the loop of Henle during a graduated increase in the luminal-filtered Mg load. Hypermagnesemia, as discussed earlier, however, results in a marked depression of Mg resorption in this segment. *In vivo* studies in animals and humans, however, have demonstrated a TmMg that probably reflects a composite of tubular reabsorption processes, as shown in Fig. 5 (Rude *et al.,* 1980; Rude and Ryzen, 1986).

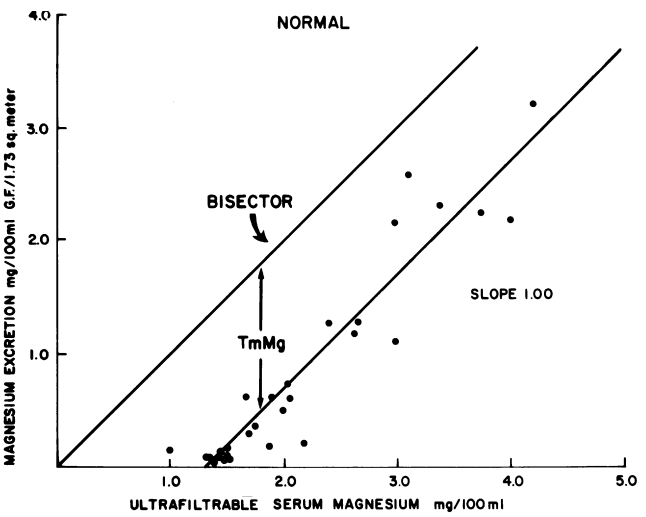

Figure 5 Urinary magnesium excretion is plotted against ultrafiltrable serum Mg in normal subjects before and during magnesium infusion. Data are related to a bisector that corresponds to the theoretical value of magnesium excretion if no magnesium were reabsorbed (Rude *et al.,* 1980).

During Mg deprivation, Mg virtually disappears from the urine (Barnes *et al.,* 1958). Despite the close regulation of Mg by the kidney, there has been no hormone or factor described that is responsible for renal Mg homeostasis. Micropuncture studies have shown that PTH changes the potential difference in the cortical thick ascending limb and increases Mg reabsorption (Quamme and De Rouffignac, 2000; Cole and Quamme, 2000). When given in large doses in humans or other species, PTH decreases urinary Mg excretion (Bethune *et al.,* 1968; Massry *et al.,* 1969). However, patients with either primary hyperparathyroidism or hypoparathyroidism usually have a normal serum Mg concentration and a normal TmMg, suggesting that PTH is not an important physiological regulator of Mg homeostasis (Rude *et al.,* 1980). Glucagon, calcitonin, and ADH also affect Mg transport in the loop of Henle in a manner similar to PTH (Quamme and De Rouffignac, 2000; Cole and Quamme, 2000); the physiological relevance of these actions is unknown. Little is known about the effect of vitamin D on renal Mg handling. An overall view of Mg metabolism is shown in Fig. 6.

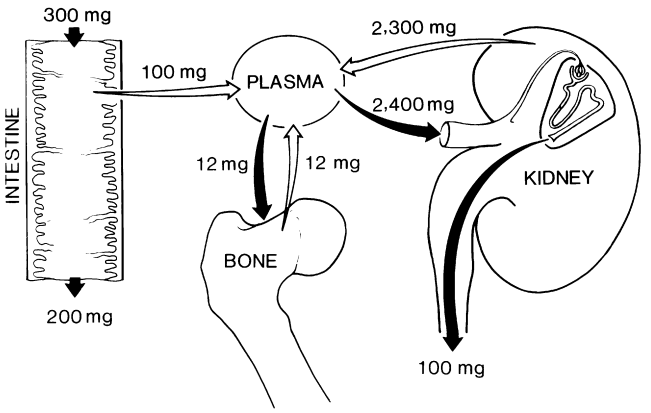

Figure 6 Schematic representation of magnesium metabolism.

Intracellular Mg

Within the cell, Mg is compartmentalized and most of it is bound to proteins and negatively charged molecules such as ATP, ADP, RNA, and DNA; in the cytoplasm, about 80% of Mg is complexed with ATP ((Gupta and Moore, 1980; Frausta da Silva and Wilkens, 1991; Romani *et al.,* 1993a). Significant amounts of Mg are found in the nucleus, mitochondria, and endoplasmic and sarcoplasmic reticulum as well as in the cytoplasm (Gunther, 1986; Romani *et al.,* 1993a). Total cell Mg concentration has been reported to range between 5 and 20 m*M* (Gunther, 1986; Romani *et al.,* 1993a). The concentration of free ionized Mg^{2+}, which has been measured in the cytoplasm of mammalian cells, has ranged from 0.2 to 1.0 m*M,* depending on cell type and means of measurement (Raju *et al.,* 1989; London, 1991; Romani and Scarpa, 1992; Romani *et al.,* 1993b). It constitutes 1–5% of the total cellular Mg. The Mg^{2+} concentration in the cell cytoplasm is maintained relatively constant even when the Mg^{2+} concentration in the extracellular fluid is experimentally varied to either high or low nonphysiological levels (Dai and Quamme, 1991; Quamme *et al.,* 1993; Romani *et al.,* 1993b). The relative constancy of the Mg^{2+} in the intracellular milieu is attributed to the limited permeability of the plasma membrane to Mg and to the operation of specific Mg transport systems, which regulate the rates at which Mg is taken up by cells or extruded from cells (Flatman, 1984; Romani *et al.,* 1993a; Murphy, 2000). Although the concentration differential between the cytoplasm and the extracellular fluid for Mg^{2+} is minimal, Mg^{2+} enters cells down an electrochemical gradient due to the relative electronegativity of the cell interior. Maintenance of the normal intracellular concentrations of Mg^{2+} requires that Mg be actively transported out of the cell (Murphy, 2000).

Studies in mammalian tissues and isolated cells suggest the presence of specific Mg transport systems. Early *in vivo* studies, using the radioactive isotope ^{28}Mg, suggested that tissues vary with respect to the rates at which Mg exchange occurs and the percentage of total Mg that is readily exchangeable (Rogers and Mahan, 1959). The rate of Mg exchange in heart, liver, and kidney exceeded that in skeletal muscle, red blood cells, brain, and testis (Romani *et al.,* 1993a). These studies do show that, albeit slow in some tissues, there is a continuous equilibration of Mg between cells and the extracellular fluid. An increased cellular Mg content has been reported for rapidly proliferating cells, indicating a possible relationship between the metabolic state of a cell and the relative rates of Mg transport into and out of cells (Cameron *et al.,* 1980).

Mg transport out of cells appears to require the presence of carrier-mediated transport systems, possibly regulated by the concentration of Mg^{2+} within the cell (Romani *et al.,* 1993a; Gunther, 1993). The efflux of Mg from the cell is coupled to Na transport and requires energy (Romani *et al.,* 1993a; Gunther, 1993; Murphy, 2000). Muscle tissue, which is incubated in isotonic sucrose, a low sodium buffer, or in the presence of ouabain as a metabolic inhibitor, has been shown to accumulate large amounts of Mg. These studies also suggest that the efflux of Mg from the cell is coupled with the movement of sodium down its electrochemical gradient into the cell. Maintenance of this process would require the subsequent extrusion of sodium by the Na^+,K^+-ATPase. There is also evidence for a Na-independent efflux of Mg, however (Gunther, 1993). Mg influx appears to be linked to Na and HCO_3 transport, but by a different mechanism than efflux (Gunther, 1993; Gunther and Hollriegl, 1993). The molecular characteristics of the Mg transport proteins have not been described. Studies in prokaryotes, however, have identified three separate transport proteins for Mg (Smith and Maguire, 1993).

Mg transport in mammalian cells is influenced by hormonal and pharmacological factors. Mg^{2+} efflux from isolated perfused rat heart and liver (Romani and Scarpa, 1990a,b; Gunther *et al.,* 1991; Gunther, 1993) or thymocytes (Gunther and Vormann, 1990) is stimulated after short-term acute exposure to β-agonists and permeant cAMP. Because intracellular Mg^{2+} does not change, a redistribution from the mitochondria was suggested, as cAMP can induce Mg^{2+} release from this compartment (Romani and Scarpa, 1992) or by altered buffering of Mg within the cell (Murphy, 2000). In contrast, Mg^{2+} influx was stimulated by β-agonists after a more prolonged exposure in hepatocytes, as well as in adipocytes and vascular smooth muscle, presumably mediated by protein kinase A (Zama and Towns, 1986; Ziegler *et al.,* 1992; Gunther, 1993; Romani *et al.,* 1993b). However, the rate of Mg uptake by the mouse lymphoma S49 cell line is inhibited by β-adrenergic agents (Maguire, 1984). Activation of protein kinase C by diacyl-glycerol or by phorbol esters also stimulates Mg^{2+} influx and does not alter efflux (Grubbs and Maguire, 1986; Romani *et al.,* 1993a).

Growth factors may also influence Mg^{2+} uptake by cells. Epidermal growth factor has been shown to increase Mg transport into a vascular smooth muscle cell line (Grubbs, 1991). Insulin and dextrose were found to increase ^{28}Mg uptake by a number of tissues, including skeletal and cardiac muscle, in which total cellular Mg content increased as

well (Lostroh and Krahl, 1973). Increased amounts of total intracellular Mg following treatment with insulin *in vitro* have been reported in uterine smooth muscle and chicken embryo fibroblasts (Aikawa, 1960; Sanui and Rubin, 1978). An insulin-induced transport of Mg into cells could be one factor responsible for the fall in the serum Mg concentration observed during insulin therapy of diabetic ketoacidosis (Kumar *et al.,* 1978). The effect of insulin on total cellular Mg may differ from its effects on intracellular-free Mg^{2+}. Measurements of intracellular-free Mg^{2+} in frog skeletal muscle failed to show an effect of insulin (Gupta and Moore, 1980); however, other studies demonstrated that insulin increases Mg^{2+} in human red blood cells, platelets, lymphocytes, and heart (Hwang *et al.,* 1993; Barbagallo *et al.,* 1993; Hua *et al.,* 1995; Romani *et al.,* 2000).

It is hypothesized that this hormonally regulated Mg uptake system controls intracellular Mg^{2+} concentration in cellular subcytoplasmic compartments. The Mg^{2+} concentration in these compartments would then serve to regulate the activity of Mg-sensitive enzymes.

Role of Magnesium in Bone and Mineral Homeostasis

Because of the prevalence of Mg in both cells and bone, as well as its critical need for numerous biological processes in the body, it is not surprising that this mineral plays a profound role in bone and mineral homeostasis. Our understanding of the role of magnesium has developed principally through observations of the effect of Mg depletion in both humans and animals. Mg influences the formation and/or secretion of hormones that regulate skeletal homeostasis and the effect of these hormones on bone. Mg can also directly affect bone cell function, as well as influence hydroxyapatite crystal formation and growth. These areas are discussed later and are outlined in Table III.

Parathyroid Hormone Secretion

Calcium is the major regulator of PTH secretion. Mg, however, modulates PTH secretion in a manner similar to calcium. A number of *in vitro* and *in vivo* studies have demonstrated that acute elevations of Mg inhibit PTH secretion, whereas an acute reduction stimulates PTH secretion (Sherwood, 1970; Cholst *et al.,* 1984; Ferment *et al.,* 1987; Toffaletti *et al.,* 1991 Rude, 1994). These data suggest that Mg could be a physiologic regulator of PTH secretion. While early investigations indicated that Mg was equipotent to calcium in its effect on parathyroid gland function (Sherwood, 1970), more recent studies demonstrated that Mg has approximately 30–50% the effect of calcium on either stimulating or inhibiting PTH secretion (Wallace and Scarpa, 1982; Ferment *et al.,* 1987; Toffaletti *et al.,* 1991; Rude, 1994). The finding in humans that a 5% (0.03 m*M*) decrease in serum ultrafilterable Mg did not result in any detectable change in intact serum PTH concentration while a 5.5% (.07 m*M*) decrease in ionized calcium resulted in a 400% increase in serum PTH supports this concept (Toffaletti *et al.,* 1991).

The inhibitory effects of Mg on PTH secretion may be dependent on the extracellular calcium concentration (Brown *et al.,* 1984). At physiological calcium and Mg concentrations, these divalent cations were found to be relatively equipotent at inhibiting PTH secretion from dispersed bovine parathyroid cells (Brown *et al.,* 1984). At a low calcium concentration (0.5 m*M*), however, a threefold greater Mg concentration was required for similar PTH inhibition. Altering the Mg concentration did not diminish the ability of calcium to inhibit PTH secretion. Differences have also been noted in the effect of Mg and calcium on the biosynthesis of PTH *in vitro.* Changes in calcium over the range of 0 to 3.0 m*M* resulted in increased PTH synthesis (Hamilton *et al.,* 1971; Lee and Roth, 1975), whereas changes in Mg over the range of 0 to 1.7 m*M* had no effect.

Table III Effect of Mg Depletion on Bone and Mineral Metabolism

Effect	Potential mechanism(s)
1. Decreased PTH secretion	Altered phosphoinositol activity Decreased adenylate cyclase activity
2. Decreased PTH action	Decreased adenylate cyclase activity Altered phosphoinositol activity
3. Decreased serum $1,25(OH)_2D$	Decreased serum PTH Renal PTH resistance (decrease in 1α-hydroxylase activity)
4. Impaired vitamin D metabolism and action	Decreased $1,25(OH)_2D$ formation Decreased intestinal epithelial cell and osteoblast activity Skeletal resistance to vitamin D
5. Impaired bone growth/osteoporosis	Decreased PTH and $1,25(OH)_2D$ formation and action Decreased effect of insulin and IGF-1 Direct effect to decrease bone cell activity Increased cytokine production
6. Altered hydroxyapatite crystal formation	Impaired calcium binding to hydroxyapatite Directly alter crystal growth

The effect of Mg on PTH secretion appears to act through the Ca^{2+}-sensing receptor, which mediates the control of extracellular calcium on PTH secretion (Brown *et al.,* 1993). Mg^{2+} was shown to bind to this receptor, but with much less efficiency than Ca^{2+} (Herbert, 1996). Mg may also regulate calcium transport into the cell through other ion channels (Miki *et al.,* 1997). Acute changes in the serum Mg concentration may therefore modulate PTH secretion and should be considered in the evaluation of the determination of serum PTH concentrations.

Mg Depletion and Parathyroid Gland Function

While acute changes in extracellular Mg concentrations will influence PTH secretion qualitatively similar to calcium, it is clear that Mg deficiency markedly perturbs mineral homeostasis (Rude *et al.,* 1976; Rude, 1994). Hypocalcemia is a prominent manifestation of Mg deficiency in humans (Rude *et al.,* 1976; Rude, 1994), as well as in most other species (Shils, 1980; Anast and Forte, 1983). In humans, Mg deficiency must become moderate to severe before symptomatic hypocalcemia develops. A positive correlation has been found between serum Mg and calcium concentrations in hypocalcemic hypomagnesemic patients (Rude *et al.,* 1976). Mg therapy alone restored serum calcium concentrations to normal in these patients within days (Rude *et al.,* 1976). Calcium and/or vitamin D therapy will not correct the hypocalcemia (Rude *et al.,* 1976; Rude, 1994). Even mild degrees of Mg depletion, however, may result in a significant fall in the serum calcium concentration, as demonstrated in experimental human Mg depletion (Fatemi *et al.,* 1991). One major factor resulting in the fall in serum calcium is impaired parathyroid gland function. Low Mg in the media of parathyroid cell cultures impairs PTH release in response to a low media calcium concentration (Targovnik *et al.,* 1971). Determination of serum PTH concentrations in hypocalcemic hypomagnesemic patients has shown heterogeneous results. The majority of patients have low or normal serum PTH levels (Anast *et al.,* 1972; Suh *et al.,* 1973; Chase and Slatopolsky, 1974; Rude *et al.,* 1976, 1978). Normal serum PTH concentrations are thought to be inappropriately low in the presence of hypocalcemia. Therefore, a state of hypoparathyroidism exists in most hypocalcemic Mg-deficient patients. Some patients, however, have elevated levels of PTH in the serum (Rude *et al.,* 1976, 1978; Algrove *et al.,* 1984). The administration of Mg will result in an immediate rise in the serum PTH concentration regardless of the basal PTH level (Anast *et al.,* 1972; Rude *et al.,* 1976, 1978). As shown in Fig. 7, 10 mEq of Mg administered intravenously over 1 min caused an immediate marked rise in serum PTH in patients with low, normal, or elevated basal serum PTH concentrations. This is distinctly different than the effect of a Mg injection in normal subjects where, as discussed earlier, Mg will cause an inhibition of PTH secretion (Cholst *et al.,* 1984; Fatemi *et al.,* 1991). The serum PTH concentration will gradually fall to normal within several days of therapy with return of the serum calcium concentration to normal (Anast *et al.,*

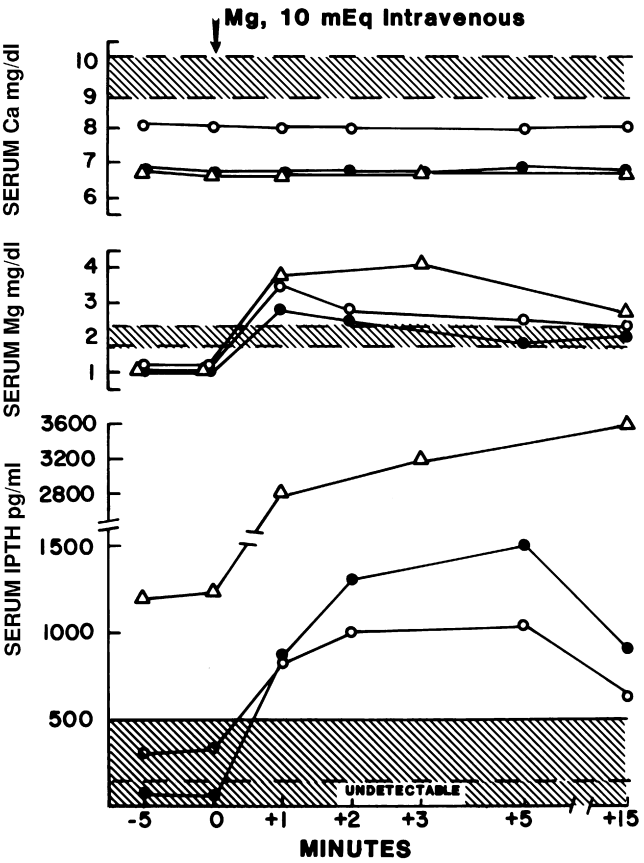

Figure 7 The effect of an IV injection of 10 mEq Mg on serum concentrations of calcium, magnesium, and immunoreactive parathyroid hormone (IPTH) in hypocalcemic magnesium-deficient patients with undetectable (●), normal (○), or elevated (Δ) levels of IPTH. Shaded areas represent the range of normal of each assay. The broken line for the IPTH assay represents the level of detectability. The magnesium injection resulted in a marked rise in PTH secretion within 1 min in all three patients (Rude *et al.,* 1978).

1972; Rude *et al.,* 1976, 1978). The impairment in PTH secretion appears to occur early in Mg depletion. Normal human subjects placed experimentally on a low Mg diet for only 3 weeks showed similar but not as marked changes in the serum PTH concentrations (Fatemi *et al.,* 1991) in which there was a fall in both serum calcium and PTH concentrations in 20 of 26 subjects at the end of the dietary Mg deprivation period. The administration of intravenous Mg at the end of this Mg depletion period resulted in a significant rise in the serum PTH concentration qualitatively similar to that observed in hypocalcemic Mg-depleted patients shown in Fig. 7, whereas a similar Mg injection suppressed PTH secretion prior to the low Mg diet. In this study, as with hypocalcemia hypomagnesemic patients, some subjects had elevations in the serum PTH concentration. The heterogeneous serum PTH values may be explained on the severity of Mg depletion. As the serum Mg concentration falls, the parathyroid gland will react normally with an increase in PTH secretion. As intracellular Mg depletion develops, however, the ability of the parathyroid to secrete PTH is impaired, resulting in a fall in serum PTH levels with a resultant fall in the serum calcium

concentration. This concept is supported by the observation that the change in serum PTH in experimental human Mg depletion is correlated positively with the fall in red blood cell intracellular-free Mg^{2+} (Fatemi *et al.,* 1991). A slight fall in red blood cell Mg^{2+} resulted in a increase in PTH. However, a greater decrease in red blood cell Mg^{2+} correlated with a progressive fall in serum PTH concentrations.

It is conceivable that either PTH synthesis and/or PTH secretion may be affected. However, as the *in vitro* biosynthesis of PTH requires approximately 45 min (Hamilton *et al.,* 1971), the immediate rise in PTH following the administration of intravenous magnesium to Mg-deficient patients strongly suggests that the defect is in PTH secretion.

Mg Depletion and Parathyroid Hormone Action

The above discussion strongly supports the notion that impairment in the secretion of PTH in Mg deficiency is a major contributing factor in the hypocalcemia. However, the presence of normal or elevated serum concentrations of PTH in the face of hypocalcemia (Rude *et al.,* 1976, 1978; Rude, 1994) suggests that there may also be end organ resistance to PTH action. In hypocalcemic Mg-deficient patients treated with Mg, the serum calcium concentration does not rise appreciably within the first 24 hrs, despite elevated serum PTH concentrations (Rude *et al.,* 1976; Rude, 1994), which also suggests skeletal resistance to PTH because exogenous PTH administered to hypoparathyroid patients causes a rise in the serum calcium within 24 hrs (Bethune *et al.,* 1968). Clinical studies have reported resistance to exogenous PTH in hypocalcemic Mg-deficient patients (Estep *et al.,* 1969; Woodard *et al.,* 1972; Rude *et al.,* 1976; Rude, 1994). In one study, the parathyroid extract did not result in elevation in the serum calcium concentration or urinary hydroxyproline excretion in hypocalcemic hypomagnesemic patients as shown in Fig. 8 (Estep *et al.,* 1969). Following Mg repletion, however, a clear response to PTH was observed. PTH has also been shown to have a reduced calcemic effect in Mg-deficient animals (MacManus *et al.,* 1971; Levi *et al.,* 1974; Forbes and Parker, 1980). The ability of PTH to resorb bone *in vitro* is also diminished greatly in the presence of low media Mg (Raisz and Niemann, 1969). In one study of isolated perfused femur in the dog, the ability of PTH to simulate an increase in the venous cyclic AMP was impaired during perfusion with low Mg fluid, suggesting skeletal PTH resistance (Freitag *et al.,* 1979). Not all studies have shown skeletal resistance to PTH, however (Salet *et al.,* 1966; Stromme *et al.,* 1969; Suh *et al.,* 1973, Chase and Slatopolsky, 1974). It appears likely that skeletal PTH resistance may be observed in patients with more severe degrees of Mg depletion. Patients in whom a normal calcemic response to PTH was demonstrated were in subjects who had been on recent Mg therapy (Salet *et al.,* 1966; Stromme *et al.,* 1969; Suh *et al.,* 1973, Chase and Slatopolsky, 1974). Patients who have been found to be resistant to PTH have, in general, not had prior Mg administration (Estep *et al.,* 1969; Woodard *et al.,* 1972; Rude *et al.,* 1976; Rude, 1994). Consistent with this notion is that in the Mg-depleted rat, normal responses to PTH were observed when the serum Mg concentration was 0.95 mg/dl (Hahn *et al.,* 1972); however, in another study, rats with a mean serum Mg of 0.46 mg/dl were refractory to PTH (MacManus *et al.,* 1971). In addition, a longitudinal study of Mg deficiency in dogs demonstrated a progressive decline in responsiveness to PTH with increasing degrees of Mg depletion (Levi *et al.,* 1974).

Calcium release from the skeleton also appears to be dependent on physicochemical processes as well as cellular activity (Pak and Diller, 1970; MacManus and Heaton, 1970). Low Mg will result in a decrease in calcium release from bone (Pak and Diller, 1970; MacManus and Heaton, 1970) and may be another mechanism for hypocalcemia in Mg deficiency.

The renal response to PTH has also been assessed by determining the urinary excretion of cyclic AMP and/or phosphate (Figs. 8 and 9) in response to exogenous PTH. In

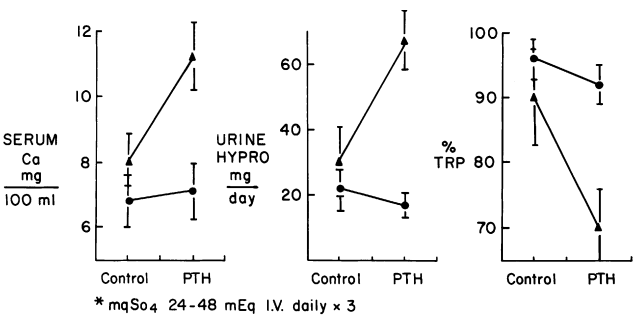

Figure 8 Mean and standard deviations of serum calcium concentration and urinary hydroxyproline and phosphate excretion in hypocalcemic magnesium-deficient patients before (●) and after (▲) 3 days of parenteral magnesium therapy (Estep *et al.,* 1969).

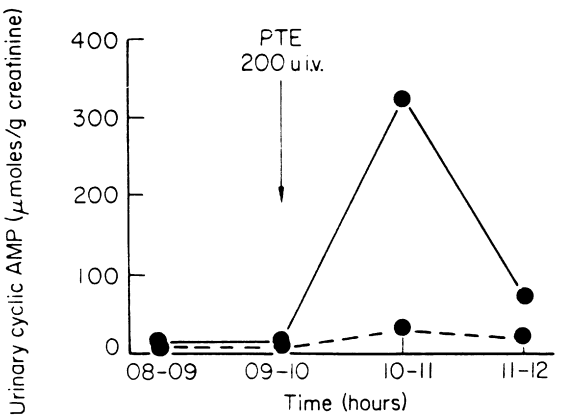

Figure 9 The effect of an IV injection of 200 units of parathyroid extract on the excretion of urinary cyclic AMP in a magnesium-deficient patient before (●---●) and after (●—●) 4 days of magnesium therapy. Urine was collected for four consecutive 1-hr periods, two before and two after the PTE injection. While Mg deficient, the patient had a minimal rise in urinary cyclic AMP in response to PTH, but following Mg therapy the response was normal (Rude *et al.,* 1976).

some patients, a normal effect of PTH on urinary phosphate and cyclic AMP excretion has been noted (Anast *et al.,* 1972; Suh *et al.,* 1973; Chase and Slatopolsky, 1974). In general, these were the same subjects in which a normal calcemic effect was also seen (Anast *et al.,* 1972; Suh *et al.,* 1973; Chase and Slatopolsky, 1974). In other studies, with more severely Mg-depleted patients, an impaired response to PTH has been observed (Estep *et al.,* 1969; Rude *et al.,* 1976; Medalle and Waterhouse, 1973; Rude, 1994). A decrease in urinary cyclic AMP excretion in response to PTH has also been described in the Mg-deficient dog and rat (Levi *et al.,* 1974; Forbes and Parker, 1980).

Mechanism of Impaired Mineral Homeostasis in Mg Depletion

The mechanism for impaired PTH secretion and action in Mg deficiency remains unclear. It has been suggested that there may be a defect in the second messenger systems in Mg depletion. PTH is thought to exert is biologic effects through the intermediary action of cyclic AMP (Bitensky *et al.,* 1973; Neer, 1995). Adenylate cyclase has been universally found to require Mg for cyclic AMP generation, both as a component of the substrate (Mg-ATP) and as an obligatory activator of enzyme activity (Northup *et al.,* 1982). There appears to be two Mg^{2+}-binding sites within the adenylate cyclase complex: one resides on the catalytic subunit and the other on the guanine nucleotide regulatory protein, Ns (Cech *et al.,* 1980; Maguire, 1984). The requisite role that Mg^{2+} plays in adenylate cyclase function suggests that factors that would limit the availability of Mg^{2+} to this enzyme could have significant effects on the cyclic nucleotide metabolism of a cell and hence overall cellular function. It is clear that some patients with severe Mg deficiency have a reduced urinary excretion of cyclic AMP in response to exogenously administered PTH (Rude *et al.,* 1976). In addition, PTH was shown to have a blunted effect in causing a rise in cyclic AMP from isolated perfused tibiae in Mg-deficient dogs (Freitag *et al.,* 1979). These observations correspond well with the impaired calcemic and phosphaturic effects of PTH in Mg-deficient patients and animals as discussed earlier.

While Mg^{2+} is stimulatory for adenylate cyclase, Ca^{2+} may inhibit or activate enzyme activity (Sunahara *et al.,* 1996). Nine isoforms of adenylate cyclase have been identified whose activities are modulated by both Mg^{2+} and Ca^{2+} (Sunahara *et al.,* 1996). In plasma membranes from parathyroid, renal cortex, and bone cells, Ca^{2+} will competitively inhibit Mg^{2+}-activated adenylate cyclase activity (Rude, 1983, 1985; Oldham *et al.,* 1984). In parathyroid plasma membranes, at a Mg^{2+} concentration of 4 m*M,* Ca^{2+} was found to inhibit adenylate cyclase in a bimodal pattern described in terms of two calcium inhibition constants with K_i values of 1–2 and 200–400 μM (Oldham *et al.,* 1984). At a lower Mg^{2+} concentration (0.5 m*M*) the only adenylate cyclase activity expressed was that inhibitable by the high-affinity Ca^{2+}-binding site. With increasing Mg concentrations, the fraction of total adenylate cyclase activity subject to high-affinity calcium inhibition became progressively less. Thus, the ambient Mg^{2+} concentrations can markedly affect the susceptibility of this enzyme to the inhibitory effects of Ca^{2+}. Total intracellular calcium has been observed to rise during Mg depletion (George and Heaton, 1975; Ryan and Ryan, 1979). Mg is not only important for the operation of Mg^{2+}, Ca^{2+}-dependent ATPase, but may also be countertransported during the uptake and release of calcium through calcium channels (Romani and Scarpa, 1992; Romani *et al.,* 1993a). The combination of higher intracellular Ca^{2+} and increased sensitivity to Ca^{2+} inhibition due to Mg depletion could explain the defective PTH secretion in Mg deficiency. An increase in the release of intracellular Ca^{2+} via the phosphoinositol system is also possible, as discussed later. A similar relationship between Mg^{2+} and Ca^{2+} was described for adenylate cyclase obtained from bone (Rude, 1985). Ca^{2+} caused a competitive inhibition of Mg^{2+}-activated skeletal adenylate cyclase with a high-affinity Ca^{2+}-binding site with a K_iCa of 1–2 μM. Lowering the Mg^{2+} concentration increased overall Ca^{2+} inhibition. Thus, a fall in the intracellular Mg^{2+} concentration would render the adenylate cyclase enzyme more susceptible to inhibition by the prevailing intracellular Ca^{2+} concentrations and may be a mechanism by which both PTH secretion and PTH end organ action are compared in Mg deficiency.

Adenylate cyclase is a widely distributed enzyme in the body, and if the hypothesis just given were true, the secretion and action of other hormones mediated by adenylate cyclase might also exhibit impaired activity in Mg deficiency. This has not been found to be true, as the actions of ACTH, TRH, GnRH, and glucagon are normal in Mg depletion (Cohan *et al.,* 1982). Prior investigations have suggested that Mg affinity for adenylate cyclase is higher (lower K_aMg) in liver, adrenal, and pituitary than in parathyroid (for reviews, see Rude and Oldham, 1985; Rude, 1994). In one study, investigation of K_aMg and K_iCa in tissues from one species (guinea pig) demonstrated that under agonist stimulation the K_aMg from liver $<$ thyroid $<$ kidney $=$ bone and the $K_i Ca^{2+}$ for liver $>$ renal $>$ kidney $=$ bone (Rude and Oldham, 1985). These data suggest that adenylate cyclase regulation by divalent cations varies from tissue to tissue and may explain the greater propensity for disturbed mineral homeostasis in Mg deficiency.

While cyclic AMP is an important mediator of PTH action, current studies do not suggest an important role in mediating Ca^{2+}-regulated PTH secretion (Brown, 1991; Dunlay and Hruska, 1990). PTH has been shown to activate the phospholipase C second messenger system (Dunlay and Hruska, 1990). PTH activation of phospholipase C leads to the hydrolysis of phosphatidylinositol 4,5-bisphosphate to inositol-1,4,5-triphosphate (IP_3) and diacylglycerol. IP_3 binds to specific receptors on intracellular organelles (endoplasmic reticulum, calciosomes), leading to an acute transient rise in cytosolic Ca^{2+} with a subsequent activation of calmodulin-dependent protein kinases. Diacylglycerol

activates protein kinase C. Mg depletion could perturb this system via several mechanisms. First, a Mg^{2+}- dependent guanine nucleotide-regulating protein is also involved in the activation of phospholipase C (Babich *et al.,* 1989; Litosch, 1991). Mg^{2+} has also been shown to be a noncompetitive inhibitor of IP_3-induced Ca^{2+} release (Volpe *et al.,* 1990). A reduction of Mg^{2+} from 300 to 30 μM increased Ca^{2+} release in response to IP_3 by two-to threefold in mitochondrial membranes obtained from canine cerebellum (Volpe *et al.,* 1990). The Mg concentration required for a half-maximal inhibition of IP_3-induced Ca^{2+} release was 70 μU. In these same studies, Mg^{2+} was also found to inhibit IP_3 binding to its receptor. Mg, at a concentration of 500 μM, decreased maximal IP_3 binding threefold (IC_{50} 200 μM) (Volpe *et al.,* 1990). These Mg^{2+} concentrations are well within the estimated physiologic intracellular range (200–500 μM) and therefore Mg^{2+} may be an important physiological regulator of the phospholipase C second messenger system.

The effect of Mg depletion on cellular function in terms of the second messenger systems is most complex, potentially involving substrate availability, G protein activity, release and sensitivity to intracellular Ca^{2+}, and phospholipid metabolism.

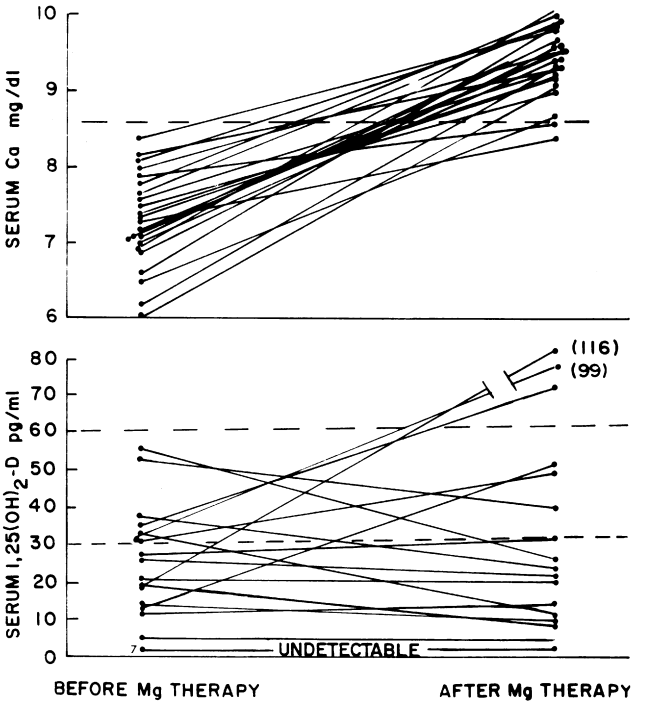

Figure 10 Serum concentrations of calcium and 1,25-diydroxyvitamin D in hypocalcemic magnesium-deficient patients before and after 5–8 days of parenteral magnesium therapy. The broken line represents the upper and lower limits of normal for serum 1,25-dihydroxyvitamin D and the lower limit of normal for the serum calcium (Rude *et al.,* 1985).

Mg Depletion and Vitamin D Metabolism and Action

Mg may also be important in vitamin D metabolism and/or action. Patients with hypoparathyroidism, malabsorption syndromes, and rickets have been reported to be resistant to therapeutic doses of vitamin D until Mg was administered simultaneously (for review, see Rude, 1994). Patients with hypocalcemia and Mg deficiency have also been reported to be resistant to pharmacological doses of vitamin D (Medalle *et al.,* 1976; Leicht *et al.,* 1990), 1α hydroxyvitamin D (Ralston *et al.,* 1983; Selby *et al.,* 1984) and 1,25-dihydroxyvitamin D (Graber and Schulman, 1986). Similarly, an impaired calcemic response to vitamin D has been found in Mg-deficient rats (Lifshitz *et al.,* 1967), lambs (McAlleese and Forbes, 1959), and calves (Smith, 1958).

The exact nature of altered vitamin D metabolism and/or action in Mg deficiency is unclear. Intestinal calcium transport in animal models of Mg deficiency has been found to be reduced in some (Higuchi and Lukert, 1974) but not all (Coburn *et al.,* 1975) studies. Calcium malabsorption was associated with low serum levels of 25-hydroxyvitamin D in one study (Lifshitz *et al.,* 1967), but not in another (Coburn *et al.,* 1975), suggesting that Mg deficiency may impair intestinal calcium absorption by more than one mechanism. Patients with Mg deficiency and hypocalcemia frequently have low serum concentrations of 25-hydroxyvitamin D (Rude *et al.,* 1985; Fuss *et al.,* 1989) and therefore nutritional vitamin D deficiency may be one factor. Therapy with vitamin D, however, results in high serum levels of 25-hydroxyvitamin D without correction of the hypocalcemia (Medalle *et al.,* 1976), suggesting that the vitamin D nutrition is not the major reason. In addition, conversion of radiolabeled vitamin D to 25-hydroxyvitamin D was found to be normal in three Mg-deficient patients (Lukert, 1980). Serum concentrations of 1,25-dihydroxyvitamin D have also been found to be low or low normal in most hypocalcemic Mg-deficient patients (Rude *et al.,* 1985; Fuss *et al.,* 1989; Leicht *et al.,* 1992). Mg-deficient diabetic children, when given a low calcium diet, did not exhibit the expected normal rise in serum 1,25-dihydroxyvitamin D or PTH (Saggese *et al.,* 1988); the response returned to normal following Mg therapy (Saggese *et al.,* 1991). Because PTH is a major trophic for 1,25-dihydroxyvitamin D formation, the low serum PTH concentrations could explain the low 1,25-dihydroxyvitamin D levels. In support of this is the finding that some hypocalcemic Mg-deficient patients treated with Mg have a rise in serum 1,25-dihydroxyvitamin D to high normal or to frankly elevated levels, as shown in Fig. 10 (Rude *et al.,* 1985). Most patients, however, do not have a significant rise within 1 week after institution of Mg therapy, despite a rise in serum PTH and normalization of the serum calcium concentration (Fig. 10) (Rude *et al.,* 1985). These data suggest that Mg deficiency in humans also impairs the ability of the kidney to synthesize 1,25-dihydroxyvitamin D. This is supported by the observation that the ability of exogenous administration of 1-34 human PTH to normal subjects after 3 weeks of experimental Mg depletion resulted in a significantly lower rise in serum 1,25-dihydroxyvitamin D concentrations than before institution of the diet (Fatemi *et al.,* 1991). It appears, therefore, that the renal synthesis of 1,25-dihydroxyvitamin

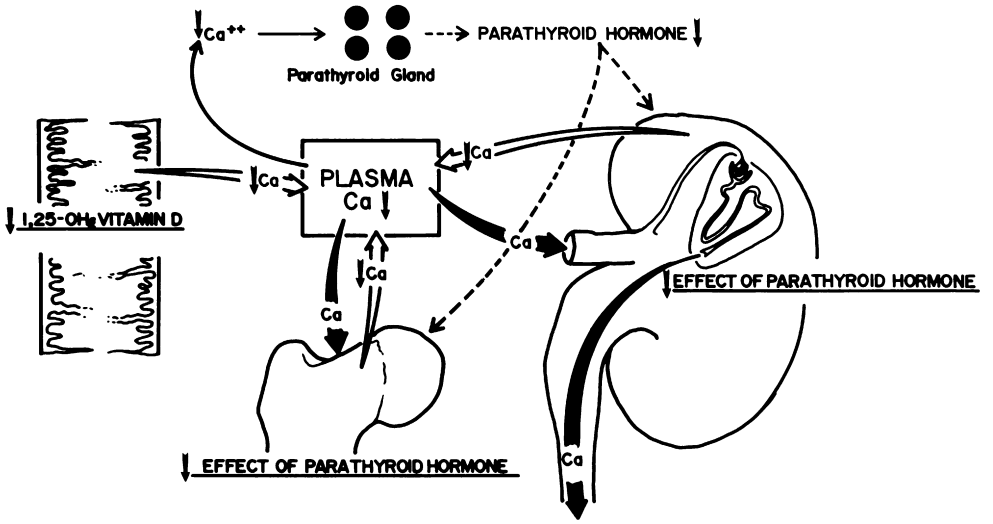

Figure 11 Disturbance of calcium metabolism during magnesium deficiency. Hypocalcemia is caused by a decrease in PTH secretion, as well as renal and skeletal resistance to the action of PTH. Low serum concentrations of 1,25-dihydroxyvitamin D may result in reduced intestinal calcium absorption (Rude and Oldham, 1990).

D is sensitive to Mg depletion. While Mg is known to support 25-hydroxy-1α-hydroxylase *in vitro* (Fisco and Traba, 1992), the exact Mg requirement for this enzymatic process is not known.

The association of Mg deficiency with impaired vitamin D metabolism and action therefore may be due to several factors, including vitamin D deficiency (Rude *et al.,* 1985; Carpener, 1988; Fuss *et al.,* 1989; Leich and Biro, 1992) and a decrease in PTH secretion (Anast *et al.,* 1972; Such *et al.,* 1973; Chase and Slatopolsky, 1974; Rude *et al.,* 1976, 1978), as well as a direct effect of Mg depletion on the ability of the kidney to synthesize 1,25-dihydroxyvitamin D (Rude *et al.,* 1985; Fuss *et al.,* 1989; Fatemi *et al.,* 1991). In addition, Mg deficiency may directly impair intestinal calcium absorption (Higuchi and Lukert, 1974; Rude *et al.,* 1976, 1985). Skeletal resistance to vitamin D and its metabolites may also play an important role (Lifshitz *et al.,* 1967; Ralston *et al.,* 1983; Selby *et al.,* 1984; Graber and Schulman, 1986). It is clear, however, that the restoration of normal serum 1,25-dihydroxyvitamin D concentrations is not required for normalization of the serum calcium level (Fig. 9). Most Mg-deficient patients who receive Mg therapy exhibit an immediate rise in PTH, followed by normalization of the serum calcium prior to any change in serum 1,25-dihydroxyvitamin D concentrations (Rude *et al.,* 1985; Fuss *et al.,* 1989). An overall view of the effect of Mg depletion on calcium metabolism is shown in Fig. 11.

Magnesium Depletion: Skeletal Growth and Osteoporosis

Women with postmenopausal osteoporosis have decreased nutrition markers, suggesting that osteoporosis is associated with nutritional deficiencies (Rico *et al.,* 1993). While low calcium intake is one of these nutritional factors (Rico *et al.,* 1993), a large segment of our population also has low dietary Mg intake (Morgan *et al.,* 1985; Marier, 1986). Mg deficiency, when severe, will disturb calcium homeostasis markedly, resulting in impaired PTH secretion and PTH end organ resistance, leading to hypocalcemia (Rude, 1998). Mg exists in macronutrient quantities in bone, and long-term mild-to-moderate dietary Mg deficiency has been implicated as a risk factor for osteoporosis.

EPIDEMIOLOGICAL STUDIES

Epidemiologic studies have provided a major link associating dietary Mg inadequacy to osteoporosis. One cross-sectional study assessed the effect of dietary nutrients on appendicular (radius, ulna, and heel) bone mineral density (BMD) in a large group of Japanese-Americans living in Hawaii (Yano *et al.,* 1985). In 1208 males (age 61–81), whose mean Mg intake was 238 $\pm$ 111 mg/day, no correlation of Mg intake with BMD was observed at any site. In a subgroup of 259 of these subjects who took Mg supplements, however (mean Mg intake of 381 mg/day), BMD was correlated positively with Mg intake at one or more skeletal sites. In 912 females (age 43–80) whose Mg intake was 191 $\pm$ 36 mg/day, a positive correlation with BMD was also observed. In contrast to males, no correlation with BMD was found in females who took Mg supplements (total Mg intake of 321 mg/day). In a smaller study of women aged 35–65 (17 premenopausal, mean Mg intake 243 $\pm$ 44 mg/day; 67 postmenopausal, mean Mg intake 249 $\pm$ 68 mg/day) in which BMD was measured in the distal forearm, no cross-sectional correlation was observed with Mg intake in either group (Freudenheim *et al.,* 1986). Longitudinal observation over 4 years, however, demonstrated that loss of bone mass was related inversely to Mg intake in premenopausal women ($p < 0.05$) and had a similar trend in the postmenopausal group ($p < 0.085$). In another cross-sectional study, a positive correlation of BMD of the forearm (but not femur or spine) was found in a larger group of 89 premenopausal

women (age 37.8 ± 0.8; Mg intake of 243 ± 9 mg/day), but no similar correlation was found in 71 recently menopausal women age 58.9 ± 0.9 (Mg intake of 253 ± 11 mg/day) (Angus *et al.,* 1988). In contrast, a study of 194 older postmenopausal women (age 69–97; mean Mg intake of 288 mg/day) demonstrated a significant positive correlation with BMD of the forearm (Tranquilli *et al.,* 1994).

Studies have concentrated on BMD of the axial skeleton. Sixty-six premenopausal women (age 28–39) whose Mg intake was 289 ± 73 mg/day had a significant relationship between dietary Mg intake and rate of change of BMD of the lumbar spine and total body calcium over a 1-year period (Houtkooper *et al.,* 1995). A cross-sectional study that combined 175 premenopausal and postmenopausal women aged 28–74 (mean Mg intake was 262 ± 70 mg/day) found no correlation with BMD at the lumbar spine, femoral neck, or total body calcium (Michaelsson *et al.,* 1995). In a study of 994 premenopausal women aged 45–49, whose Mg intake was 311 ± 85 mg/day, New *et al.* (1997) did find a significant correlation of BMD of the lumbar spine with Mg intake. A significant difference was also observed in lumbar spine BMD between the highest and the lowest quartiles of dietary Mg intake. A report by this same group in a study of 65 pre- and postmenopausal women aged 45–55 again found higher bone mass of the forearm (but not femoral neck or hip) in subjects consuming a Mg intake of 326 ± 90 mg/day (New *et al.,* 2000). Women with a high childhood intake of fruits (Mg and potassium) did have higher femoral neck BMD than those on a lower fruit intake, however. Another cross-sectional study assessed Mg intake in older males and females (age 69–97) (345 males and 562 females), as well as a 2-year longitudinal study of a subset of these subjects (229 males and 399 females) (Tucker *et al.,* 1999). In the cross-sectional analysis in males, Mg intake (300 ± 110 mg/day) was correlated with BMD of the radius and hip. In the 4-year longitudinal study of these subjects, a positive inverse relationship between bone loss of the hip and Mg intake was observed. A positive cross-sectional correlation of BMD of the hip was also observed in females (Mg intake of 288 ± 106 mg/day), but not in the longitudinal assessment. Finally, dietary Mg intake in a large population of non-Hispanic white males and females from the NHANES III database was found by multiple regression analysis to predict BMD at several sites in the proximal femur (Carpenter *et al.,* 2000).

In a study of younger individuals, the effect of dietary Mg intake of preadolescence girls (age 9–11) on bone mass/quality in these young women was evaluated at age 18–19 (Wang *et al.,* 1999). Ultrasound determination of bone mass of the calcaneus in 35 black women (Mg intake 237 ± 83 mg/day) and in 26 white women (Mg intake 240 ± 61 mg/day) was performed. Mg intake was related positively to quantitative ultrasound properties of bone, suggesting that this nutrient was important in skeletal growth and development.

In summary, these epidemiological studies link dietary Mg intake to bone mass. Exceptions appear to include women in the early postmenopausal period in which the effect of acute sex steroid deficiency may mask the effect of dietary factors such as Mg. In addition, diets deplete in Mg are usually deficient in other nutrients, which affect bone mass as well. Therefore, further investigations are needed to provide a firm relationship of dietary Mg inadequacy with osteoporosis.

Bone Turnover

In two of the epidemiological studies cited earlier, markers of bone turnover were determined. In one, where no correlation was found between BMD and dietary Mg intake, serum osteocalcin did not correlate with Mg (or any other nutrient) intake (Michaelsson *et al.,* 1995). New *et al.* (2000) also found that serum osteocalcin was not associated with the dietary intake of Mg or other nutrients. Mg intake, however, was significantly negatively correlated with the urinary excretion of pyridinoline and deoxypyridinoline, suggesting that a low Mg diet was associated with increased bone resorption (New *et al.,* 2000).

The affect of short-term administration of Mg on bone turnover in young normal subjects has been conflicting. Magnesium, 360 mg per day, was administered for 30 days in 12 normal males aged 27–36 (mean dietary intake prior to supplementation was 312 mg/day) and markers of bone formation (serum osteocalcin and C terminus of type I procollagen) and bone resorption (type I collagen telopeptide) were compared with 12 age-matched controls (Dimai *et al.,* 1998). Markers of both formation and resorption were suppressed significantly however, only during the first 5–10 days of the study. A similar trial of 26 females aged 20–28 in a double-blind, placebo-controlled, randomized crossover design has been reported (Doyle *et al.,* 1999). Magnesium, 240 mg/day, or placebo was administered for 28 days (mean dietary Mg intake was 271 mg/day prior to and during the study). No effect of Mg supplementation was observed on serum osteocalcin, bone-specific alkaline phosphatase, or urinary pyridinoline and deoxypyridinoline excretion.

Mg Status in Osteoporosis

Few studies have been conducted assessing Mg status in patients with osteoporosis, despite interest in the possible role that dietary Mg insufficiency may play as a risk factor for osteoporosis. A small group of 15 osteoporotic subjects (10 female, 5 male) aged 70–85 (the presence or absence of osteoporosis was determined by radiographic features) was compared to 10 control nonosteoporotic subjects (Cohen and Kitzes, 1983). Both groups had normal serum Mg concentrations, which were not significantly different from each other. The Mg tolerance test, however, revealed a significantly greater retention in the osteoporotic patients (38%) as compared to 10% in the control subjects, suggesting Mg deficiency. In a second study by this group, 12 younger women aged 55–65 with osteoporosis (as determined by X-ray) had significantly lower serum Mg concentrations than 10 control subjects; however, no difference in the Mg tolerance test was observed (Cohen *et al.,* 1983). Red blood cell Mg was found to be significantly lower in 10 postmenopausal women who had at least one vertebral fracture as compared to 10 subjects with degenerative osteoarthritis;

however, no difference in plasma Mg was found (Reginster *et al.,* 1985). In a second report, 10 postmenopausal women aged 68.9 ± 9 with vertebral crush fracture were compared to 10 nonosteoporotic women aged 67.2 ± 6 years (Reginster, 1989). In comparison to the 10 controls, the osteoporotic subjects had a significantly lower serum Mg, but no difference was noted in red blood cell Mg.

The majority of body Mg (50–60%) resides in the skeleton, and skeletal Mg reflects Mg status. In the two studies cited earlier in which a Mg deficit was suggested by either Mg tolerance testing or low serum Mg concentration, the Mg content of iliac crest trabecular bone was reduced significantly in osteoporotic patients (Cohen and Kitzes, 1983; Cohen *et al.,* 1983). Two additional studies also found a lower bone Mg content in elderly osteoporotic patients (Manicourt *et al.,* 1981; Milachowski *et al.,* 1981). However, no difference in bone Mg content between osteoporotic subjects and bone obtained from cadavers was found (Reginster, 1989). Another study found no difference between patients with osteoporosis and control subjects in cortical bone (Basle *et al.,* 1990), while two studies reported higher bone Mg content in osteoporosis (Basle *et al.,* 1990; Burnell *et al.,* 1982).

In summary, Mg status has been assessed in very few osteoporotic patients. Low serum and red blood cell Mg concentrations, as well as a high retention of parenterally administered Mg, suggest a Mg deficit; however, these results are not consistent from one study to another. Similarly, while a low skeletal Mg content has been observed in some studies, others have found normal or even high Mg content. Larger scale studies are needed.

Effect of Mg Therapy in Osteoporosis

The effect of dietary Mg supplementation on bone mass in patients with osteoporosis has not been studied extensively. Administration of 600 mg of Mg per day to 19 patients over 6–12 months (Abraham, 1991) was reported to increase BMD of the calcaneus (11%) compared to a 0.7% rise in 7 control subjects. All subjects were postmenopausal (age 42–75) and on sex steroid replacement therapy. Subjects who received Mg also received 500 mg of calcium per day, as well as many other dietary supplements, however, making if difficult to conclude that Mg alone was the sole reason for the increase in bone mass. In a retrospective study, Mg (200 mg per day) given to 6 postmenopausal women (mean age 59) was observed to have a small nonsignificant 1.6% rise in bone density of the lumbar spine; no change was seen in the femur (Eisinger and Clairet, 1993). Stendig-Linberg *et al.* (1993) conducted a 2-year trial in which 31 postmenopausal osteoporotic women were administered 250 mg Mg per day, increasing to a maximum of 750 mg per day for 6 months depending on tolerance. All subjects were given 250 mg Mg per day from months 6 to 24. Twenty-three age-matched subjects served as controls. At 1 year there was a significant 2.8% increase in bone density of the distal radius. Twenty-two of the 31 subjects had an increase in bone density while 5 did not change. Three subjects that showed a decrease in bone density had primary hyperparathyroidism and one underwent a thyroidectomy. No significant effect of Mg supplementation was shown at 2 years, although only 10 subjects completed the trial. In a small uncontrolled trial, a significant increase in bone density of the proximal femur and lumbar spine in celiac sprue patients who received approximately 575 mg Mg per day for 2 years was reported (Rude and Olerich, 1996). These subjects had demonstrated evidence of reduced free Mg in red blood cells and peripheral lymphocytes.

In summary, the effect of Mg supplements on bone mass has generally led to an increase in bone mineral density, although study design limits useful information. Larger long-term, plabeco-controlled, double-blind investigations are required.

Osteoporosis in Patients at Risk for Mg Deficiency

Osteoporosis may occur with greater than usual frequency in certain populations in which Mg depletion is also common. These include diabetes mellitus (Levin *et al.,* 1976; McNair *et al.,* 1979, 1981; Hui *et al.,* 1985; Saggese *et al.,* 1988; Krakauer *et al.,* 1995), chronic alcoholism (Bikle *et al.,* 1985; Lindholm *et al.,* 1991; Peris *et al.,* 1992), and malabsorption syndromes (Molteni *et al.,* 1990; Mora *et al.,* 1993). Changes in bone and mineral metabolism in patients with diabetes mellitus and alcoholism are surprisingly similar to those in Mg depletion as discussed earlier. Serum PTH and/or $1,25(OH)_2D$ concentrations have been found to be reduced in both human and animal studies (McNair *et al.,* 1979; Hough *et al.,* 1981; Imura *et al.,* 1985; Ishida *et al.,* 1985; Nyomba *et al.,* 1986; Saggese *et al.,* 1988; Verhaeghe *et al.,* 1990). A prospective study of pregnant diabetic women demonstrated a fall in serum $1,25(OH)_2D$ during pregnancy rather than the expected rise observed in normal women (Kuoppala, 1988). These subjects were also found to have reduced serum Mg concentrations. Diabetic children, with reduced serum Mg and calcium concentrations and low bone mineral content, were shown to have an impaired rise in serum PTH and $1,25(OH)_2D$ in response to a low calcium diet; this defect normalized following Mg repletion (Saggese *et al.,* 1988, 1991). Similar observations were found in the diabetic rat (Welsh and Weaver, 1988). Duodenal calcium absorption has also been reported to be low in diabetic rats (Nyomba *et al.,* 1989; Verhaeghe *et al.,* 1990). The calcium malabsorption may be due to low serum $1,25(OH)_2D$, a duodenal calbindin D_{9K} has been found to be reduced (Nyomba *et al.,* 1989; Verhaeghe *et al.,* 1990).

The reduction in bone mass in diabetes mellitus and alcoholism also appears to be related to a decrease in bone formation, similar to what is observed in experimental Mg depletion (see later). A histomorphometric study of bone has shown decreased bone formation, bone turnover, osteoid, and osteoblast number (Tamayo *et al.,* 1981; Goodman and Hori, 1984; Verhaeghe *et al.,* 1990; Hough *et al.,* 1991; Bouillon, 1991). Reduced bone turnover is supported by the finding that serum osteocalcin, a marker of osteoblast activity, is low

in humans (Pietschmann *et al.,* 1988; Rico *et al.,* 1989) and in rats (Ishida *et al.,* 1988; Verhaeghe *et al.,* 1990).

Magnesium Depletion and Osteoporosis: Experimental Animal Models

The effect of dietary Mg depletion on bone and mineral homeostasis in animals has been studied since the 1940s. Most studies have been performed in the rat. Dietary restriction has usually been severe, ranging from 0.2 to 8 mg per 100 chow (normal = 50–70 mg/100 g). A universal observation has been a decrease in growth of the whole body as well as the skeleton (Lai *et al.,* 1975; McCoy *et al.,* 1979; Mirra *et al.,* 1982; Carpenter *et al.,* 1992; Boskey *et al.,* 1992; Kenny *et al.,* 1994; Gruber *et al.,* 1994). The epiphyseal and diaphyseal growth plate is characterized by thinning and a decrease in the number and organization of chrondrocytes (Mirra *et al.,* 1982). Osteoblastic bone formation has been observed by quantitative histomorphometry to be reduced, as shown in Fig. 12 (Carpenter *et al.,* 1992; Gruber *et al.,* 1994, Rude *et al.,* 1999). Serum and bone alkaline phosphatase (Mirra *et al.,* 1982; Loveless and Heaton, 1976; Lai *et al.,* 1975), serum and bone osteocalcin (Boskey *et al.,* 1992; Carpenter *et al.,* 1992; Creedon *et al.,* 1999), and bone osteocalcin mRNA (Carpenter *et al.,* 1992; Creedon *et al.,* 1999) have been reduced, suggesting a decease in osteoblastic function. This is supported by an observed decrease in collagen formation and sulfation of glycosaminoglycans (Trowbridge and Seltzer, 1967). A decrease in tetracycline labeling has also suggested impaired mineralization (Carpenter *et al.,* 1992; Jones *et al.,* 1980). Data on osteoclast function have been conflicting. A decrease in urinary hydroxyproline (MacManus and Heaton, 1969) and dexoypyridinoline (Creedon *et al.,* 1999) has suggested a decrease in bone resorption; however, Rude *et al.* (1999) reported an increase in the number and activity of osteoclasts in the Mg-deficient rat, as shown in Fig. 13. Bone from Mg-deficient rat, has been described as brittle and fragile (Lai *et al.,* 1975; Duckworth *et al.,* 1940). Biomechanical testing has directly demonstrated skeletal fragility in both rat and pig (Boskey *et al.,* 1992; Kenny *et al.,* 1992; Miller *et al.,* 1965; Heroux *et al.,* 1974; Smith and Nisbet, 1968). Osteoporosis has been observed to occur in dietary Mg depletion by 6 weeks or longer (Boskey *et al.,* 1992; Carpenter *et al.,* 1992; Rude *et al.,* 1999; Heroux *et al.,* 1974; Smith and Nisbet, 1968), as shown in Fig. 14. Bone implants into Mg-deficient rats have also shown osteoporosis in the implanted bone (Belanger *et al.,* 1975; Schwartz and Reddi, 1979). The effect of higher than the recommended dietary Mg intake on mineral metabolism in the rat has been reported (Toba *et al.,* 2000). In this study, increasing dietary Mg from 48 to 118 mg/100 g chow

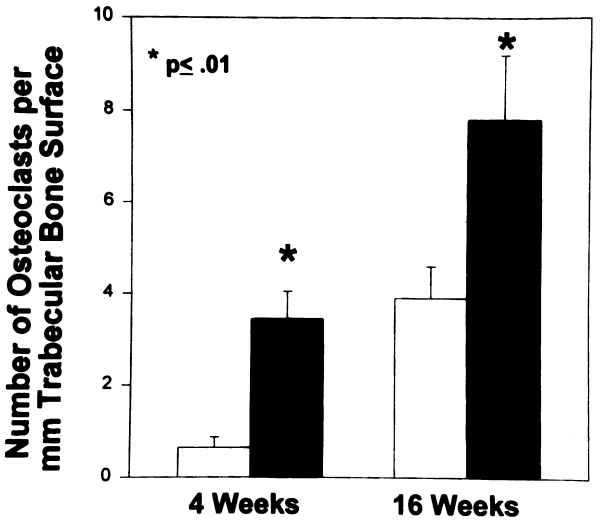

Figure 13 After 4 and 16 weeks of magnesium deficiency in the rat (solid bars), the osteoclast number was elevated significantly compared to controls (open bars) (Rude *et al.,* 1999) $^{*}p < 0.01$.

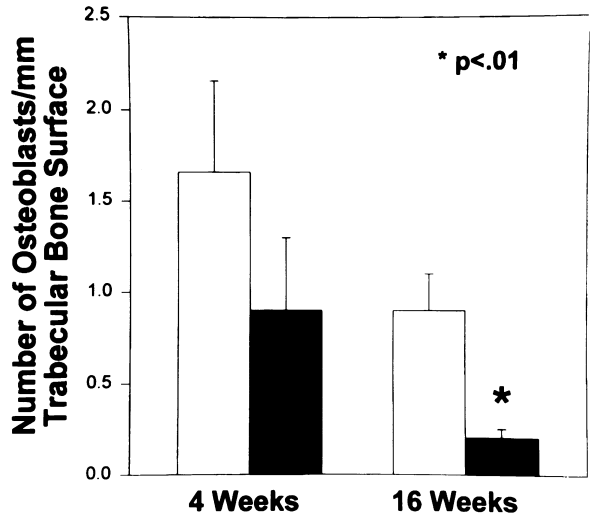

Figure 12 After 16 weeks of magnesium deficiency in the rat (solid bars), the osteoblast number was reduced significantly compared to controls (open bars) (Rude *et al.,* 1999) $^{*}p < 0.01$.

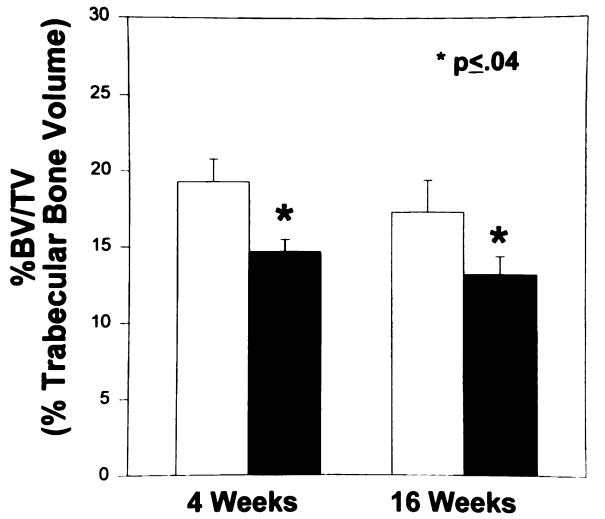

Figure 14 Magnesium deficiency in the rat (solid bars) resulted in a significant reduction in trabecular bone volume compared to control animals (open bars) at both 4 and 16 weeks (Rude *et al.,* 1999) $^{*}p < 0.04$.

resulted in a decrease in bone resorption and an increase in bone strength in ovariectomized rats. No loss of BMD was observed, suggesting a beneficial effect of Mg in acute sex steroid deficiency.

POSSIBLE MECHANISMS FOR MG DEFICIENCY-INDUCED OSTEOPOROSIS

Several potential mechanisms may account for a decrease in bone mass in Mg deficiency. Mg is mitogenic for bone cell growth, which may directly result in a decrease in bone formation (Liu *et al.,* 1988). Mg also affects crystal formation; a lack of Mg results in a larger, more perfect crystal, which may affect bone strength, as discussed later (Cohen *et al.,* 1983).

Mg deficiency can perturb calcium homeostasis and result in a fall in both serum PTH and $1,25(OH)_2D$ as discussed earlier (Rude *et al.,* 1978; Fatemi *et al.,* 1991). Because $1,25(OH)_2D$ stimulates osteoblast activity (Azria, 1989) and the synthesis of osteocalcin and procollagen (Franchesche *et al.,* 1988), decreased formation of $1,25(OH)_2D$ may be a major cause of decreased bone formation, such as that observed in experimental Mg deficiency (Heroux *et al.,* 1975; Jones *et al.,* 1980; Kenney *et al.,* 1994). Similarly, PTH has been demonstrated to be trophic for bone (Marcus, 1994) and therefore impaired PTH secretion or PTH skeletal resistance may result in osteoporosis.

Because insulin promotes amino acid incorporation into bone (Hahn *et al.,* 1971), stimulates collagen production (Wettenhall *et al.,* 1969), and increases nucleotide synthesis by osteoblasts (Peck and Messinger, 1970), insulin deficiency or resistance may alter osteoblast function in diabetes. However, insulin also causes an increase in intracellular Mg, and because Mg has been shown to be trophic for the osteoblast (Liu *et al.,* 1988), insulin deficiency may result in intracellular Mg depletion and impaired osteoblast activity. Serum IGF-1 levels have also been observed to be low in the Mg-deficient rat, which could affect skeletal growth (Dorup *et al.,* 1991).

While the explanation just given may explain low bone formation, it does not explain the observation of an increase in osteoclast bone resorption. Acute Mg depletion in the rat and mouse has demonstrated an immediate rise in substance P followed by a rise in inflammatory cytokines (TNFα, IL-1, IL-6, and IL-11) (Weglicki *et al.,* 1996). These cytokines could contribute to an increase in osteoclastic bone resorption and explain the uncoupling of bone formation and bone resorption observed in the rat (Rude *et al.,* 1999). Whether these possibilities are valid for the suboptimal chronic dietary Mg deficit in human osteoporosis in unknown. Further studies are needed to explore these possibilities.

Magnesium and Mineral Formation

Mg may also independently influence bone mineral formation. In *in vitro* studies, Mg has been shown to bind to the surface of hydroxyapatite crystals and to retard the nucleation and growth of hydroxyapatite and its precrystalline intermediate, amorphorous calcium phosphate (Blumenthal *et al.,* 1977; Bigi *et al.,* 1992; Sojka and Weaver, 1995). Mg has also been demonstrated to compete with calcium for the same absorption site on hydroxyapatite (Aoba *et al.,* 1992). Therefore, surface-limited Mg may play a role in modulating crystal growth in the mineralization process.

In vivo studies have demonstrated that as the Mg content of bone decreases, the hydroxyapatite crystal size increases, whereas high Mg content results in smaller crystals. Rats fed excess Mg have smaller mineral crystal in their bone than control pair-fed animals (Burnell *et al.,* 1986). In contrast, Mg-deficient rats have a significant increase inhydroxyapatite crystal size (Boskey *et al.,* 1992). Clinical studies are also consistent with this effect of Mg on crystal formation. A crystallinity index determined by infrared spectrophotometry has shown larger and more perfect bone mineral crystals along with decreased bone Mg in bone samples obtained from patients with diabetes mellitus, postmenopausal osteoporosis, and alcoholic osteoporosis (Blumenthal *et al.,* 1977; Cohen and Kitzes, 1981; Cohen *et al.,* 1983; Sojka and Weaver, 1995). These conditions are known to have a high incidence of Mg depletion. In contrast, uremic patients, characterized by high serum Mg levels, have smaller, less perfect crystals and high bone Mg (Blumenthal *et al.,* 1977; Cohen and Kitzes, 1981; Cohen *et al.,* 1983; Sojka and Weaver, 1995). An inverse correlation was found to exist between bone Mg and crystallinity index. The effect of these findings on crystallization in terms of bone strength and bone metabolism has yet to be elucidated.

Mg may also have another indirect effect on crystallization by influencing both osteocalcin formation and osteocalcin binding to hydroxyapatite. Osteocalcin has been shown to inhibit the conversion of brushite to hydroxyapatite and the nucleation of mineral formation (Wians *et al.,* 1990). Therefore, the decrease in osteocalcin production, as suggested by decreased serum and bone osteocalcin, in Mg depletion may influence mineralization. However, Mg has also been demonstrated to inhibit the binding of osteocalcin to hydroxyapatite by reducing the number of available hydroxyapatite-binding sites for osteocalcin (Wians *et al.,* 1983). Maximal inhibition occurred at 1.5 m*M* Mg, which is within the physiologically relevant concentration range.
